Energy system transitions in small islands can produce synergies with SDG implementation, and can lead to transformational outcomes. The Pacific island territory of Tokelau has demonstrated a nationwide energy transition, sourcing 100% of their energy needs from solar power (Michalena and Hills, 2018), and many other countries such as Fiji, Niue, Tuvalu, Vanuatu, Solomon Islands and Cook Islands also have 100% renewable energy targets. Benefits of small island distributed energy systems (such as solar photovoltaic (PV) systems) include less need for large, centralized infrastructure; reduced reliance on volatile fossil fuel markets; enhanced international climate negotiations power and enhanced local job markets/skills (Dornan, 2015; Cole and Banks, 2017; Weir, 2018). Additionally, renewable systems can enhance resilience to hydro-meteorological disasters (Weir and Kumar, 2020). For example, well secured ground based PV systems withstood cyclones in the Pacific island of Tonga during cyclone Gita and across the Caribbean during Hurricane Maria with power restored in days rather than weeks associated with more centralized systems (Weir and Kumar, 2020). Yet, a multitude of challenges remain. In the Pacific islands region, these include: the high up front capital investment of renewables; lack of private sector investment; limited renewable energy data for policy making; land tenure/rent costs; ongoing infrastructure maintenance skills and requirements; political turnover; failed experimentation; difficulty in obtaining and transporting replacement parts and a highly corrosive environment for equipment (Dornan, 2015; Cole and Banks, 2017; Lucas et al., 2017; Weir, 2018; Weir and Kumar, 2020). The example of Pacific energy transitions demonstrates that a nuanced and context specific analysis of synergies and trade-offs for energy transitions is required in order to lessen the impact on fragile economies and maximize benefits for remote populations.

Labor migration is increasingly recognized as a significant factor that can contribute to climate resilient development pathways for small islands. In the Pacific Islands region, labor mobility schemes are already allowing for climate change adaptation and economic development to occur in labor migrants' countries of origin (Smith and McNamara, 2015; Klepp and Herbeck, 2016; Dun et al., 2020). Dun et al. (2020) demonstrates that temporary or circular migrants from the Solomon Islands, working in Australia under its Seasonal Worker Program (similar programs operate in other developed countries), are using the money they earn to invest in adaptation and development activities back home. Similarly, labor migrants from Vanuatu, Kiribati, and Samoa contribute to development and in-situ climate change adaptation (at a household, village, and regional level) that enable discussions about more resilient futures for their countries (Barnett and McMichael, 2018; Parsons et al., 2018).

Box 18.4: Adaptation and the Sustainable Development Goals

The achievement of the SDGs represents near-term positive sustainability as well as indicating the quality of development processes and actions (inclusion and social justice, degrowth and alternative development models, planetary health, well-being, equity, solidary, plural knowledges and human-nature connectivity) that enable CRD in the long term (18.2.2.2, 18.2.5.3). A key question is the extent to which adaptation actions (or non-action) may contribute to (or undermine) SDG achievement, and in particular to shift the quality of development processes and engagement within the political, economic, ecological, socio-ethical and knowledge-technology arenas and hence contribute to CRDPs. Here, the relationship between adaptation and SDGs is illustrated through an examination of SDG3 good health and well-being and SDG16 peace, justice and strong institutions. These two are foundational to social equity and justice that underpin sustainability outcomes as well as enablers of CRD.

Table Box 18.4.1 (below) provides a set of examples of how adaptation actions can either contribute to or undermine SDG achievement, for SDGs 2, 3, 6, 11 and 16. In general, evidence suggests positive effects of formal interventions as well as household and community-based adaptation strategies on discrete social variables among target populations, particularly if they are shaped by the local context and needs, with real participation and leadership by target populations (Remling and Veitayaki, 2016; Buckwell et al., 2020; McNamara et al., 2020; Owen, 2020). For example, integrated adaptation approaches to the Water-Energy-Food (WEF) Nexus aiming to build resilience in those sectors can lead to increased resource use efficiency and coherent strategies for managing the complex interactions and tradeoffs among the water, energy and food SDGs (Mpandeli et al., 2018; Nhamo et al., 2020). One such approach could involve cultivating indigenous crops suited to harsh growing conditions, which would allow for agricultural expansion for food and energy without increased water withdrawals (Mpandeli et al., 2018). Overall, adaptation commitments aiming to build resilience of vulnerable populations have typically shown to contribute to SDGs focused on ending extreme poverty (SDG 1), improving food security (SDG 2), improving access to water (SDG 6), ensuring clean energy (SDG 7), tackling climate change (SDG 13) and halting land degradation and deforestation (SDG 15) (Antwi-Agyei et al., 2018).

However, evidence also suggests limitations of adaptation actions, with the objectives and actions often being too narrow to address social justice and enable CRD. As such, adaptation actions can sometimes undermine SDG achievement through exacerbating social vulnerability, inequity and uneven power relations (Antwi-Agyei et al., 2018; Atteridge and Remling, 2018; Paprocki, 2018; Mikulewicz, 2019; Satyal et al., 2020; Scoville-Simonds et al., 2020). This is due to adaptation practices often not accounting for the differentiated ways in which minority groups are especially vulnerable. For example, designs of emergency shelters should consider the fear of social stigma or abuse faced by women and girls (Pelling and Garschagen, 2019).

Such maladaptive adaptation practices can undermine SDG achievement through increasing vulnerability of marginalized groups by failing to address the underlying root causes of vulnerability and poverty that are related to political economy, power dynamics and vested interests more broadly, instead treating the symptoms as the cause (Magnan et al., 2016; Ajibade and Egge, 2019; Schipper, 2020). For example, evidence exists of flood defense measures through large scale infrastructure development leading to the violent displacement of poor communities, forcibly resettling people in areas far from their employment or pushing up land and housing costs without providing compensation (Fuso Nerini et al., 2018; Reckien et al., 2018). Moreover, sectoral approaches to adaptation that fail to acknowledge the linkages between SDGs can counter development efforts and generate further tradeoffs (Terry, 2009; Rasul and Sharma, 2016; von Stechow et al., 2016; Klinsky et al., 2017; Hallegatte et al., 2019).

The literature recommends a set of strategies for ensuring that adaptation actions are aligned with SDG achievement and do not further perpetuate poverty and inequality. These include ensuring that marginalized voices are central to adaptation decision-making, with participatory approaches that empower and compensate affected communities (Moser and Ekstrom, 2011; Broto et al., 2015; Pelling and Garschagen, 2019; Palermo and Hernandez, 2020). Gender mainstreaming and gender transformative approaches within climate policies can also help ensure gender-sensitive design of adaptation projects, with appropriate equity analyses of policy (Klinsky et al., 2017) decisions to identify the actual implications of trade-offs for vulnerable groups (Beuchelt and Badstue, 2013; Alston, 2014; Bowen et al., 2017; Fuso Nerini et al., 2018).

In addition, a substantial literature also argues for policy coherence measures that adopt whole-of-government approaches and mainstream and nationalize SDG targets within national climate policies (Nilsson et al., 2012; Le Blanc, 2015; Ari, 2017; Collste et al., 2017; Dzebo et al., 2017; Nilsson and Weitz, 2019). Institutional coordination mechanisms that aim to break down silos between different agencies and actors at the national level are suggested as beneficial for avoiding tradeoffs between adaptation actions and SDGs (Mirzabaev et al., 2015; Howlett and Saguin, 2018; Scherer et al., 2018). However, these need to be paired with an investigation of the deep-seated ideologies and vested interests that are creating goal conflicts and negatively impacting marginalized groups to begin with (Purdon, 2014; Bocquillon, 2018). Ultimately, adaptation measures need to acknowledge and address the underlying drivers that make certain groups particularly vulnerable, such as social disenfranchisement, unequal power dynamics and historical legacies of colonialism and exploitation (Magnan et al., 2016; Schipper, 2020)

Table Box 18.4.1: Examples of linkages between adaptation and the SDGs. For several key SDGs aligned with the concept of CRD, the table below identifies evidence from the literature where adaptation policies and practices contribute to achievement of the SDG as well as where they undermine achievement of the SDG.

SDG	***Evidence of adaptation contributing to SDG***	***Evidence of adaptation undermining SDG***
SDG 2: Zero Hunger	Adaptation measures implemented by smallholder farmers (e.g. adjustments in farm operations timing, on-farm diversification, soil-water management)	Some adaptation policies can increase land and food prices, negatively impacting smallholder farmers (Fuso Nerini et al., 2018; Zavaleta et al., 2018; Albizua et al., 2019)

	exhibit higher levels of productivity and technical efficiency in food production (Bai et al., 2019; Sloat et al., 2020; Khanal et al., 2021) Some climate smart agriculture measures (e.g. intercropping) can significantly increase yields and contribute to zero hunger (Lipper et al., 2014; Arslan et al., 2015; Saj et al., 2017)	Potential tradeoffs for food production through adaptation actions within the water or energy sector, if integrated approaches not taken (Howells et al., 2013; FAO, 2014; Biswas and Tortajada, 2016)
SDG 3: Good Health and Wellbeing	Increased resilience of societies and reduced vulnerability through investments in public health care and access (Marmot, 2020; Mullins and White, 2020) Adaptation measures that leverage solidarity, equity and nature connectedness contribute to physical and psychological health and wellbeing (Gambrel and Cafaro, 2009; Capaldi et al., 2015; Soga and Gaston, 2016; Woiwode, 2020)	Societal measures beyond adaptation required to address underlying causes of inequities that drive poor health and well-being, including cuts in public spending and neoliberalization and commodification of healthcare (Hall, 2020; Walsh and Dillard-Wright, 2020)
SDG 6: Clean Water and Sanitation	Integrated water resources management as an adaptation strategy (Tan and Foo, 2018; Sadoff et al., 2020)	Potential tradeoffs for water security through adaptation actions within the food or energy sector, if integrated approaches not taken (Howells et al., 2013; Rasul and Sharma, 2016; Mpandeli et al., 2018) Local, regional, or national "grabs" for water from shared resources to with poorly defined property rights (Olmstead, 2014)
SDG 11: Sustainable Cities and Communities	Vulnerability reducing adaptation measures that aim to upgrade informal settlements, create affordable housing and protect populations living in disaster prone areas (Major et al., 2018; Sanchez Rodriguez et al., 2018; Ajibade and Egge, 2019)	Need to ensure that adaptation measures understand how power dynamics and cultural norms shape urban form and communities' vulnerability and adaptive capacity (Sanchez Rodriguez et al., 2018) Risk of built infrastructure aiming to increase resilience ignoring local population needs and creating low-skilled jobs that concentrate land, capital and resources in the hands of the elite (Ajibade and Egge, 2019)
SDG 16: Peace, Justice and Strong Institutions	Potential for adaptation projects to support livelihoods incomes and resource management, and thereby reduce tensions and the risk of conflicts (Matthew, 2014; Dresse et al., 2018; Barnett, 2019)	Studies from Bangladesh, Cambodia and Nepal found that climate change adaptation-related policies and projects were an underlying cause of natural resource-based conflicts, as well as land dispossession and exclusion, entrenchment of dependency relations, elite capture, and inequity (Sovacool, 2018; Sultana et al., 2019) Adaptation projects can reinforce top-down knowledge and decision-making processes, asymmetric power relations and elite capture of adaptation resources (Nightingale, 2017; Eriksen et al., 2021b) Need for conflict-sensitive adaptation approaches that aim to 'do no harm' (Babcicky, 2013; Ide, 2020)

[END BOX 18.4 HERE]

18.2.5.2 Mitigation

Mitigation entails greenhouse gas emissions reductions, avoidance, and removal and sequestration, as well as management of other climate forcing factors (WGIII AR6). There are numerous individual and system mitigation options throughout the economy and within human and natural systems (very high confidence) (Chapter 16; 18.5). Limiting global average warming has been found to reduce climate risks (IPCC, 2018a; IPCC, 2019b), and limiting global average warming to any temperature level has also been found to be associated with broad ranges of emissions pathways representing socioeconomic, technological, market, physical uncertainties (very high confidence) (Rose and Scott, 2018; Rose and Scott, 2020). Pathways consistent with limiting warming to 2˚C and below have been found to require significant deployment of mitigation options spanning energy, land use, and societal transformation (WGIII AR6 Chapter 3 and Chapter 4; 18.3). and substantial economic, energy, land use, policy, and societal transformation (WGIII AR6 Chapter 3 and Chapter 4). Such emissions pathways would represent deviations from current trends that raise issues about their feasibility and therefore plausibility (Rose and Scott, 2018; Rose and Scott, 2020).

The technical and economic challenge of limiting warming has been found to increase non-linearly with greater ambition, fewer mitigation options, less than global cooperative policy designs, and delayed mitigation action (WGIII AR6 Chapter 3; Table 18.2). Table 18.2 provides a high-level summary of pathway characteristic ranges based on the WGIII AR6 assessment. Global pathways find large regional differences in mitigation potential, as well as the degree of regional non-linearity with greater mitigation ambition. These represent opportunities for mitigation, but how this effort and cost would be facilitated and distributed respectively is a policy question.

Table 18.2 illustrates that greater climate ambition implies more aggressive emissions reductions in each region, and earlier regional peaking of emissions (if they have not peaked to date). Near-term regional emissions increases are possible, even for 1.5°C compatible pathways, but significantly lower emissions than today are shown in all regions by 2050. Increases in total regional energy consumption, as well as fossil energy, are observed for many pathways, even in the most ambitious where energy consumption growth is potentially slower compared to less ambitious pathways. By 2050, regional fossil energy declines, but is not eliminated in any region. Regional growth in electricity use is substantial in all pathways, even the most ambitious, with the growth continuing and accelerating with time and regional dependence on electricity (share of total energy consumption) also growing significantly. The broad ranges are an indication of uncertainty and risk for regional transitions, noting that full uncertainty is likely broader than what is captured by emissions scenario databases (Rose and Scott, 2018; Rose and Scott, 2020). Among other things, pathways commonly assume idealized climate policies with immediate implementation; and model infeasibilities (i.e., models unable to solve) increase with climate ambition and pessimism about mitigation technologies (e.g., Clarke et al., 2014; Bauer et al., 2018; Rogelj et al., 2018; Muratori et al., 2020), highlighting the increasing challenge and potential for actual infeasibility with lower global warming targets. Together, Table 18.2 provides insights into the increasingly demanding system and development transitions associated with lower global warming levels, as well as some of the low-carbon transition uncertainties and risks (see also Figure 18.5).

Past assessment has evaluated representative mitigation strategies in terms of economic, technological, institutional, socio-cultural, environmental/ecological, and geophysical viability, as well as relationships to sustainable development goals (de Coninck et al., 2018). The strategies assessment analysis has been updated for AR6 (Cross-Chapter Box FEASIB). These assessments identify types of barriers that could affect an option's feasibility. Among other things, this work finds that, other than public transport and non-motorized transport, every other mitigation option evaluated had at least one feasibility dimension that represented a barrier or obstacle. The barriers also imply that there are trade-offs in these feasibility dimensions to consider. The assessment of mitigation option-sustainable development relationships identifies related literature and derives aggregate characterizations. Concerns about the potential sustainable development implications of some mitigation technologies may be motivation for precluding the use of some mitigation options. For instance, the potential food security and environmental quality implications of bioenergy have received significant attention in the literature (e.g., Smith et al., 2013). However, constraining or precluding the use of bioenergy without or with CCS could have significant implications for the cost of pursuing ambitious climate goals, and potentially the attainability of those goals (e.g., Clarke et al., 2014; Bauer et al., 2018; Rogelj et al., 2018; Muratori et al., 2020). Bioenergy is not unique in this regard. Social and sustainability concerns have also been raised about the large-scale deployment of many low-carbon technologies, e.g., REDD+, wind, solar, nuclear, fossil with CCS, and batteries. See WGIII Chapter 3 for examples of the potential implications of limiting or precluding different low-carbon technologies.

Overall, like with adaptation options, insights from this aggregate feasibility and sustainable development mapping work are high-level and difficult to apply to a specific mitigation context. The feasibility, ranking, and sustainable development implications of mitigation options, as well as the list of options themselves, for a given location will vary from location-to-location, with different criteria and weighting of criteria that reflect the relevant social priorities and differences in markets, technology options, and policies for managing risks and trade-offs. Integrated evaluation of criteria and options is needed here as well, that accounts for the relevant geographic context and interactions between options, systems, and implications.

Analyses of the potential implications of mitigation on sustainable development has various strands of literature—studies exploring general greenhouse gas mitigation feedbacks to society, assessments of mitigation implications on specific societal objectives other than climate, and literature evaluating mitigation implications specifically for sustainable development objectives (WGIII AR6 Chapter 3, Chapter 4, Chapter 17). In general, mitigation alters development opportunities by constraining the emissions future society can produce, which affects markets, resource allocation, economic structure, income distribution, consumers, and the environment (besides climate) (very high confidence). Examples of general development feedbacks from mitigation, include estimated price changes, macroeconomic costs, and low carbon energy and land system transformations (e.g., WGIII AR6 Chapter 3 and Chapter 4) (Fisher et al., 2007; Clarke et al., 2014; Popp et al., 2014; Rose et al., 2014; Weyant and Kriegler, 2014; Bauer et al., 2018; Rogelj et al., 2018). Examples of mitigation implications for specific other variables of societal interest include evaluating potential effects on air pollutant emissions, crop prices, water, and land use change (e.g., McCollum et al., 2018b; Roy et al., 2018), while the literature evaluating mitigation implications specifically for sustainable development objectives includes evaluations on energy access, food security, and income equality (e.g., Roy et al., 2018; Arneth et al., 2019; Mbow et al., 2019). Proxy indicators are frequently used to represent whether there might be implications for a sustainable development objective. For example, changes in energy prices are used as a proxy for effects on energy security (e.g., Roy et al., 2018). This is common with aggregate modelling studies, like those associated with global or regional emissions scenarios and energy systems.

Figure 18.5, derived from WGIII scenarios data, illustrates estimated relationships between mitigation and various sustainable development proxy variables for different global regions. Figure 18.5 illustrates synergies and trade-offs with mitigation, as well as regional heterogeneity, that can intensify with the level of climate ambition—synergies in air pollutants, such as black carbon, NOx, and SO2; and trade-offs in overall economic development, household consumption, food crop prices, and energy prices for electricity and natural gas. For comparison, recent IPCC assessments also observed similar synergies and trade-offs but did not directly make comparisons regarding overall development nor evaluate potential climates above 2˚C (Rogelj et al., 2018; Roy et al., 2018; Mbow et al., 2019). Regional non-linearity in the economic costs of mitigation with greater climate ambition (i.e., costs rising at an increasing rate with lower warming goals) can be significant within individual models (Rose and Scott, 2018; Rose and Scott, 2020). Figure 18.5 also illustrates transition risks in the potential for significant synergistic and trade-off implications with, for instance, potentially large regional commodity price implications and household consumption losses, as well as more significant air pollution benefits. Note that the 1.5˚C results in Figure 18.5 (and Table 18.2) are biased by model infeasibilities. Many models are unable to solve, especially with less optimistic assumptions, resulting in small sample sizes and a different representation of models compared to the 2˚C and higher results.

Results like those in Figure 18.5 illustrate that mitigation-development trade-offs and balancing of societal priorities are inevitable and need to be considered. For instance, Roy (2018) found that none of the 1.5˚C and 2˚C pathways assessed achieved all of the UN's Sustainable Develop Goals (SDGs). A newer literature is developing evaluating the potential for managing SDG trade-offs. For instance, Roy et al. (2018) discuss the potential for policies that address distributional implications, such as payments, food support, revenue recycling, as well as education, retraining, and technology outreach, subsidies, or prioritization. Recent studies have begun to estimate potential payments to offset trade-offs, such as related to food, water, and energy access (e.g., McCollum et al., 2018a). These analyses estimate investments to address specific trade-offs; however, with mitigation redirecting resources away from other productive activities, there is a need to also evaluate the aggregate economy-wide, distributional, and welfare effects, including the redistribution effects of managing sustainable development trade-offs.

There are a wide range of mitigation options and systems to consider, with assessment suggesting that a diverse portfolio is practical for pursing climate policy ambitions. However, local context will impact mitigation choices, with unique sustainable development priorities, available mitigation options, sustainable development synergies and trade-offs, and policy design and implementation possibilities.

Table 18.2: Emissions pathway regional characteristics from WGIII scenarios database for pathways associated with different global warming levels (1.5˚C, 2˚C, 3˚C, and 4˚C). Sample sizes: n = 13-15, 151-160, 66, and 34 emissions pathways for 1.5˚C, 2˚C, 3˚C, and 4˚C global warming levels respectively. Sample size ranges for the same warming level indicate that the sample size varies by variable due to differences in model reporting. Sample size varies by warming level due to model infeasibilities and differences in model reporting.

Variable	**Peak global warming to 2100**	**Asia**	**Latin America**	**Middle East / Africa**	**OECD**	**Reforming Economies**

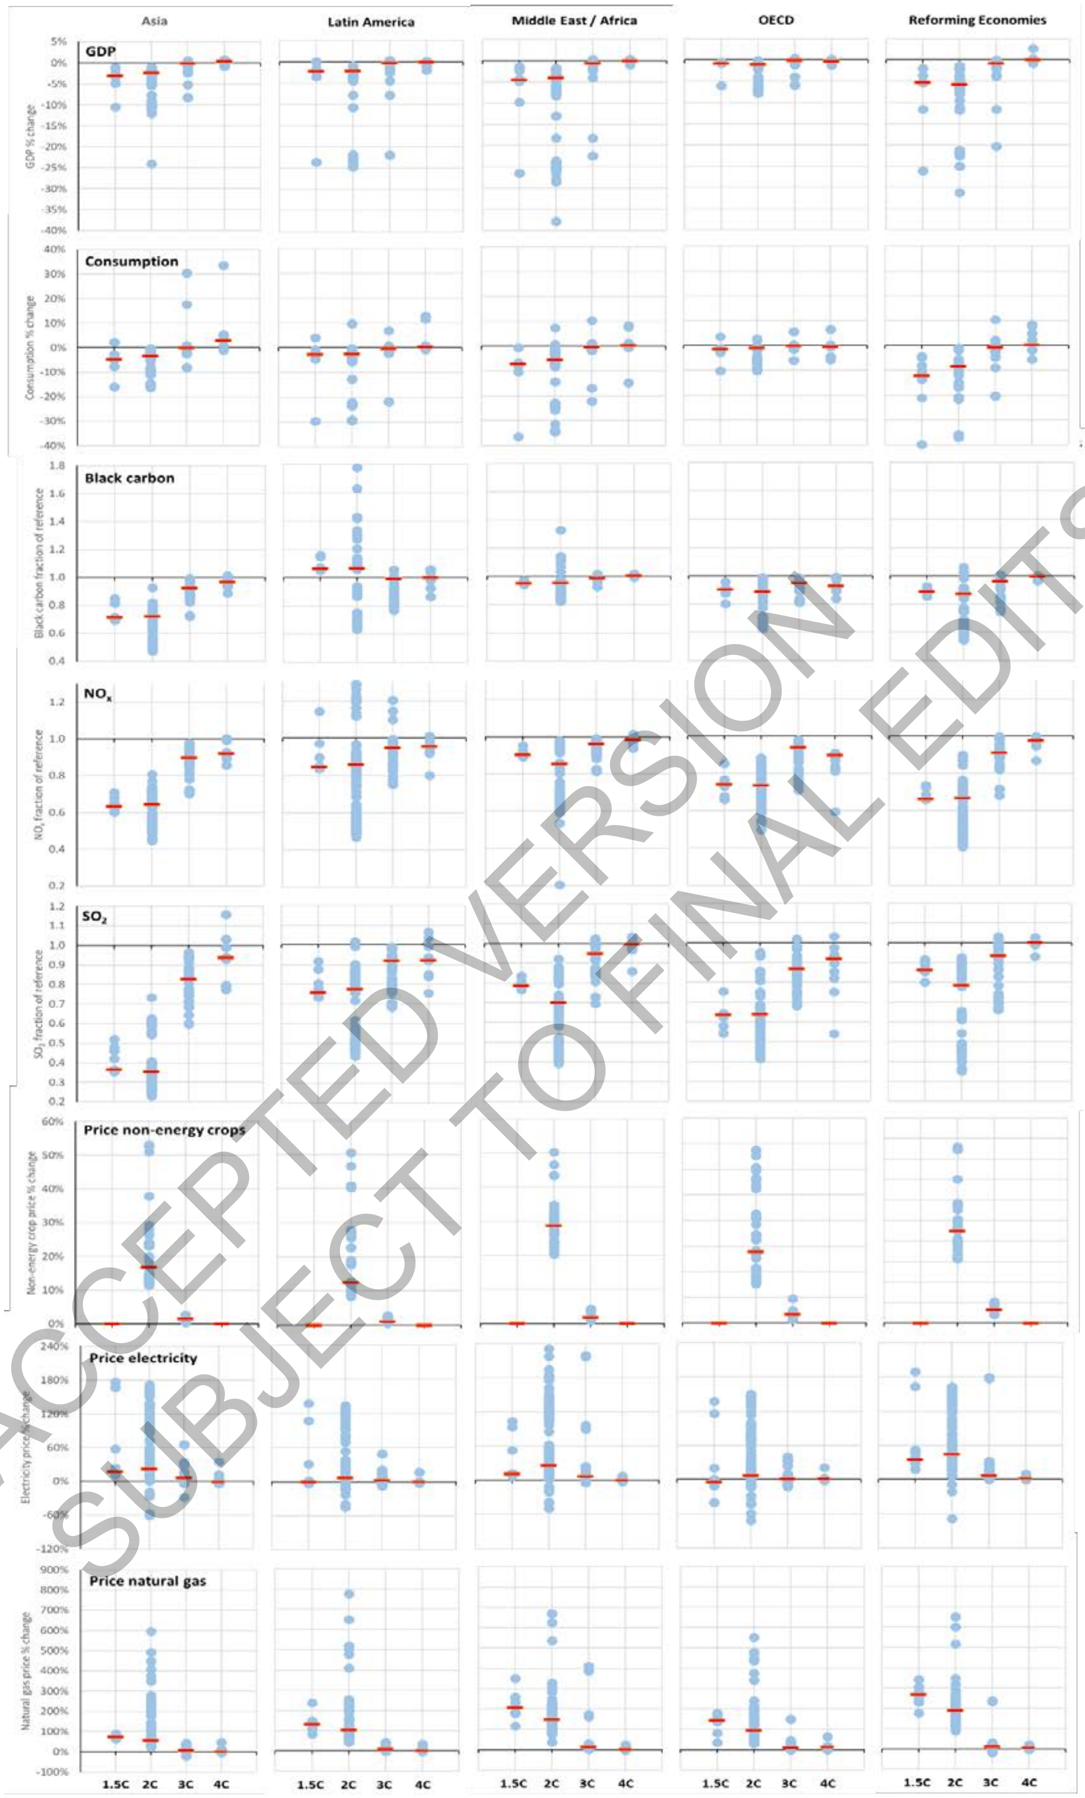

Figure 18.5: Implications of mitigation for different global mean temperature outcomes on various development and sustainable development proxy variables. Example of 2050 global implications of mitigation for different global mean temperature outcomes on various development and sustainable development proxy variables. Developed from the

scenarios associated with (Bauer et al., 2018). Data sample sizes (not shown, but to be added) vary across temperature levels and variables due to model infeasibilities and model differences in reporting.

18.2.5.3 Combining adaptation, mitigation, and sustainable development options

In practice, adaptation, mitigation, and sustainable development interventions are likely to be implemented in portfolio packages rather than as individual discrete options in isolation (*high agreement, limited evidence*). However, there is a dearth of literature estimating optimal portfolios of global adaptation and mitigation strategies. This is not surprising given the geographic-specific nature of climate impacts and adaptation and the information and computational complexity of representing that detail, as well as mitigation options and interactions. There are, however, different literatures relevant to considering potential combinations of adaptation, mitigation, and sustainable development.

At the most aggregate level, there is a long-standing literature exploring economically optimal global trade-offs between climate risks and mitigation (e.g., Manne and Richels, 1992; Nordhaus, 2017; Rose, 2017), as well as global stochastic analysis exploring global risk hedging for a small number of uncertainties (e.g., (Lemoine and Traeger, 2014). Recent work has found optimal global emissions and climate pathways to be highly sensitive to uncertainties and plausible alternative assumptions, with uncertainties throughout the causal chain from society to emissions to climate to climate damages shown to imply a wide range of different possible economically optimal pathways (Rose, 2017). Among other things, this work identifies assumptions consistent with limiting warming to different temperature levels. For example, the combination of potential annual climate damages of 15% of global GDP at 4˚C of warming and a less sensitive climate system were consistent with an economically efficient global pathway limiting warming to 2˚C. In addition, this work highlights the importance of characterizing and managing uncertainties. These types of global aggregate analyses inform discussions regarding long-run global pathways and goals but are of limited value to local near-term planning.

As discussed in Section 18.2.5.3.1, there are synergies and trade-offs mitigation, adaptation, and sustainable development. For instance, the literature on the global cost-effectiveness of mitigation pathways provides insights regarding aggregate synergies and trade-offs between mitigation and sustainable development (e.g., Figure 18.5). Furthermore, linkages between mitigation and adaptation options have been shown, such as expected changes in energy demand due to climate change interacting with energy system development and mitigation options, changes in future agricultural production practices to manage the risks of potential changes in weather patterns affecting land based emissions and mitigation strategies, or mitigation strategies placing additional demands on resources and markets which increases pressure on and costs for adaptation, or ecosystem restoration that provides carbon sequestration and natural and managed ecosystem resiliency benefits, but also could constrain mitigation and impact consumer welfare (WGIII AR6).

Non-linearities are an important consideration in evaluating risk management combinations. Non-linearities have been estimated in global and regional mitigation costs and potential economic damages from climate change (WGIII AR6 Chapter 3; (Clarke et al., 2014; Burke et al., 2015; Rose, 2017). Non-linear mitigation costs mean increasingly higher costs for each additional incremental reduction in emissions (or incremental reduction in global average temperature). Non-linear estimated economic climate damage means increasingly higher damages for each additional incremental increase in climate change (e.g., global average temperature) *(very high confidence*). Non-linearities are also suggested in estimated changes in key risks and adaptation costs (Chapter 16, WGII sector and regional chapters). However, to date, they have not been as explicitly characterized. These non-linearities imply non-linearities in climate risk management synergies and trade-offs with sustainable development. Not only do trade-offs vary by climate level, as do synergies, but they increase at an increasing rate and their relative importance can shift across climate levels *(very high confidence*). Some of this is evident in results like those shown in Figure 18.5 for mitigation (keeping in mind differences in sample sizes across temperature levels). Uncertainty about the degree of non-linearity in mitigation, climate damages, key risks, and adaptation costs creates uncertainties in the strength of the trade-offs and synergies, but also represents opportunities. For instance, additional mitigation options and more economically efficient policy designs have been shown to reduce mitigation costs and the non-linearities in mitigation costs *(very high confidence*) (WGIII AR6 Chapter 3). The same is true for adaptation options and adaptation costs.

Infeasibilities of mitigation and adaptation options (Section 18.4.2.2.1 and 18.4.2.2.2), as well as global pathways (WGIII AR6 Chapter 3), are also relevant to consideration of combinations of risk management options. Infeasibility of options implies higher costs and greater cost non-linearity due to fewer and/or more expensive options, while infeasibility of pathways bounds some of the uncertainty about the pathways relevant to decision-making and planning.

18.2.5.3.1 Trade-offs in adaptation, mitigation, and climate-resilient development

Since AR5, a growing body of literature has emerged that frames adaptation processes as endogenous socioeconomic dynamics, exogenous driving forces, and explicit decisions (Barnett et al., 2014; Maru et al., 2014; Butler et al., 2016; Kingsborough et al., 2016; Werners et al., 2018). Central to this framing is a shift away from viewing adaptation as discrete sets of options that are selected and implemented to manage risk, to thinking about adaptation as a social process that evolves over time, includes multiple decision-points, and requires dynamic adjustments in response to new information about climate risk, socioeconomic conditions, and the value of potential adaptation responses *(very high confidence)* (Haasnoot et al., 2013; Wise et al., 2016). This aligns adaptation with aspects of development thinking, including questions around the capacity and agency of different actors to effect change, the governance of adaptation, and the contingent nature of adaptation needs and effectiveness on the future evolution of society and climate change risk.

While ensuring development and adaptation produce synergies that allow for the achievement of sustainable development is challenging, modelling exercises suggest that there are pathways where synergies among the SDGs are realized *(very high confidence)* (Roy et al., 2018; Van Vuuren et al., 2019) (18.5), particularly if longer time-horizons are used. These pathways require progress on multiple social, economic, technological, institutional, and governance aspects of development including building human capacity, managing consumption behavior, decarbonization of the global economy, improving food and water security, modernizing cities and infrastructure, and innovations in science and technology (Van Vuuren et al., 2019) (18.3). In addition, Olsson et al, (Olsson et al., 2014) and Roy et al. (2018) emphasize the importance of integrating considerations for social justice and equity in the pursuit of sustainable development (Gupta and Pouw, 2017).

The significant overlaps and linkages between development and adaptation practice and a lack of conceptual clarity about adaptation pose a conundrum for scholars (e.g., Bassett and Fogelman, 2013; Webber, 2016), who raise concerns that this potentially leads to trade-offs or mislabeling (Few et al., 2017). This framing of adaptation and development can result in competition between attainment of sustainable development and policies to reduce the impacts of climate change (Ribot, 2011). Such trade-offs are illustrated by (Moyer and Bohl, 2019) who use a baseline development trajectory based on current trends to project progress on SDGs by 2030. This work concluded that only marginal gains are likely to be achieved under that pathway over the next decade (Barnes et al., 2019).

Emerging evidence also suggests that many adaptation-labelled strategies may exacerbate existing poverty and vulnerability or introduce new inequalities, for example by affecting certain disadvantaged groups more than others, even to the point of protecting the wealthy elite at the expense of the most vulnerable (Eriksen et al., 2019). Pelling et al. (2016) find that adaptation has been conceived and implemented in such a manner that most projects preserve rather than challenge the status quo. Specifically, the potential for knowledge and the goals of adaptation to be contested by different actors and stakeholders and the need to sustain progress over extended periods of time can constrain the ability to effectively implement actions that lead to sustainable development outcomes that are protected from the impacts of climate change while also delivering climate mitigation outcomes, that is, for climate resilient development (Bosomworth et al., 2017; Bloemen et al., 2019). This creates the possibility for specific adaptation actions to result in outcomes that undermine greenhouse gas mitigation and/or broader development goals (Fazey et al., 2016; Wise et al., 2016; Magnan et al., 2020). For example, a study in Bangladesh revealed how local elites and donors used adaptation projects as a lever to push vulnerable populations away from their agrarian livelihoods and into uncertain urban wage labour (Paprocki, 2018). These types of outcomes are categorised as maladaptation, interventions that increase rather than decrease vulnerability, and/or undermine or eradicate future opportunities for adaptation and development (Barnett and O'Neill, 2010; Juhola et al., 2015; Magnan et al., 2016; Antwi-Agyei et al., 2017; Schipper, 2020). This inadvertent impact on equity appears to fundamentally contradict a benevolent understanding of transformative adaptation that also champions social justice (Patterson et al., 2018), thus posing long-term maladaptation in opposition to transformative adaptation (Magnan et al., 2020).

Similarly, mitigation efforts, while reducing emissions, can also increase climate impacts vulnerability and undermine adaptation efforts. The same can be said for some poverty alleviation and sustainable development efforts that increase vulnerability for specific segments of the population. For example, in Central America, an evaluation of twelve rural renewable energy projects (either for CDM, early warning systems or rural electrification goals) found that some mitigation and poverty alleviation projects increased vulnerability to families—by excluding them, not adhering to local safety and quality codes and standards, or significantly altering community power dynamics and contributing to conflict (Ley, 2017; Ley et al., 2020).

Synergies between adaptation, mitigation and sustainable development might be promoted by prioritizing those CRD strategies most likely to generate synergies *(very high confidence)* (Roy et al., 2018; Karlsson et al., 2020). This could include focusing on poverty alleviation that improves adaptive capacity (e.g., Kaya and Chinsamy, 2016; Kuper et al., 2017; Ley, 2017; Sánchez and Izzo, 2017; Stańczuk-Gałwiaczek et al., 2018; Ley et al., 2020); renewable energy systems that improve water management and preservation of river ecological integrity (e.g., Berga, 2016; Rasul and Sharma, 2016); or internalizing positive externalities, such as subsidies for mitigation options thought to also improve water use efficiency (e.g., Roy et al., 2018). Similarly, trade-offs might be managed by prioritizing strategies such as disqualifying mitigation options thought to have negative social implications (Section 18.2.5.3.1), internalizing externalities, such as placing a fee or constraint on a negative externality or related activity (e.g., WGIII AR6 Chapter 13) (Bistline and Rose, 2018), or using complementary policies, such as transfer payments to offset negative mitigation, adaptation, or sustainable development strategy implications *(very high confidence)* (e.g., McCollum et al., 2018b). Roy et al. (2018) discusses the latter, noting, for instance, the possibility of complementary sustainable development payments to avoid global energy access, food security, and clean water trade-offs.

SR1.5 and AR6 assessments of system transitions also find opportunities for synergies and managing trade-offs (18.3; Cross-Chapter Box FEASIB). Within each system, mitigation and adaptation options are assessed for their specific benefits and the impacts they can have on one another, as well as with sustainable development. For example, within energy system transitions, the three adaptation options (power infrastructure resilience, reliability of power systems, efficient water use management) have strong synergies with mitigation. While not all mitigation options have strong synergies, the trade-offs can be managed when adaptation and sustainable development goals are also considered. Under land and other ecosystems system transitions, the main trade-off is the competition for land-use between potential alternative uses, e.g., sustainable agriculture, afforestation/reforestation, purpose-grown biomass for energy. On the other hand, assessment of urban and infrastructure system transitions finds mainly synergies between mitigation and adaptation options with trade-offs that are considered manageable, and there is growing evidence of rural landscape infrastructure benefits to adaptation.

Overall, this literature is relatively new and still developing. It highlights the importance of sets of societal priorities and policy design. However, it is not well developed in terms of joint optimization of multiple priorities, evaluating alternative mechanisms and shifts in trade-offs, and evaluating redistribution implications with transfers.

18.2.5.3.2 Risk management combinations with lower to higher climate change

The different strands of literature discussed above can be integrated to help inform thinking about combinations of approaches to risk management. Globally, low climate change projections, versus higher climate change projections, imply greater mitigation, lower climate risks, and less adaptation. This implies greater mitigation trade-offs in terms of overall economic development, food crop prices, energy prices, and overall household consumption, but lower climate risk, with sustainable development synergies like human health and lower adaptation trade-offs, and an uneven distribution of effects *(very high confidence)* (Roy et al., 2018).

Sustainable development considerations could be used to prioritize mitigation options, but as noted earlier there are trade-offs, with a potentially significant impact on the economic cost of mitigation, as well as a potential trade-off in terms of the climate outcomes that are still viable (WGIII AR6 Chapter 3). For instance, all of the 1.5˚C scenarios used in IPCC (2018a) deploy carbon dioxide removal technologies

(Rogelj et al., 2018). Without these technologies, most models cannot generate pathways that limit warming to 1.5˚C, and those that do adopt strong assumptions about global policy development and socioeconomic changes. Sustainable development might also affect the design of policies by prioritizing specific sustainable development objectives. However, there are trade-offs here as well, with costs and the distribution of costs varying with alternative policy designs. For instance, prioritizing air quality has climate co-benefits but does not ensure the lowest cost climate strategy (Arneth et al., 2009; Kandlikar et al., 2009). Similarly, prioritizing land protection has a variety of co-benefits but could increase food prices significantly, as well as the overall cost of climate mitigation (IPCC, 2019b). In this context with lower climate risk and adaptation levels and larger mitigation effort, managing mitigation trade-offs could be a sustainable development priority. Furthermore, sustainable development could also be tailored to facilitate adaptation as well as manage mitigation costs.

Globally, high climate change projections imply lower mitigation effort, higher climate risks, and greater adaptation. This implies lower mitigation trade-offs, but greater climate risk with greater demand of adaptation and potential for trade-offs in terms of competing sustainable development priorities. Sustainable development considerations could affect adaptation options. For instance, constraining options such as relocation or facilitating adaptation capacity and community resilience. Sustainable development might also be tailored to affect the climate outcome by shaping the development of emissions. In this context with greater climate risk and adaptation levels and less mitigation effort, facilitating adaptation and managing adaptation costs and trade-offs could be a sustainable development priority.

Locally, there are many qualitative similarities to the global perspective in thinking about risk management combinations across lower versus higher climates. However, there is one very important difference. Local decision makers are confronted with uncertainty about what others will do beyond their local jurisdiction. With future climate a function of the sum of global decisions, sustainable development planning needs to consider the possibility of more and less emissions reduction action globally and the potential associated climates. This implies the need for sustainable development to manage for the possibility of higher climates by further facilitating adaptation and managing adaptation trade-offs. Prioritizing sustainable development locally is also supported by the insight that the impacts on poverty depend at least as much or more on development than on the level of climate change (*very high confidence*) (Wiebe et al., 2015; Hallegatte and Rozenberg, 2017).

There is nothing in the current literature to suggest that CRD is necessarily associated with a specific climate outcome, like limiting global average warming 1.5˚C or 2˚C, or a specific pathway. Instead, there are many possible pathways for climate-resilient development (*medium agreement, limited evidence*) (e.g., David Tàbara et al., 2018; O'Brien, 2018). The current literature suggests that different mixes of adaptation and mitigation strategies, and sustainable development and trade-off management priorities, measures, and reallocations (Section 18.5.3.1), will be appropriate for different expected climates and locations (18.1.2); while trade-offs between climates will be dictated by relative non-linearities, feasibilities, shifts in priorities, and trade-off and reallocation options across future climates.

Finally, it is important to note that there is currently limited information available regarding the following: (1) local implications of 1.5˚C versus warmer futures with respect to avoided impacts and sustainable development implications and interactions and applying global conclusions to local, national, and regional settings can be misleading, (2) local context-specific synergies and trade-offs with respect to adaptation, mitigation, and sustainable development for 1.5˚C futures, and (3) standard indicators for monitoring factors related to CRD (Roy et al., 2018).

18.3 Transitions to Climate Resilient Development

A key finding emerging from the IPCC SR1.5 is the critical role that system transitions play in enabling mitigation pathways consistent with a 1.5°C or less world (IPCC, 2018a; IPCC, 2019b).Such transitions are similarly critical for the broader pursuit of climate-resilient development, and the various AR6 special reports as well as subsequent literature provide new evidence of why such transitions are needed for CRD, as well as both the opportunities for accelerating system transitions and their limitations for delivering on the goals of CRD.

18.3.1 System Transitions as a Foundation for Climate Resilient Development

In the AR6, system transitions are defined as "*the process of changing (the system in focus) from one state or condition to another in a given period of time*" (IPCC, 2018a; IPCC, 2019b). In the climate change solution space, system transitions represent an important mechanism for linking and enabling mitigation, adaptation, and sustainable development options and actions (*very high confidence*). SR1.5C identified the need for rapid and far-reaching transitions in four systems – energy, land and terrestrial ecosystems, urban and infrastructure, and industrial systems (IPCC, 2018b; IPCC, 2018a) (1.5.1 and 18.1). The SRCCL expanded on this with a focus on terrestrial systems, while SROCC added additional evidence from ocean and cryosphere systems. This section assesses the four system transitions discussed in the SR1.5C assessment in the context of CRD, while also extending the assessment to consider societal transitions as a cross-cutting, fifth transition important for climate-resilient development. Literature to support this assessment is also drawn from AR6 regional and sectoral chapters, which is synthesized later in this chapter (18.5).

As discussed in Box 18.3 (Hölscher et al., 2018), system transitions are linked to system transformation, which is defined as "*a change in the fundamental attributes of a system including altered goals or values*" (Figure 18.1) (IPCC, 2018a). In a systems context, transitions focus on 'complex adaptive systems; social, institutional and technological change in societal sub-systems', while transformations are "*large scale societal change processes … involving social-ecological interactions"* (IPCC, 2018a) (Box 18.1). Although system transitions are often identified in the literature as being necessary processes for large-scale transformations (Roggema et al., 2012; Hölscher et al., 2018), thereby making them a core enabler of CRD. Yet, they are not necessarily transformative in themselves.

18.3.1.1 Energy Systems

Recent observed changes in global energy systems include continued growth in energy demand, led by increased demand for electricity by industry and buildings *(very high confidence*) (AR6 WGIII Chapter 2). Growth in energy demand has also been driven by increased demand for industrial products, materials, building energy services, floor space, and all modes of transportation. This growth in demand, however, has been moderated by improvements in energy efficiency in industry, buildings, and transportation sectors (*very high confidence*) (AR6 WGIII Chapter 2). There is also a trend of moving away from coal towards cleaner fuels, due to lower natural gas prices and lower cost renewable technologies, and structural changes away from more energy-intensive industry.

Features of sustainable development such as enhanced energy access, energy security, reductions in air pollution, and economic growth continue to be the dominant influence on the evolution of energy systems and decision-making regarding energy investments and portfolios (*very high confidence*) (WGIII AR6 Chapter 6). To date, climate policy has been comparatively less influential in driving energy transitions globally. Yet, there are examples at the local, regional, and national level of policy incentivizing rapid changes in energy systems (*very high confidence*) (WGIII AR6 Chapter 6). Many sustainable development priorities have co-benefits in terms of climate mitigation, such as air pollution and conservation policies reducing short-lived climate forcers and sequestering carbon respectively, as well adaptation benefits, such as improved energy access and environmental quality enhancing adaptive capacity (*very high confidence*) (WGIII AR6 Chapter 6) (de Coninck et al., 2018). Alternatively, sustainable development projects can have negative climate implications with, for instance, hydroelectric projects shut down by droughts or floods resulting in greater use of bunker and fuel oil, as well as natural gas.

In addition to sustainable development priorities driving change in energy systems, observed energy system trends have implications for sustainable development (e.g., IEA et al., 2019). Observed changes in energy system size, rate of growth, composition and operations impact energy access, equity, environmental quality and wellbeing, with both synergies and trade-offs, including recent improvements in global access to affordable, reliable, and modern energy services. For instance, in some countries, such as the United States, there has been a significant shift away from coal as a fuel source for electricity generation in favor of natural gas. More recently, however, renewables have emerged as the dominant form of new electricity generation (Gielen et al., 2019). Similarly, for energy access in developing countries, renewable energy or hybrid distributed generation systems are increasingly being prioritized due to challenges associated with access, costs and environmental impacts from traditional fossil fuel-based energy technologies (Mulugetta et al., 2019).

Energy systems have been a historical driver of climate change, but are also adversely affected by climate change impacts, including short-term shocks and stressors from extreme weather as well as long-term shifts in climatic conditions (*very high confidence*). The potential for such factors is often incorporated into local system designs, operations, and response strategies. There have been changes in observed weather and extreme event hazards for the energy system, but to date many are not attributable solely to anthropogenic climate change (USGCRP, 2017; IPCC, 2021a). Nevertheless, with observed extremes shifting outside of what has been observed historically, existing design criteria and operations may not be optimal for future climate conditions and contingencies (Chapter 16; sectoral and regional chapters). Overall, there is limited historical evidence on the efficacy of adaptation responses in reducing vulnerability of energy systems (*high agreement, limited evidence*). However, sustainable development trends, such as improving incomes, reducing poverty, and improving health and education have reduced vulnerability (Chapter 16), and improvements in system resiliency to extreme weather events and more efficient water management have occurred that have synergies with adaptation and sustainable development in general.

Available literature indicates that greenhouse gas emissions reductions have been achieved in response to climate actions including financial incentives to promote renewable energy, carbon taxes and emissions trading, removal of fossil fuel subsidies, and promotion of energy efficiency standards *(very high confidence)* (WGIII AR6 Chapter 6). Such policies tend to lead to a lower carbon intensity of GDP, due to structural changes in the use of energy and the adoption of new energy technologies. However, other drivers of change are also present and thus ongoing energy transitions and their future evolution are a response to both climatic and non-climatic considerations, with broader sustainable development priorities being a significant driver of change (see WGIII AR6 Chapter 6).

18.3.1.2 Urban and infrastructure systems

Urban areas their associated infrastructure are critical targets for CRD processes. This is a function of urban areas being the dominant settlement pattern with over 55% of the global population living in cities (World Bank, 2021). As a consequence, urban areas are also the focal point for energy use, land use change, and consumption of natural resources, thereby making them responsible for an estimated 70% of global CO2 emissions (Johansson et al., 2012; Ribeiro et al., 2019). The trend toward increasing urbanization is anticipated to create both challenges and opportunities for sustainable development, as well as climate action (Güneralp et al., 2017; Li et al., 2019a).

The built environment is increasingly exposed to climate stresses and more frequent co-occurrences of climate shocks than in the past. This has the potential to increase rates of building and infrastructure degradation, increase damage from extreme weather events. The existing adaptation gaps and everyday risks within many cities, particularly those of the global South, combined with escalating risk from climate change, makes rapid progress in enhancing urban resilience a high priority for CRD (Pelling et al., 2018; Davidson et al., 2019; Lenzholzer et al., 2020). Strategic investments in disaster risk reduction, including climate-resilient green infrastructure, updated building codes, and land use planning can provide significant long-term cost savings and social benefits. Moreover, evaluating the relative merits of "fail safe" versus "safe to fail" approaches to infrastructure planning can help to identify more design principles that are more robust to the uncertainties of climate change and urbanization (Kim et al., 2017a; Kim et al., 2019).

Much of the literature on urban resilience and sustainability focuses on addressing discrete challenges for urban infrastructure sub-systems. Climate change has the potential to enhance stress on lifeline infrastructure services such as the provision of electricity, water and wastewater, communications, and transportation – sub-systems which often underdeveloped in many regions of the world (Arku and Marais, 2021; Sitas et al., 2021). For example, a warming and more variable climate can increase stress on electricity grids by reducing transmission efficiency, increasing cooling demand requirements, and by increasing exposure to climate shocks such as heat waves, floods, and storms (Bartos and Chester, 2015; Auffhammer et al., 2017; Perera et al., 2020). Accordingly a significant focus on the energy transition is on achieving the dual goals of reducing the carbon footprint of energy while also increasing resilience of energy supply to current and future threats.

For example, renewable energy generation and storage technologies that modular and distributed and provide enhanced resilience to shocks and stresses from climate change (Venema and Temmer, 2017a).

Similarly, building and maintaining urban water systems that are resilient to climate shocks requires significant changes in water demand, infrastructure, and management. Enhancing redundancy in water supply and the flexibility to shift between surface and groundwater options aids adaptation. Decentralized water supply and sanitation options are now feasible and can provide greater resilience than most centralized systems (Parry, 2017), provided they have adequate supply (Leigh and Lee, 2019; Rabaey et al., 2020). Water conservation and green infrastructure options for stormwater management are proven approaches for reducing climate risks (Venema and Temmer, 2017b), with adaptation and mitigation co-benefits. Water demand management and rainwater harvesting contribute to climate change mitigation and increase adaptive capacity by increasing resilience to climate change impacts such as drought and flooding (Paton et al., 2014; Berry et al., 2015). In addition, they can contribute to restoring urban ecosystems that offer multiple ecosystem services to citizens (Berry et al., 2015) (see WGIII AR6 Chapter 8). The context-appropriate development of green spaces, protecting ecosystem services and developing nature-based solutions, can increase the set of available urban adaptation options (IPCC, 2018b), while creating opportunities for more complex and dynamic approaches to urban water management (Franco-Torres et al., 2020). For example, the Netherlands' 'Room for the River' policy focuses on ont only achieving higher flood resilience, but also improving the quality of riverine areas for human and ecological wellbeing (Busscher et al., 2019).

An overarching focus of urban sustainability is the reversal of long-standing trends of ecosystem fragmentation and degradation that have resulted in growing separation between human and natural systems within urban environments (IPBES, 2019) (see WGIII AR6 Chapter 8). Urban ecosystems and the integration of nature-based solutions and green infrastructure into urban areas can yield benefits that facilitate achievement of the SDGs. There has been growing recognition of urban ecosystems as social, cultural, and economic assets that can support economic development while also enhancing resilience to extreme weather events and improving air and water quality (Shaneyfelt et al., 2017; Matos et al., 2019). Investing in urban ecosystems and green infrastructure can provide lower-cost solutions to multiple urban development challenges when compared to traditional infrastructure systems (Terton, 2017). Relatedly, agriculture, while largely a rural system, is increasingly expanding within urban areas. Urban agriculture enables citizens to fulfil some of their food needs, improving urban resilience to food shortages, enhancing biodiversity, and increasing coping capacity during disasters (Demuzere et al., 2014; Clucas et al., 2018) (see WGIII AR6 Chapter 8). Strengthening urban agroecosystems therefore increases resilience to supply shocks from climate change impacts and can contribute to community cohesion (Temmer, 2017a).

Overall, the discourse in the literature regarding the future of cities emphasizes the importance of viewing cities as more than just their physical infrastructure that can be made more resilient through engineering solutions (Davidson et al., 2019). Rather, urban areas are increasingly conceptualized as complex socioecological or sociotechnical systems (*very high confidence*) (Patorniti et al., 2017; Patorniti et al., 2018; Visvizi et al., 2018; Savaget et al., 2019). Such frameworks integrate physical, cyber, social, and ecological elements of cities in pursuit of resilience and sustainability transitions, and they recognize the role of governance and engagement processes as being central to system change (Temmer, 2017b). Nevertheless, some authors have cautioned that urban transitions will be associated with synergies as well as trade-offs with respect to sustainable development (*very high confidence*) (Maes et al., 2019; Sharifi, 2020).

[START BOX 18.5 HERE]

Box 18.5: The Implications of the Belt and Road Initiative (BRI) for Climate Resilient Development

In 2013, Chinese President Xi Jinping announced plans for a grand transcontinental infrastructure initiative. China would work with partner countries under two programs termed the Silk Road Economic Belt and the 21st Century Maritime Silk Road. Together, these have come to be known as the Belt and Road Initiative (BRI). Set to encompass 4.4 billion people and a cumulative GDP of around $21 trillion, the BRI has been implemented in over 120 countries with wide infrastructure funding gaps, as exemplified by the China-Myanmar Gas Pipeline, Gwadar Port in Pakistan, Trans-Mongolian Railway, China Belarus Industrial Park, and urban rehabilitation in Ethiopia. Its stated objectives even extend beyond infrastructure connectivity to include trade promotion, financial integration, policy coordination and cultural dialogue. Having been written into the Communist Party's constitution in 2017, the BRI will be China's flagship international development strategy for years to come.

The 126 countries participating in the BRI account for 23% of global GDP, but also 28% of global carbon emissions (PBCSF, 2019). By 2050, even based on an optimistic scenario, the total carbon emission by these countries will be 17% higher than what would be allowed under a 2°C carbon budget (Duan et al., 2018). The BRI covers regions with high reserve of carbon-based fuels and could have significant impact on global energy consumption and carbon emission patterns. For example, according to the EIA statistics, the proven reserves of oil, natural gas, and coal in nations under the BRI make up 58.8%, 79.9%, and 54.0% of the world's total (China Meteorological Administration, 2019).

Meanwhile, countries along the BRI are highly vulnerable to the impact of climate change, spanning highly diverse climate zones with fragile ecological conditions. Currently, many of the regions have a low level of infrastructure development and high population densities (The People's Republic of China, 2017). Changes in temperature, precipitation, vegetation and hydrological conditions could in turn pose threats to the development and operation of infrastructure projects in these regions. Given the scope and scale of the BRI, a key question is whether it will incentivize continued exploitation of available fossil fuel resources or provide the innovation and economic development needed to transition participating nations to more resilient and less carbon-intensive economies.

BRI and its commitment to climate resilient development (CRD)

Recognizing these feedbacks between the BRI and climate change, the Chinese government, included climate change in developing the key guiding documents on BRI development in 2015. These include "*taking into consideration the impact of climate change, strengthening exchange and cooperation with countries along the Belt and Road, leveraging the support and guarantee function of Chinese meteorological departments in promoting the BRI*" (NDRC, 2015). The second BRI Forum held in 2019 reiterated the importance of green development "*as the foundation of the BRI*" and promoted green infrastructure development and green investment, in addition to plans for increasing capacity in response to climate change, promoting low-carbon infrastructure, energy source, climate-related disaster alarm system, climate finance integration, as well as low-carbon technology development.

The Chinese Meteorological Administration, the governmental agency responsible for climate change related issues, responded to BRI official guidelines by establishing BRI integrated meteorological service system and proposed meteorological development plan 2017-2025 (China Meteorological Administration, 2019), which includes policy coordination on climate change, promoting intergovernmental cooperation, completing BRI disaster prevention and relief mechanisms, strengthening climate change support capacity, enhancing prediction and evaluation capacity related with climate change (China Meteorological Administration, 2019). China has established South-South cooperation in support of other countries to mitigate climate change. Efforts have been made to promote joint research with countries along the BRI on regional climate change, climate change prediction, and develop products in response to climate conditions in different regions.

The China Clean Development Mechanism Fund (CCDMF) is a national climate fund that supports low carbon growth and climate resilience in China (UNFCCC, 2017). More than USD 81 million in grants committed to support over 200 projects. A combination of funding enterprises, mobilizing market capital and achieving verified emission reduction effects contributes to a direct reduction of over seven million tons of CO2 equivalent. Government representatives from Brazil, Vietnam, and Cambodia have already visited CCDMF to learn more about this type of climate financing.

Trade-offs between BRI and CRD

Despite the implementation of such financing mechanisms for low-carbon development, their net effect is not necessarily sufficient to offset the carbon footprint generated by overseas fossil fuel projects funded or financed by China. As such, BRI stakeholders must navigate a number of trade-offs among different objectives of the initiative.

For the Chinese government and state-owned enterprises, an immediate trade-off is that between the short-term profits gained through carbon-intensive infrastructure investments overseas and long-term sustainable development with the introduction of low-carbon technology in infrastructure development. On one hand, the energy solutions that China proposes tend to involve carbon-intensive infrastructures such as coal factories, which increases carbon emissions of these countries. But at the same time, China also provides climate finance for these countries in support of renewable energy projects such as hydropower projects and solar panel production facilities.

For the governments and people hosting BRI projects, the tradeoff is between short-term economic prosperity and long-term sustainable development. Infrastructure development driven by carbon-intensive technologies are cheaper and more consistent for developing countries (for example, electricity generated through coal-based power plants is more consistent than that generated through hydropower stations), which is conducive to more rapid industrialization of these countries, generating immediate urbanization and economic prosperity. Yet the industrialization process would exacerbate carbon emission and accelerate the climate change process, with long-term impact on food security, livelihood, migration, water demand, disease control, posing potential hazards to sustainable development in these regions.

Winners and losers in incorporating CRD into BRI development

An emphasis on CRD within the BRI could create a number of opportunities for sustainable development. For example, adherence to CRD principles of low-carbon development would incentive growth of renewable energy, clean technologies, thereby growing the global market for such goods and services. This could have significant benefits for developing nations of the BRI in terms of enabling sustainability transitions that might otherwise not be feasible. However, a CRD orientation of the BRI would also have consequences for fossil fuel and carbon-intensive industries. This could affect both private and state-owned enterprises in BRI nations resulting in stranded assets, loss of some forms of employment.

18.3.1.3 Land, Oceans, and Ecosystems

Land, oceans, and terrestrial ecosystems are in transition globally, with anthropogenic factors including climate change being a major driving force *(very high confidence)* (IPBES, 2019) (Box 6). Seventy-five per cent of the land surface has been significantly altered, 66 percent of the ocean area is experiencing increasing cumulative impacts, and over 85 percent of wetland areas have been lost (IPBES, 2019). Since 1970, only four out of eighteen recognized ecosystem services assessed have improved in their functioning: agricultural production, fish harvest, bioenergy production and material harvests. The other 14 ecosystem services have declined (IPBES, 2019), raising concerns about the capacity of ecosystems and their services to support sustainable and climate-resilient development.

Given the pressures on land, oceans, and ecosystems, enhancing resilience to climate change and other pressures of human development is a core priority of transition in these systems. Yet, there are a few recorded initiatives that provide evidence of successful improvement in ecosystem resilience (*high agreement, limited evidence*). Similarly, although there is significant evidence that a broad range of adaptation initiatives have been pursued across global regions and sectors, including a rapid expansion of nature- or ecosystem-based solutions (Mainali et al., 2020), there is limited evidence of how these planned climate adaptation efforts have contributed to enhanced ecosystem resilience. Additional research is necessary to evaluate these efforts in terms of their performance and also to identify mechanisms for scaling them up in different contexts. As an example, Paik (Paik et al., 2020) record the increased diffusion of salt tolerant rice varieties in the Mekong River Delta, which is at risk of sea-level rise and an associated saline intrusion. This is a low-cost adaption to saline ingress, that increases food productivity and reduces the risk of outmigration for this vulnerable agricultural region.

Evidence of the interactions between ecosystems and resilience come from a range of sources including both regional and sectoral examples (Box 18.2; Tables 18.7‑18.8. For example, regional examples suggest that the use of land to produce biofuels could increase the resilience of production systems and address mitigation needs (Box 2.2). Nevertheless, the potential of BECCS to induce maladaptation needs deeper analysis (Hoegh-Guldberg et al., 2019). Climate Smart Forestry (CSF) in Europe provides an example of the use of sustainable forest management to unlock the EU's forest sector potential (Nabuurs et al., 2017). This is in response to diverse climate impacts ranging from pressure on spruce stocks in Norway and the Baltics, on regional biodiversity in the Mediterranean region, and the opportunity to use afforestation and reforestation to store carbon in forests (Nabuurs et al., 2019). CSF considers the full value chain from forest to wood products and energy and uses a wide range of measures to provide positive incentives to firmly integrate climate objectives into the forestry sector. CSF has three main objectives; (i) reducing and/or removing greenhouse gas emissions; (ii) adapting and building forest resilience to climate change; and (iii) sustainably increasing forest productivity and incomes (Verkerk et al., 2020).

Other solutions focus on specific subsectors. Mutually supportive climate and land policies have the potential to save resources, amplify social resilience, support ecological restoration, and foster engagement and collaboration between multiple stakeholders. (IPCC, 2019f, C.1). Land-based solutions can combat desertification in specific contexts: water harvesting and micro-irrigation, restoring degraded lands using drought-resilient ecologically appropriate plants, agroforestry, and other agroecological and ecosystem-based adaptation practices (IPCC, 2019f, B.4.1). Reducing dust and sand storms and sand dune movement can lessen the negative effects of wind erosion and improve air quality and health. Depending on water availability and soil conditions, afforestation, tree planting and ecosystem restoration programs, using native and other climate resilient tree species with low water needs, can reduce sand storms, avert wind erosion, and contribute to carbon sinks, while improving micro-climates, soil nutrients and water retention (IPCC, 2019f, B.4.2).

Coastal blue carbon ecosystems, such as mangroves, salt marshes and seagrasses, can help reduce the risks and impacts of climate change, with multiple co-benefits. Over 150 countries contain at least one of these coastal blue carbon ecosystems and over 70 contain all three. Successful implementation of measures of carbon storage in coastal ecosystems could assist several countries in achieving a balance between emissions and removal of greenhouse gases. Carbon storage in marine habitats can be up to 1,000 tC ha–1, higher than most terrestrial ecosystems. Conservation of these habitats would also sustain a wide range of ecosystem services, assist with climate adaptation by improving critical habitats for biodiversity, enhancing local fishery production, and protect coastal communities from SLR and storm events (IPCC, 2019b). Ecosystem-based adaptation is a cost-effective coastal protection tool that can have many co-benefits, including supporting livelihoods, contributing to carbon sequestration and the provision of a range of other valuable ecosystem services (IPCC, 2019b).

Diversification of food systems is another component of land, ocean, and ecosystem transitions that are consistent with CRD. Balanced diets, featuring plant-based foods, such as those based on coarse grains, legumes, fruits and vegetables, nuts and seeds, and animal-sourced food produced in resilient, sustainable and low-GHG emission manner, are major opportunities for adaptation and mitigation and improving human health. By 2050, dietary changes could free several million sq. km of land and provide a mitigation potential of 0.7 to 8.0 GtCO2eq yr-1, relative to business-as-usual projections.

For coastal systems, many frameworks for climate resilience and adaptation have been developed since the AR5 (Hoegh-Guldberg et al., 2014; Settele et al., 2014) with substantial variations in approach between and within countries, and across development status. Few studies have assessed the success of implementing these frameworks due to the time-lag between implementation, monitoring, evaluation and reporting (IPCC, 2019g). As an example, the Nature-Based Climate Solutions for Oceans initiative has the potential to: restore, protect and manage coastal and marine ecosystems, adapt to climate change, improve coastal resilience, and enhance their ability to sequester and store carbon (Hoegh-Guldberg et al., 2019).

Polar regions will be profoundly different in the future. The degree and nature of that difference will depend strongly on the rate and magnitude of global climate change, which will influence adaptation responses regionally and worldwide. Future climate-induced changes in the polar oceans, sea ice, snow and permafrost will drive habitat and biome shifts, with associated changes in the ranges and abundance of ecologically important species (IPCC, 2019g). Innovative tools and practices in polar resource management and planning show strong potential in improving society's capacity to respond to climate change. Networks of protected areas, participatory scenario analysis, decision support systems, community-based ecological monitoring that draws on local and indigenous knowledge and self-assessments of community resilience contribute to strategic plans for sustaining biodiversity and limit risk to human livelihoods and wellbeing. Experimenting, assessing, and continually refining practices while strengthening links with decision making has the potential to ready society for the expected and unexpected impacts of climate change (IPCC, 2019g).

[START BOX 18.6 HERE]

Box 18.6: The Role of Ecosystems in Climate-Resilient Development

Ecosystems and their services closely relate to CRD. Climate change has impacted ecosystems across a range of scales, and those impacts have been exacerbated by other ecological impacts associated with human activities. Ecosystem based adaptation strategies have been developed and is crucial to CRD. However, knowledge and evidence still missing, and cultural services—in contrast to provision and regulation services as main benefits and supporting services as co-benefits—are less well addressed in the literature.

Ecosystems play a key role in CRD

A key element of CRD is ensuring that actions taken to mitigate climate change do not compromise adaptation, biodiversity, and human needs. Maintaining ecosystem health, linked to planetary health, is an integral part of the goals of CRD. The 2005 Millennium Ecosystem Assessment defined ecosystem services as "*the benefits people obtain from ecosystems*", and categorized the services in to provisioning, regulating, supporting, and cultural services (Millennium Ecosystem Assessment, 2005; IPBES, 2019). The 2019 Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) broadened the definition to "*the contributions, both positive and negative, of living nature to the quality of life for people*", and developed a classification of 18 categories (IPBES, 2019).

Table Box 18.6.1 demonstrates how ecosystem services connect to sustainable development goals (SDGs) and CRD. MEA's provisioning service generally connects to the IPBES' material services, mostly contributing to the SDG cluster associated with nature's contribution to people (NCP) (Millennium Ecosystem Assessment, 2005; IPBES, 2019) and to "**D**evelopment" in CRD. MEA's regulating and supporting services connect to IPBES' non-material services, contributing to SDG clusters of Nature and Driver of change in nature and NCP and to "**R**esilience" in CRD. MEA's cultural services connect to IPBES' non-material services, contributing to SDG clusters of good quality of lift (GQL) and to **E**nabling conditions for CRD.

Table Box 18.6.1: Ecosystem services (based on the Millennium Ecosystem Assessment, MEA, and the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services, IPBES, classifications) and their connections to sustainable development goals (SGCs) and climate resilient development (CRD) (Millennium Ecosystem Assessment, 2005; IPBES, 2019).

Ecosystem services		SDGs	CRD
MEA	**IPBES**		
Provisioning services	11 Energy 12 Food and feed 13 Materials and assistance 14 Medicinal, biochemical, and genetic resources	1 No poverty 2 Zero hunger 3 Good health and well-being 11 Sustainable cities communities 7 Affordable clean energy 8 Decent work and economic growth 9 Industry, innovation, and infrastructure 12 Responsible consumption and production	**D**evelopment
Regulating services	3 Regulation of air quality 4 Regulation of climate 5 Regulation of ocean acidification 6 Regulation of freshwater quantity, location, and timing 7 Regulation of freshwater and coastal water quality	6 Clean water and sanitation 13 Climate action	**C**limate adaptation and mitigation

	9 Regulation of hazards and extreme events 10 Regulation of organisms detrimental to humans		
Supporting services	1 Habitat creation and maintenance 2 Pollination and dispersal of seeds 8 Formation, protection, and decontamination of soils and sediments 18 Maintenance of options	14 Life below water 15 Life on land	
Cultural services	15 Learning and inspiration 16 Physical and psychological experiences 17 Supporting identities	4 Quality education 5 Gender equality 10 Reduce inequality 16 Peace, justice, and strong institutions 17 Partnerships for the goals	**E**nabling Conditions

Climate change impacts on ecosystems and their services

Climate change connects to ecosystem services through two links: climate change and its influence on ecosystems as well as its influence on services (Chapter 2.2). The key climatic drivers are changes in temperature, precipitation, and extreme events, which are unprecedented over millennia and highly variable by regions (Chapter 2.3, 3.2; Cross-Chapter Box EXTREMES in Chapter 2). These climatic drivers influence physical and chemical conditions of the environment, and worsen the impacts of non-climate anthropogenic drivers including eutrophication, hypoxia, sedimentation (Chapter 3.4). Such changes have led to changes in terrestrial, freshwater, oceanic and coastal ecosystems at all different levels, from species shifts and extinctions, to biome migration, and to ecosystem structure and processes changes (Chapter 2.4, 2.5, 3.4, Cross-Chapter Box MOVING PLATE in Chapter 5). Changes in ecosystems leads to changes in ecosystem services including food and limber prevision, air and water quality regulation, biodiversity and habitat conservation, and cultural and mental support (Chapter 2.4, 3.5). Table Box 18.6.2 presents examples of climate change's impact on ecosystems and their services from other chapters in the WGII report. The degradation of ecosystem services is felt disproportionately by people who are already vulnerable due to historical and systemic injustices, including women and children in low-income households, Indigenous or other minority groups, small-scale producers and fishing communities, and low-income countries (Chapter 3.5, 4.3, 5.13).

Table Box 18.6.2: Examples of key risks to ecosystems from climate change and their connections to ecosystem services (ES) in the WGII report and cross-chapter papers (CCPs). (See Table 1 for the description of the categories of ES)

Climate factors	Key risk	ES			
		P	R	S	C
***Terrestrial and freshwater ecosystems* (Chapter 2, 4, 5; CCP 1; CCP 7; CCP 3; CCP 5)**					
- Increase in average and extreme temperatures - Changes in precipitation amount and timing - Increase in aridity - Increase in frequency and severity of drought - Increased atmospheric CO_2	Species extinction and range shifts	X		X	X
	Ecosystem structure and process change	X	X		
	Ecosystem carbon loss	X	X		
	Wildfire		X	X	
	Water cycle & scarcity	X	X		
***Ocean and coastal* (Chapter 3; CCP 1; CCP 6)**					
- Ocean warming - Marine heatwaves - Ocean acidification - Loss of oxygen - Sea level rise - Increased atmospheric CO_2 - Extreme events	Species extinction and range shifts	X		X	X
	Ecosystem structure and process change	X	X		
	Habitat loss	X		X	
	Ocean carbon sink less effective		X		
	Erosion and land loss	X	X		
***Food, Fiber, and other Ecosystem Products* (Chapter 5)**					
- Global warming	Species distribution	X			

- Water stress - Extreme events - Ocean acidification - Salt intrusion	Timing of key biological events change	X			
	Corp productivity and quality decrease	X			
	Diseases and insect	X			

Adaptation practices and enabling conditions for CRD

Ecosystem protection and restoration, ecosystem-based adaptation (EbA), and nature-based solution (NbS) can lower climate risk to people and achieve multiple benefits including food and material provision, climate mitigation, and social benefits (Chapter 2.6, 3.6, 4.6, 5.13,6.3, 8.6). Table Box 18.6.3 presents some examples of ecosystem adaptation practices reported in WGII sectoral and regional chapters and CCPs, as well as their co-benefits, potential for maladaptation, and enabling conditions. Many of the strategies focus on integrated systems (managing for multiple objectives and trade-offs) as well as the fair use of resources. However, there is limited evidence of the extent to which adaptation is taking place and virtually no evaluation of the effectiveness of adaptation in the scientific literature (Chapter 2.6, 3.5). Enabling conditions for the successful implementation ecosystem-based practice include regional and community-based based approaches, multistakeholder and multi-level governance approaches, Integration of Local Knowledge and Indigenous Knowledge, finance, and social equity (Chapter 2.6, 3.6).

Table Box 18.6.3: Examples of adaptation practices and their connections to ecosystem services (ES) and climate resilient development pathways (CRDP) in the WGII sectoral and regional chapters and cross-chapter papers (CCPs). (See Table 1 for the description of the categories of ES and CRDP)

Adaptation practices (and - *examples*)	**Main benefit (and & co-benefit; - trade off; + enabling conditions; X barrier and potential maladaptation)**	**ES**			
		P	**R**	**S**	**C**
Agroforestry (Table 2.7; Table 5.ES; Chapter 5.10.4; Chapter 5.12.5.2; Box 5.10; Table 16.2) - *Climate Adaptation and Maladaptation in Cocoa and Coffee Production* (Box 5.7)	Food provision **&** Fuel (wood) provision, carbon sequestration, biodiversity and ecosystem conservation, diversification and improved economic incomes, water and soil conservation, and aesthetics **+** Secure tenure arrangements, supporting Indigenous knowledge, inclusive networks and socio-cultural values, access to information and management skill **X** Higher water demand; disruption of hydrology; loss of native biodiversity; reduced resilience of certain plants; degraded soil and water quality; improper and increased use of agrochemicals, pesticides, and fertilizers	***	**		**

[END BOX 18.6 HERE]

18.3.1.4 Industrial systems

Industrial emissions have been growing faster since 2000 compared to emissions in any other sector, driven by increased extraction and production of basic materials (Crippa et al., 2019; IEA, 2019) (*very high confidence*). About one-third of the total emissions are contributed by the industry sector, if indirect emissions from energy use are considered (Crippa et al., 2019). The COVID-19 pandemic has caused a significant decrease in demand for fuels, oil, coal, gas, and nuclear energy (IEA, 2020). However, there is concern that the rebound in the crisis will reverse this trend (IEA, 2020). Accordingly, the literature suggests a combined set of measures is beneficial for facilitation a transition of industrial systems in support of CRD. This includes (i) dematerialization and decarbonization of industrial systems, (ii) establishment of supportive governance, policies, and regulations, and (iii) implementation of enabling corporate strategies.

Decarbonization and dematerialization strategies have been proposed as key drivers for the transition of industrial systems (Fischedick et al., 2014; Worrell et al., 2016). The former involves limiting carbon emissions from industrial processes (IEA, 2017; Hildingsson et al., 2019), while the latter involves improving material efficiency, developing circular economies, raw material demand management, environmentally friendly product and process innovations, and environmentally friendly supply chain management (Worrell et al., 2016; Petrides et al., 2018).

Recent modelling suggests that stocks of manufactured capital, including buildings, infrastructure, machinery, and equipment, stabilize as countries develop and decouple from GDP (*high agreement, medium evidence)*. For instance, Bleischwitz et al. (2018) confirmed the occurrence of a saturation effect for materials in four energy-intensive sectors (steel, cement, aluminum and copper) in five industrialized countries (Germany, Japan, the United Kingdom, the United States and China). High growth in the supply of materials may still drive global demand for new products in the coming years for developing countries that are still far from saturation levels. Therefore, accelerating industrial transitions to drive the decoupling of industrial emissions from economic growth and facilitate broader transformation in industrial systems can be one component of CRD.

Continued transitions in the industrial sector will be contingent on technological innovation. Although technologies exist to drive emissions in industrial sectors to very low or zero emissions, but they require 5 to 15 years of innovation, commercialization, and intensive policies to ensure uptake (Åhman et al., 2017) (*high agreement, medium evidence*). For instance, several options exist to reduce GHG emission related to steel production process including increasing the share of the secondary route (Pauliuk et al., 2013), hydrogen-based direct reduced iron (Vogl et al., 2018), aqueous electrolysis rout (Cavaliere, 2019), and plasma process (Quader et al., 2016).

Industrial transitions are also contingent upon consumer behavior in terms of preferences for, and rates of, consumption of industrial products. Sustainable consumption can play an important role in sustainable production (Allwood et al., 2013; Allwood et al., 2019). This suggests feedbacks between industrial production and consumption in driving industrial transitions. For example, sustainable consumption can be triggered and/or enabled through sustainable production processes that provide more sustainable options to consumers as well as public or private promotional campaigns that promote those options. Meanwhile, demand from consumers for more sustainable options helps to drive the expansion of markets and innovation among industrial producers to meet that demand.

18.3.1.5 Societal systems

This chapter contributes a fifth system transition in addition to the four which have already been introduced by SR1.5: the societal systems transition. While society and people also feature in the other systems transitions, the purpose of defining a fifth transition is to explicitly highlight the challenges associated with changes in behavior, attitudes, values and consciousness required to achieve CRD. One caveat of considering transitions in societal systems is the limit to which the nature of change is known: transitions accomplish reconfigurations towards a relatively known destination. Historical and current differences between and within nations translate to a multitude of equally valid but diverse priorities for development, for example the understanding of development toward progress as linear has been challenged as being a Western concept by scholars of colonialization (Sultana et al., 2019). Thus societal transitions are understood as being intrinsically diverse for the purpose of achieving climate resilient development.

The four systems transitions identified in SR1.5 already include a component of societal change – for example, attitude change is part of public acceptance that facilitates shifts in energy including changing electricity to renewables (Ch 4 SR1.5 4.3.1.1) and developing nuclear power (4.3.1.3), and behavioral change is a part of shifting irrigation practices to drive required land and ecosystems transitions (4.3.2.1).

Extracting societal transitions also allows for a detailed examination of other societal dimensions that facilitate systems transitions, for example justice issues relating to water and energy access and distribution, and land use. Societal transition, sometimes known as 'societal transformation', is an established concept in different literatures, as described below. Transformation and transition are terms often used as synonyms (Hölscher et al., 2018) although different schools of thought understand them as sub-components of each other, eg. transition driving transformation, or transformation driving transition. For a more detailed discussion on the differences between transition and transformation represented in the literature, see Box 18.1.

Societal transitions for the purpose of this report are understood as the collection of shifts in attitudes, values, consciousness and behavior required to move toward CRD. This builds on the SR1.5 (IPCC, 2018a: 599) definition of societal (social) transformation: "A profound and often deliberate shift initiated by communities toward sustainability, facilitated by changes in individual and collective values and behaviors, and a fairer balance of political, cultural, and institutional power in society." This includes accepting IK/LK as an equally valid form of knowledge as compared with Western, scientific knowledge (see Cross-Chapter Box INDIG) and recognition of the role of shifting gender norms to achieve climate resilience (see Cross-Chapter Box GENDER). Changes associated with societal transitions are not specific to defined systems (e.g. energy, industry, land/ecosystems or urban/infrastructure). Rather, these sectoral systems are embedded within broader societal systems, including e.g. political systems, economic systems, knowledge systems, cultural systems (Davelaar, 2021; Turnhout et al., 2021; Visseren-Hamakers et al., 2021). Changes that happen in these broader social systems can therefore prompt changes in all systems embedded within them, meaning that societal transition is key to transforming across a range of sectors and topics (Leventon et al., 2021). Furthermore, societal transition requires changes in individual behaviors, but also in the broader conditions that shape these behaviors. These broader conditions are largely related to questions of power, in enforcing dominant political economies and social-technological mindsets (Stoddard et al., 2021). This section also briefly describes the various trains of research on societal transitions and transformation.

Because of the multiple sectors, interests and scales that are involved in societal transitions, understanding and creating evidence on transitions requires shifting across system boundaries and finding ways to transcend disciplinary silos. Relevant research includes work within the topic of transformation and transitions (Hölscher et al., 2018). Transformations literature can be split into multiple sub-concepts and requires engagement with multiple schools of thought (Feola, 2015; Feola et al., 2021). Much focus within transformations research is currently related to biodiversity conservation (Massarella et al., 2021), and transitions work tends towards a focus in urban areas (Loorbach et al., 2017). Though there is also work in both that is more broadly labelled as sustainability transformations or transitions (Luederitz et al., 2017). Furthermore, there is likely to be much relevant literature that does not explicitly label itself as transformations or transitions (Feola et al., 2021). For example, we could look to political science theories on policy change (Leventon et al., 2021) and historical perspectives on social change. Bridging these divides will require a deeper rethinking in the research community to undo power structures that marginalize diverse knowledges (Caniglia et al., 2021; Lahsen and Turnhout, 2021).

There are a number of concepts proposed as pathways to creating societal transitions; usually centered around the idea of working with individuals and communities to change their mindsets as a way to change the way they manage their local environments or behave. Transformations work explores how values are pathways towards sustainability, for example by changing values, through making values explicit, through negotiation, and by eliciting values (Horcea-Milcu et al., 2019). Human nature connections is a further concept that is identified as a way to shift values and behaviors across a range of disciplines (Ives et al., 2017). The role of learning and indigenous knowledge is also explored (Lam et al., 2020). These three concepts have had particular salience in discussions around transformations for biodiversity conservation and restoration, related to the IPBES assessment on Values (Pascual et al., 2017; Peterson et al., 2018). They largely focus on the need to engage with people's values, connections and knowledge to better manage the social-ecological system they are in.

Focusing on bottom-up and community-led transformations, there is emphasis on the role of grassroots organizations in transformations. Community actions around specific locations or topics have parallels to the idea of transformative spaces. They are sites of innovative activity (Seyfang and Smith, 2007). Grassroots organizations can bridge the local and the political scales by politicizing actors and creating new interactions between individuals and political processes (Novák, 2021). They are a collective approach to pushing for both individual and societal change (Sage et al., 2021).

Despite a current lack of empirical evidence, there are numerous frameworks emerging for exploring societal transitions across levels. There is focus on pathways for sustainability transitions, which tends to look at projected, normative scenarios for the future, and explore or back-cast the institutional and societal changes that are required to get there (Westley et al., 2011; Sharpe et al., 2016). There is also work that looks at scaling up of smaller sustainability initiatives, through processes of scaling up, scaling out and scaling deep (Moore et al., 2015; Lam et al., 2020). In particular, systems thinking provides an organizing framework for bringing together multiple disciplines and perspectives, to understand problem framings, and normative and design aspects of social systems and behaviors (Foster-Fishman et al., 2007). Within this, Meadows (1999) framework of leverage points for systems transformation has been operationalized within the sustainability transformations debate (Abson et al., 2017). Here, system properties relating to system paradigms and design are leverage points where interventions can create greatest system change; shallower leverage points relate to materials and processes. This framework is increasingly being used across a range of sustainability problems as boundary objects for cross-disciplinary, critical research (Fischer and Riechers, 2019; Leventon et al., 2021; Riechers et al., 2021).

Analyses of societal transitions have had limited engagement with adaptation questions. The focus of the sub-field of sustainability transitions on a few industrialized nations, mostly in North America and Europe, limited the field's development to assumptions born from the experiences in those areas. More recent studies have sought to understand sustainability transitions in other countries, especially emerging economies (Wieczorek, 2018; Köhler et al., 2019). In particular, China has received attention from scholars on sustainability transitions (Huang et al., 2018; Lo and Castán Broto, 2019; Castán Broto et al., 2020; Huang and Sun, 2020). As a result, some pressing issues related to societal transitions for adaptation have received limited attention compared with that paid to other system transitions. However, more recently, scholarship has begun examining transitions that have turned to nature and nature-based solutions. Adaptive transitions are an intermediary step towards sustainability transitions whereby multiple actions at material and institutional levels are combined towards improving adaptation outcomes (Pant et al., 2015; Scarano, 2017).

Table 18.3: Specific options for facilitating the five system transitions that can support CRD

Transition	Examples	Reference
Energy Systems	• Fuel switching from coal to natural gas • Expansion of renewable energy technologies • Financial incentives to promote renewable energy • Reduced energy intensity of industry • Improvements in power system resilience and reliability • Increased water use efficiency in electricity generation • Energy demand management strategies	(Gielen et al., 2019) (Mulugetta et al., 2019) (IEA et al., 2019) AR6 WGIII Chapter 2
Urban and infrastructure systems	• Increased investment in physical and social infrastructure • Enhance urban and regional planning • Enhanced governance and institutional capacity supports post-disaster recovery and reconstruction (Kull, 2016)	(IPCC, 2018b): D3.1)
Land, Oceans, and Ecosystems	• Expanding access to agricultural and climate services • Strengthening land tenure security and access to land • Empowering women farmers • Improved access to markets • Facilitating payments for ecosystem services	(IPCC, 2019f): C2.1) (IPCC, 2019f): C4.5) (IPCC, 2019f): C4)

	• Promotion of healthy and sustainable diets • Enhancing multi-level governance by supporting local management of natural resources • Strengthening cooperation between institutions and actors • Building on local, indigenous and scientific knowledge funding, and institutional support • Monitoring and forecasting • Education and climate literacy and social learning and participation	
Industrial systems	• Promote material efficiency and high-quality circularity • Materials demand management (IEA 2019, 2020) • Application of new processes and technologies for GHG emission reduction • Carbon pricing or regulations with provisions on competitiveness to drive innovation and systemic carbon efficiency • Low-cost, long-term financing mechanisms to enable investment and reduce risk • Better planning of transport infrastructure • Labour market training and transition support • Electricity market reform • Regulations – standards and labelling, material efficiency • Mandating technologies and targets • Green taxes and carbon pricing, preferential loans and subsidies • voluntary action agreements, expanded producer responsibilities • information programs: monitoring, evaluation, partnerships, and research and development • government provisioning of services—government procurements, technology push and market-pull	(Åhman et al., 2017; Bataille et al., 2018; Material, 2019) (Tanaka, 2011; Schwarz et al., 2020) (Ciwmb, 2003) (Romero Mosquera, 2019) (Tanaka, 2011) (Ryan et al., 2011; Boyce, 2018) (Taylor, 2008) (UNEP, 2018b) (Kaza et al., 2018) (Söderholm and Tilton, 2012) (Bataille et al., 2018) (Ghisetti et al., 2017) (Taylor, 2008; Fischedick et al., 2014; Hansen and Lema, 2019) (Crippa et al., 2019; IEA, 2019) (Cavaliere, 2019; IEA, 2020)(Vogl et al., 2018)(Pauliuk et al., 2013; Quader et al., 2016)
Societal Systems	• Inclusive governance • Empowerment of excluded stakeholders, especially women and youth • transforming economies • finance and technology aligned with local needs • overcoming uneven consumption and production patterns • allowing people to live a life in dignity and enhancing their capabilities • involving local governments, enterprises and civil society organisations across different scales	(Fazey et al., 2018b; O'Brien, 2018; Patterson et al., 2018) (MRFCJ, 2015; Dumont et al., 2019) (Popescu et al., 2017; David Tàbara et al., 2018) (de Coninck and Sagar, 2015; IEA, 2015; Parikh et al., 2018) (Dearing et al., 2014; Häyhä et al., 2016; Raworth, 2017) (Klinsky and Winkler, 2018), (Hajer et al., 2015; Labriet et al., 2015; Hale, 2016; Pelling et al., 2016; Kalafatis, 2017; Lyon, 2018) (Holden et al., 2017) (Cundill et al., 2014; Butler et al., 2016; Ensor, 2016; Fazey et al., 2016;

	• reconceptualising development around well-being rather than economic growth (Gupta and Pouw, 2017), • rethinking, prevailing values, ethics and behaviour • improving decision-making processes that incorporate diverse values and world views • creating space for negotiating diverse interests and preferences	Gorddard et al., 2016; Aipira et al., 2017; Chung Tiam Fook, 2017; Maor et al., 2017) (O'Brien and Selboe, 2015; Gillard et al., 2016; DeCaro et al., 2017; Harris et al., 2018; Lahn, 2018; Roy et al., 2018) Sections 5.6.1 and 5.5.3.1

Cross-Chapter Box GENDER: Gender, Climate Justice and Transformative Pathways

Authors: Anjal Prakash (India), Cecilia Conde (Mexico), Ayansina Ayanlade (Nigeria), Rachel Bezner Kerr (Canada/USA), Emily Boyd (Sweden), Martina A Caretta (Sweden), Susan Clayton (USA), Marta G. Rivera Ferre (Spain), Laura Ramajo Gallardo (Chile), Sharina Abdul Halim (Malaysia), Nina Lansbury (Australia), Oksana Lipka (Russia), Ruth Morgan (Australia), Joyashree Roy (India), Diana Reckien (Netherlands/Germany), E. Lisa F. Schipper (Sweden/UK), Chandni Singh (India), Maria Cristina Tirado von der Pahlen (Spain/USA), Edmond Totin (Benin), Kripa Vasant (India), Morgan Wairiu (Solomon Islands), Zelina Zaiton Ibrahim (Malaysia).

Contributing Authors: Seema Arora-Jonsson (Sweden/India), Emily Baker (USA), Graeme Dean (Ireland), Emily Hillenbrand (USA), Alison Irvine (Canada), Farjana Islam (Bangladesh/ United Kingdom), Katriona McGlade (United Kingdom/Germany), Hanson Nyantakyi-Frimpong (Ghana), Nitya Rao (United Kingdom /India), Federica Ravera (Italy), Emilia Reyes (Mexico), Diana Hinge Salili (Fiji), Corinne Schuster-Wallace (Canada), Alcade C. Segnon (Benin), Divya Solomon (India), Shreya Some (India), Indrakshi Tandon (India), Sumit Vij (India), Katharine Vincent (United Kingdom/South Africa), Margreet Zwarteveen (The Netherlands)

Key Messages

- Gender and other social inequities (e.g., racial, ethnic, age, income, geographic location) compound vulnerability to climate change impacts (*high confidence*). Climate justice initiatives explicitly address these multi-dimensional inequalities as part of a climate change adaptation strategy. [Box 9.2: Vulnerability Synthesis: Differential Vulnerability by Gender and Age in Ch 9]

- Addressing inequities in access to resources, assets, and services as well as participation in decision-making and leadership is essential to achieving gender and climate justice (*high confidence*).

- Intentional long-term policy and program measures and investments to support shifts in social rules, norms, and behaviours are essential to address structural inequalities and support an enabling environment for marginalised groups to effectively adapt to climate change (*very high confidence*). [Equity and Justice box in Ch 17]

- Climate adaptation actions are grounded in local realities so understanding links with SDG 5 is important to ensure that adaptive actions do not worsen existing gender and other inequities within society (e.g., leading to maladaptation practices) *(high confidence).* [17.5.1]

- Adaptation actions do not automatically have positive outcomes for gender equality. Understanding the positive and negative links of adaptation actions with gender equality goals, (i.e., SDG 5), is important to ensure that adaptive actions do not exacerbate existing gender-based and other social inequalities [16.1.4.4]. Efforts are needed to change unequal power dynamics and ´to foster inclusive decision-making for climate adaptation to have a positive impact for gender equality *(high confidence).*

- There are very few examples of successful integration of gender and other social inequities in climate policies to address climate change vulnerabilities and questions of social justice, (*Very high confidence*).

Gender, climate justice, and climate change

This Cross-Chapter Box highlights the intersecting issues of gender, climate change adaptation, climate justice, and transformative pathways. A gender perspective does not centre only on women or men but examines structures, processes, and relationships of power between and among groups of men and women and how gender, particularly in its non-binary form, intersects with other social categories such as race, class, socio-economic status, nationality, or education to create multidimensional inequalities (Hopkins, 2019). A gender transformative approach aims to change structural inequalities. Attention to gender in climate change adaptation is thus central to questions of climate justice that aim for a radically different future (Bhavnani et al., 2019). As a normative concept highlighting the unequal distribution of climate change impacts and opportunities for adaptation and mitigation, climate justice (Wood, 2017; Jafry et al., 2018; Chu and Michael, 2019; Shi, 2020a) calls for transformative pathways for human and ecological wellbeing. These address the concentration of wealth, unsustainable extraction, and distribution of resources (Schipper et al., 2020a; Vander Stichele, 2020) as well as the importance of equitable participation in environmental decision-making for climate justice (Arora-Jonsson, 2019).

Research on gender and climate change demonstrates that an understanding of gendered relations is central to addressing the issue of climate change. This is because gender relations mediate experiences with climate change, whether in relation to water (Köhler et al., 2019) (see also Sections 4.7, 4.3.3; 4.6.4, 5.3), forests (Arora-Jonsson, 2019), agriculture (Carr and Thompson, 2014; Balehey et al., 2018; Garcia et al., 2020) (see also Chapter 4, Section 5.4), marine systems (Mcleod et al., 2018; Garcia et al., 2020) (see also Section 5.9) or urban environments (Reckien et al., 2018; Susan Solomon et al., 2021) (see also Chapter 6). Climate change has direct negative impacts on women's livelihoods due to their unequal control over and access to resources (e.g., land, credit) and because they are often the ones with the least formal protection (Eastin, 2018) (see also Box 9.2 in Ch 9). Women represent 43% of the agricultural labour force globally, but only 15% of agricultural landholders (OECD, 2019b). Gendered and other social inequities also exist with non-land assets and financial services (OECD, 2019b) often due to social norms, local institutions, and inadequate social protection (Collins et al., 2019b). Men may experience different adverse impacts due to gender roles and expectations (Bryant and Garnham, 2015; Gonda, 2017). These impacts can lead to irreversible losses and damages from climate change across vulnerability hotspots (Section 8.3).

Participation in environmental decision-making tends to favour certain social groups of men, whether in local environmental committees, international climate negotiations (Gay-Antaki and Liverman, 2018) or the IPCC (Nhamo and Nhamo, 2018). Addressing climate justice reinforces the importance of considering the legacy of colonialism on developing regional and local adaptation strategies. Scholars have criticized climate programs for setting aside forestland that poor people rely on and appropriating the labor of women in the global South without compensatory social policy or rights; where women are expected to work with Non Timber Forest Products to compensate for the lack of logging and for global climate goals but where their work of social reproduction and care is paid little attention (Westholm and Arora-Jonsson, 2015; Arora-Jonsson et al., 2016). A global ecologically unequal exchange, biopiracy, damage from toxic exports, or the disproportionate use of carbon sinks and reservoirs by high-income countries enhance the negative impacts of climate change, women in LDC's and SIDS also endure the harshest impacts of the debt crisis due to imposed debt measures in their countries (Appiah and Gbeddy, 2018; Fresnillo Sallan, 2020). The austerity measures derived as conditionalities for fiscal consolidation in public services increases gender-based violence (Castañeda Carney et al., 2020) and brings additional burdens for women in the form of increasing unpaid care and domestic work (Bohoslavsky, 2019).

Gendered vulnerability

Land, ecosystem, and urban transitions to climate-resilient development need to address gender and other social inequities to meet sustainability and equity goals, otherwise, marginalised groups may continue to be excluded from climate change adaptation. In the water sector, increasing floods and droughts and diminishing groundwater and runoff have gendered effects on both production systems and domestic use (Sections 4.3.1, 4.3.3, 4.5.3). Climate change is reducing the quantity and quality of safe water available in many regions of the world and increasing domestic water management responsibilities (*high confidence*). In regions with poor drinking water infrastructure, it is forcing, primarily women and girls, to walk long distances to access water, and limiting time available for other activities, including education and income generation (Eakin et al., 2014; Kookana et al., 2016; Yadav and Lal, 2018). Water insecurity and the lack of water, sanitation, and hygiene (WASH) infrastructure have resulted in psychosocial distress, gender-based violence, as well as poor maternal and child health and nutrition (Collins et al., 2019a; Wilson et al., 2019; Geere and Hunter, 2020; Islam et al., 2020; Mainali et al., 2020) (Sections 4.3.3 and 4.6.4.4) (*high confidence*). Climate-related extreme events also affect women's health – by increasing the risk of maternal and infant mortality, disrupting access to family planning and prevention of mother to child transmission regimens for HIV positive pregnant women (Undrr, 2019) (see also Section 7.2). Women and the elderly are also disproportionately affected by heat events (Section 7.1.7.2.1, 7.1.7.2.3, 13.7.1).

Extreme events impact food prices and reduce food availability and quality, especially affecting vulnerable groups, including low-income urban consumers, wage labourers, and low-income rural households who are net food buyers (Green et al., 2013; Fao, 2016) (Section 5.12). Low-income women, ethnic minorities, and Indigenous communities are often more vulnerable to food insecurity and malnutrition from climate change impacts, as poverty, discrimination, and marginalisation intersect in their cases (Vinyeta et al., 2016; Clay et al., 2018) (Section 5.12). Increased domestic responsibilities of women and youth, due to migration of men, can increase their vulnerability due to their reduced capacity for investment in off-farm activities and reduced access to information (Sugden et al., 2014; O'Neil et al., 2017) (Section 4.3; 4.6) (*high confidence*).

In the forest sector, the increased frequency and severity of drought, fires, pests and diseases, and changes to growing seasons, has led to reduced harvest revenues, fluctuations in timber supply and availability of wood (Lamsal et al., 2017; Fadrique et al., 2018; Esquivel-Muelbert et al., 2019). Climate programs in the global South such as REDD+ have led to greater social insecurity and the conservation of the forests have led to more pressure on women to contribute to household incomes but without enough supporting market access mechanisms or social policy (Westholm and Arora-Jonsson, 2015; Arora-Jonsson et al., 2016). In countries in the global North, reduced harvestable wood and revenues have led to employment restructuring that has important gendered effects and negatively affects community transition opportunities (Reed et al., 2014).

Integrating gender in climate policy and practice

Climate change policies and programs across regions reveal wide variation in the degree and approach to addressing gender inequities (see Table SMCCB GENDER.2). In most regions where there are climate change policies that consider gender, they inadequately address structural inequalities t resulting from climate change impacts, or how gender and other social inequalities can compound risk (*high confidence*). Experiences show that it is more frequent to address specific gender inequality gaps in access to resources. Regionally, Central and South American countries (section 12.5.8) have a range of gender-sensitive or gender-specific policies such as the intersectoral coordination initiative Gender and Climate Change Action Plans (PAGcc), adopted in Perú, Cuba, Costa Rica, and Panamá (Casas Varez, 2017), or the Gender Environmental policy in Guatemala that has a focus on climate change (Bárcena-Martín et al., 2021). However, countries often have limited commitment and capacity to evaluate the impact of such policies (Tramutola, 2019). In North and South America, policies have failed to address how climate change vulnerability is compounded by the intersection of race, ethnicity, and gender (Radcliffe, 2014; Vinyeta et al., 2016) (see also section 14.6.3). gender is rarely discussed in African national policies or programmes beyond the initial consultation stage (Holvoet and Inberg, 2014; Mersha and van Laerhoven, 2019), although there are gender and climate change action strategies in countries such as Liberia, Mozambique, Tanzania, and Zambia (Mozambique and IUCN, 2014; Zambia and IUCN, 2017). European climate change adaptation strategies and policies are weak on gender and other social equity issues (Allwood, 2014; Boeckmann and Zeeb, 2014; Allwood, 2020), while in Australasia, there is a lack of gender-responsive climate change policies. In Asia, there are several countries that recognize gendered vulnerability to climate change (Jafry, 2016; Singh et al., 2021b), but policies tend to be gender-specific, with a focus on targeting women, for example in the national action plan on climate change as in India (Roy et al., 2018) or in national climate change plan as in Malaysia (Susskind et al., 2020).

Potential for Change and Solutions

The sexual division of labour, systemic racism and other social structural inequities lead to increased vulnerabilities and climate change impacts for social groups such as women, youth, Indigenous peoples, ethnic minorities. Their marginal positions not only affect their lives negatively but their work in maintaining healthy environments is ignored and invisible in policy affecting their ability to work towards sustainable adaptation and aspirations in the SDGs (Arora-Jonsson, 2019). However, attention to the following has the potential to bring about change:

Creation of new, deliberative policy-making spaces that support inclusive decision-making processes and opportunities to (re)negotiate pervasive gender and other social inequalities in the context of climate change for transformation (Tschakert et al., 2016; Harris et al., 2018; Ziervogel, 2019; Garcia et al., 2020). (*high confidence*)

Increased access to reproductive health and family planning services, which contributes to climate change resilience and socio-economic development through improved health and well-being of women and their children, including increased access to education, gender equity, and economic status (Onarheim et al., 2016; Starbird et al., 2016; Lopez-Carr, 2017; Hardee et al., 2018) (Sections 7.4) (*high confidence*).

Engagement with women's collectives is important for sustainable environments and better climate decision-making whether at the global, national, or local levels (Westholm and Arora-Jonsson, 2018; Agarwal, 2020). The work of such collectives in maintaining their societies and environments and in resisting gendered and community violence is unacknowledged (Jenkins, 2017; Arora-Jonsson, 2019) but is indispensable especially when combined with good leadership, community acceptance, and long-term economic sustainability (Chu, 2018; Singh, 2019) (Section 4.6.4). Networking by gender experts in environmental organizations and bureaucracies has also been important for ensuring questions of social justice (Arora-Jonsson and Sijapati, 2018).

Investment in appropriate reliable water supplies, storage techniques, and climate-proofed WASH infrastructure as key adaptation strategies that reduce both burdens and impacts on women and girls (Alam et al., 2011; Woroniecki, 2019) (Sections 4.3.3 and 4.6.44).

Improved gender-sensitive early warning system design and vulnerability assessments to reduce vulnerabilities, prioritising effective adaptation pathways to women and marginalized groups (Mustafa et al., 2019; Tanner et al., 2019; Werners et al., 2021).

Established effective social protection, including both cash and food transfers, such as the universal public distribution system (PDS) for cereals in India, or pensions and social grants in Namibia, that have been demonstrated to contribute towards relieving immediate pressures on survival and support processes at the community level, including climate effects (Kattumuri et al., 2017; Lindoso et al., 2018; Rao et al., 2019a; Carr, 2020).

Strengthened adaptive capacity and resilience through integrated approaches to adaptation that include social protection measures, disaster risk management, and ecosystem-based climate change adaptation (*high confidence*), particularly when undertaken within a gender-transformative framework (Gumucio et al., 2018; Bezner Kerr et al., 2019; Deaconu et al., 2019) (Cross-Chapter Box NATURAL in Chapter 2, Section 5.12, Section 5.14).

For example, gender-transformative and nutrition-sensitive agroecological approaches strengthen adaptive capacities and enable more resilient food systems by increasing leadership for women and their participation in decision-making and a gender-equitable domestic work (*high confidence)* (Gumucio et al., 2018; Bezner Kerr et al., 2019; Deaconu et al., 2019) (Cross-Chapter Box NATURAL in Chapter 2, Section 5.12, Section 5.14)

New initiatives such as the Sahel Adaptive Social Protection Program represent an integrated approach to resilience that promotes coordination among social protection, disaster risk management, and climate change adaptation. Accompanying measures including, health, education, nutrition, family planning, among others (Daron et al., 2021).

Climate change adaptation and SDG 5

Adaptation actions may reinforce social inequities, including gender unless explicit efforts are made to change (Nagoda and Nightingale, 2017; Garcia et al., 2020) (*high evidence and high agreement*). Participation in climate action increases if is inclusive and fair (Huntjens and Zhang, 2016). Roy et al. (2018) assessed links among various SDGs and mitigation options. Adaptation actions are grounded in local realities especially in terms of their impacts so understanding links with the goals of SDG 5 becomes more important to make sure that adaptive actions do not worsen prevalent gender and other social inequities within society (*high evidence, high agreement)*. In the IPCC 1.5°C Special Report, Roy et al. (2018) assessed links between various SDGs and mitigation options, adaptation options were not considered. The current SDG 13 climate action targets do not specifically mention gender as a component for action, which makes it even more imperative to link SDG 5 targets and other gender-related targets to adaptive actions under SDG 13 to ensure that adaptation projects are synergistic rather than maladaptive (16.3.2.6, Table 16.6) (Susan Solomon et al., 2021).

This assessment is based on a systematic rapid review of scientific publications (McCartney et al., 2017; Liem et al., 2020) published on adaptation actions in 9 sectors from 2014 to 2020 (see Table SMCCB GENDER.1) and how they integrated gender perspectives impacting gender equity. The assessment is based on over 17,000 titles and abstracts that were initially found through keyword search and were reviewed. Finally, 319 relevant papers on case studies, regional assessments, and meta-reviews were assessed. Gender impact was classified by various targets under SDG 5. Following the approach taken in Roy et al. (2018) and (Hoegh-Guldberg et al., 2019), the linkages were classified into synergies (positive impacts or co-benefits) and trade-offs (negative impacts) based on the evidence obtained from the literature review which is finally used to develop net impact (positive or negative) scores (See Table Cross-Chapter Box GENDER.1 and Supplementary Material)

Table Cross-Chapter Box GENDER.1: Interrelations between SDG5 (gender equality) and adaptation initiatives in 9 major sectors

Sector	**Adaptation categories**			
	Ecosystem-based	***Technological /infrastructure /information***	***Institutional***	***Behavioural / cultural***
Terrestrial & freshwater ecosystem	□□		□□	
Ocean & coastal ecosystem	□□	□	□□□

Table Notes:
Potential net synergies and trade-offs between a sectoral portfolio of adaptation actions and SDG 5 are shown. Colour codes showing the relative strength of net positive and net negative impacts and confidence levels. The strength of net positive and net negative connections across all adaptation actions within a sector are aggregated to show sector-specific links. The links are only one-sided on how adaptation action is linked to gender equality (SDG5) targets and not vice versa. Adaptation options assessed in Ecosystem-based actions are: 22 in number, options in Technological /infrastructure /information are 10, in Institutional are 17 and in Behavioural/ cultural are 13. The assessment presented here is based on literature presenting impacts on gender equality and equity of various adaptation actions implemented in various local contexts and in regional climate change policies (Table SMCCB GENDER.2).

Adaptation actions being implemented in each sector in different local contexts can have positive (synergies) or negative (trade-offs) effects with SDG5. This can potentially lead to net positive or net negative connections at an aggregate level. How they are finally realized depends on how they are implemented, managed, and combined with various other interventions in particular, place-based circumstances. Ecosystem-based adaptation actions and terrestrial & freshwater ecosystems have higher potential for net positive connections (Roy et al., 2018) (Table Cross-Chapter Box GENDER.1 and Supplementary Material). Adaptation in terrestrial and freshwater ecosystems has the strongest net positive links with all SDG-5 targets (*medium evidence, low agreement*). For example, community-based natural resource management increases the participation of women, especially when they are organised into women's groups (Pineda-López et al., 2015; de la Torre-Castro et al., 2017) (Supplementary Material). For poverty, livelihood and sustainable development sector adaptation actions have generated more net negative scores (*low evidence, low agreement*) (Table Cross-Chapter Box GENDER.1). For example, patriarchal institutions and structural discriminations curtail access to services or economic resources as compared to men, including less control over income, fewer productive assets, lack of property rights, as well as less access to credit, irrigation, climate information, and seeds which devaluate women's farm-related adaptation options (Adzawla et al., 2019; Friedman et al., 2019; Ullah et al., 2019) (Supplementary Material).

Among the adaptation actions, ecosystem-based actions have the strongest net positive links with SDG-5 targets (Table Cross-Chapter Box GENDER.1, Table SMCCB GENDER.1). In the health, well-being and changing communities' sector, this is with *high evidence and medium agreement*, while in all other sectors there is *medium evidence and low agreement*. Net negative links are most prominent in institutional adaptation actions (Table Cross-Chapter Box GENDER.1). For example, in mountain ecosystems, changes in gender roles in response to climatic and socioeconomic stressors is not supported by institutional practices, mechanisms, and policies that remain patriarchal (Goodrich et al., 2019). Additionally, women often have less access to credit for climate change adaptation practices, including post-disaster relief, for example, to deal with salinization of water or flooding impacts (Hossain and Zaman 2018). Lack of coordination among different city authorities can also limit women's contribution in informal settlements towards adaptation. Women are typically underrepresented in decision-making on home construction and planning and home-design decisions in informal settlements, but examples from Bangladesh show they play a significant role in adopting climate-resilient measures (e.g., the use of corrugated metal roofs and partitions which is important in protection from heat) (Jabeen, 2014; Jabeen and Guy, 2015; Araos et al., 2017; Susan Solomon et al., 2021).

Towards climate-resilient, gender-responsive transformative pathways

The climate change adaptation and gender literature call for research and adaptation interventions that are 'gender-sensitive' (Jost et al., 2016; Thompson-Hall et al., 2016; Kristjanson et al., 2017; Pearce et al., 2018a) and "gender-responsive", as established in Article 7 of the Paris Agreement (UNFCCC, 2015). In addition, attention is drawn to the importance of 'mainstreaming' gender in climate/development policy (Alston, 2014; Rochette, 2016; Mcleod et al., 2018; Westholm and Arora-Jonsson, 2018). Many calls have been made to consider gender in policy and practice (Ford et al., 2015; Jost et al., 2016; Rochette, 2016; Thompson-Hall et al., 2016; Kristjanson et al., 2017; Mcleod et al., 2018; Lau et al., 2021; Singh et al., 2021b). Rather than merely emphasising the inclusion of women in patriarchal systems, transforming systems that perpetuate inequality can help to address broader structural inequalities not only in relation to gender but also other dimensions such as race and ethnicity (Djoudi et al., 2016; Pearse, 2017; Gay-Antaki, 2020). Adaptation researchers and practitioners play a critical role here and can enable gender-transformative processes by creating new, deliberative spaces that foster inclusive decision-making and opportunities for renegotiating inequitable power relations (Tschakert et al., 2016; Ziervogel, 2019; Garcia et al., 2020).

To date, empirical evidence on such transformational change is sparse, although there is some evidence of incremental change (e.g., increasing women's participation in specific adaptation projects, mainstreaming gender in national climate policies). Even when national policies attempt to be more gendered, there is criticism that they use gender-neutral language or include gender analysis without proposing how to alter differential vulnerability (Mersha and van Laerhoven, 2019; Singh et al., 2021b). More importantly, the mere inclusion of women and men in planning does not necessarily translate to substantial gender-transformative action, for example in National Adaptation Programmes of Action across sub-Saharan Africa (Holvoet and Inberg, 2014; Nyasimi et al., 2018) and national and sub-national climate action plans in India (Singh et al., 2021b). Importantly, there is often an overemphasis on the gender binary (and household headship as an entry point), which masks complex ways in which marginalisation and oppression can be augmented due to the interaction of gender with other social factors and intra-household dynamics (Djoudi et al., 2016; Thompson-Hall et al., 2016; Rao et al., 2019a; Lau et al., 2021; Singh et al., 2021b).

Climate justice and gender transformative adaptation can provide multiple beneficial impacts that align with sustainable development. Addressing poverty (SDG 1), energy poverty (SDG 7), WaSH (SDG 6), health (SDG 3), education (SDG 4) and hunger (SDG 2) —along with inequalities (SDG 5 and SDG 10) - improves resilience to climate impacts for those groups that are disproportionately affected (women, low-income and marginalised groups). Inclusive and fair decision-making can enhance resilience (SDG 16; Section 13.4.4), although adaptation measures may also lead to resource conflicts (SDG 16; Section 13.7). Nature-based solutions attentive to gender equity also support ecosystem health (SDGs 14 and 15) (Dzebo et al., 2019). Gender and climate justice will be achieved when the root causes of global and structural issues are addressed, challenging unethical and unacceptable use of power for the benefit of the powerful and elites (MacGregor, 2014; Wijsman and Feagan, 2019; Vander Stichele, 2020). Justice and equality need to be at the centre of climate adaptation decision-making processes. A transformative pathway needs to include the voice of the disenfranchised (MacGregor, 2020; Schipper et al., 2020a).

[END CROSS-CHAPTER BOX GENDER HERE]

18.3.2 Accelerating Transitions

Successfully implementing climate actions and managing trade-offs between mitigation, adaptation and sustainable development (18.2.4) has important time considerations that imply significant urgency, making substantive progress in system transitions critical for CRD. Both the SDGs and the Sendai Framework, for example, have target dates of 2030. Meanwhile, the Paris Agreement sets specific time horizons for NDCs and the SR1.5 indicated that limiting warming to 1.5°C would similarly require substantial climate action by 2030 (IPCC, 2018a). While the literature is unambiguous regarding the need for significant system transitions to achieve CRD (Section 18.1.3), the current pace of global emissions reductions, poverty alleviation, and development of equitable systems of governance is incommensurate with these policy time tables (Rogelj et al., 2010; Burke et al., 2016; Oleribe and Taylor-Robinson, 2016; Kriegler et al., 2018; Frank et al., 2019; Sadoff et al., 2020). As noted previously in the AR5, "*delaying action in the present may reduce options for climate-resilient pathways in the future*" (Denton et al., 2014: 1123). Accordingly, significant acceleration in the pace of system transitions is necessary to enable the implementation of mitigation, adaptation, and sustainable development initiatives consistent with CRD *(very high confidence*).

Studies since the AR5 directly address the issue of how to accelerate transitions within the broader system transitions, sustainability transitions, and socio-technical transitions literature (Frantzeskaki et al., 2017; Gliedt et al., 2018; Gorissen et al., 2018; Johnstone and Newell, 2018; Kuokkanen et al., 2019; Markard et al., 2020). Such literature explores several core themes to facilitate acceleration, which are aligned with the discussion later in this chapter on arenas of engagement for CRD (Section 18.4.3). One dominant theme is accelerating the implementation of sustainability or low-carbon policies that target specific sectors or industries (Bhamidipati et al., 2019). For example, Altenburg and Rodrik (Altenburg and Rodrik, 2017) discuss green industrial polices including taxes, mandated technology phase outs, and the removal of subsidies as means of constraining polluting industries. Kivimaa et al. (Kivimaa and Martiskainen, 2018; Kivimaa et al., 2019a; Kivimaa et al., 2019b; Kivimaa et al., 2020) and Vihemäki et al. (2020) discuss low-carbon transitions in buildings, noting the important role that intermediaries play in facilitating policy reform. Nikulina et al. (2019) identify mechanisms for facilitating policy change in personal mobility including political leadership, combining carrots and sticks to incentivize behavioral change, and challenging current policy frameworks. These various examples reflect a fragmented approach to system transitions, suggesting a large portfolio of such transition initiatives would be required to accelerate change or more fundamental and cross-cutting policy drivers are needed (*high agreement, limited evidence*). Policies that seek to promote social justice and equity, for example, could ultimately catalyze a broader range of sustainability and climate actions than policies designed to address a specific sector or class of technology (Delina and Sovacool, 2018; White, 2020).

In contrast with formal government policies, a second theme in accelerating transitions is that of civic engagement (see also 18.4.3), which is reported to be an important opportunity for driving transitions forward (*high agreement, medium evidence*). Ehnert et al. (2018) describe local organizations and civic engagement in policy processes as an important engine for sustainability activities in European states. Similarly, Ruggiero et al. (2021) note the potential to use civic organizations to appeal to local identities in order to mobilize citizens to pursue energy transition initiatives among communities in the Baltic Sea region. Gernert et al. (2018) attribute such influence to the ability of grassroots movements to bypass traditional social and political norms and thereby experiment with new behaviors and processes. Moreover, civic engagement is also the foundation for collective action including protest and civil disobedience (Welch and Yates, 2018, Section 18.5.3.7). However, Haukkala (2018) observes that while green-transition coalitions in Finland could be an agent of change driving energy transitions, the diversity of views among the various grassroots actors could make consensus building difficult, thereby slowing transition initiatives.

A third theme is that of innovation, generally, and sustainability-oriented innovation, specifically (de Vries et al., 2016; Geradts and Bocken, 2019; Loorbach et al., 2020), which creates opportunities for overcoming existing transition barriers *(very high confidence*). For example, Valta (2020) describes the role of innovation ecosystems – partnerships among companies, investors, governments, and academics – in accelerating innovation (see also World Economic Forum, 2019). Burch et al. (Burch et al., 2016) describe the role of small and medium-sized business entrepreneurship in promoting rapid innovation. Innovation extends beyond pure technology considerations to consider innovation in practices and social organization (Li et al., 2018; Psaltoglou and Calle, 2018; Repo and Matschoss, 2020). Zivkovic (2018), for example, discusses "innovation labs" as accelerators for addressing so-called wicked problems like climate change through multi-stakeholder groups. Meanwhile, Chaminade and Randelli (2020) describe a case study where structural preconditions and place-based agency were important drivers of transitions to organic viticulture in Tuscany, Italy.

The fourth theme is that of transition management (Goddard and Farrelly, 2018), particularly vis a vis, disruptive technologies (Iñigo and Albareda, 2016; Kuokkanen et al., 2019) or broader societal disruptions (Brundiers, 2020; Davidsson, 2020; Hepburn et al., 2020; Schipper et al., 2020b). Recent literature has given attention to how actors can use disruptive events, such as disasters, as a window-of-opportunity for accelerating changes in policies, practices, and behaviors (*high agreement, medium evidence*) (Brundiers, 2018; Brundiers and Eakin, 2018). This is consistent with concepts in resilience thinking around 'building back better' after disasters (Fernandez and Ahmed, 2019). For example, Hepburn et al. discuss fiscal recovery packages for COVID-19 as a means of accelerating climate action, with a particular influence on clean physical infrastructure, building efficiency retrofits, investment in education and training, natural capital investment, and clean research and development (Andrijevic et al., 2020b).

18.4 Agency and Empowerment for Climate Resilient Development

As reflected in the discussion of societal transitions (18.3), people and their values and choices play an instrumental role in CRD. The agency of people to act on CRD is grounded in their worldviews, beliefs, values, and consciousness (Woiwode, 2020) and is shaped through social and political processes including how policies and decision-making recognize the voices, knowledges and rights of particular actors over others *(very high confidence)* (Harris and Clarke, 2017; Nightingale, 2017; Bond and Barth, 2020; Muok et al., 2021). Since the AR5, evidence on diverse forms of engagement by and among social, political and economic actors to support climate resilient development and sustainability outcomes, has increased. New forms of decision-making and engagement are emerging within the formal policy making and planning sphere, including co-production of knowledge, interventions grounded in the arts and humanities, civil participation and partnerships with business (Ziervogel et al., 2016a; Roberts et al., 2020). In addition, the set of actors that drive climate and development actions are recognized to extend beyond government and formal policy actors to include civil society, education, industry, media, science and art (Ojwang et al., 2017; Solecki et al., 2018; Heinrichs, 2020; Omukuti, 2020). This makes the power dynamics among actors and institutions critical for understanding the role of actors in CRD (Buggy and McNamara, 2016; Camargo and Ojeda, 2017; Silva Rodríguez de San Miguel, 2018).

The formal space for national, sub-national and international adaptation governance emerged at COP 16 (UNFCCC, 2010) when adaptation was recognized as a similar level of priority as greenhouse gas mitigation. The Paris Agreement (UNFCCC, 2015) built on this and the 2030 Sustainable Development Agenda (United Nations, 2015) to link adaptation to development and climate justice. It also highlighted the importance of multi-level adaptation governance, including new non-state voices and climate actors that widen the scope of adaptation governance beyond formal government institutions. For example, individuals can act as agents of changes in their own behavior, such as via change in their consumption patterns, but also generate change within organizations, fields of practice, and the political landscape of governance. Accordingly, these interactions among actors across different scales implies the need for wider modes of, and arena for, engagement around adaptation in order to accommodate a diversity of perspectives (*high agreement, medium evidence*) (Chung Tiam Fook, 2017; Lesnikowski et al., 2017; IPCC, 2018a).

In most regions, such new institutional and informal arrangements are at an early stage of development (*high agreement, limited evidence*). Further clarification and strengthening are needed to enable the fair sharing of resources, responsibilities, and authorities to enable climate action to enable climate-resilient development (Wood et al., 2017; IPCC, 2018a; Reckien et al., 2018). These are strongly linked to contested and complementary worldviews of climate change and the actors that use these worldviews to justify, direct, accelerate and deepen transformational adaptation and climate action.

18.4.1 Political Economy of Climate Resilient Development

Political economy studies (i.e., the origins, nature and distribution of wealth, and the ideologies, interests, and institutions that shape it) explicitly addressing CRD are quite limited. Yet, there is an extensive post-AR5 literature on political economy associated with various elements relevant to CRD including climate change and development (Naess et al., 2015); vulnerability, adaptation, and climate risk (Sovacool et al., 2015; Sovacool et al., 2017; Barnett, 2020); energy, decarbonization, and negative emissions technologies (Kuzemko et al., 2019; Newell, 2019); degrowth and low-carbon economies (Perkins, 2019; Newell and Lane, 2020); solar radiation management (Ott, 2018); planetary health and sustainability transitions and transformation (Kohler et al., 2019) (Gill and Benatar, 2020).

Four key insights regarding the nexus of political economy and CRD emerge from this literature. First, political economy drives coupled development-climate change trajectories and determines vulnerability, thereby potentially subjecting those least responsible for climate change to the greatest risk (Sovacool et al., 2015; Barnett, 2020). The prevailing political economy is itself now at risk as its legitimacy, viability and sustainability are called into question (Barnett, 2020). Yet, as underpinning ideologies, interests and institutions change, the drivers of vulnerability are often appropriated, the adaptation agenda is depoliticized, and market-based solutions advocated (Barnett, 2020).

Second, assessment of this literature suggests four attributes of the political economy of adaptation influence development trajectories in diverse settings, from Australia to Honduras and the Maldives (Sovacool et al., 2015), as delivered through the Global Environment Facility's Least Developed Countries Fund (Sovacool et al., 2017). These include enclosure (public resources or authority captured by private interests); exclusion (stakeholders are marginalized from decision-making); encroachment (natural systems and ecosystem services compromised); and entrenchment (inequality exacerbated). These attributes hamper adaptation efforts, and reveal the political nature of adaptation (Dolšak and Prakash, 2018) and by extension CRD. Paradoxically, development initiatives labelled as 'risk' reduction or resilience building or 'equitable and environmentally sustainable', such as coastal restoration efforts in Louisiana, USA, can compound inequity and climate risk, and perpetuate unsustainable development (Gotham, 2016; Eriksen et al., 2021b).

Third, a long-held view is that the effects of mitigation are global while those of adaptation are local. A political economy perspective, however, underscores cross-scale linkages, and shows that local adaptation efforts, vulnerability and climate resilience are manifest in development trajectories that are shaped by both local and trans-local drivers, and defined by unequal power relations that cross scales and levels (Sovacool et al., 2015; Barnett, 2020; Newell, 2020), including in key sectors like energy (Baker et al., 2014) and agriculture (Houser et al., 2019), as well as emergent blocs like BRICS (Power et al., 2016; Schmitz, 2017); and sub-national constellations, like cities (Fragkias and Boone, 2016; Béné et al., 2018).

Fourth, transitions towards CRD may be technically and economically feasible but are 'saturated' with power and politics (Tanner and Allouche, 2011) (18.3), necessitating focused attention to political barriers and enablers of CRD (Newell, 2019). With a narrow window of time to contain dangerous levels of global warming, political economy research calls for CRD trajectories that counter the globalized neoliberal hegemony (Newell and Lane, 2020), especially given the pandemic, and the intersection of economic power and public health, environmental quality, climate change, and human and indigenous rights (Bernauer and Slowey, 2020; Schipper et al., 2020b).

Given these insights, CRD can be understood as the sum of complex multi-dimensional processes consisting of large numbers of actions and social choices made by multiple actors from government, the private sector, and civil society, with important influences by science and the media *(very high confidence*). These actions and social choices are determined by the available solution space and options, along with a range of enabling conditions (Section 18.4.2) that are largely bounded by individual and collective worldviews, and related ethics and values. This view is consistent with sustainable development being a *process constituted by multiple actions that are contested and have path dependencies and context-sensitive synergies and trade-offs with natural and embedded human systems* as well as bounded by multiple and contested knowledges and worldviews (Goldman et al., 2018; Heinrichs, 2020; Nightingale et al., 2020; Schipper et al., 2020b).

18.4.2 Enabling Conditions for Near-Term System Transitions

Given actors, institutions, and their engagement is fundamental to supporting system transitions needed for CRD (18.3) this section assesses recent literature with respect to how the values, choices and behaviors of those actors enable or constrain specific enabling conditions. Such enabling conditions represent opportunities for policymakers to pursue actions that contribute to CRD beyond direct risk management options such as climate adaptation and greenhouse gas mitigation (18.2.5.1, 18.2.5.2).

18.4.2.1 Governance and Policy

An overarching enabling conditions for achieving system transitions and transformations is the presence of enabling governance systems *(very high confidence).* Recent literature on the translation of governance into system transitions in practice suggests four key actions are important. The first is the critical reflection on so-called 'development solutions,' alternatively framed by some as 'empty promises,' that worsen climate risk, inequity, injustice and ultimately lead to unsustainable development (Mikulewicz, 2018; Mikulewicz and Taylor, 2020). Examples include development aid (Scoville-Simonds et al., 2020), large-scale development projects such as biofuel production in Ethiopia (Tufa et al., 2018), and urban growth management in Vietnam (DiGregorio, 2015). The second is the recognition that while the power of different actors and institutions is often tied to access to resources and the ability to constrain the actions of others, other dimensions of power such as its ability to produce knowledge as well as its contingency on circumstances and relationships are also important in enabling energy transitions: (Avelino et al., 2016; Avelino and Wittmayer, 2016; Lockwood et al., 2016; Ahlborg, 2017; Avelino and Grin, 2017; Partzsch, 2017; Smith and Stirling, 2018). Third, governance systems can help to develop productive interactions between formal government institutions, the private sector, and civil society including the provision 'safe arenas' for social actors to deliberate and pursue transitional and transformational change (Haukkala, 2018; Törnberg, 2018;

Strazds; Ferragina et al., 2020; Koch, 2020) (18.3.1, Box 18.1). Fourth, governance can address challenges such as climate change from a systems perspective and pursue interventions that address the interactions among development, climate change, equity and justice, and planetary health (Harvey et al., 2019; Hölscher et al., 2019). This is evidenced by recent experience with the COVID-19 pandemic response as well as ongoing escalation of disaster risk associated with extreme weather events (Walch, 2019; Cohen, 2020; Schipper et al., 2020b; Wells et al., 2020).

One output from systems of governance is formal policy frameworks and policies that influence processes and outcomes of system transitions that support CRD (18.1.3). The Paris Agreement, for example, provides a framework for CRD by defining a mitigation-centric goal of 'limiting warming to well below 2°C and enabling a transition to 1.5°C' (UNFCCC, 2015). It also provides for a broadly defined global adaptation goal (UNFCCC, 2015: Art. 7.1). The Nationally Determined Contributions (NDCs) are the core mechanism for achieving and enhancing climate ambitions under the Paris Agreement. However, the pursuit of a given NDC within a specific country will likely necessitate a range of other policy interventions that have more immediate impact on technologies and behavior, implicating transitions in energy, industry, land, and infrastructure *(very high confidence* (18.3.1). SDG-relevant activities are increasingly incorporated into climate commitments in the NDCs (at last count 94 NDCs also addressed SDGs), contributing to several (154 out of the 169) SDG targets (Brandi and Dzebo; Pauw et al., 2018). This reflects the potential of the NDCs as near-term policy instruments and sign-posts for progress toward CRD (*medium agreement, limited evidence*) (McCollum et al., 2018b).

As reflected by the SDGs (and SDG 13 specifically), the mainstreaming of climate change concerns into development policies is one mechanism for pursuing sustainable development and CRD *(very high confidence*). However, such mainstreaming has also been critiqued for perpetuating 'development as usual', reinforcing established development logics, structures and worldviews that are themselves contributing to climate change and vulnerability (O'Brien et al., 2015) and for obscuring and depoliticizing adaptation choices into technocratic choices (Murtinho, 2016; Webber and Donner, 2017; Benjaminsen and Kaarhus, 2018; Khatri, 2018; Scoville-Simonds et al., 2020). The coordinated implementation of sustainable development policy and climate action is nonetheless crucial for ensuring that the attainment of one does not come at the expense of others (Stafford-Smith et al., 2017). For example, aggressive pursuit of climate policies that facilitate transitions in energy systems can undermine efforts to secure sustainability transitions in other systems (18.3.1.1, 18.2.5.3, Table 18.7).

Several non-climate international policy agreements provide context for CRD such as the 1948 UN Universal Declaration of Human Rights, the UN Declaration on the Rights of Indigenous Peoples (Hjerpe et al., 2015); the Convention on Biological Diversity (CBD; UNFCCC, 1992) as well as the more recent Sendai Framework for Disaster Risk Reduction (UNDRR, 2015) and the 'new humanitarianisms' which seeks to reduce the gap between emergency assistance and longer term development (Marin and Naess, 2017). Collectively they provide a global policy framework that protects people's rights that are potentially threatened by climate change (Olsson et al., 2014). These policies are relevant to transitions across multiple systems, particular in societal systems toward more equitable and just development.

18.4.2.2 Economics and Sustainable Finance

18.4.2.2.1 Economics

System transitions toward CRD is contingent on reducing the costs of current climate variability on society while making investments that prepare for the future effects of climate change. Climate change and responses to climate change will affect many different economic sectors both directly and indirectly (Stern, 2007; IPCC, 2014a; Hilmi et al., 2017). As a consequence, the characteristics of economic systems will play an important role in determining their resilience *(very high confidence*). These effects will occur within the context of other developments, such as a growing world population, which increases environmental pressures and pollution (González-Hidalgo and Zografos, 2019; González-Hidalgo and Zografos, 2020). This impact is higher for developing countries than for high-income countries (Liobikienė and Butkus, 2018). While looking for sustainable climate-resilient policies, many complex and interconnected systems, including economic development, must be considered in the face of global-scale changes (Hilmi and Safa, 2010).

Miller (2017) discusses some of the planning for, and application of, adaptation measures that improve sustainability noting the importance of considering a range of factors including complexities of interconnected systems, the inherent uncertainties associated with projections of climate change impacts, and the effects of global-scale changes such as technological and economic development for decision makers. For example, addressing climate impacts in isolation is unlikely to achieve equitable, efficient, or effective adaptation outcomes *(very high confidence*). Instead, integrating climate resilience into growth and development planning allows decision makers to identify what sustainable development policies can support climate resilient growth and poverty reduction and understand better how patterns and trends of economic development affect vulnerability and exposure to climate impacts across sectors and populations, including distributional effects (Doczi, 2015). Markkanen and Anger-Kraavi (2019) highlighted that climate change mitigation policy can influence inequality both positively and negatively. Although higher levels of poverty, corruption and economic and social inequalities can increase the risk of negative outcomes, these potential negative effects would be mitigated if inequality impacts were taken into consideration in all stages of policy making *(very high confidence*).

The primary objective of economic and financial incentives around carbon emissions is to redirect investment from high to low carbon technologies (Komendantova et al., 2016). Recent years have seen policy interventions to incentivize transitions in energy, land, and industrial systems to address climate change and sustainability focus on price-based, as opposed to quantity-based, interventions. Price-based interventions aim at leveraging market mechanisms to achieve greater efficiency in the allocation of resources and costs of mitigating climate change. For example, carbon pricing initiatives around the world today cover approximately 8 gigatons of carbon dioxide emissions, equivalent to about 20% of global fossil energy fuel emissions and 15% of total carbon dioxide greenhouse gas emissions (Boyce, 2018). Meanwhile, environmental taxes and green public procurement push producers to eliminate the negative environmental effects of production (Danilina and Trionfetti, 2019). There are several advantages for environmental taxation including environmental effectiveness, economic efficiency, the ability to raise public revenue, and transparency *(very high confidence*). These gains can provide more resource-efficient production technologies and positively affect economic competitiveness (Costantini et al., 2018).

Policies encouraging eco-innovation, defined as "*new ideas, behavior, products, and processes that contribute to a decreased environmental burden*" (Yurdakul and Kazan, 2020), can positively affect economic competitiveness. By implementing policies to encourage eco-innovation, countries enhance their energy efficiency. These gains can provide more resource-efficient production technologies and positively affect economic competitiveness *(very high confidence*) (Liobikienė and Butkus, 2018) (Costantini et al., 2018). Other than eco-innovation, it is important to also consider exnovation, meaning the phasing out of old technologies, as otherwise the expansion of supply could lead to a rebound due to cheaper prices for carbon-based products (Arne Heyen et al., 2017; David, 2017). Hence, decarbonization strategies that set limits to carbon-based trajectories can be beneficial. Quantity-based interventions—or so-called 'command-and-control' policies—involve constraints on the quantity of energy consumption or greenhouse gas emissions through laws, regulations, standards and enforcement, with a focus on effectiveness rather than efficiency.

For a transition from dirty (more advanced) technologies to clean (less advanced) ones, market-based instruments such as carbon taxes should be considered alongside subsidies and other incentives that stimulate innovation (Acemoglu et al., 2016). Research and development in energy technologies, for example, can help reduce costs of deployment and therefore the costs of operating in a carbon-constrained world. Hémous (2016) indicates that a unilateral environmental policy which includes both clean research subsidies and trade tax can ensure sustainable growth, but unilateral carbon taxes alone might increase innovation in polluting sectors and would not generally lead to sustainable growth.

18.4.2.2.2 Climate finance

Achieving progress on system transitions will be contingent on the ability of actors and institutions to access the financing they need to invest in innovation, adaptation and mitigation, and broader system change *(very high confidence*). By greening their investment portfolios, investors can support reduction in vulnerability to the consequences of climate change and the reduction of greenhouse gas emissions. Finance can contribute to the reduction of GHG emissions, for example, by efficiently pricing the social cost of carbon, by reflecting the transition risks in the valuation of financial assets, and by channeling investments in low-carbon technologies (OECD, 2017). At the same time, there is a growing need to spur greater public and private capital into climate adaptation and resilience including climate-resilient infrastructure and nature-based solutions to climate change. For instance, the Green Climate Fund, established within the framework of the UNFCCC, is assisting developing countries in adaptation and mitigation initiatives to counter climate change.

Recent evidence sheds light on the magnitude and pervasiveness of climate risk exposure for global banks and financial institutions. According to Dietz et al. (2016), up to about 17% of global financial assets are directly exposed to climate risks, particularly the impacts of extreme weather events on assets and their outputs. However, when indirect exposures via financial counterparts are considered, the share of assets subject to climate risks is much larger (40-54%) (Battiston et al., 2017). Hence, the magnitude of climate-change-related risks is substantial, and similar to the ones that started the 2008 financial crisis (*high agreement, limited evidence*).

Financial actors increasingly recognize that the generation of long-term, sustainable financial returns is dependent on a stable, well-functioning and well-governed social, environmental and economic systems *(very high confidence*) (Shiller, 2012; Schoenmaker and Schramade, 2020). Institutional approaches to a variety of environmental domains (Krueger et al., 2019), which seek to integrate the pursuit of green strategies with financial returns include targeted investments in green assets (e.g., green bonds, clean energy public equity) and specialized funds/vehicles for as renewable energy infrastructure (Tolliver et al., 2019; Gibon et al., 2020); cleantech venture capital and alternative finance (Gianfrate and Peri, 2019); investment screening to steer capital to green industries (Nielsen and Skov, 2019; Ambrosio et al., 2020); and active ownership to influence organizational behavior (Silvola and Landau, 2021).

Despite the expansion of green mandates across the investment chain, definitions of some of the asset classes associated with green investing are ambiguous and poorly defined. The EU taxonomy for sustainable activities is a promising step in the right direction. For example, a "green" label for bonds is often stretched to encompass financing facilities of issuers that misrepresent the actual environmental footprint of their operations (the so-called risk of "greenwashing"). Even in cases where the bonds' proceeds are actually used to finance green projects, investors often remain exposed to both the green and "brown" assets of the issuers (Gianfrate and Peri, 2019; Flammer, 2020). The heterogeneity of metrics and rating methodologies (along with inherent conflict of interests between issuers, investors and score/rating providers) results in inconsistent and unreliable quantification of the actual environmental footprint of corporate and sovereign issuers (Battiston et al., 2017; Busch et al.).

In order to promote financial climate-related disclosures for companies and financial intermediaries, the financial system could play a key role in pricing carbon and in allocating capital toward low-carbon emission companies (Aldy and Gianfrate, 2019; Bento and Gianfrate, 2020; Aldy et al., 2021). Stable and predictable carbon-pricing regimes would significantly contribute to fostering financial innovation that can help further accelerate the decarbonization of the global economy even in jurisdictions which are more lenient in implementing climate mitigation actions *(very high confidence*) (Baranzini et al., 2017). A growing number of financial regulators are intensifying efforts to enhance climate-related disclosure of financial actors. In particular, the Financial Stability Board created the Task Force on Climate-related Financial Disclosures (TCFD) to improve and increase reporting of climate-related financial information. Several countries are considering implementing mandatory climate risk disclosure in line with TCFD's recommendations. Central Banks are also considering mandatory disclosure and climate stress-testing for banks. For instance, in November 2020 the European Central Bank (ECB) published a guide on climate-related and environmental risks explaining how the ECB expects banks to prudently manage and transparently disclose such risks under current prudential rules. The ECB also announced that banks in the Euro-zone will be stress tested on their ability to withstand climate change related risks. In addition to disclosure requirements and stress-testing, some Central Banks are considering the possibility of steering or tilting the allocation of their assets to favor the less polluting issuers (Schoenmaker, 2019). This, in turn, would translate into lower cost of capital for cleaner sectors, significantly accelerating the greening of the real economy.

[START BOX 18.7 HERE]

Box 18.7: 'Green' Strategies of Institutional Investors

Negative and positive screening. Investors assess the carbon footprint of issuers and identify the best and worst performers (Boermans and Galema, 2019). The issuers with excessive carbon footprint are divested and fall into the "exclusion lists" (negative screening). Alternatively, the investors commit to pick only the best in class (positive screening). As a bare minimum, screening approaches force more transparent environmental reporting from issuers. In the most optimistic scenario, in order to avoid exclusion lists issuers may progressively divest their non-green operations. In the long term, the combination of positive and negative screening will reward sustainable issuers relative to non-green sectors, thus reducing the cost of capital for less polluting entities.

Active ownership. Equity investors can exercise the voting rights at shareholders' meetings in relation to governance and business strategy, including the environmental performance. In addition, institutional investors engage with the management and the boards of directors of investee companies. Active ownership is therefore defined as the full exercise of the rights that accrue to the "owners" of the securities issued by companies (Dimson et al., 2015; Dimson et al., 2020). Active owners are entitled to question and challenge the robustness of financial analyses and the risk assessment behind strategic decisions including the environmental footprint ones. For instance, since fossil fuel businesses face the prospect of dramatic business decline (Ansar et al., 2013) and must revisit their business model to survive, active ownership by institutional investors may foster the transition to cleaner production and supply chain. Companies more exposed to carbon risks particularly need the active support of long-term shareholders. In turn, investors adopting an active ownership approach can manage their holdings' exposure to climate change risks, thus protecting the value of their investments on a long-term horizon (Krueger et al., 2019).

Specialized financial instruments and investors. New asset classes have been created to address the climate change challenge. Also specialized investment funds and vehicles came to life with the primary objective of addressing climate issues. While these financial instruments and funds prioritize the achievement of climate objectives, they do not sacrifice financial returns and are able to attract private capital. To mention a few examples:

- *Green bonds* are typically issued by companies, banks, municipalities, and governments with the commitment to use the proceeds exclusively to finance or refinance green projects, assets or business activities. These bonds are equivalent to any other bond issued by the same entity except for the label of "greenness" that ideally is verified ex-ante at the launch and ex-post when the proceeds are actually used by the issuer. Early evidence show that green bonds do not penalize financially issuers (Gianfrate and Peri, 2019; Flammer, 2020).
- *Carbon funds* are designed to help countries achieve long-term sustainability typically financing forest conservation. They are intended to reduce climate change impacts from forest loss and degradation.
- *Project finance.* New renewable energy initiatives are likely to recur more and more to project finance. Project finance relies on the creation of a special purpose vehicle (SPV), which is legally and commercially self-contained and serves only to run the renewable energy project. The SPV is financed without (or very limited) guarantees from the sponsors (typically energy companies: investors are therefore paid back on the basis only of SPV's future cash flows only and cannot recourse on the sponsors' assets (Steffen, 2018).
- *Cleantech venture capital*. These funds invest exclusively in early-stage companies working on innovative but not yet fully tested clean technologies. The risk profile of such investments is usually very high. The extent to which this segment of the financial industry can successfully support "deep" energy innovations is still debated (Gaddy et al., 2017). When cleantech start-ups develop hardware requiring a high upfront investment, support from the public sector seems necessary in order to attract further investments from large corporations and patient institutional investors.
- *Crowdfunding and alternative finance* are emerging as a channel to both finance small-scale clean energy projects as well as fund early stage innovative clean technologies (Cumming et al., 2017; Bento et al., 2019).

[END BOX 18.7 HERE]

18.4.2.3 Institutional capacity

Institutional capacity for system transitions refers to the capacity of structures and processes, rules, norms, and cultures to shape development expectations and actions aimed at durable improvements in human well-being. The AR5 highlighted the need for strong institutions to create enabling environments for adaptation and greenhouse gas mitigation action (Denton et al., 2014). Institutions stand within the social and political practices and broader systems of governance that ultimately drive adaptation and development processes and outcomes. They are thus produced by them and can become tools by which some actors constrain the actions of others (Gebreyes, 2018). As a consequence, they and can become a significant barrier to change, whether incremental or more transformational *(very high confidence*). The post-AR5 focus on transformational adaptation and resilience present in the literature suggests that institutions that enable system transitions toward CRD are secure enough to facilitate a wide range of voices, and legitimate enough to change goals or processes over time, without reducing confidence in their efficacy.

The limited literature on institutions and pathways relevant to system transitions and CRD suggests that institutions are most effective when taking a development-first approach to adaptation. This is consistent with the principles of CRD which emphasizes not simply reducing climate risk, but rather making development processes resilient to the changing climate. There is agreement in this literature that such an approach allows for the effective integration of climate challenges into existing policy and planning processes *(very high confidence*) (Pervin et al., 2013; Kim et al., 2017b; Mogelgaard et al., 2018). However, this approach generally rests on an incremental framing of institutional change (Mahoney and Thelen, 2009) based on two critical assumptions. The first is that existing processes and institutions are capable of bringing about system transitions that generate desired development outcomes and thus can be considered appropriate vehicles for the achievement of CRD. A large critical literature questions the efficacy of formal state and multilateral institutions. The evidence for the ability of local, informal institutions to achieve development goals remains uneven, with robust evidence of positive impacts on public service delivery, but more ambiguous evidence on behavior changes associated with strengthened institutions (Berkhout et al., 2018). The second is that the mainstreaming of adaptation will bring about changes to currently unsustainable development practices and pathways, instead of merely strengthening development-as-usual by subsuming adaptation to existing development pathways and allowing them to endure in the face of growing stresses (Eriksen et al., 2015; Godfrey-Wood and Otto Naess, 2016; Scoville-Simonds et al., 2020). There is evidence that countries with poor governance have limited adaptation planning or action at the national level, even when other determinants of adaptive capacity are present (Berrang-Ford et al., 2014). This suggests that, in these contexts, adaptation efforts are likely to be subsumed to existing government goals and actions, rather than having transformational impact.

18.4.2.4 Science, Technology & Innovation

Ongoing innovations in technology, finance, and policy have enabled more ambitious climate action over the past decade, including significant growth in renewable energy, electrical vehicles, and energy efficiency. However, access to, and the benefits of, that innovation have not been evenly distributed among global regions and communities and continued innovation is needed to facilitate climate action and sustainable development *(very high confidence*). Policymakers need useful science and information (Kirchhoff et al., 2013; Calkins, 2015; IPCC, 2019f) to make informed decisions about possible risks, and the benefits, costs, and trade-offs of available adaptation, mitigation, and sustainable development solutions (i.e., Article 4.1 of the Paris Agreement; UNFCCC, 2015). Moreover, recent literature has emphasized the need for deep technological, as well social, changes to avert the risks of conventional development trajectories (Gerst et al., 2013; IPCC, 2014a).

An effective and innovative technological regime is one that is integrated with local social entities across different modes of life, local governance processes (Pereira, 2018; Nightingale et al., 2020); and local knowledge(s), which increasingly support adaptation to socio-environmental drivers of vulnerability (Schipper et al., 2014; Nalau et al., 2018; IPCC, 2019f). These actors and their knowledge are often ignored in favor of knowledge held by experts and policymakers, exacerbating uneven power relations (Naess, 2013; Nightingale et al., 2020). For example, achieving sustainability and shifting towards a low carbon energy system (e.g., hydropower dams, wind farms) remains a contested space with divergent interests, values and prospects of future (Bradley and Hedrén, 2014; Avila, 2018; Mikulewicz, 2019), and potential impacts on human rights as embodied by the Paris Agreement (UNFCCC, 2015). A number of studies have emphasized the limits of relying upon technology innovation and deployment (e.g., expansion of renewable energy systems and/or carbon capture) as a solution to challenges of climate change and sustainable development (18.3.1.2). This is because such solutions may fail to consider the local historical contexts and barriers to participation of vulnerable communities, restricting their access to land, food, energy, and resources for their livelihoods.

18.4.2.5 Monitoring and Evaluation Frameworks

Enabling system transitions toward CRD is dependent in part on the ability to monitor and evaluate system transitions and broader development pathways to identify effective interventions and barriers to their implementation *(very high confidence*). However, the monitoring and evaluation of individual system transitions, much less CRD, remains highly challenging for multiple reasons (Persson, 2019). The highly contextual nature of resilience, adaptation and sustainable development means that, unlike climate mitigation, it is difficult to define universal metrics or targets for adaptation and resilience (Pringle and Leiter, 2018), (Brooks et al., 2014). This is demonstrated by the Paris Agreement's global goal for adaptation, The mismatch between timescales associated with resilience and adaptation interventions and those over which the results of such interventions are expected to become apparent tends to result in a focus on the measurement of spending, outputs, and short-term outcomes, rather than longer-term impacts (Brooks et al., 2014; Pringle and Leiter, 2018). The need to assess resilience and adaptation against a background of evolving climate hazards, and to link resilience and adaptation with development outcomes, present further methodological challenges *(very high confidence*) (Brooks et al., 2014).

Currently, the ability to monitor different components of CRD are in various stages of maturity *(very high confidence*). Monitoring of the sustainable development goals, for example, is a routine established practice at global and regional levels, and UNDP publishes annual updates on progress toward the SDGs (United Nations, 2021). For resilience, Brooks et al. (2014) identify three broad approaches to its measurement, each of which could offer potential mechanisms for monitoring progress toward CRD. One is a 'hazards' approach, in which resilience is described in terms of the magnitude of a particular hazard that can be accommodated by a system, useful in contexts where thresholds in climate and related parameters can be identified and linked with adverse impacts on human populations, infrastructure and other systems (Naylor et al., 2020). An 'impacts' approach is one in which resilience is measured in terms of actual or avoided impacts and is suited for tracking adaptation success in delivering CRD over longer timescales, for example at the national level (Brooks et al., 2014). Finally, a 'systems' approach is one where resilience is described in terms of the characteristics of a system using quantitative or qualitative indicators which are often associated with different 'dimensions' of resilience (Serfilippi and Ramnath, 2018; Saja et al., 2019). This allows measurement of key indicators that are proxies for resilience at regular intervals, even in the absence of significant climate hazards and associated disruptions (*very high confidence*) (Brooks et al., 2014) (see also Cross-Chapter Box ADAPT in Chapter 1). Similar criteria could be applied to evaluating adaptation options and their implementation as well as various interventions in pursuit of SDGs.

18.4.3 Arenas of Engagement

Much of the enabling conditions for system transitions discussed in 18.4.2 are inherently linked to actors and their agency in pursuing system change. Yet, a significant literature has developed since the AR5 exploring note only the role of different actors in pursuing adaptation, mitigation, and sustainable development options, but also how those actors interact with one another to drive outcomes. CRD pathways are determined by the interactions between societal actors and networks, including government, civil society and the private sector, as well as science and the media. The resultant social choices and cumulative private and public actions (and inactions) are institutionalized through both formal and informal institutions that evolve over time and seek to provide societal stability in the face of change. The degree to which the emergent pathways foster just and climate resilient development depends on how contending societal interests, values and worldviews are reconciled through these interactions. These interactions occur in many different arenas of engagement, i.e., the settings, places and spaces in which societal actors interact to influence the nature and course of development, including political, economic, socio-cultural, ecological, knowledge-technology and community arenas (Figures 18.1, 18.2).

For example, political arenas range from formalized election and voting procedures to more informal and less transparent practices, like special interest lobbying. Town squares and streets can become sites of political struggle and dissent, including protests against climate inaction. As a more specific case-in-point, the formal space for national, sub-national and international adaptation governance emerged at COP 16 (UNFCCC, 2010) when adaptation was recognized as having a similar level of priority as mitigation. The Paris Agreement (UNFCCC, 2015) built on this and the 2030 Sustainable Development Agenda (United Nations, 2015) to link adaptation to development and climate justice, widening the scope of adaptation governance beyond formal government institutions. It also highlighted the importance of multi-level adaptation governance, including non-state voices from civil society and the private sector. This implied the need for wider arenas and modes of engagement around adaptation (Chung Tiam Fook, 2017; Lesnikowski et al., 2017; IPCC, 2018a) that facilitate coordination and convergence among these diverse actors including individual citizens to collectively solve problems and unlock the synergies between adaptation and mitigation and sustainable development (IPCC, 2018a; Romero-Lankao et al., 2018).

There are many other visible and less visible arenas of engagement in the other interconnected spheres of societal interaction spanning scales from the local to international level. The metaphor of arenas derives from diverse social and political theory, with applications in studies of, among other things, governance transformation and transitions (Healey, 2006; Jørgensen, 2012; Jørgensen et al., 2017). It underscores that these arenas can be enduring or temporary in nature, are historically situated and often spatially bounded, and signifies the many different mechanisms by which societal actors interact in dynamic and emergent ways. Power and politics impact access and influence in these arenas of engagement – with varying levels of inclusion and exclusion shaping the nature and trajectory of development. In practice, some arenas of engagement are 'struggle arenas' as different societal actors strive to influence the trajectory of development, with inevitable winners and losers.

Institutional arrangements to foster CRD are at an early stage of development in most regions (*medium agreement, limited evidence*). They need to be further clarified and strengthened to enable a sharing of resources and responsibilities that facilitate climate actions embracing climate resilience, equity, justice, poverty alleviation and sustainable development (Wood et al., 2017; IPCC, 2018a; Reckien et al., 2018). These endeavours are strongly influenced by how contested and complementary worldviews about climate change and development are mobilised by societal actors to justify, direct, accelerate and deepen transformational climate action or entrench maladaptive business as usual practices (18.4.3.1).

18.4.3.1 Worldviews

Worldviews are overarching systems of meaning and meaning-making that inform how people interpret, enact, and co-create reality (De Witt et al., 2016). Worldviews shape the vision, beliefs, attitudes, values, emotions, actions, and even political and institutional arrangements. As such, they can promote holistic, egalitarian approaches to enable, accelerate and deepen climate action and environmental care (Ramkissoon and Smith, 2014; De Witt et al., 2016; Lacroix and Gifford, 2017; Sanganyado et al., 2018; Brink and Wamsler, 2019). Alternatively, they can also serve as significant barriers to system transitions and transformation, based on anthropocentric, mechanistic and materialistic, worldviews and the utilitarian, individualist or skeptical values and attitudes they often promote *(very high confidence*) (Beddoe et al., 2009; van Egmond and de Vries, 2011; Stevenson et al., 2014; Zummo et al., 2020).

Traditional, modern and postmodern worldviews have different, and in many ways, complementary potentials for integrative diverse approaches to climate action and sustainable development. They can also destabilize climate-sensitive societal values (van Egmond and de Vries, 2011; Van Opstal and Hugé, 2013; De Witt et al., 2016; Shaw, 2016) which are predictors of concern (Shi et al., 2015). Among the challenges of strongly different climate-related worldviews, is that they rarely co-exist. Some worldviews become incompatible or hostile to other worldviews, openly seeking to dominate, eliminate or segregate competing perspectives (*medium agreement, medium evidence*) (de Witt, 2015; Jackson, 2016; Nightingale, 2016; Xue et al., 2016; Goldman et al., 2018).

To address these difficult contests, climate- and global environmental change-related worldviews are often scientized. This can exclude other worldviews which ultimately narrows understanding of climate change and the solution space. Hence, the post-AR5 literature on worldviews focuses on the numerous meanings, associations, narratives and frames of climate change and how these shape perceptions, attitudes and values (Morton, 2013; Boulton, 2016; Hulme, 2018; Nightingale Böhler, 2019). The recognition of the diversity of interpretations and meanings has led to multidisciplinary and transdisciplinary research that incorporates the humanities and the arts (Murphy, 2011; Elliott and Cullis, 2017; Steelman et al., 2019; Tauginienė et al., 2020), feminist studies (MacGregor, 2003; Demeritt et al., 2011; Bell, 2013; Brink and Wamsler, 2019; Plesa, 2019) and religious studies (Sachdeva, 2016; McPhetres and Zuckerman, 2018) to examine diverse understandings of reality and knowledge possibilities around climate change. In addition, literature on cultural cognition, epistemological plurality and relational ontologies draws on non-Western worldviews and forms of knowledge (Goldman et al., 2018) (Jackson, 2016; Nightingale, 2016; Xue et al., 2016).

On the other hand, the tendence for certain worldviews to dominate the policy discourse has the potential to exacerbate social, economic and political inequities *(very high confidence*). ontological, epistemic and procedural injustices. Research aimed at exploring the existing political ontology and knowledge politics of exclusion that marginalize certain communities and actors originated in academic, or scientific perspectives. This includes institutions such as the IPCC and is subsequently replicated in social representations, including the media, public policy and the development agenda, narrowing possibilities for social transformation (Jackson, 2014; Luton, 2015; Escobar, 2016; Burman, 2017; Newman et al., 2018; Sanganyado et al., 2018; Wilson and Inkster, 2018).

[START CROSS-CHAPTER BOX INDIG HERE]

Cross-Chapter Box INDIG: The Role of Indigenous Knowledge and Local Knowledge in Understanding and Adapting to Climate Change

Authors: Tero Mustonen (Finland), Sherilee Harper (Canada), Gretta Pecl (Australia), Vanesa Castán Broto (Spain), Nina Lansbury (Australia), Andrew Okem (Nigeria/South Africa), Ayansina Ayanlade (Nigeria), Jackie Dawson (Canada), Pauline Harris (Aotearoa-New Zealand), Pauliina Feodoroff (Finland), Deborah McGregor (Canada)

Indigenous knowledge refers to the understandings, skills and philosophies developed by societies with long histories of interaction with their natural surroundings (UNESCO, 2018; IPCC, 2019a). Local knowledge refers to the understandings and skills developed by individuals and populations, specific to the places where they live (UNESCO, 2018; IPCC, 2019a). Indigenous knowledge and local knowledge are inherently valuable but have only recently begun to be appreciated and in western scientific assessment processes in their own right (Ford et al., 2016). In the past these often endangered ways of knowing have been suppressed or attacked (Mustonen, 2014). Yet these knowledge systems represent a range of cultural practices, wisdom, traditions, and ways of knowing the world that provide accurate and useful climate change information, observations, and solutions (*very high confidence*) (Table Cross-Chapter Box INDIG.1). Rooted in their own contextual and relative embedded locations, some of these knowledges represent unbroken engagement with the earth, nature and weather for many tens of thousands of years, with an understanding of the ecosystem and climatic changes over longer-term timescales that is held both as knowledge by Indigenous Peoples and Local Peoples as well as in the archaeological record (Barnhardt and Angayuqaq, 2005; UNESCO, 2018).

Indigenous Peoples around the world often hold unique worldviews that link today's generations with past generations. In particular, many Indigenous Peoples consider concepts of responsibility through intergenerational equity, thereby honouring both past and future generations (Matsui, 2015; McGregor et al., 2020). This can often be in sharp contrast to environmental valuing and decision-making that occurs in Western societies (Barnhardt and Angayuqaq, 2005). Therefore, consideration of Indigenous knowledge and local knowledge needs to be a priority in the assessment of adaptation futures (Nakashima et al., 2012)(Ford et al., 2016) (Chapter 1), although adequate Indigenous cultural and intellectual property rights require legal and non-legal measures for recognition and protection (Janke, 2018).

Indigenous knowledge and local knowledge are crucial to address environmental impacts, such as climate change, where the uncertainty of outcome is high and a range of responses are required (Mackey and Claudie, 2015). However, working with this knowledge in an appropriate and ethically acceptable way can be challenging. For instance, questions of data 'validity' and the requirement to communicate such knowledge in the dominant language can lead to inaccurate portrayals of Indigenous knowledge as inferior to science. This may overlook the uniqueness of Indigenous knowledge and then lead to the overall devaluation of Indigenous political economies, cultural ecologies, languages, educational systems, and spiritual practices (Smith, 2013; Sillitoe, 2016; Naude, 2019; Barker and Pickerill, 2020). Furthermore, Indigenous knowledge is too often only sought superficially – focusing only on the 'what', rather than the 'how' of climate change adaptation and/or seen through the lenses of 'romantic glorification' leaving little room for the knowledge to be expressed as authored by the communities and knowledge holders themselves (Yunkaporta, 2019).

Multiple knowledge systems and frameworks

Indigenous knowledge systems include not only the specific narratives and practices to make sense of the world, but also profound sources of ethics and wisdom. They are networks of actors and institutions that organise the production, transfer and use of knowledge (Löfmarck and Lidskog, 2017). There is a pluralism of forms of knowledge that emerge from oral traditions, local engagement with multiple spaces, and Indigenous cultures (Peterson et al., 2018). Recognising such multiplicity of forms of knowledge has long been an important concern within sustainability science (Folke et al., 2016). Less dominant forms of knowledge should not be put aside because they are not comparable or complementary with scientific knowledge (Brattland and Mustonen, 2018; Mustonen, 2018; Ford et al., 2020; Ogar et al., 2020). Instead, Indigenous knowledge and local knowledge can shape how climate change risk is understood and experienced, the possibility of developing climate change solutions grounded in place-based experiences, and the development of governance systems that match the expectations of different Indigenous knowledge and local knowledge holders (*very high confidence*).

Different frameworks that enable the inclusion of Indigenous knowledge have emerged from efforts to utilise more than one knowledge system (*high evidence, high agreement*). For example, the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) has developed a 'nature's contribution to peoples' framework that provides a common conceptual vocabulary and structural analysis (Díaz et al., 2015; Tengö et al., 2017; Díaz et al., 2018; Peterson et al., 2018). The IPBES approach complements other efforts to study areas of intersection between scientific and Indigenous worldviews (Barnhardt and Angayuqaq, 2005; Huaman and Sriraman, 2015) or 'boundaries' that illustrate 'blind spots' in scientific knowledge (Cash et al., 2003; Clark et al., 2016; Brattland and Mustonen, 2018). These frameworks highlight areas of collaboration but provide less guidance in areas where sources of evidence conflict across different knowledge systems (Löfmarck and Lidskog, 2017). These experiences suggest that the inclusion of Indigenous knowledge and local knowledge in international assessments may transform the process of assessment of scientific, technical, and socio-economic evidence (*medium evidence, high agreement*). These knowledge systems also point to novel discoveries that may be still unknown to the scientific world but have been known by communities for millennia (Mustonen and Feodoroff, 2020).

The importance of free and prior-informed consent

Obtaining free and prior-informed consent is a necessary but not sufficient condition to engage in knowledge production with Indigenous Peoples (Sillitoe, 2016). Self-determination in climate change assessment, response, and governance is critical (Chakraborty and Sherpa, 2021), and Indigenous Peoples are actively contributing to respond to climate change (Etchart, 2017). Climate change assessment and adaptation should be self-determined and led by Indigenous Peoples, acknowledge the importance of developing genuine partnerships, respect Indigenous knowledge and ways of knowing, and acknowledge Indigenous Peoples as stewards of their environment (Country et al., 2016; Country et al., 2018; ITK, 2019; Barker and Pickerill, 2020; Chakraborty and Sherpa, 2021). Supporting Indigenous Peoples' leadership and rights in climate adaptation options at the local, regional, national and international levels is an effective way to ensure that such options are adapted to their living conditions and do not pose additional detrimental impacts to their lives (*very high confidence*). Chapter 18 shows that the transformations required to deliver climate resilient futures will create societal disruptions, with impacts that are most often unevenly experienced by groups with high exposure and sensitivity to climate change, including Indigenous Peoples and local communities (Schipper et al., 2020a). Climate-resilient futures depend on finding strategies to address the causes and drivers of deep inequities (Chapter 18). For example, climate resilient futures will depend on recognising the socio-economic, political and health inequities that often affect Indigenous Peoples (Mapfumo et al., 2016; Ludwig and Poliseli, 2018) (*very high confidence*).

International conventions to support and utilize Indigenous knowledge and local knowledge

Several tools within international conventions may support instruments to develop equitable processes that facilitate the inclusion Indigenous knowledge and leadership in climate change adaptation initiatives. The International Labour Convention 69 recognised Indigenous People's right to self-determination in 1989 (ILO, 1989). The United Nations' Declaration on the Rights of Indigenous Peoples (United Nations, 2007) includes articles on the right to development (Article 23), the right to maintain and strengthen their distinctive spiritual relationship and to uphold responsibilities to future generations (Article 25), and the right to the conservation and protection of the environment and the productive capacity of their territories (Article 29). Article 26 upholds the right to the lands, territories and resources, the right to own, use, develop and control the lands, and legal recognition and protection of these lands, territories, and resources. Indigenous Peoples are also recognized within the Sustainable Development Goals as a priority group (Carino and Tamayo, 2019). International events such as the 'Resilience in a time of uncertainty: Indigenous Peoples and Climate Change' Conference brought together Indigenous Peoples' representatives and government leaders from around the world to discuss the role of Indigenous Peoples in climate adaptation (UNESCO, 2015).

The value of Indigenous knowledge and local knowledge in climate adaptation planning

There have been increasing efforts to enable Indigenous knowledge holders to participate directly in IPCC assessment reports (Ford et al., 2012; Nakashima et al., 2012; Ford et al., 2016). Adaptation efforts have benefited from the inclusion of Indigenous knowledge and local knowledge (IPCC, 2019e) (*very high confidence*). Moreover, it has been recognized that including Indigenous knowledge and local knowledge in IPCC reports can contribute to overcoming the combined challenges of climate change, food security, biodiversity conservation, and combating desertification and land degradation (IPCC, 2019c) (*high confidence*). Limiting warming to 1.5°C necessitates building the capability of formal assessment processes to respect, include and utilize Indigenous knowledge and local knowledge (IPCC, 2018a) (*medium evidence, high agreement*).

However, these efforts have been accompanied by a recognition that 'integration' of Indigenous knowledge and local knowledge cannot mean that those knowledge systems are subsumed or required to be validated through typical scientific means (Gratani et al., 2011; Matsui, 2015). Such a critique of 'validity' can be inappropriate, unnecessary, can disrespect Indigenous Peoples' own identities and histories, limits the advancement and sharing of these perspectives in the formal literature, and overlooks the structural drivers of oppression and endangerment that are associated with Western civilization (Ford et al., 2016). Moreover, by underutilizing Indigenous knowledge and local knowledge systems, opportunities that could otherwise facilitate effective and feasible adaptation action can be overlooked. We should also reserve space for the understanding that each cultural knowledge system, building on linguistic-cultural endemicity, is unique and inherently valuable.

Indigenous Peoples have often constructed their ways of knowing using oral histories as one of the vehicles of mind and memory, observance, governance, and maintenance of customary law (Table Cross-Chapter Box INDIG.2). These ways of knowing can also incorporate the relationships between multiple factors simultaneously which adds particular value towards understanding complex systems that is in contrast to the dominant reductionist, Western approach- noting that non-reductionist approaches also exist (Ludwig et al., 2014; Hoagland, 2017).

For climate research, the role of oral histories as a part of Indigenous knowledge and local knowledge is extremely relevant. For example, ocean adaptation initiatives can be guided by oral historians and keepers of knowledge who can convey new knowledge and baselines of ecosystem change over long-time frames (Nunn and Reid, 2016). Oral histories can also convey cultural indicators and linguistic devices of species identification as a part of a local dialect matrix and changes in ecosystems and species using interlinkages not available to science (Mustonen, 2013; Frainer et al., 2020). Oral histories attached to maritime place names, especially underwater areas (Brattland and Nilsen, 2011), can position observations relevant for understanding climate change over long ecological timeframes (Nunn and Reid, 2016). Species abundances, well-being and locations are some of the examples present in the ever-evolving oral histories as living ways of knowing. Indigenous knowledge and oral histories may also have the potential to convey governance, moral, and ethical frameworks of sustainable livelihoods and cultures (Mustonen and Shadrin, 2020) rooted in the particular Indigenous or local contexts that are not otherwise available in written or published forms.

Climate change research involving Indigenous Peoples and local communities has shown that the generation, innovation, transmission, and preservation of Indigenous knowledge is threatened by climate change (Kermoal and Altamirano-Jiménez, 2016; Simonee et al., 2021). This is because Indigenous knowledge is taught, local knowledge is gained through experience, and relationships with the land are sustained through social engagement within and among families, communities, and other societies (Tobias J.K, 2014; Kermoal and Altamirano-Jiménez, 2016). The knowledge that has traditionally been passed on in support of identity, language and purpose has been disrupted at an intergenerational level (Lemke and Delormier, 2017). Many of these dynamics have affected local knowledge transfers equally (Mustonen, 2013). This scenario represents a tension for Indigenous Peoples, where Indigenous knowledge in the form of land-based life ways, languages, food security, intergenerational transmission and application are threatened by climate change, yet in parallel, these same practices can enable adaptation and resilience (McGregor et al., 2020).

Table Cross-Chapter Box INDIG.1: Examples of Indigenous knowledge and local knowledge about climate change used in this Assessment Report

Issue	Examples of Indigenous Peoples' and local communities' action	Context, peoples, and location	Source
Climate forecasting/early warning	Phenological cues to forecast and respond to climate change	Smallholder farmers, Delta State, Nigeria	Ch9
	Forecasting of weather and climate variation through observation of the natural environment (e.g. changes in insects, and wildlife).	Afar pastoralists, north-eastern Ethiopia	
	Observation of wind patterns to plan response to coastal erosion/flooding	Inupiat, Alaska, US	Ch14
	Sky and moon observation to determine the onset of rainy season	Maya, Guatemala	Ch12
Fire hazards	Prescribed burning	Indigenous nations in Venezuela, Brazil, Guyana, Canada, and US	Ch12 Ch14
Crop yield / food security	Water management, native seeds conservation and exchange, crop rotation, polyculture, and agroforestry	Mapuche, Chile	Ch12
	Crop association (milpa) agroforestry, land preparation and tillage practices, native seed selection and exchange, adjusting planting calendars,	Maya, Guatemala	Ch12
	Harvesting rain-water and the use of maize landraces by Indigenous farmers to adapt to climate impacts and promote food security in Mexico	Yucatán Peninsula, Mexico	Ch14
Livelihood and well-being	Cultural values ingrained in knowledge system: reciprocity, collectiveness, equilibrium, and solidarity	Quechua, Cusco, Peru	Ch12
Ecosystem degradation	Ecosystem restoration including rewilding	Sámi, Nenets, and Komi, Scandinavia and Siberia	Ch13
	Collaboration with researchers, foresters, and landowners to manage native black ash deciduous trees against emerald ash borer	Indigenous Nations in Canada and US	Ch14

Table Cross-Chapter Box INDIG.2: Case Study Summary

Region	Summary
Africa	Many rural smallholder farmers in Africa use their ingrained Indigenous knowledge systems to navigate climatic changes as many do not have access to Western systems of weather forecasting. Instead, these farmers have been reported to use observations of clouds and thunderstorms, and migration of local birds to determine the start of the wet season, as well as create temporary walls by rivers to store water during droughts. Indigenous knowledge systems should be incorporated into strategic plans for climate change adaptation policies to help smallholder farmers cope with climate change (Mapfumo et al., 2016).
Arctic	For local Inuit hunters and others who travel across Arctic land, ice and sea, there is evidence that the most accurate approach to reduce risk and enable informed decision-making for safe travel, is to combine Indigenous knowledge and local observations of weather with official online weather and marine services information that is available nationally (Simonee et al., 2021). Combining Inuit and local knowledge of weather, water, ice, and climate information with official forecasts has provided local hunters with more accurate, locally relevant information, and has on several occasions helped to avoid major weather-related accidents.
Latin America	In Venezuela, Brazil, and Guyana, Indigenous knowledge systems have led to a lower incidence of wildfires, reducing the risk of rising temperatures and droughts (Mistry et al., 2016). The Mapuche Indigenous Peoples in Chile use various traditional and sustainable agricultural practices, including: native seed conservation and exchange (*trafkintu*), crop rotation, polyculture, and tree-crop association. They also give thanks to Mother Earth through rituals to nurture socioecological sustainability (Parraguez-Vergara et al., 2018). In rural Cusco Region of Peru, “cultures values known in Quechua as *ayni* (reciprocity), *ayllu* (collectiveness), *yanantin* (equilibrium) and *chanincha* (solidarity)” have led to successful adaptation to climate change (Walshe and Argumedo, 2016).
Māori (Aotearoa New Zealand)	The traditional calendar system (*maramataka*) used by the Māori in Aotearoa-New Zealand incorporates ecological, environmental and celestial Indigenous knowledge. Māori practitioners are collaborating with scientists through the Effect of Climate Change on Traditional Māori Calendars project (Harris et al., 2017) to examine if climatic changes are impacting the use of the *maramataka*, which can be used as a framework to identify and explain environmental changes. Observations are being documented across Aotearoa, New Zealand to improve understandings of environmental changes and explore the use of Indigenous Māori knowledge in climate change assessment and adaptation.
Skolt Sámi (Finland)	In 2011, the Skolt Sámi in Finland began the first co-governance initiative where collaborative management and Indigenous knowledge were utilized to effectively manage a river and Atlantic Salmon (*Salmo salar*). This species is culturally and spiritually significant to the Skolt Sámi and has been adversely impacted by rising water temperatures and habitat loss (Brattland and Mustonen, 2018; Feodoroff, 2020; Ogar et al., 2020) (see also CCP Polar). Using Indigenous knowledge, they mapped changes in catchment areas and used cultural indicators to determine the severity of changes. Through collaborative management efforts that utilized both Indigenous knowledge and science, spawning and juvenile habitat areas for trout and grayling were restored, demonstrating the autonomous community capacity (Huntington et al., 2017) of the Indigenous Skolt Sámi and the capacity of Indigenous knowledge to address climate change impacts and detection of very first microplastics pollution together with science (Pecl et al., 2017; Brattland and Mustonen, 2018; Mustonen and Feodoroff, 2020).

[END CROSS-CHAPTER BOX INDIG HERE]

18.4.3.2 Political and government arenas

Climate resilient development is embedded in social systems, in the political economy and its underlying ideologies, interests and institutions (see 18.4.1). The pursuit of CRD, and shifting development pathways away from prevailing trends, unfolds in an array of political arenas, from the offices of bureaucrats to parliament buildings, sidewalks and streets, to discursive arenas in which governance actors interact – from the village level to global forums (Jørgensen et al., 2017; Montoute et al., 2019; Sørensen and Torfing, 2019; Pasquini, 2020). Paradoxically, the post-AR5 literature suggests that political arenas are often used to shut down efforts to explore the solution space for climate change and sustainable development (*medium agreement, robust evidence*) (e.g., Kenis and Mathijs, 2012; Kenis and Mathijs, 2014; Beveridge and Koch, 2016; Kenis and Lievens, 2016; Driver et al., 2018; Meriluoto, 2018; Swyngedouw, 2018; Mocca and Osborne, 2019). Power relationships among different actors create opportunities for people to be included or excluded in collective action (Siméant-Germanos, 2019) (18.3.1.6, 18.4.3.5). Therefore, as evidenced by examples from the UK (MacGregor, 2019) and China (Huang and Sun, 2020) small-scale collective environmental action has transformative potential in part due to its ability to increase levels of cooperation among different actors (*medium agreement, limited evidence*) (Green et al., 2020; Blühdorn and Deflorian, 2021).

In addition to the 'arm's length' acts of voting, social mobilisation, protest, and dissent can be critical catalysts for transformative change (Porta, 2020). These are competitions for recognition, power, and authority (Nightingale, 2017) that take place in settings. This is evidenced by experiences from the energy sector in Bangladesh which became a contested national policy domain and where social movements eventually transformed the nation's energy politics (Faruque, 2017). Similarly, in Germany, the nation's energy transition led to marked changes in agency, legal frameworks, and energy markets drove the proliferation of so-called municipalizations of energy systems – a reversal of years of system privatization (Becker et al., 2016). Meanwhile, experience in Bolivia demonstrate that the transformative potential of political conflict depends on transcending narrow issues to form broad coalitions with a collective identity that challenge prevailing development objectives and trajectories (Andreucci, 2019). Such examples illustrate the power of the communities as a vanguard against environmentally destructive practices (Villamayor-Tomas and García-López, 2018). Social movements have been successful at countering fossil fuel extraction (Piggot, 2018) and open up political opportunities in the face of increasing efforts to capture natural resources (Tramel, 2018) and are bolstered by resistance from within some corporations and/or their shareholders (Fougère and Bond, 2016; Swaffield, 2017).

Coincident with these social movements targeting climate change and sustainability has been a rise of political conservatism and populism as well as growth in misinformation (*high agreement, medium evidence*) (Mahony and Hulme, 2016; Swyngedouw, 2019). This reflects efforts to maintain the status quo by actors in positions of power in the face of rising social inertia for climate action (Brulle and Norgaard, 2019). Political arenas of the future may even require a new body politic that includes non-humans and a new geo-spatial politics (Latour et al., 2018).

As introduced in the discussion of governance as an enabling condition (18.4.2.1), a wide range of actors are involved in successful adaptation, mitigation, and sustainability policy and practice including national, regional and local governments, communities, and international agencies (Lwasa, 2015). As of 2018, 197 countries had between them over 1,500 laws and policies addressing climate change as compared to 60 countries with such legislation in 1997 when the Kyoto Protocol was agreed upon (Nachmany et al., 2017; Nachmany and Setzer, 2018). In judicial branches, climate change litigation is increasingly becoming an important influence on policy and corporate behavior among investors, activists, and local and state governments (Setzer and Byrnes, 2019). There is enhanced action on climate change at both national and subnational levels, even in cases where national policies are inimical as in USA (Carmin et al., 2012; Hansen et al., 2013).

The strong role of governments in climate action has implications for the nature of democracy, the relationship between the local and the national state, and between citizens and the state (Dodman and Mitlin, 2015). More integration of government policy and interventions across scales, accompanied by capacity building to accelerate adaptation is needed *(very high confidence*). Key needs include enhanced funding, clear roles and responsibilities, increased institutional capability, strategic approaches, community engagement, judicial integrity (Lawrence et al., 2015). More resources, and more active involvement of the private sector and civil society can help maintain adaptation on the policy agenda. Multilevel adaptation approaches are also relevant in low-income countries where local governments have limited financial resources and human capabilities often leading to dependency on national governments and donor organizations (Donner et al., 2016; Adenle et al., 2017).

Unlike mitigation, adaptation has traditionally been viewed as a local process, involving local authorities, communities, and stakeholders (Preston et al., 2015). The literature on the governance of adaptation continues to emphasize that local governments have demonstrated leadership in implementation by collaborating with the private sector and academia. Local governments can also play a key role (Melica et al., 2018; Romero-Lankao et al., 2018) in converging mitigation and adaptation strategies, coordinating and develop effective local responses, enabling community engagement and more effective policies around exposure and vulnerability reduction (Fudge et al., 2016). Local authorities are well-positioned to involve the wider community in designing and implementing climate policies and adaptation implementation (Slee, 2015; Fudge et al., 2016). Local governments also help deliver basic services, and protect their integrity from climate impacts (Austin et al., 2015; Cloutier et al., 2015; Nalau et al., 2015; Araos et al., 2017). However, the resource limitations of local governments as well as their small geographic sphere of influence suggests the need for more funding for this from higher levels of government, particularly national governments, to address adaptation gaps *(very high confidence*) (Dekker, 2020). Local adaptation implementation gaps can be linked to limited political commitment at higher levels of government and weak cooperation between key stakeholders (Runhaar, 2018). Incongruities and conflicts can exist between adaptation agendas pursued by national governments and the spontaneous adaptation practices of communities. There may be grounds for re-evaluating current consultative processes integral to policy development, if narrow technical approaches emerge as the norm for adaptation (Smucker et al., 2015).

Therefore, the traditional view of adaptation as a local process has now widened to recognize it as a multi-actor process that transcends scales from the local and sub-national to national and even international *(very high confidence* (Mimura et al., 2014). Many of the impacts of climate change are both local and transboundary, so that local, bilateral and multilateral cooperation are needed (Nalau et al., 2015; Donner et al., 2016; Magnan and Ribera, 2016; Tilleard and Ford, 2016; Lesnikowski et al., 2017). National policies and transnational governance should be seen as complementary, especially where they favor transnational engagement with sub- and non-state actors (Andonova et al., 2017). National governments typically act as a pivot for adaptation coordination, planning, determining policy priorities, and distributing financial, institutional and sometimes knowledge resources. National governments are also accountable to the international community through international agreements. National governments have helped enhance adaptive capacity through building awareness of climate impacts, encouraging economic growth, providing incentives, establishing legislative frameworks conducive to adaptation, and communicating climate change information (Berrang-Ford et al., 2014; Massey et al., 2014; Austin et al., 2015; Huitema et al., 2016).

18.4.3.3 Economic and financial arenas

The performance of local, national, and the global economies is a priority consideration shaping perceptions of climate risk and the costs and benefits of different policy responses to climate change. The most commonly used indicator of performance is gross domestic product (GDP) (Hoekstra et al., 2017). Traditionally, national development efforts have sought to maximize the growth of GDP under the assumption that GDP growth equates not only to economic prosperity (including poverty reduction) but also to increased efficiency and reduced environmental externalities (Ota, 2017). Such assumptions often employ models such as the environmental Kuznets curve (EKC) that postulates that economic development initially increases environmental impacts, but these trends eventually reverse with continued economic growth. Wealthy nations of the global North, including for example the United States, Great Britain, Iceland, Japan, have had success over the past decade in reducing their greenhouse gas emissions while growing their economies *(very high confidence*). However, attempts to empirically test EKC in different national contexts has yielded mixed results. Case studies in Myanmar, China, and Singapore, for example, suggest that the impacts of GDP on environmental quality are contingent on the development context and the environmental impact under consideration (Aung et al., 2017; Lee and Thiel, 2017; Xu, 2018; Chen and Taylor, 2020). In addition, an extensive literature now argues that current patterns of development, and the economic systems underpinning that development, are unsustainable (Washington and Twomey, 2016), and thus economic growth may not necessarily continue indefinitely in the absence of more concerted effort to pursue sustainable development, including reducing the impacts of climate change.

Given such criticisms of the link between development and economic growth, a growing number of researchers argue for the need for alternatives to GDP to guide development and evaluate the costs and benefits of different policy interventions (Hilmi et al., 2015). For example, while GDP growth can drive growth in income, it can also drive growth in inequality which can undermine poverty reduction efforts *(very high confidence*) (Fosu, 2017). Hence, recent years have seen significant interest in the concept of well-being as a more robust measure for linking policy and the economy with sustainable development for a healthy Anthropocene era (Fioramonti et al., 2019).

Another mechanism for evaluating environmental performance is to include environmental data in the System of National Accounts (SNA) through the System of Environmental-Economic Accounting (SEEA) introduced by the UN. As the international statistical standard for environmental-economic accounting (Pirmana et al., 2019), SEEA includes natural capital resources in national accounting. A number of recent studies conclude that failure to account for natural capital in macroeconomic impact assessments results in overly optimistic outcomes (Pirmana et al., 2019; Jendrzejewski, 2020; Naspolini et al., 2020), (Banerjee et al., 2019; Kabir and Salim, 2019; Keith et al., 2019). For example, Jendrzejewski (2020) inserted natural capital into a computable general equilibrium model of the 2017 European windstorm on state-owned forests in Poland. This resulted in more negative assessment of impacts, suggesting excluding natural capital could lead to erroneous investments, strategies. or policies. Similarly, other studies rely on Quality of life (QOL) measurements as alternatives for GDP. Estoque et al. (2018) suggested a “QOL-Climate” assessment framework, designed to capture the social-ecological impacts of climate change and variability.

Another alternative to GDP is Green GDP which seeks to incorporate the environmental consequences of economic growth (Boyd, 2007; Stjepanović et al., 2017; Stjepanović et al., 2019). Green GDP is difficult to measure, because it is difficult to evaluate the environmental depletion and ecological damages of growth (Stjepanović et al., 2019). Although there is no consensus in measuring Green GDP, attempts have been made for select countries including the United States (Garcia and You, 2017), Europe (Stjepanović et al., 2019), China (Chi and Rauch, 2010; Yu et al., 2019; Wang et al., 2020), Ukraine and Thailand (Harnphatananusorn et al., 2019), and Malaysia (Vaghefi et al., 2015). Le (2016) illustrated the potential negative impacts of climate change vulnerability on green growth. Some studies have suggested that focusing on green growth as the only strategy to address climate change would be risky. Hickel and Kallis (2020) argue that green growth is likely to be a misguided goal due to the difficulties of separating economic growth from resource use and, therefore, carbon emissions (see also (Antal and van den Bergh, 2014). Therefore, alternative strategies are required (Hickel and Kallis, 2020). In addition, green growth should also be able to justly respond to social movements involving contestation, internal debates and tensions (Mathai et al., 2018).

The emphasis on Green GDP is mirrored by another concept, Blue Growth, that focuses on the pursuing sustainable development through the ecosystem services derived from ocean conservation (Mustafa et al., 2019). Synthesis studies suggest that more intensive use of ocean resources, such as scaling up seaweed aquaculture, can be used to enhance CO2eq sequestration, thereby contributing to greenhouse gas mitigation, while also achieving other economic goals (Lillebø et al., 2017; Froehlich et al., 2019). Similarly, Sarker et al. (2018) present a framework for linking Blue Growth and climate resilient development in Bangladesh, with Blue Growth representing an opportunity for adapting to climate change. Bethel et al. (2021) also links Blue Growth to resilience, noting that a Blue economy can help facilitate recovery from the COVID-19 pandemic. Nevertheless, consistent with earlier assessment of enabling conditions for system transitions (18.4.2.1), implementation of Blue Growth initiatives is contingent upon the successful achievement of social innovation as well as creating an inclusive and cooperative governance structure *(very high confidence*) (Larik et al., 2017; Soma et al., 2018).

A potential critique of the various alternative metrics and models for economic development is that they are all framed in the context of growth. Over the past decade, ecological economists and political scientists have proposed Degrowth (e.g., Kallis, 2011; Demaria et al., 2013) and managing without growth (e.g., Jackson, 2009) as a solution for achieving environmental sustainability and socio-economic progress. Such concepts are a deliberate response to concerns about ecological limits to growth and the compatibility between growth-oriented development and sustainability (Kallis et al., 2009). Sustainable degrowth is not the same as negative GDP growth which is typically referred to as a recession (Kallis, 2011). Degrowth goes beyond criticizing economic growth; it explores the intersection among environmental sustainability, social justice, and well-being (Demaria et al., 2013). Under current economic and fiscal policies (see Box 18.8), degrowth has been argued as an unstable development paradigm because declining consumer demand leads to rising unemployment, declining competitiveness, and a spiral of recession (Jackson, 2009: 46). More comprehensive modelling of socio-economic performance understands the segments of sufficient social transformation to guarantee maintenance and rise in wellbeing coupled with reduced 'footprints' (Raworth, 2017; Hickel, 2019; D'Alessandro et al., 2020).

START BOX 18.8 HERE

Box 18.8: Macroeconomic policies in support of Climate-Resilient Development

Climate change risk may differ from other economic and financial risks in a number of ways: climate change is global; involves long-term impact; and involves a great deal of uncertainty; and with the possibility of irreversible change (Hansen, 2021). The macroeconomic implications will differ across countries with less developed countries are likely to suffer more relative to more advanced ones (Batten, 2018). Hence, policymakers need to understand the impact of climate change on macroeconomic issues such as potential output growth, capital formation, productivity, and long run level of interest rates, in order to better design policy interventions, be it monetary or fiscal (Economides and Xepapadeas, 2018; Bank of England, 2019; Rudebusch, 2019). As discussed, below a range of fiscal tools can be leveraged to mitigate the effects of climate change (Krogstrup and Oman, 2019).

Monetary Policy

Changes in climate and subsequent policy responses could increase volatility of food and energy prices, resulting in higher headline inflation rates. Thus, Central Banks (CBs) have to pay careful attention to underlying inflationary factors in order to maintain their inflationary targets. In response, CBs can take a number of actions. For example, they could require that collateral comprises assets that support the move to low-carbon economy, or their refinancing operations and crisis facilities could incentivize borrowers' move to low-carbon activities, particularly in countries where CBs' mandate has been expanded to account for climate impact (Papoutsi et al., 2021). Other actions that CBs could take include adoption of sustainable and responsible investment principles (Rudebusch, 2019), require financial firms to disclose their climate related risks (ECB, 2020; Lee, 2020). Despite these opportunities, there is ongoing debate regarding whether CBs should actively use monetary policy to address climate change and its risks (Honohan, 2019).

Fiscal policy

The application of green fiscal policies to address climate change could lead to environmental benefits including environmental revenues that may be used for broader fiscal reforms (OECD, 2021). As the US aims at becoming carbon neutral by 2050, fiscal policies at the national, sectoral, and international level can help to achieve this goal, along with investment, regulatory, and technology policies (Parry, 2021). The effectiveness of green fiscal policies are through their fiscal potential, opportunities for efficiency gains, distributional and macroeconomic impacts, and their political economy implications (Metcalf, 2016). The International Monetary Fund argues public support for green policies may rise in response to the COVID-19 crisis (IMF, 2017). For example, Leibenluft (2020) argues that investments to combat climate change should be an important component of the efforts to rebuild the economy in the wake of COVID-19. Such action is justified not only on ecological and social welfare grounds, but from a long-term fiscal perspective. For example, climate change impacts and/or efforts to adapt to those impacts drive increased spending in areas such as public health and disaster mitigation or response. Preventive and corrective actions would strengthen resilience to shocks and alleviate the financial constraints they create, particularly for small countries (Catalano et al., 2020). For example, Mallucci (2020) found that natural disasters exacerbate fiscal vulnerabilities and trigger sovereign defaults in seven Caribbean countries. Ryota (2019) illustrates how to include natural disaster and climate change in a fiscal policy framework to developing countries.

Carbon pricing

Pricing of greenhouse gases, including carbon, is a crucial tool in any cost-effective climate change mitigation strategy, as it provides a mechanism for linking climate action to economic development (IMF/OECD, 2021). By 2019, 57 nations around the world had implemented or scheduled implementation of carbon pricing. These initiatives cover 11 gigatons of carbon dioxide or about 20% of greenhouse gases emissions. Carbon prices in existing initiatives range between $1 and $127 per ton of carbon dioxide, while 51% of the emissions that are covered are priced more than $10 per ton of carbon dioxide. Moreover, in 2018, Governments raised about $44 billion in carbon pricing revenues (World Bank, 2019). However, the carbon prices are lower than the levels required for attaining the ambitious goal of climate change mitigation, and therefore, prices would need to increase if pricing alone is going to be used to drive compliance with the Paris Agreement. Higher carbon prices would also be warranted if prices are based on the social cost of carbon, which represents the present value of the marginal damage to economic output caused by carbon emissions (Cai and Lontzek, 2018). This cost needs to be considered with the social benefits of reducing carbon emissions through cost-benefit analyses in order to make the intended regulation acceptable.

Taxes

Carbon taxes represent another financial mechanism for addressing climate (Metcalf, 2019), 2019b). For example, the implementation of a carbon tax and a value-added tax on transport fuel in Sweden resulted in a reduction of CO2 emissions from transport of about 11% in which the carbon tax had the largest share (Andersson, 2019). In the United States, for example, a carbon tax could increase fiscal flexibility by collecting new revenues that can be redeployed to finance reforms and help stimulate economic growth. However, U.S. tax-inclusive energy prices would have to be 273% higher than laissez faire levels in 2055 in order to meet international agreements (Casey, 2019). Similarly, limiting global warming to 2 degrees or less would likely require a carbon tax rate in the Asia/Pacific region to be significantly higher than $25 per ton (IMF, 2021). Therefore, using tax revenues to issue payments back to taxpayers that are disproportionately impacted or to redistribute capital among regions may be one of the most important features of carbon tax policies. Although the average effect of carbon tax on welfare would be positive, some regions (56%) will gain and some regions (44%) lose (Scobie, 2013). Therefore, large transfer payments are needed to compensate those losing from carbon tax (Krusell and Smith, 2018). IMF (2019) argues that, of the various mitigation strategies to reduce fossil fuel CO2 emissions, carbon taxes are the most powerful and efficient, because they allow firms and households to find the lowest-cost ways of reducing energy use and shifting toward cleaner alternatives.

Subsidies

The World Bank has been encouraging both developed and developing states, especially those with petroleum reserves, to use the removal of subsidies as a mechanism for promoting energy transitions away from fossil fuels. The transition has led to social unrest in some cases, especially where there is a culture of entitlement to low-cost energy because it is an indigenous resource. Such reforms have been more effective when governments have been able to clearly show how savings are applied to social and health programs that benefit human well-being. Nevertheless, policy makers should not underestimate the complexity of issues involved in the removal of subsidies that will increase the cost of carbon and hasten the transition to cleaner fuels (Scobie, 2017; Scobie et al., 2018; Chen et al., 2020a). A crucial issue to take into account is the harmful effects some subsidies have on biodiversity. Although governments agreed in 2010 to make progress on reducing subsidies in 2010, by 2020 few governments had identified specific incentives to remove or taken action toward their removal. Further investigation of the positive and negative effects of subsidy redirection or elimination on people and the environment (Dempsey et al., 2020).

END BOX 18.8 HERE

18.4.3.4 Knowledge-technology and ecological arenas

Knowledge-technology arenas comprise the interaction in knowledge spaces connected to technology transitions. The institutional and political architecture through which knowledge and technology interact is described in sustainability transitions literature (Fazey et al., 2018b; Sengers et al., 2019l Kanger, 2020 #3709). A common theme explored in that literature is the ability of actors to access and apply various forms of knowledge as a means of effecting change. Different forms of innovation are recognized as a core enabling condition for achieving system transitions for CRD (18.3.3; Cross-Chapter Box INDIG). However, while scientific and technology knowledge may be useful, in some cases, they remain subordinate to political agendas, or are controlled by actors in positions of power and thus not equitably distributed *(very high confidence*) (Mormina, 2019). Participatory decision-making, for example, assumes that multiple actors, with differing motivations, agency and influence, engage with climate decision making and co-produce actions. Yet, some actors may not participate in the process if the proposed actions do not align with their motivations or if they do not have adequate agency (Roelich and Giesekam, 2019). Hence, effectively using knowledge to inform policy is challenging for both scientists, policymakers, and civil society alike.

Science, technology, and innovation (STI) policies are expected to shape expectations of the potential for a better world based on clean technologies, higher labor productivity, economic growth and a healthier environment (Schot and Steinmueller, 2018; Mormina, 2019). STI policies are considered as 'social goods for development'. Hence, STI policies are often proposed or implemented as means of addressing environmental challenges such as climate change along with sustainable development goals such as the reduction of inequality, poverty, and environmental pollution (Mormina, 2019). Realizing the benefits of STI, however, may be contingent on building broader STI capacity and bolstering nations' systems of innovation (*very high confidence)* (Mormina, 2019). This could include building global research partnerships to address priority STI needs as well as long-standing gaps between the global North and South. Such an approach shifts the framing of STI as one focused on individual investigators to one comprised of building knowledge networks. It also creates opportunities for integration of disparate forms of knowledge and innovation, including local and indigenous knowledge, into global knowledge systems (Cross-Chapter Box INDIG).

Furthermore, an extensive literature increasingly incorporates natural and ecological systems as knowledge domains relevant to understanding opportunities for sustainability and CRD. For example, the literature on socioecological systems (SES) (Sterk et al., 2017; Holzer et al., 2018; Avriel-Avni and Dick, 2019; Martínez-Fernández et al., 2021) as well as social, ecological, and technological systems (SETS) (McPhearson and Wijsman, 2017; Webb et al., 2018; Ahlborg et al., 2019), explicitly integrate ecological knowledge into sustainability including concepts such as planetary boundaries (18.1.1), adaptation and nature-based solutions, natural resources management, rights and access to nature, and understanding of how humans govern society-nature interactions in the face of climate change (Benjaminsen and Kaarhus, 2018; Mikulewicz, 2019; Nightingale et al., 2020). Some of these interactions are explained in Cross-Chapter Box INDIG including conflict over which knowledges are recognized as valuable in understanding and responding to climate change and therefore shape the nature of climate actions. Actor engagement in stewardship, solidarity, inclusion of multiple knowledges and nature-society connectedness can highlight the intertwined nature of ecological change and knowledge relations thereby support shifts to sustainability (Pelling, 2010; Hulme, 2018; Ives et al., 2019; Nightingale et al., 2020) (see also Box 18.6).

The expanding definition of what constitutes credible, relevant, and legitimate knowledge is leading to the democratization of knowledge and efforts to address historical inequities in access to knowledge (Ott and Kiteme, 2016; Rowell and Feldman, 2019). This is reflected in the communication of science, which is increasingly focused on reducing the distance between internal scientific and public communication and more engagement in public science governance and knowledge production (Waldherr, 2012; Peters, 2013). One innovative approach in co-production of knowledge is mobilizing communities through citizen science (Heigl et al., 2019). This also presents additional opportunities to incorporate local knowledge with scientific research, and better match scientific capability to societal needs.

18.4.3.5 Community arenas

Societal choices and development trajectories emerge from decisions made in different arenas which intersect and interact across levels and scales, in diverse institutional settings - some formal with their associated instruments and interventions, while others are informal. Since AR5, both formal and informal setting are increasingly arenas of debate and contestation regarding development choices and pathways *(very high confidence*) (see 18.4.4, Chapters 1, 6, 8, 10 and 17). Community arenas exist from the local to the global scale and constitute the many interactions between governance actors, often transcending any one scale to reflect the emergent outcomes of interactions in political, economic, socio-cultural, knowledge-technology and ecological arenas of engagement. Actions within and between these five arenas hence come together in the community arena of engagement. While community engagement is often described at the level of villages and cities (Ziervogel et al., 2021) (Chapter 8), communities in terms of people interacting with each other sharing worldviews, values and behaviors, also exist at the regional and global levels. For example, civil society engagement in climate action reached a peak in 2019, notably through the global youth movement which led to large global mobilisation and street demonstrations on all continents and in many large cities (Bandura and Cherry, 2020; Han and Ahn, 2020; Martiskainen et al., 2020). Calling for enhanced climate action by governments and other societal actors, the youth movement was supported by many other societal groups and networks, including arenas of community interaction.

While the SR1.5 (de Coninck et al., 2018) for the first time comprehensively assessed behavioral dimensions of climate change adaptation, most literature still has a greater focus on what triggers mitigation behavior (Lorenzoni and Whitmarsh, 2014; Clayton et al., 2015). Meanwhile, with CRD still a relatively young concept, there is little literature focused on what motivates action in pursuit of CRD rather than its subcomponents of climate action and sustainable development. Nevertheless, a common motivation that is emerging in the literature is clinically significant levels of climate distress among individuals (Bodnar, 2008), which is experienced as a continuing distress over a changed landscape which no longer offers solace, also known as solastalgia (*high agreement, medium evidence*) (Albrecht et al., 2007). This is accompanied by a shift from blaming natural forces for disasters to attributing it to human negligence which is known to lead to more acute perceptions of risk as well as more prolonged PTSD than trauma arising from non-human causes. Improving social connections, acknowledging anxiety, reconnecting to nature, and finding creative ways to re-engage are identified as ways of managing this growing anxiety (Lertzman, 2010; Clayton et al., 2017). Climate action in communities at various scales could fulfil many of these needs.

18.4.4 Frontiers of Climate Action

After decades of limited government action and social inertia to reduce the risk of climate change, there is also increasing social dissent toward the current political, economic and environmental policies to address climate (Brulle and Norgaard, 2019; Carpenter et al., 2019). Social movements are demanding radical action as the only option to achieve the mobilization necessary for deep societal transformation *(very high confidence*) (Hallam, 2019; Berglund and Schmidt, 2020).

Prompted by SR1.5, new youth movements seek to use science-based policy to break with incremental reforms and demand radical climate action beyond emissions reductions (Hallam, 2019; Klein, 2020; Thackeray et al., 2020; Thew et al., 2020). Recent social movements and climate protests embrace new modalities of action related to political responsibility for climate injustice through disruptive collective political action (Young, 2003; Langlois, 2014). This is complemented by a regenerative culture and ethics of care (Westwell and Bunting, 2020). These new social movements are based on nonviolent methods of resistance, including actions classified as dutiful, disruptive and dangerous dissent (O'Brien, 2018).

The new climate movement mixes messages of fear and hope to propel urgency and the need to respond to a climate emergency (Gills and Morgan, 2020). While some consider the mix between fear and hope as beneficial to success depending on psychological factors (Salamon, 2019) or political geography (Kleres and Wettergren, 2017) others warn of the risks of a rhetoric of emergency and its political outcomes (Hulme and Apollo-University Of Cambridge Repository, 2019; Slaven and Heydon, 2020).

Research shows that new climate movements have increased public awareness, and also stimulated unprecedented public engagement with climate change *(very high confidence*) (Lee et al., 2020; Thackeray et al., 2020) and has helped rethink the role of science with society (Isgren et al., 2019). Such movements may represent new approaches to accelerate social transformation and have resulted in notable political successes, such as declarations of climate emergency at the national and local level, as well as in universities. Their methods have also proven effective to end fossil fuel sponsorship (Piggot, 2018). Social demands for radical action are likely to continue to grow, as there is growing discontent with political inertia and a rejection of reformist positions.

Box 18.9: The Role of the Private Sector in Climate Resilient Development via Climate Finance, Investments and Innovation.

Climate finance broadly refers to resources that catalyze low-carbon and climate-resilient development. It covers the costs and risks of climate action, supports an enabling environment and capacity for adaptation and mitigation, and encourages R&D and deployment of new technologies. Climate finance can be mobilized through a range of instruments from a variety of sources, international and domestic, public and private (see Sections 18.4.2.2).

The private sector has particular competencies which can make significant contributions to adaptation, through innovative technology, design of resilient infrastructure, development and implementation of improved information systems and the management of major projects. The private sector can be seen as a "supplier of innovative goods and services" to meet the adaptation priorities of developing countries with expertise in technology and service delivery (Biagini and Miller, 2013).

Future investment opportunities in CRD are in water resources, agriculture and environmental services. Provision of clean water is another opportunity, requiring investment in water purification and treatment technologies such as desalination, and wastewater treatment. Weather and climate services are a possible area for private investment. (Hov et al., 2017; Hewitt et al., 2020).

18.5 Sectoral and Regional Synthesis of Climate Resilient Development

Prior sections of this chapter assessed the literature relevant to CRD inclusive of climate risk management, systems transitions and transformation, and actors and the arenas in which they engage one another to enable or constrain CRD. Here, this knowledge is explored in different climatological and development contexts through a synthesis of CRD-relevant assessments within the WGII sectoral and regional chapters.

18.5.1 Regional Synthesis of Climate-Resilient Development

In synthesizing regional knowledge relevant to the pursuit of CRD, this section first considers geographic heterogeneity in regional responses of common climate variables to increases in globally averaged temperatures. Such heterogeneity is a key driver of climate risk in different global regions, as well as human and natural systems within those regions. This is followed by synthesis of various national development indicators, aggregated to the regional level, as well as various challenges, opportunities, and options supporting CRD reported within WGII regional chapters.

18.5.1.1 Climate Change Risk for Different Global Regions

Two important elements of understanding the opportunities and challenges associated with the pursuit of CRD in different regional contexts are a) the geographic variability in climate conditions that shape livelihoods, behaviors, and responses of human and natural systems; and b) how those conditions could shift in the future in response to climate change, which determines the additional burden that climate change could create for adaptation and sustainable development.

The climate analyses of WGI provide information on regional differences in temperature, rainfall, and sea-surface temperatures for different global regions and how they are projected to change in response to different levels of aggregate global warming (Table 18.4). Such data reveal that even when aggregated to broad geographic regions, significant variations exist for all of these parameters, which is a function of the baseline climatology of each region. For example, temperatures in Africa and Australia are, on average, warmer than in Europe or North America. Significant variations are also observed for rainfall variables. Such regional variation in climate conditions is part of the regional context that shapes current patterns of development of the past present and future. They influence biodiversity and natural resource availability as well as exposure to climatic extremes (tropical storms, heat waves, and drought) that contribute to disasters.

The WGI data also indicate that increases in globally averaged temperatures will have different consequences for regional climate change (Table 18.4), including variation in the magnitude and, for precipitation, even the direction of change (*very high confidence*). For example, although average temperatures, daily minimum temperature, and the number of days over a given thresholds are projected to increase in all regions except Antarctica, the magnitude of the change varies. Moreover, little change is projected for daily maximum temperatures across different regions. Nevertheless, the number of days over different temperature thresholds such as 35°C increases markedly in most regions, reflecting the disproportionate impact that global warming has on the tails of temperature distributions. Given outcomes in many systems including public health, agriculture, ecosystems and biodiversity, and infrastructure are often associated with biophysical thresholds (e.g., physiological or design thresholds), those regions where such thresholds are increasingly exceeded due to climate change may experience disproportionately higher impacts (*very high confidence*). Given such temperatures occur more frequently in regions such as Africa and Central and South America, this disproportionate exposure is exacerbated by disproportionate vulnerability, adaptation gaps, and development needs (*very high confidence*; 18.2.4; Table 18.4).

The regional response of precipitation to globally averaged temperatures increases is less clear than temperature, in part due to high intra-region variability. Average daily precipitation remains fairly stable in all global regions in response to higher magnitudes of global warming (Table 18.4). However, 5-day precipitation totals provide a clearer signal of increasing hydrologic activity in response to higher globally averaged temperatures (Table 18.4). Such data no not necessarily reflect changes in rainfall extremes that could occur with downstream consequences for hazards such as drought or flooding. Similarly, while SSTs are more uniform across global ocean basins, all basins are anticipated to warm in response to higher globally averaged temperatures (Table 18.5). Unlike temperature, however, SST increases are anticipated to be only a fraction of the globally averaged increase in temperature, due in large part to the heat capacity of the oceans. Nevertheless, such higher SSTs have implications not only for ocean ecosystems and the distribution of marine species, but also for weather patterns, such as formation and intensity of tropical cyclones (*very high confidence*).

The other aspect of the regional climate responses to global temperature increases that is important for CRD is the marked differences observed between changes in response to 1.5°C versus 4°C of warming. Higher levels of global warming are associated with higher regional changes, including changes in extremes of temperature. This in turn increases climate risk to exposed and vulnerable human and natural systems, thereby increasing demand for adaptation. If that demand is not met, then the adaptation gap will be larger with greater risk of loss and damage (*very high confidence)* (Schaeffer et al., 2015; Chen et al., 2016; United Nations Environment Programme, 2021). This is true not only for regions, but also at the sectoral level (18.5.2). Therefore, CRD pathways must balance the demands for emissions reductions to reduce exposure, adaptation to manage residual climate change risks, and sustainable development to address vulnerability and enhance capacity for sustainable development.

Table 18.4: Projected continental level result ranges for select temperature and precipitation climate change variables by global warming level. Ranges are 5th and 95th percentiles from SSP5-8.5 WGI CMIP6 ensemble results. There is little variation in the 5th and 95th percentile values by GWL across the SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5 projections. 18.5.1.2 Regional Perspectives on Climate-Resilient Development

The various regional chapters within the AR6 WGII report each provide insights into progress toward CRD as well as the opportunities and challenges associated with future pursuit of different CRD pathways. Common indicators of development reflect the significant diversity that exists across different global regions with respect to their development context (*very high confidence)*. For example, the Human Development Index, recently adjusted to reflect the effect of planetary pressures (PPAHDI), illustrates the overall higher levels of development of North America and European countries of the global North as well as Australasia compared with Asia, Africa, Central and South America and small islands of the global South. Generally, this reflects the higher levels of vulnerability and greater need for both sustainable development to reduce poverty and support sustainable economies as well as climate action to address climate risk (Table 18.6).

However, even within a given region, there is significant variation in PPAHDI among nations. Such differences reflect fundamental differences in historical patterns of development, as well as current development needs and challenges, and they imply differences in what future development pathways would be consistent with CRD. In addition, nations and regions with lower PPAHDI values suggests greater capacity challenges for both greenhouse gas mitigation and climate adaptation. However, nations and regions with high PPAHDI values also tend to have higher per capita CO_2e emissions production, indicating that economic development based on fossil fuel use undermines both efforts on climate action as well as the SDGs (*very high confidence*) (Figure 18.6). Such challenges are also reflected by differential Gini coefficients and metrics of state fragility among regions, which reflect inequities in income distribution and broader vulnerability of nations and regions to shocks and stressors (Figure 18.6). In addition, high variation is observed in CO2 emissions production, even among comparatively wealthy nations, suggesting CO2e emissions of some nations are tightly coupled to development, while others have pursued more carbon neutral development trajectories. Even within regions such as Africa, Asia, Central and South America, and Europe, large within-region variations are observed in inequality and state fragility, suggesting high variability among nations. Given the emphasis in the sustainable development and CRD literature on equity and vulnerability, addressing such determinants of vulnerability is a core design principle for CRD pathways.

In addition to development indicators, the literature assessed in the WGII regional chapters indicates that different regions experience a range of development challenges and opportunities that affect the pursuit of CRD (*very high confidence*). These represent dimensions of governance, institutions, economic development, capacity, and social and cultural factors that shape decision-making, investment, and development trajectories. For example, significant challenges exist within regions with respect to managing debt and the ability to fund or finance climate action and sustainable development interventions (*very high confidence*). On the other hand, a broad range of opportunities exist to pursue CRD including challenges with debt and financing of adaptation competing policy objectives, social protection programs, economic diversification, investing in education and human capital development, and expanding disaster risk reduction efforts (*very high confidence*).

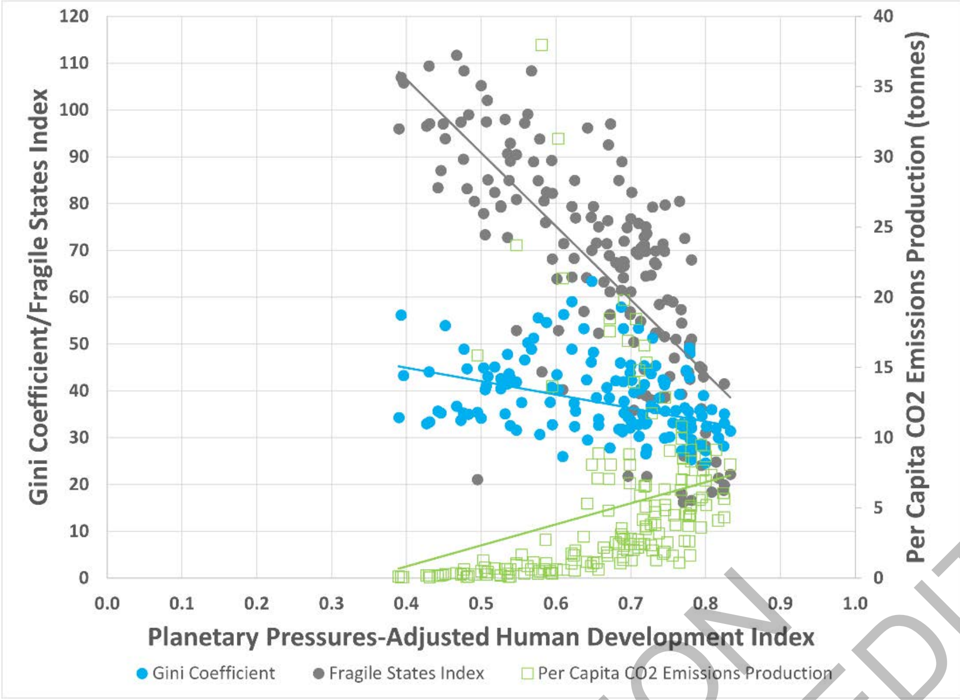

Figure 18.6: Relationship among development indicators relevant to climate-resilient development. National Gini coefficients (most recent year available; n=141; (World Bank, 2021)), the Fragile States Index (2021; n=163; (Fund for Peace, 2021)), and per capita CO2 emissions (2018; n=169; (Human Development Report Office, 2020)) are plotted against the Planetary Pressures-Adjusted Human Development Index (2020, n=163; (Human Development Report Office, 2020)

There are a wide variety of more focused options for climate action and sustainable development (*very high confidence*). Such options have potential for synergies and trade-offs including implications for greenhouse gas mitigation, land use change and conservation, food and water, or social equity. Despite variation in development context, regional assessments suggest CRD efforts will be associated with some common features. For example, in all regions, existing vulnerability and inequality exacerbate climate risk and therefore pose challenges to CRD (*very high confidence*). Furthermore, low prioritization of sustainability and climate action in government decision making, low perceptions of climate risk, and path dependence in governance systems and decision-making processes all pose barriers to system transitions, transformation, and CRD (*very high confidence*).

18.5.2 Sectoral Synthesis of Climate-Resilient Development

The sectoral chapters of the WGII report provide insights regarding how development processes interact with sectors to shape the potential for climate-resilient development. Similar to global regions, each sector is associated with various challenges, opportunities, and options that enable or constrain CRD (Table 18.7). A number of challenges are common across sectors and mirror those associated with different regions. For example, issues associated with natural resource dependency, access to information for decision-making, access to human and financial capital, and path dependence of institutions represent barriers that must be overcome if sectors are to support transitions that enable CRD. These challenges are more acute within vulnerable communities or nations where capacity to innovate and invest are constrained and social inequities reinforce the status quo (*very high confidence*). At the same time, a number of sector-specific opportunities for mitigation, adaptation, and sustainable development can be used to integrate sectors into CRD pathways. This could include policies and planning initiatives to enhance sector sustainability and resilience as well as capacity building and greater inclusion of different actors and groups in decision making including capitalizing on local and indigenous knowledge as a mechanism for more representative and equitable action.

In addition, the sectoral assessments identify a broad range of specific adaptation, mitigation, and sustainable development options that could play a role in facilitating CRD. Many of these options appear initially to be specific to a given sector. For example, options for the water sector (Chapter 4) are assessed independently from those for health and well-being (Chapter 7). In practice, however, evidence suggests the importance of thinking about sectoral options as cross-cutting, mutually supportive, and synergistic packages rather than singular options. First, each of the sectoral chapters has links to multiple SDGs (Table 18.7), implying each sector is important for achieving a range of sustainability goals that extend beyond sectoral boundaries. Moreover, progress across multiple sectors simultaneously creates opportunities for synergies for achieving the SDGs, but also enhances the risk of potential trade-offs (*very high confidence*). Second, a number of options are common to multiple sectors. For example, options associated with ecosystem-based adaptation and nature-based approaches to environmental management appear in multiple sectors (Table 18.7). Similarly, climate-smart agriculture and agroecological approaches to food systems create opportunities for food security, but those same options also benefit land-based ecosystems, water, poverty and livelihoods, and human well-being. Joint implementation

18.5.3 Feasibility and Efficacy of Options for Climate-Resilient Development

While both the sectoral and regional assessments indicate a rich toolkit of management options is available to decision-makers to facilitate CRD, two key uncertainties undermine efforts to implement those options. The first is the feasibility of implementation. Options that seem promising could nevertheless encounter implementation barriers due to cost, absence of necessary capacity, lack of public acceptance, or competition with alternative options. Progress in the literature since the AR5 and SR1.5 reports enables improved consideration for options feasibility for both mitigation (SR1.5 ref) and adaptation (Cross-Chapter Box FEASIB). This assessment allows the range of available options to be considered in a more critical light, particular when on is considering opportunities for implementation over the near-term. Meanwhile, the other challenge is that of option efficacy. Significant uncertainties remain regarding how well a given option will perform in a specific context and whether it is capable of adequately addressing risk (18.6.1). Such uncertainties can undermine the pursuit of CRD or at least efforts to accelerate system transitions that support CRD (*medium evidence, medium agreement)* (18.3). Accordingly, closer examination of option implementation in the real world, including within different sectoral and regional contexts, would enhance the knowledge available to decision-makers regarding which options will best fit the needs of a given CRD pathway.

Table 18.6: Regional synthesis of dimensions of climate-resilient development. For each region, quantitative information is provided on common development indicators including the planetary pressures-adjusted human development index (PPHDI, 2020, n=169; (Human Development Report Office, 2020)), Gini coefficients (GINI, most recent year available; n=156; (World Bank, 2021)), Fragile States Index (FRAGILITY; 2021; n=173; (Fund for Peace, 2021)), and per capita CO2 emissions production (CO2/PC, 2018; n=169; (Human Development Report Office, 2020)). Each indicator is associated with a mean value among nations within a specific region as well as the range (minimum to maximum) value. In addition, the table contains evidence of sustainable development challenges and opportunities as well as adaptation/sustainable development options and potential synergies and trade-offs associated with their implementation. Synergies and trade-offs are categorized as follows: (T) Trade-off among policies and practices; (S+) Synergy among policies and practices that enhances sustainability; (S-) Synergy among policies and practices that undermines sustainability.

Region	***Development Indicators mean (range)***		***Challenges***	***Opportunities***	***Options***	***Synergies and Trade-Offs***
Africa	PPAHDI	0.53 (0.39-0.72)	• institutional and financial challenges in programming and implementing activities to support concrete adaptation measures (9.14.5) • high debt levels exacerbate fiscal challenges and undermine economic resilience (9.14) • insufficient development and adaptation finance and accessibility of finance (9.14.5) • complexity of estimating the costs and benefits for adaptation measures in specific contexts (9.14.2) • exclusions of migrants and other vulnerable populations from social programs (9.9.4) • mismatch between the supply of, and demand for, climate services (9.5)	• climate change literacy can enable the mainstreaming of climate change into national and sub-national developmental agendas (9.4.2) • Adaptive responses can be used as an opportunity for comprehensive, transformative change (9.6.2) • Investments in human capital, can facilitate socioeconomic development and poverty reduction (9.9.1) • Strengthening the participation of women in decision-making as well as advance traditional and local knowledge can support climate action and sustainable livelihoods (9.9.3)	• strengthening climate services (9.4.2) • ecosystem based adaptation (9.11.4.2) • economic diversification (9.12.3) • intensive irrigation9.15.2 • agricultural and livelihood diversification (9.12.3) • drought resistant crop varieties (9.15.2) • soil and water conservation (9.15.2	• (T) competing uses for water such as hydropower generation, irrigation, and ecosystem requirements create trade-offs among different management objectives (9.7.3) • (T) migration in response to unfavorable environmental conditions provides opportunities for farmers but puts pressure on the provision of social services and reduces farm labor (9.15.2) • (T) intensive Irrigation contributes to the development of agriculture but has come at a cost to ecosystem integrity and human well-being (9.15.2)
	GINI	42.8 (27.6-63.4)				
	FRAGILITY	87.3 (57.0-110.9)				
	CO2/PC	1.1 (0.0-8.1)				
Asia	HPAHDI	0.65 (0.47-0.78)	• migration and displacement (Box 10.6) • uneven economic development (10.4.6) • rapid land use change (10.4.6)	• Investing in climate-resilient and sustainable infrastructure can be a source of green jobs as well as a means of reducing climate vulnerability (10.6.2)	• risk insurance 10.5.5 • climate-smart agriculture 10.4.5.5, (Table 10.6) • wetland protection and restoration (Table 10.6)	• (S+) nature-based adaptation solutions, wetland protection, and climate-smart agriculture enhance carbon sequestration (Table 10.6)
	GINI	34.9 (26.6-43.9)				
	FRAGILITY	73.6				

		(32.3-111.7)	• increasing inequality (10.4.6) • large, socially differentiated vulnerable populations (10.4.6)	• sustainable development pathways that connect climate change adaptation and disaster risk reduction efforts can reduce climate vulnerability and increase resilience (10.6.2) • social protection programs can develop risk management strategies to address loss and damage from climate change (10.5.6)	• aquifer storage and recovery (Table 10.6) • integrated smart water grids (Table 10.6) • disaster risk management (Table 10.6) • early warning systems (Table 10.6) • resettlement and migration (Table 10.6) • nature-based solutions in urban areas • coastal green infrastructure (Table 10.6)	• (S+) disaster risk reduction and capacity building has synergistic interactions with climate adaptation when the two are effectively integrated (10.6.2) • (S+) environmental sustainability has benefits for relieving poverty and promoting social equity (10.6.4) • (T) intensive irrigation and other forms of water consumption can have a negative effect on water quality and aquatic ecosystems (10.6.3)
	CO2/PC	6.3 (0.3-38.0)				
Australasia	PPAHDI	0.75 (0.70-0.81)	• Underinvestment in adaptation, particularly in public health systems, given current and projected risks (11.3.6.3) • Underlying social and economic vulnerabilities exacerbate disadvantage among particular social groups (11.8.2) • Competing policy and planning objectives within governments (11.7.2) • Limits to adaptation across the region and among neighbors (11.7.2) • Fear of litigation and demands for compensation create disincentives for climate adaptation (11.7.2) • different climate change risk perceptions among different groups (11.7.2)	• implementation of national policies and guidance on climate adaptation and resilience (Box 11.5) • cooperation among individual farmers for adaptation and regional innovation (11.7.1) • enhancing understanding of Indigenous knowledge and practices (Table 11.11)	• climate adaptation services, planning and tools from government and private sector providers (11.7.1) • enhancing governance frameworks (Table 11.17) • building capacity for adaptation (Table 11.17) • community partnership and collaborative engagement(Table 11.17) • flexible decision-making (Table 11.17) • reducing systemic vulnerabilities (Table 11.17) • providing adaptation funding and compensation mechanisms (Table 11.17) • addressing social attitudes and engagement in adaptation and climate action (Table 11.17)	• (T) adapting to fire risk in peri-urban zones introduces potential trade-offs among ecological values and fuel reduction in treed landscapes (11.3.5)

Table 18.7: Sectoral synthesis of dimensions of climate-resilient development. For each sectoral chapter of the WGII report, this table identifies those SDGs that are discussed in the relevant chapter as being particularly relevant to the sector. In addition, the table contains evidence of sustainable development challenges and opportunities as well as adaptation/sustainable development options and potential synergies and trade-offs associated with their implementation. Synergies and trade-offs are categorized as follows: (T) Trade-off among policies and practices; (S+) Synergy among policies and practices that enhances sustainability; (S-) Synergy among policies and practices that undermines sustainability.

Sector	*Relevant SDGs*	*Challenges*	*Opportunities*	*Options*	*Trade-offs*
Terrestrial and freshwater ecosystems and their services	SDG 1, SDG 2, SDG 3, SDG 6, SDG 7, SDG 9, SDG 10, SDG 11,	• low capacity for dispersal limits range shifts to match climate (2.6.1) • constraints on the evolution of greater stress tolerance among species (2.4.2, 2.6.1) • altered peatland drainage and repeated disturbances pose	• nature based solutions offer the opportunity to address climate change and biodiversity problems in an integrated way (2.6) • adaptation can be integrated with the protection of biodiversity and land-based	• habitat restoration, connectivity, and creation of protected areas (Table 2.5) • integrated landscape management (Table Cross-Chapter Box NATURAL.1 in Chapter 2)	• (S+) ecosystem-based adaptation measures, such as restoration of forests and wetlands for flood and erosion control help maintain freshwater supply and quality (2.2.2) • (S-) over-grazing/stocking of pastures and grasslands can result

	SDG 12, SDG 13, SDG 15, SDG 17	barriers to restoration of tropical peatlands (2.4.3) • demonstrating the efficacy of natural flood management efforts poses challenges to its deployment (2.6.5) • uncertainties in climate and socioeconomic projections constrain adaptation planning and implementation (2.7)	climate change mitigation initiatives (2.6.2)	• community-based natural resource management (2.6.5.7) • maintain or restore natural species and structural diversity (Table Cross-Chapter Box NATURAL.1 in Chapter 2) • restoration of hydrological flows and catchment vegetation (Table Cross-Chapter Box NATURAL.1 in Chapter 2) • control of feral herbivores with (Table Cross-Chapter Box NATURAL.1 in Chapter 2) • reduce non-climatic stressors to land-based ecosystems (Table 2.6)	in soil erosion and the loss of biodiversity (Table Cross-Chapter BoxNATURAL1 in Chapter 2) • (T) planting non-native monocultures for mitigation can reduce biodiversity and resilience • (T) inappropriate hydrological restoration can result in increased methane emissions (Table Cross-Chapter Box NATURAL1 in Chapter 2) • (T) afforestation/reforestation and bioenergy initiatives can conflict with other land uses such as food and timber production (Table Cross-Chapter Box BECCS, 2.2.2, Box 2.2)
Ocean and coastal ecosystems and their services	SDG1, SDG2, SDG3, SDG5, SDG7, SDG8, SDG9, SDG10, SDG11, SDG12, SDG13, SDG14	• shifts in the distribution of fish species across exclusive economic zones present governance, ecological, and conservation challenges (3.4.3) • resource constraints impede the implementation of ecosystem-based and community-based adaptation for low- to middle-income nations (3.6.2) • governance in marine social-ecological systems is highly complex with poorly-defined legal frameworks (3.6.2) • "Coastal squeeze" challenges adaptation, creating tensions between coastal development and coastal habitat management (3.6.3)	• development assistance can help address resource constraints associated with marine ecosystem management (3.6.3) • improving coordination among actors and projects will contribute to achieving SDGs (3.6.3) • private finance can support restoration of blue-carbon systems (3.6.3) • joint implementation of coastal and marine management initiatives can address governance challenges across scales and sectors (3.6.3) • ocean-based renewable energy options can reduce reliance on imported fuel (3.6.3)	• maritime spatial planning and integrated coastal management (3.6.2; Figure 3.2.6) • adaptive and sustainable fisheries management (3.6.2) • habitat restoration (3.6.2) • fishery mobility (Figure 3.6.2) • assisted evolution (Figure 3.2.6) • increase participation in management and governance (Figure 3.2.6) • nature-based solutions (3.6.2) • hard and soft infrastructure (Figure 3.2.6) • livelihood diversification (Figure 3.6.2)	• (S+) adaptation in ocean and coastal systems can be designed in ways that substantially contribute to the SDGs and not only support but allow the attainment of social, environmental and economic targets (3.6.4) • (S+) blue/green economies can reduce emissions and finance adaptation pathways (3.6.3) • (T) built infrastructure conflicts with mitigation goals and can create potential ecological, social and cultural impacts that undermines ecosystem health (3.6.2)

				• disaster mitigation and response (Figure 3.2.6) • finance and market mechanisms (Figure 3.2.6)	
Water	SDG 1, SDG 2, SDG 3, SDG 6, SDG 7, SDG 10, SDG 11, SDG 13	• uncertainty in future water availability (Box 4.1, Box 4.4) • lack of sufficient data, information and knowledge in understanding the water energy food nexus (Box 4.6) • increasing urbanization is creating new and difficult demands for urban water management. (4.3.4) • barriers to adapting water-dependent livelihoods in rural communities (4.3.1) • mainstreaming water management across sectors and enhancing finance for adaptation (4.3.5) • path-dependency of institutions, and the speed at which these allow for changes in the decision-making process (4.5.3)	• a resilient circular economy delivers access to water, sanitation, wastewater, and ecological flows (Box 4.7) • adaptive sanitation systems and sustainable urban drainage contribute to a 'one health approach' which can prevent water and sanitation contamination risks during floods and droughts. (Box 4.7) • climate-proof infrastructure would reduce infection risks in flood-prone areas (Box 4.7) • governance can derive legitimacy from inclusion of multiple stakeholders, including women, indigenous communities and young people (4.6.6) • Indigenous and local knowledge can help ensure solutions align with the interests of communities (FAQ 4.5)	• changes in crop cultivars and agronomic practices (4.5) • changes in irrigation and water management practices (4.5) • water and soil conservation (4.5) • migration and off-farm livelihood diversification (4.5) • collective action, policies and institutions (4.5) • economic and financial incentives (4.5) • training and capacity building (4.5) • flood risk reduction measures (4.5) • urban water management (4.5) • water, sanitation, and hygiene adaptations (4.5) • agro-forestry and forestry responses (4.5) • livestock and fishery responses (4.5) • indigenous and local knowledge (4.5) • energy related adaptations (4.5)	• (S+) increasing the proportion of sewerage, treated wastewater, recycling and safe reuse would help reach climate and water targets (Box 4.7) • (S+) solar irrigation pumps provide for income diversification for small and marginal farmers while also generating renewable energy (Box 4.7) • (T) desalination of seawater or brackish inland water is energy-intensive, high salinity brine, and other contaminants (4.5.5) • (T) negative-emission technologies, such as direct air capture can result in a net increase in water consumption (4.5.5)
Food, fiber, and other ecosystem products	SDG1, SDG2, SDG3, SDG4, SDG5, SDG6,	• increased cost and management challenges of providing safe food (5.2.2) • warming-induced shifts of species create resource allocation	• integrated approaches to food, water, health, biodiversity and energy that involve vulnerable groups can help to address current and future food security challenges, reduce vulnerability	• livelihood diversification (5.4.4) • social protection policies and programs (5.4.4) • changes in crop management including irrigation,	• (S+) agricultural production systems that integrate crops, livestock, forestry, fisheries and aquaculture can increase food production per unit of land, reduce

	SDG7, SDG9, SDG9, SDG10, SDG11, SDG12, SDG13, SDG14, SDG15, SDG16	challenges among different fishing fleets (5.2.1) • challenges related to REDD+ implementation and forest use (5.6.3) • differences in perceptions about the validity of different forms of knowledge (5.8.4) • inequality in access to climate services (5.14.1) • lack of support, policies, and incentives for the adoption of agroecological approaches (BIOECO.1) • financial barriers limit implementation of adaptation options in agriculture, fisheries, aquaculture and forestry (5.14.3)	of Indigenous people, small-scale landholders and pastoralists, and promote resilient ecosystems. (5.12.3, 5.13.2; 5.14) • agroforestry delivers benefits for climate change mitigation, adaptation, desertification, land degradation, and food security and is considered to have broad adaptation and moderate mitigation potential (5.10.4) • partnerships between key stakeholders such as researchers, forest managers, and local actors can lead to a shared understanding of climate-related challenges and more effective decisions. (5.6.3)	fertilizers, planting schedules, and crop varieties (5.4.4.1) • adjusting water management for forage production (5.5.4) • rotational grazing of livestock (5.5.4) • fire management to control woody thickening of grass (5.5.4) • using more suitable livestock breeds or species (5.5.4) • migratory pastoralist activities (5.5.4) • monitor and manage the spread of pests, weeds, and diseases (5.5.4) • nature- or ecosystem-based strategies (5.12.5.2)	climatic risk, and reduce emissions (Chapter 5 ES) • (S+) integrated approaches to food, water, health, biodiversity and energy can help address current and future food security challenges, reduce vulnerability of Indigenous people, small-scale landholders and pastoralists, and promote resilient ecosystems. (5.12.3, 5.13.2; 5.14) • (T) growing biomass demand for producing sustainable bioproducts competes with food production with potential effects on food prices and knock-on effects related to civil unrest (BIOECO.1)
Cities, settlements and key infrastructure	SDG11, SDG13, SDG17	• poor municipal funding, data collection, and collaboration hinders sustainable development initiatives, capacity building, and climate action (6.1.5, 6.4.5, 6.4.9) • high urbanization rates pose challenges to areas that already have high levels of poverty, unemployment, informality, and housing and service backlogs (6.2.1) • Limited capacity for early-warning systems in low-income countries (6.3.2) • lack of administrative capacities, coordination across sectors and efforts, transparency and accountability slows sustainability transitions and disaster risk reduction (Case Study 6.4)	• urban ecological infrastructure including green, blue, turquoise and others can be a source of nature-based solutions that can improve both adaptation and mitigation in urban areas (6.1.2) • transition architecture movements can drive urban adaptation (6.4.1) • transformative capacities support adaptation efforts and systemic change processes (6.4.4) • incorporating Indigenous and local knowledge help generate more people-oriented and place-specific adaptation policies (6.4.7) • climate finance offers the opportunity to overcome structural impediments to climate action (Box 6.5)	• green infrastructure, sustainable land use and planning, and sustainable water management (6.1.2) • nature-based solutions (6.3.3) • insurance (6.3.2) • switching to air cooling for thermal power plants (6.3.4) • increasing the efficiency of hydro and thermoelectric power plants (6.3.4) • changing reservoir operation rules (6.3.4) • upgrading infrastructure and strengthening, or relocating (critical) assets (6.3.4) • including green, blue, turquoise and nature-based solutions (Cross-Chapter Box URBAN in Chapter 6)	• (S+) sustainable urban energy planning that includes opportunities to avoid and reduce the UHI effect can provide synergies for both climate mitigation and adaptation in urban areas (Cross-Chapter Box URBAN in Chapter 6) • (S+) natural ventilation and passive energy strategies can capture synergies between climate mitigation and adaptation (Cross-Chapter Box URBAN in Chapter 6) • (S+) community-based adaptation has potential to be better integrated to enhance well-being and create synergies with the Sustainable Development Goals • (T) urban mitigation efforts can create trade-offs with adaptation such as intensifying the Urban

			• urban ecological infrastructure can be a source of nature-based solutions that can improve both adaptation and mitigation in urban areas (Cross-Chapter Box URBAN in Chapter 6) • high density environments coupled with other design measures can provide mitigation and adaptation benefits (Cross-Chapter Box URBAN in Chapter 6)	• cooling networks (Cross-Chapter Box URBAN in Chapter 6) • early warning systems (Table 6.4) • resource demand and supply side management strategies (Table 6.4) • enhanced monitoring of air quality in rapidly developing cities (Table 6.4) • investment in air pollution controls (Table 6.4) • core and shell preservation, elevation and relocation for heritage buildings (6.3.2)	Heat Island (UHI) effect (Cross-Chapter Box URBAN in Chapter 6) • (T) efforts aimed at increasing adaptation may undermine mitigation objectives by increasing investment in hard infrastructure that increases emissions (Cross-Chapter Box URBAN in Chapter 6) • (T) lack of open and green spaces may induce long-distance leisure trips thereby increasing emissions and (Cross-Chapter Box URBAN in Chapter 6)
Health, wellbeing and the changing structure of communities	SDG3, SDG5, SDG8, SDG10, SDG13	• a lack of capacity for adaptation has resulted in only moderate or low levels of adaptation implementation across different countries (7.4.2) • transitioning to renewable energy sources presents opportunities for realizing health co-benefits (7.4.4) • shifting to healthier plant-rich diets can reduce GHG emissions and reduce land-use (Cross-Chapter Box HEALTH in Chapter 7) • future flows of migration within and between countries are likely to respond strongly to particular combinations of climatic hazards and may present challenges for future adaptation policies and programs • climate change disruptions to natural environments can be expected to disrupt livelihood practices, stimulate higher rates	• COVID-19 recovery investments offer an opportunity to contribute to climate resilient development through a green, resilient, healthy and inclusive recovery (Cross-Chapter Box COVID in Chapter 7) • investing in basic infrastructure for all can transform development opportunities, increase adaptive capacity and reduce climate risk (Cross-Chapter Box HEALTH in Chapter 7) • Integrated agroecological systems offer opportunities to increase dietary diversity while building local resilience to climate-related food insecurity (7.4.2) • Incorporating climate change and health considerations into disaster reduction and management strategies could	• improved building and urban design including use of passive cooling systems (Table 7.2) • better access to public health systems for the most vulnerable (Table 7.2) • deployment of renewable energy sources (Table 7.2) • improved water, sanitation and hygiene conditions (Table 7.2) • early-warning system of vector-borne diseases, insecticide treated bed nets, and indoor spraying of insecticide (Table 7.2) • targeted efforts to develop vaccines for infectious diseases exacerbated by climate change (Table 7.2) • improved personal drinking and eating habits (Table 7.2)	• (T) energy strategies for energy efficiency and GHG emissions reductions can generate health co-benefits through improved air quality but may slow poverty reduction efforts (7.4.2, 7.4.5) • (S+) investing in adaptation for health and community wellbeing has the potential to generate considerable co-benefits in terms of reducing impacts of non-climate health challenges • (S+) investments in mitigating greenhouse gas emissions will not only reduce risks associated with dangerous climate change, but will increase population health and wellbeing through a number of pathways. (7.4)

		of outmigration to urban centers, and in some instances necessitate planned or organized relocations of exposed settlements (Cross-Chapter Box MIGRATE in Chapter 7)	potentially improve funding opportunities (7.4.2) • adaptive urban design that provides access to healthy natural spaces can promote social cohesion and mitigate mental health challenges (7.4.2)	• improved food storage, food processing, and food preservation (Table 7.2) • emergency shelters for people to escape heat (Table 7.2) • improved funding and access to mental health care (Table 7.2) • improved education for girls and women (Table 7.2) • improved maternal and child health services (Table 7.2)	
Poverty, livelihoods and sustainable development	SDG1, SDG2, SDG3, SDG5, SDG10, SDG14	• use of political frameworks for decision-making that are unfavorable towards adaptation and system transitions (Table 8.4) • attitudes toward risk and other cultural values limit responses (Table 8.4) • psychological distress causes insecurity and behaviors that increase vulnerability (Table 8.4) • limited financial resources to support adaptation projects (8.2.2, Table 8.4) • small-holder farmers have poor access to markets and land tenure (8.6.1) • unsuitable infrastructure may increase exposure (Table 8.4) • lack of access to technologies that can support adaptation (Table 8.4) • gender-based inequalities constrain women's access to resources for adaptation (Table 8.7) • poverty constrains livelihood diversification, resilience or adaptive capacity (Table 8.7)	• polycentric governance, adaptive governance, multi-level governance, collaborative governance, or network governance are increasingly used to understand transitions towards climate-compatible development (8.6.2) • well-coordinated and integrated nexus approaches to adaptation offer opportunities to build resilient systems while harmonizing interventions, mitigating trade-offs and improving sustainability (8.6.2) • income from new livelihood activities can support recovery following disasters linked to climate variability and change (8.4.5) • improving industrial processes can contribute to the optimized use of energy, reuse of waste, reducing GHG emissions, use of biomass and more efficient equipment (Table 8.3) • industrialization and technological innovation in rural areas may assist vulnerable	• expanded private sector activity and public-private partnerships (8.6.1) • credit and insurance (8.6.1) • use of climate-smart agricultural practices and technologies (8.6.1) • crop insurance (8.6.1) • conservation agriculture (8.6.1) • changing farmers' perception and enhancing farmers' adaptive capacity (8.6.1) • REDD+ (8.6.1) • improving industrial processes (Table 8.3) • renewable energy and energy efficiency (Table 8.3) • smart electricity grids (8.6.1) • green buildings (8.6.1) • efficient fuels (8.6.1) • pollution control investments (8.6.1) • public transit and non-motorized transport with increased use of biofuels (8.6.1)	• (S+) agriculture technologies facilitate mitigation to climate change and adaptation such as saving water while maintaining grain yield (8.6.1) • (S+) sustainable pastoralism increases carbon sequestration but can also contribute to adaptation by changing grazing management, livestock breeds, pest management, and production structures (8.6.1) • (S+) REDD+ may provide adaptation benefits by enhancing households' economic resilience through positive livelihood impacts (8.6.1) • (S+) solar energy contributes to reducing GHG emissions and improving air quality (8.6.1) • (S+) hydropower contributes to mitigation and adaptation through water resource availability for irrigation and drinking water (8.6.1) • (S+) green roofed buildings contribute to cooler temperatures, thereby reducing energy use for air-conditioning (8.6.1)

		• indigenous peoples and other populations with strong attachments to place face barriers to adaptation (Table 8.7) • local institutions face ongoing challenges in gaining support from higher governance levels, particularly in developing countries. (8.5.2)	communities through provision of resources, enhanced forecast information, or reuse of biowaste (Table 8.3) • responses to climate change can create significant development opportunities including job creation and livelihood diversification (8.4.3)	• integrated natural resource management (Table 8.2) • disaster risk management (Table 8.2) • relocation of vulnerable communities (Table 8.2) • Education and communication (Table 8.2) • land use planning (Table 8.3)	• (T) mitigation measures such as bioenergy may result in trade-offs with efforts to achieve sustainable development, eradicate poverty and reduce inequalities (8.6.1) • (T) migration to urban centers can be a form of adaptation, but can increase the vulnerability of communities of origin or at destinations (8.2.2)

18.6 Conclusions and Research Needs

18.6.1 Knowledge Gaps

Research to improve the understanding of CRD currently exists in a nascent state, because, as noted in the AR5, "*integrating climate change mitigation, climate change adaptation, and sustainable development is a relatively new challenge*" (Denton et al., 2014). While a large volume of literature has emerged since the AR5 that spans the nexus of sustainable development, CRD, and climate action, the identified research gaps in AR5 (Denton et al., 2014) continue to be priorities for informing CRD. These include enhancing understanding of mainstreaming of climate change into institutional decision-making, managing risk under conditions of uncertainty, catalyzing system transitions and transformation, and processes for enhancing participation, equity, and accountability in sustainable development (*very high confidence*).

The more recent literature adds significant context to the concept of CRD, but also introduces broader perspectives regarding its significance in the arena of climate action. Hence, concepts that are both complementary to, and competitive with, CRD, such as climate safe', 'climate compatible' and 'climate smart' development (Huxham et al., 2015; Kim et al., 2017b; Ficklin et al., 2018; Mcleod et al., 2019) (18.1.1). These different framings of the intersection between sustainable development and climate action are used in different communities of research and practice, which complicates efforts to provide clear guidance to decision-makers regarding the goals of CRD and how best to achieve it. This is attributable in part to persistent conceptual confusion and disciplinary divides over more fundamental concepts such as resilience and sustainability (Rogers et al., 2020; Zaman, 2021), not to mention contested perspectives regarding development (Lo et al., 2020; Song et al., 2020a; Morton, 2021) (*medium agreement; medium evidence*).

Reconciling different perspectives on CRD is not simply a matter of academic debate. Climate action, resilience, and sustainable development are all active areas of policy and practice with significant economic, social, environmental, and political implications (18.1.3). Hence, enhancing the role of CRD as a practical framework for development and a guide for action may necessitate improving the science-policy discourse regarding CRD (Winterfeldt, 2013; Jones et al., 2014; Ryan and Bustos, 2019). This includes consideration for risk and science communication; decision analysis and decision support systems; and mechanisms for knowledge co-production between scientists and public policy actors (*very high confidence)*.

In addition, the AR6 WGII report highlights a number of elements of CRD that are associated with significant knowledge gaps and uncertainties. As a result, enhancing the value of CRD as a unifying concept in development would benefit from further conceptualization and socialization of the concept as well as efforts to address the following knowledge gaps:

- The challenges posed by different levels of global warming to achieving CRD and the magnitude and nature of the adaptation gap (and associated finance needs) that must be addressed to enable climate resilience.
- The efficacy of different adaptation, mitigation, and sustainable development interventions in reducing climate risk and/or enhancing opportunities for CRD in the short, medium and long term.
- How different CRD pathways can be designed such that they illustrate opportunities for the practical pursuit of CRD in a manner consistent with principles of inclusion, equity, and justice.
- How deliberative, participatory learning can be integrated into approaches to CRD in order to enhance the representation of diverse actors, forms of knowledge, governance regimes, economic systems, and models for decision-making in CRD.
- The synergies and trade-offs associated with the implementation of different policy packages and the design principles and development contexts that enhance the ability to successfully manage potential trade-offs.
- The limits of incremental system transitions to achieving CRD on a timeline that reflects the urgency associated with the Paris Agreement and the Sustainable Development Goals.
- The capacity of governments, social institutions, and individuals to drive large-scale social transformations that open up the solutions space for CRD.

- Best practices for avoiding maladaptation and ensuring that adaptation interventions are designed so they do not exacerbate vulnerability to climate change to support CRD.

18.6.2 Conclusions

The concept of CRD presents an ambitious agenda for actors at multiple scales – global to local, particularly in the manner in which it reframes climate action to integrate a broader set of objectives than simply reducing greenhouse gas emissions or adapting to the impacts of climate change. Specifically, recent literature extends policy goals for climate action beyond avoiding dangerous interference with the climate system to adopt normative goals of meeting basic human needs, eliminating poverty and enabling sustainable development in ways that are just and equitable. This creates a policy landscape for climate action that is not only richer, but also more complex in that it situates responses to climate change squarely within the development arena. Current policy goals associated with the Paris Agreement, Sendai Framework, and the SDGs imply aggressive timetables. Yet, as noted in the AR5 and supported by more recent literature (Section 18.2.1), the world is neither on track to achieve all of the SDGs nor fulfil the Paris Agreement's objective of limiting warming to well-below 2°C (Denton et al., 2014; IPCC, 2018a). This places aspirations for CRD in a precarious position. Transitions will be necessary across multiple systems (Section 18.1.3). While some may be already underway, the pace of those transitions must accelerate, and societal transformations may be necessary, to enable CRD (18.3, 18.4, Box 18.1)

Given the pace of climate change and the inherent challenge of sustainable development, particularly in the face of inevitable disruptions and setbacks such as the COVID-19 pandemic (Cross-Chapter Box COVID in Chapter 7), the feasibility of achieving CRD is an open question. Rapid changes will be required to shift public and private investments, strengthen institutions and orient them toward more sustainable policies and practices, expand the inclusiveness of governance and the equity of decision-making, and shift societal and consumer preferences to more climate-resilient lifestyles. Nevertheless, the collective body of recent literature on CRD, system transitions, and societal transformation, combined with the assessments within recent IPCC Special Reports (IPCC, 2018a; IPCC, 2019b; IPCC, 2019d) indicate that there are a broad range of opportunities for designing and implementing adaptation and mitigation options that enable the climate goals in the Paris Agreement to be achieved while enhancing resilience and meeting sustainable development objectives. However, options should be considered alongside the mechanisms by which societies can engage in order to create the conditions that can support the implementation of those options (Section 18.4). This includes formal policy mechanisms pursued by governments, the catalyzation of innovation by private firms and entrepreneurship, as well as informal, grassroots interventions by civil society. While there is no "one-size-fits-all" solution for CRD that will work for all actors at all scales, exploring different pathways by which actors can achieve their development and climate goals can make valuable contributions to developing effective strategies for CRD.

A fundamental challenge for achieving CRD globally is reconciling different perspectives on CRD. As noted in the AR5, "*as policy makers explore what pathways to pursue, they will increasingly face questions about managing discourses about what societal objectives to pursue*" (Denton et al., 2014: 1124). Since the AR5, such discourses have become prominent in policy debates over climate action and sustainable development due to different nations, communities, and subpopulations having different understandings of what constitutes CRD. Aggressive efforts to rapidly reduce greenhouse gas emissions or enhance resilience to climate change, for example, could have negative externalities for the development objectives of some actors. This potential for trade-offs complicates efforts to build consensus regarding what constitutes appropriate climate and development policies and practices and by whom. The CRD pathways preferred by one actor are likely to be contested by others. This means operationalizing concepts such as CRD in practice is likely to necessitate ongoing negotiation.

Ultimately, one of the critical developments within the literature is the emergence of procedural and distributive justice as key criteria for evaluating climate action and CRD more specifically. This trend not only recognizes the need to prevent vulnerable human and ecological systems from experiencing disproportionate harm from the changing climate, but also the need to prevent those same systems from being harmed by mitigation, adaptation, and sustainable development policies and practices. Failure to adequately engage with equity and justice when designing sustainability transitions could lead to maladaptation, aggravated poverty, reinforcement of existing inequalities, and entrenched gender bias and exclusion of Indigenous and marginalized communities (Jenkins et al., 2018; Fisher et al., 2019; Schipper et al., 2020b). These consequences could ultimately slow, rather than accelerate, CRD. Hence, developing programs and practices for prioritizing equity in effective transition risk management is an important dimension of enabling CRD.

As indicated by the literature assessed within this chapter, keeping windows of opportunity open for CRD will necessitate urgent action, even under diverse assumptions regarding how future mitigation and adaptation interventions evolve. If nations are to collectively limit warming to well-below 2°C, for example, unprecedented emissions reductions will be necessary over the next decade (IPCC, 2018a). These reductions would necessitate rapid progression of system transitions (18.3). If, despite the Paris Agreement, future emissions trajectories take the world beyond 2°C, a greater demand will be placed on adaptation as a means of enhancing the resilience of development. Given the long-lived nature of human systems, and the built environment in particular, significant adaptation investments would be needed over the near-term to meet this demand. Yet, it is important to note that even in the absence of consideration for climate change, substantial development needs exist for communities around the world at present. Hence, a robust strategy for the pursuit of CRDPs is a near-term focus on portfolios of policies and practices that promote of human and ecological well-being.

[START FAQ18.1 HERE]

FAQ18.1: What is a climate resilient development pathway?

Climate resilient development pathways (CRDPs) are continuous processes that strengthen sustainable development, efforts to eradicate poverty and reduce inequalities while promoting fair and cross-scalar capacities for adaptation to global warming and reduction of greenhouse gases in the atmosphere.

A pathway is defined in IPCC reports as a temporal evolution of natural and/or human systems towards a future state. These can range from sets of scenarios, narratives of potential futures to solution-oriented decision-making processes to achieve desirable societal goals.

When used in the context of climate resilient development (CRD), pathways refer to continuous processes that strengthen sustainable development, efforts to eradicate poverty, and reduce inequalities while promoting fair and cross-scalar adaptation and mitigation. As they imply deep societal changes and/or transformation, CRDPs raise questions of ethics, equity, and feasibility of options to drastically reduce emission of greenhouse gasses (mitigation) that limit global warming (e.g., to well below 2°C) and achieve desirable and livable futures and wellbeing for all.

There in no one true, correct pathway to pursue but multiple ways, modalities, depending on numerous factors, such as political, cultural and economic contexts. Pathways are not one single decision or action, nor is there an absolute, universal, fixed, final goal to be pursued, yet there are undesirable and non-CRDPs. Hence, a CRDP is a continuum of coherent, consistent decisions, actions and interventions within each country, and as a global community. While dependent on past development and its socio-ethical, political, economic, ecological and knowledge-technology outcomes at any point in time, transformation, ecological tipping points and shocks can create sudden shifts and unexpected non-linear development pathways. Actions taken today also foreclose some future potential pathways. The differentiated impacts of hurricanes and COVID-19 illustrate how the character of societal development such as equity and inclusion have enabled some societies to be more resilient than others.

[END FAQ18.1 HERE]

[START FAQ18.2 HERE]

FAQ18.2: What is climate resilient development and how can climate change adaptation (measures) contribute to achieving this?

The key purpose of CRD is to pursue sustainable development, engaging climate actions in ways that support human and planetary health and well-being, equity and justice. Climate resilient development combines adaptation and mitigation with underlying development choices and everyday actions, carried out by multiple actors within political, economic, ecological, socio-ethical and knowledge-technology arenas. The character of processes within these development arenas are intrinsic to how social choices are made, directing actions in a CRD or non-CRD direction. For example, inclusion, agency and social justice are qualities within the political arena that underpin actions that enable CRD.

CRD addresses the relationship between greenhouse gas emissions, levels of warming and related climate risks. However, CRD involves more than just achieving temperature targets. It considers the possible transitions that enable those targets to be achieved as well as the evaluation of different adaptation strategies and how the implementation of these strategies interact with broader sustainable development efforts and objectives. This interdependence between patterns of development, climate risk, and the demand for mitigation and adaptation action is fundamental to the concept of CRD. Therefore, climate change and sustainable development cannot be assessed or planned in isolation of one another.

Hence, CRD is defined as the development that deliberately adopts mitigation and adaptation measures to secure a safe climate on earth, meet basic needs for each human being, eliminate poverty and enable equitable, just and sustainable development. It halts practices causing dangerous levels of global warming. CRD may involve deep societal transformation to ensure well-being for all. CRD is now emerging as one of the guiding principles for climate policy, both at the international level, reflected in the Paris Agreement (UNFCCC, 2015) and within specific countries.

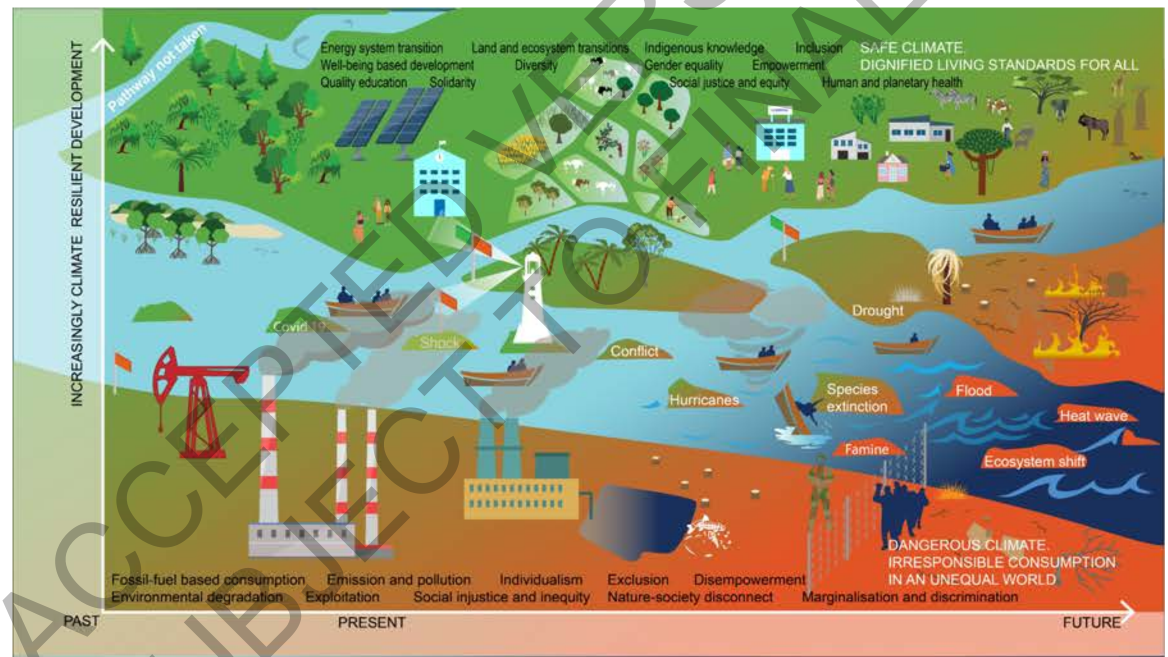

Figure FAQ18.2.1: Multiple intertwined climate resilient development pathways. Climate change adaptation is one of several climatic and non-climatic measures carried out through decision-making by multiple actors that may drive a pathway in a CRD or non-CRD direction. Adaptation, mitigation and sustainable development actions can push a society in a CRD direction, but only if these measures are just and equitable. There are multiple simultaneous pathways in the past, present and future. Societies (illustrated as boats) move on different pathways, towards CRD and non-CRD, with some pathways more dominant than others. The direction of pathways is emergent, taking place through contestations and social choices, through social transformation as well as through surprises and shocks (illustrated as rocks). Path dependency means it is possible but often turbulent to shift from a non-CRD to a CRD pathway. Such a shift becomes more difficult in as risks/shocks increase (more rocks) and non-CRD processes and outcomes progress, limiting future options. Low CRD processes and outcomes at the bottom are characterized by inequity, exclusion, polarization, environmental and social exploitation, entrenchment of business as usual, with increasing risks/shocks. High CRD processes and outcomes (at the top of the figure) are characterized by equity, solidarity, justice, human well-being, planetary health, stewardship/care and system transitions.

Climate change adaptation is one of several climatic and non-climatic measures carried out through decision-making by multiple actors that may drive a pathway in a CRD or non-CRD direction. Adaptation, mitigation and sustainable development actions can push a society in a CRD direction, but only if these measures are just and equitable. [END FAQ18.2 HERE]

[START FAQ18.3 HERE]

FAQ18.3: How can different actors across society and levels of government be empowered to pursue climate resilient development?

CRD entails trade-offs between different policy objectives. Governments, political and economic elites may play a key role in defining the direction of development at a national and sub-national scale; but in practice, these pathways can be influenced and even resisted by local people, NGOs and civil society.

Contestation and debate are inherent in its construct and implementation. An active civil society and citizenship create the enabling conditions for deliberation, protest, dissent and pressure which are fundamental for an inclusive participatory process. These enable a multiplicity of actors to engage across multiple arenas, from decision-making and everyday actions Hence, decisions and actions may be influenced by uneven interactions between actors, including socio-political relations of domination, marginalization, contestation, compliance and resistance with diverse and often unpredictable outcomes.

In this way, recent social movements and climate protests show new modalities of action related to political responsibility for inaction based on contestation. The new climate movement led mostly by youngsters, markedly seek science-based policy and more importantly, demand to break with a reformist stance and social inertia through radical climate action. This is mostly done through collective disruptive action, and non-violent resistance to promote awareness, a regenerative culture and ethics of care. These movements have resulted in notable political successes, such as declarations of climate emergency at the national and local level, as well as in universities. Also, their methods have proven effective to end fossil fuel sponsorship.

The success and importance of recent climate movements also provide elements to rethink the role of science in society. In one hand, the new climate movements demanding political action were prompted by the findings of scientific reports, mainly the IPCC (2018a) and IPBES (2019) reports. On the other hand, these movements have increased public awareness, and also stimulated public engagement with climate change at unprecedented levels.

[END FAQ18.3 HERE]

[START FAQ18.4 HERE]

FAQ18.4: What role do transitions and transformations in energy, urban and infrastructure, industrial, land and ocean ecosystems, and in society, play in climate resilient development?

The IPCC 1.5 report identified transitions and transformations in key systems, such as energy, land, and ocean ecosystems, and urban and infrastructure, that are needed for a climate resilient development. A system transitions focus helps visualize the interdependence between each system as well as how sustainable development, mitigation, and adaptation interact. A societal transformation, in terms of values and worldviews that shape aspirations, lifestyles and consumption patterns, is a constraining/enabling condition for such transformations. This report however identifies societal transformation as one of the five major transformations currently underway. It delves into the implications of this on how we assess options, value different outcomes from the perspectives of ethics, equity, justice and inclusion.

[END FAQ18.4 HERE]

[START FAQ18.5 HERE]

FAQ18.5: What are success criteria in climate resilient development and how can actors satisfy those criteria?

Climate resilient development is not a predefined goal to be achieved at a certain point or stage in the future. It is a constant process of evaluating, valuing, acting and adjusting various options for mitigation, adaptation and sustainable development, shaped by societal values as well as contestations of these. Any achievement or success is always a work in progress, with continuous, directed, intentional actions. These actions will vary according to the priorities and needs of each population or system; therefore, specific indicators will vary according to each specific context, ensuring we prioritize people, planet, prosperity, peace, and partnership, per the broad goals of the Agenda 2030 on sustainable development.

If Climate Resilient Development is defined as the development that deliberately adopts mitigation and adaptation measures to secure a safe climate, meet basic needs, eliminate poverty and enable equitable, just and sustainable development, then, the 17 United Nations' Sustainable Development Goals (SDGs) provide a good (although limited) measure of progress. They aim at ending poverty and hunger globally and protect life on land and under water until the year 2030. Although there are proven synergies between the SDGs and mitigation, there remains to explore clear synergies between the SDGs and adaptation in terms of how adaptation relates to the fulfilment of the SDGs.

[START CROSS-CHAPTER BOX FEASIB HERE]

Cross-Chapter Box FEASIB: Feasibility Assessment of Adaptation Options: An Update of the SR1.5

Authors: Debora Ley (Guatemala/Mexico), Helen Adams (United Kingdom), Malcolm Araos (Canada/USA), Ritwika Basu (India/United Kingdom), Amir Bazaz (India), Luigi Conte (Italy), Katy Davis (United Kingdom), Constantino Dockendorff (Chile/Germany), James Ford (United Kingdom/Canada), Sabine Fuss (Germany), Elisabeth A Gilmore (USA/Canada), Tania Guillén Bolaños (Nicaragua/Germany), Ove Hoegh-Guldberg (Australia), Mark Howden (Australia), Bavisha Kalyan (South Africa/USA), Laura Moro (Italy), Anuszka Mosurska (United Kingdom/Poland), Reinhard Mechler (Germany), Joana Portugal-Pereira (Brazil), Aromar Revi (India), Swarnika Sharma (India), Anne J. Sietsma (The Netherlands/United Kingdom), Chandni Singh (India), Alessandro Triacca (Italy), Bianca van Bavel (Canada/Ireland/United Kingdom), Ivan Villaverde Canosa (Spain/United Kingdom), Mustafa Babiker (Sudan/Saudi Arabia), Paolo Bertoldi (Italy), Brett Cohen (South Africa), Annette Cowie (Australia), Kiane de Kleijne (The Netherlands), Jeremy Emmet-Booth (Ireland), Amit Garg (India), Gert-Jan Nabuurs (The Netherlands), André Frossard Pereira de Lucena (Brazil), Adrian Leip (Italy/Germany), Lars J. Nilsson (Sweden), Pete Smith (United Kingdom), Linda Steg (The Netherlands), Masahiro Sugiyama (Japan)

Key Messages

The feasibility assessment presents a systematic work towards providing a suite of adaptation and mitigation options organised by system transitions. This Cross-Chapter Box assessed the feasibility over six
dimensions: geophysical, environmental-ecological, technological, economic, socio-cultural and institutional to identify factors within each dimension that present barriers to the achievement of the option. The results are presented

For energy systems transitions the options of infrastructure resilience, efficient water use and water management, and reliable power systems enable systems to work during disasters with reduced costs demonstrating the synergistic relationships of mitigation and adaptation (*high confidence*). There is high confidence in the high feasibility of infrastructure resilience and reliable power systems as they enable power systems to provide emergency services during disasters as well as for the continuance of these services during recovery periods. New evidence has focused on both options for peri-urban and rural areas through distributed generation and isolated renewable energy systems, which also provide multiple social co-benefits (medium confidence). For efficient water use and management, there is also high confidence on the synergistic potential with mitigation as it can make processes more efficient and cost effective. With regards to adaptation feasibility, efficient water use is especially useful in drought-stricken areas and provides a better water management for multiple uses (high confidence).

There are multiple options for land and other ecosystems. Forest- and biodiversity-based adaptation solutions are generally promoted on the basis of their positive impacts on adaptive and ecological capacities, increased provision of ecosystem services and goods, with a particularly strong contribution to carbon sequestration (high confidence). However, large afforestation projects and the introduction of non-native and fast-growing vegetation have been found to reduce water availability, impoverish habitats for wildlife, and reduce overall ecological resilience, threatening the achievement of some SDGs, and potentially leading to maladaptation (high confidence). In addition, over-reliance on forest-based solutions may increase the susceptibility to wildfires, with detrimental consequences both for mitigation and adaptation (medium confidence). Over the last decade, forest- and biodiversity-based solutions have gained considerable political traction and social acceptability (high confidence), but in countries with economies highly dependent on the export of agricultural commodities, opportunity costs continue to hinder the expansion of these alternatives, particularly against more profitable land uses (high confidence). In such cases, government support and innovative financial schemes, including payments for ecosystem services, are fundamental for broader adherence to forest- and biodiversity-based options.

Agroforestry solutions have strong ecological and adaptive co-benefits (high confidence), including improved provision of ecosystem services, synergies with the water-energy-land-food nexus, and positive outcomes in agricultural intensification, job diversification and household income. While broad inclusion of agroforestry schemes in countries' Nationally Determined Contributions reflect growing international interest in these strategies, insufficient financial support to small farmers continues to limit the expansion of agroforestry initiatives in developing and tropical countries.

Implementing environmentally and biodiversity-sensitive coastal defense options - often as part of Integrated Coastal Zone Management - is limited by economic, environmental, institutional and social barriers. Successful implementation requires a strong socio-economic framework and can offer diverse social, ecological and economic benefits, as well as sequestering carbon (high confidence). There is extensive experience with hard engineering coastal defense structures, which can be cost-effective in economic terms, depending on the location (*medium confidence*); however they are considered non-adaptive and unsustainable in some contexts (*medium confidence*) due to their lack of flexibility or robustness in response to a changing climate, as well as their carbon-intensiveness and potential ecological impacts (*medium confidence*).

There is *medium confidence* on the feasibility of sustainable aquaculture as adaptation measure. There are financial barriers to implementing sustainable aquaculture, even though it can improve employment opportunities, which would benefit local communities (*medium confidence*). Technical resource availability is still lacking and could represent a barrier to implementing sustainable aquaculture (*medium confidence*). Robust institutional and legal frameworks are needed to guarantee successful sustainable adaptation (*high confidence*). Social aspects, such as social acceptability, inclusiveness, and gender equity are relevant for the feasibility of sustainable aquaculture (*medium confidence*). Sustainable aquaculture is highly dependent on healthy and resilient ecosystems (*high confidence*). It can provide diverse ecosystem services and support efforts for coastal ecosystems restoration (*medium confidence*).

There are a range of strategies to improve livestock system efficiency including improved livestock diets, enhanced animal health, breeding and manure management, and grassland management. This suite of strategies has strong feasibility to build resilience while improving incomes (medium confidence) and providing mitigation co-benefits (high confidence). While technological and ecological feasibility is high, institutional, market-linked, and socio-political acceptability remain significant barriers (medium confidence).

Improving water use efficiency and water resource management under land and ecosystem transitions has high technological feasibility (high confidence) with positive resilience building and socio-economic co-benefits. However, economic and institutional barriers based on type, scale, and location of interventions
(medium confidence). Notably, inadequate institutional capacities to prepare for changing water availability, especially in the long term, unsustainable and unequal water use and sharing practices, and fragmented water resource management approaches remain critical barriers to feasibility (high confidence).

Improved cropland management includes agricultural adaptation strategies such as integrated soil management, no/reduced tillage, conservation agriculture, planting of stress-resistant or early maturing crop varieties, and mulching. These strategies have high economic and environmental feasibility (high confidence) and also have substantial mitigation co-benefits (medium confidence). However, costs, inadequate information and technical know-how, delays between actions and tangible benefits, lack of comprehensive policies, fragmentation across different sectors, inadequate access to credit, and unequal access to resources constrain technological, institutional and socio-cultural feasibility (medium confidence).

For urban and infrastructure system transitions, urban planning can support both adaptation and decarbonization by mainstreaming climate concerns, including effective land-use into urban policies, by promoting resilient and low-carbon infrastructure; and by protecting and integrating carbon-reducing biodiversity and ecosystem services into city planning (medium confidence). Urban green infrastructure and ecosystem services have high feasibility to support climate adaptation and mitigation efforts in cities, for example to reduce flood exposure and attenuate the urban heat island (high confidence). While green infrastructure options are cost-effective and provide co-benefits in terms of ecosystem services such as improved air quality or other health benefits (high confidence), there remains a need for systematically assessing co-benefits, particularly for flood risk management and sustainable material flow analysis. Governments across scales can support urban sustainable water management by undertaking projects to recycle wastewater and runoff through green infrastructure; greater coherence between urban water and riverine basin management; decentralization of water systems; supporting networks for sharing best practices in water supply and storm runoff treatment to scale sustainable management; and foregrounding equity and justice concerns, especially participation involving informal settlement residents (medium confidence).

Strong and equitable health systems can protect the health of populations in the face of known and unexpected stressors (medium confidence). Public health system adaptation is feasible where capacity is well-developed, and where options align with national priorities and engage local and international communities (medium confidence). Socio-cultural acceptability of public health adaptation is high and there is significant potential for risk-mitigation and social co-benefits where adaptation addresses the needs of vulnerable regions and populations (medium confidence). Microeconomic feasibility, and socio-economic vulnerability reduction potential are also high (high confidence), though macroeconomic feasibility may pose a significant challenge in low-income settings (medium confidence). However, inadequate institutional capacity and resource availability represent major barriers, particularly for health systems struggling to manage current health risks (high confidence).

There is strong evidence that disaster risk management (DRM) is highly feasible when supported by strong institutions, good governance, local engagement, and trust across actors (medium confidence). DRM are constrained by lack of capacity, inadequate institutions, limited coordination across levels of government (high confidence), lack of transparency and accountability and poor communication (medium confidence). There is a preference for top-down DRM processes, which can undermine local institutions and perpetuate uneven power relationships (medium confidence). However, local integration of worldviews, belief systems and Local and Indigenous Knowledge into DRM activities can facilitate successful, disability-inclusive and gender-focused DRM (medium confidence). Moves towards community-based and ecosystem-based DRM are promising but uneven and may increase vulnerability if they fail to address underlying and structural determinants of vulnerability (high confidence).

There is *high confidence* that climate services that are demand-driven and context-specific (e.g., to a particular crop or agricultural system) build adaptation capacity and enable short- and longer-term risk management decisions. Metrics to assess the economic outcomes of climate services remain insufficient to capture longer-term benefits of interventions (medium confidence). While technological capacity and political acceptance is high (medium confidence), institutional barriers, poor fit with user requirements, and inadequate regional coverage constrain the option's overall feasibility.

Risk insurance can be a feasible tool to adapt to climate risks and support sustainable development (*high confidence*). They can reduce both vulnerability and exposure, support post-disaster recovery, and reduce financial burden on governments, households, and business. Insurance mechanisms enjoy wide legal and regulatory acceptability among policy makers and are institutionally feasible (*high confidence*). However, socio-cultural and financial barriers have made insurance spatially and temporally challenging to implement (*high confidence*), even though it can improve the health and well-being of populations (*medium confidence*). The risk of generating maladaptive outcomes can further limit the uptake of insurance, as it can provide disincentives for reducing risk over the long term (*medium confidence*). Expanding the knowledge base on insurance is fundamental to successfully implement insurance among all relevant stakeholders, and ensuring an equitable access to and benefits from innovative financial products (e.g. loans) is also needed to guarantee successful uptake of insurance across all the population (*high confidence*).

Migration has been used by millions around the world to maintain and improve their wellbeing in the face of changed circumstances, often as part of labour or livelihood diversification (*very high confidence*). Properly supported and where levels of agency and assets are high, migration as an adaptation to climate change can reduce exposure and socioeconomic vulnerability (*medium confidence*). Households and communities in climate-exposed regions experience a range of intersecting stressors. These households can undertake distress migration, which results in negative adaptive and resilience outcomes (*high confidence*). Outcomes can be improved through a systematic examination of the political economy of local and regional sectors that employ precarious communities and by addressing vulnerabilities that pose barriers to *in situ* adaptation and livelihood strategies (*medium confidence*). Migrants and their sending and receiving communities can be supported through temporary labour migration schemes; improving discourses on migration; and meeting existing migration agreements and development objectives (*medium confidence*).

Planned relocation and resettlement have low feasibility as an adaptation option (*medium confidence*). Previous disaster- and development-related relocation has been expensive, contentious, posed multiple challenges for governments and amplified existing, and generated new, vulnerabilities for the people involved (*high confidence*). Planned relocation will be increasingly required as climate change undermines habitability, especially for coastal areas (*medium confidence*). Full participation of those affected, ensuring human rights-based approaches, preserving cultural, emotional and spiritual bonds to place, and dedicated governance structures and associated funding are associated with improved outcomes (*high confidence)*. Improving the feasibility of planned relocation and resettlement is a high priority for managing climate risks *(high confidence*).

CCB FEASIB.1 Scope

The Paris Climate Agreement marked a significant shift for the IPCC AR6 assessment towards a systematic exploration of climate solutions and a suite of linked adaptation and mitigation options (IPCC, 2018; IPCC, 2019). This shift was first evidenced in SR1.5, whose plenary-approved outline sought to define " Feasibility refers to the potential for a mitigation or adaptation option to be implemented. Factors influencing feasibility are context-dependent, temporally dynamic, and may vary between different groups and actors. Feasibility depends on geophysical, environmental-ecological, technological, economic, socio-cultural and institutional factors that enable or constrain the implementation of an option. The feasibility of options may change when different options are combined, and increase when enabling conditions are strengthened". Based on this mandate, SR1.5 identified (with *high confidence*) rapid and far-reaching transitions in four systems: energy, land and other ecosystems, urban and infrastructure (including transport and buildings) and industrial systems, necessary to enable pathways to limit average global warming to 1.5°C compared to pre-industrial temperatures (Bazaz et al., 2018; IPCC, 2018). This was deepened for terrestrial systems in SRCCL, while SROCC added additional evidence from ocean and cryosphere systems. The assessment includes the interactions between carbon dioxide removal and adaptation outcomes: compared to previous Assessment Reports, it is clear that the ambitious temperature targets agreed upon in Paris in 2015 will require at least some carbon dioxide removal (CDR), i.e. all 1.5°C pathways feature annual removals at Gigaton level (Rogelj et al., 2018). This necessitates assessing the interactions of CDR with adaptation.

This feasibility assessment of adaptation options is situated within four system transitions identified in SR1.5 (de Coninck et al., 2018). In this report, feasibility refers to the potential for a mitigation or adaptation option to be implemented. Factors influencing feasibility are context-dependent, temporally dynamic, and may vary between different groups and actors. Feasibility depends on geophysical, environmental-ecological, technological, economic, socio-cultural and institutional factors that enable or constrain the implementation of an option. The feasibility of options may change when different options are combined, and increase when enabling conditions are strengthened. Twenty-two key adaptation options have been identified in AR6, across these system transitions, and mapped against representative key risks at global scale (Chapter 16) (Figure 1).

This cross-chapter box first presents the methodology for the feasibility assessment of adaptation options (section 2); findings of the FA (section 3); presents S&Ts of adaptation for mitigation options and mitigation for adaptations (section 4); and knowledge gaps (section 5).

There has been growing research emphasis on synthesising adaptation literature through meta-reviews of adaptation research (Sietsma et al., 2021), adaptation readiness (Ford et al., 2015; Ford et al., 2017); adaptation progress (Araos et al., 2016a); adaptation barriers and enablers (Biesbroek et al., 2013; Eisenack et al., 2014; Barnett et al., 2015); and adaptation outcomes (Owen, 2020) [Cross-Chapter Box ADAPT in Chapter 1]. In particular, understanding which adaptation options are effective, to what risks, and under what conditions, is particularly challenging given the lack of a clearly defined, globally agreed upon adaptation goal and disagreement on the metrics to assess effectiveness (Berrang-Ford et al., 2019; Singh et al., 2021b) [Ch 17, Sec 17.5.2 on Successful adaptation]. Effectiveness studies often use metrics such as proportion of population amount of population exposure reduced or conduct cost-benefit analyses of specific options, which lend themselves well to infrastructural options (e.g. effectiveness of seawalls in reducing SLR exposure in coastal cities) but do not translate well to 'soft' adaptation options such as uptake of climate services or changing building codes.

Systems transitions RKRs	Energy Systems Transitions	Land and Ecosystems Transitions	Urband & Infrastructure Systems Transitions	Overarching Adapatation Options
Risk to coastal socio-ecological systems		• Coastal defence and hardening • Sustainable aquaculture		
Risk to terrestrial and ocean ecosystems		• Integrated coastal zone management including wetland, mangrove conservation • Sustainable forest management and conservation, reforestation and afforestation • Biodiversity management and ecosystem connectivity		• Social safety nets • Risk spreading and sharing • Risk spreading and sharing • Climate services, including EWS • Disaster risk management • Population health and health systems • Human migration and displacement • Planned relocation and resettlement
Risks associated with critical physical infrastructure, networks, and services	• Resilient power infrastructure • Improved power reliability		• Green infrastructure & ecosystem services • Sustainable land-use & urban planning	
Risk to living standards and equity		• Livelihood diversification		
Risk to human health				
Risk to food security		• Improved cropland management(including integrated soil management, conservation agriculture) • Efficient livestock systems (including improved grazing land management) Agroforestry		
Risk to water security	• Improve water use efficiency	• Water use efficiency and water resource management	• Sustainable urban water management	
Risk to peace and migration				

Figure Cross-Chapter Box FEASIB.1: Feasibility assessment option mapped against Representative Key Risks (RKRs)

CCB FEASIB.2 Methodology: feasibility assessment of adaptation options across key system transitions

Multi-dimensional feasibility of adaptation options is assessed across six dimensions. This multidimensional framework goes beyond technical or economic feasibility alone to capture how adaptation is mediated by the political environment, sociocultural norms (Evans et al., 2016), cognitive and motivational factors (van Valkengoed and Steg, 2019), economic incentives and benefits (Masud et al., 2017), and ecological conditions (Biesbroek et al., 2013).

The six feasibility dimensions are underpinned by a set of twenty indicators. Each adaptation option is scored as having high, medium or low evidence on barriers based on a review of literature published from 2018 onwards (pre-2018 literature is expected to be covered by SR1.5 but in some cases pre-2018 literature was added where relevant literature was found) that reports studies that are 1.5°C-relevant. Further details and motivations for this methodology can be found in (Singh et al., 2020c)."

The scoring process is undertaken by one author and reviewed by at least two more authors to ensure robustness and geographical coverage. While the literature does not support an assessment at different temperature levels or an assessment of how feasibility can change over time, some examples on these spatial and temporal aspects are detailed below.

CCB FEASIB.3 Findings: feasibility assessment of adaptation options across key system transitions

The following sections outline the findings of a 1.5°C-relevant feasibility assessment of adaptation options by the four system transitions. A synoptic summary of the findings of the multi-dimensional feasibility is shown at the end of this section in Figure Cross-Chapter Box FEASIB.2. The full line of sight can be found in Supplementary Material (SM).

CCB FEASIB.3.1 Energy systems transitions

The adaptation options assessed for energy system transitions are resilient power infrastructure, water management, focused on water efficiency and cooling, for all types of generation source, and reliable power systems. Since SR1.5, there has not been significant change in the feasibility of the first two options as they continue to be implemented successfully, allowing for power generation to maintain or increase its reliability during extreme weather events (high confidence) (Zhang et al., 2018) (Ali and Kumar, 2016; DeNooyer et al., 2016). As in the case of SR1.5, these options are not sufficient for the far-reaching transformations required in the energy sector, which tend to focus on technological transitions from a fossil-based to a renewable energy regime (Erlinghagen and Markard, 2012; Muench et al., 2014; Brand and von Gleich, 2015; Monstadt and Wolff, 2015; Child and Breyer, 2017; Hermwille et al., 2017). The main difference from SR1.5 is that resilient power infrastructure now includes distributed generation utilities, such as microgrids, as there is increasing evidence of its role in reducing vulnerability, especially within underserved populations (high confidence).

The option for resilient power infrastructure is considered for all types of power generation sources, and transmission and distribution systems. There is robust evidence and high agreement for the high feasibility of the economic and technological dimensions as the technologies have been used and their cost effectiveness is high, although the latter is dependent upon the generation source and location of each specific generation plant. There is medium institutional feasibility (medium evidence, medium agreement) as there are insufficient policies for resilient infrastructure, although there is high acceptability for these options.

The option of efficient water use and management also has high feasibility for the economic, technological and environmental dimensions (robust evidence, high agreement), as this option also has proven that technology and efficient water use can make operations more efficient and cost effective as well as have positive effects on the environment, especially in drought-stricken regions. There is high political acceptability, existence of water use policies, regulations and supporting institutional frameworks to ensure compliance (Ali and Kumar, 2016; DeNooyer et al., 2016; Zhang et al., 2018). There is medium evidence and high agreement for the medium feasibility of the socio-cultural dimension, especially given the evidence of resilience in distributed generation systems and independent microgrids.

Since AR5, the reliability of power systems has gained interest due to the numerous service disruptions during extreme weather events. As with resilient power systems, there is increasing evidence of the feasibility of increased reliability for both existing power plants, independently of the generation source, and for rural landscapes. The option has high confidence (robust evidence, high agreement) for the high feasibility of the technological and social dimensions. As with previous options, the technological means exist to create redundancy in power generation, transmission and distribution systems and their implementation ensures the continuous functionality of emergency services, such as communications, health, and water pumping, amongst others, in urban, peri-urban and rural landscapes (high confidence). There is high feasibility for the economic, technical and socio-cultural dimensions (the latter more prominently for decentralized systems), and medium feasibility for institutional and geophysical dimensions.

For the three options, some of the indicators within the institutional, social and geophysical dimensions have limited evidence as they haven't been the focus of research. For example, when discussing the social co-benefits of energy reliable systems of efficient water use, literature doesn't focus on intergenerational or gender issues separately from the broad range of social co-benefits the options provide, but, for example, highlight the need for electricity for communications and health centers.

CCB FEASIB.3.2 Land and ecosystems

CCB FEASIB.3.2.1 Coastal defence & hardening

There is *medium agreement* and *robust evidence* regarding the feasibility of coastal defense and hardening as adaptation options in some circumstances, which here includes hard engineering solutions and grey coastal infrastructure. Economic and social factors potentially limit the feasibility of these options as they require large investments (both construction, maintenance and monitoring) (Hamin et al., 2018; Magnan and Duvat, 2018; Morris et al., 2018; Morris et al., 2019; Nicholls et al., 2019; Hanley et al., 2020b) (CCP2.3). While these costs present challenges for rural areas, coastal defense structures may still be cost-effective in some areas, such as those with larger economies (Aerts, 2018; Lincke and Hinkel, 2018; Tiggeloven et al., 2020; Vousdoukas et al., 2020; Lima and Coelho, 2021)). Strong yet transparent and inclusive governance is key, suggesting that these measures can occasionally fail to adequately balance competing stakeholder interests. Consequently, they may disproportionately benefit wealthier people and exacerbate existing vulnerability (Kind et al., 2017; O'Donnell, 2019; Ratter et al., 2019; Siders and Keenan, 2020; Siriwardane-de Zoysa, 2020). They are also potentially maladaptive in that they are not flexible or robust in response to a changing climate (Antunes do Carmo, 2018; Hamin et al., 2018; Morris et al., 2019; Baills et al., 2020; Foti et al., 2020; Hanley et al., 2020b) and can have negative impacts on the local environment, habitats, ecosystems and services, and communities (Mills et al., 2016; Morris et al., 2018; Morris et al., 2019; Foti et al., 2020; Hanley et al., 2020b).

Recent projects have focused on improving adaptability and increasing ecological and social sustainability, by combining both hard engineering and 'softer' nature-based solutions (Morris et al., 2019; Scheres and Schüttrumpf, 2019; Schoonees et al., 2019; Van Loon-Steensma and Vellinga, 2019; Du et al., 2020; Foti et al., 2020; Winters et al., 2020; Ghiasian et al., 2021; Joy and Gopinath, 2021; Tanaya et al., 2021; Waryszak et al., 2021). For example, coastal defense might involve a combination of 'stabilizing' ecosystems (e.g. seagrasses, mangroves, salt marsh) and hard human-made structures. Such coastal defense 'mixed' structures can be part of an Integrated Coastal Zone Management (ICZM) strategy, which is covered as a separate option below.

CCB FEASIB.3.2.2 Sustainable aquaculture

There is *medium evidence* with *medium agreement* on the feasibility of sustainable aquaculture as an adaptation measure. Sustainable aquaculture (e.g. Integrated Multi-Tropic Aquaculture, polyculture, aquaponics, mangrove-integrated culture) can have socio-economic benefits for vulnerable communities and small-scale fisheries (Ahmed, 2018; Blasiak et al., 2019; Mustafa et al., 2021; Thomas et al., 2021; Xuan et al., 2021). Nevertheless, caution is important to guarantee that access to fish supply of local and vulnerable communities is not affected (Chan et al., 2019; Galappaththi et al., 2020). Access to financial resources is often a barrier to implementation, although sustainable aquaculture can increase employment opportunities that are increasingly gender equitable (Alleway et al., 2018; Leakhena et al., 2018; Valenti et al., 2018; Gopal et al., 2020), as well as increasing the resilience of coastal livelihoods to climate change (Shaffril et al., 2017; Blasiak and Wabnitz, 2018). Technological, institutional and socio-cultural factors can form barriers to the feasibility of sustainability of aquaculture (e.g. (Ahmed et al., 2018; Blasiak et al., 2019; Galappaththi et al., 2019; Boyd et al., 2020; Osmundsen et al., 2020; Stentiford et al., 2020; Mustapha et al., 2021; Xuan et al., 2021).

Sustainable aquaculture depends on healthy ecosystems (Sampantamit et al., 2020; Stentiford et al., 2020; Qurani et al., 2021). At the same time, its implementation can increase or regenerate ecosystem services, enhance ecosystem's adaptive capacity (Shaffril et al., 2017; Freduah et al., 2018; Custódio et al., 2020; Bricknell et al., 2021; Mustafa et al., 2021) and protect nursery grounds and habitats for fish and other important organisms (i.e., many commercial species are associated with mangroves). It may also prevent ecosystem degradation such as deforestation, enhancing land-use potential (Ahmed et al., 2018; Stentiford et al., 2020; Turolla et al., 2020; Mustafa et al., 2021).

Environmental as well as economic aspects are key when assessing the sustainability of aquaculture practices (Ahmed et al., 2018; Aubin et al., 2019; Bohnes et al., 2019; Galappaththi et al., 2019; Boyd et al., 2020; Galappaththi et al., 2020; Osmundsen et al., 2020; Stentiford et al., 2020; Thomas et al., 2021). A global picture of where sustainable aquaculture is possible is clearly desirable (FAO, 2018; Galappaththi et al., 2019; Bricknell et al., 2021), yet there are few new references to physical feasibility. Adaptation options for existing sustainable aquaculture need to be developed, along with institutional arrangements such as education and technical exchange, focused on developing sustainable industries (Section 8.6.2.3). Sustainable agriculture is likely to receive strong support from many countries but may experience resistance for several reasons (e.g., competition with existing industries, debates over tolerance to aesthetic changes to coastlines). Literature on this area is growing and potential barriers at the government and political levels are significant (e.g. (Jayanthi et al., 2018; Blasiak et al., 2019; Hargan et al., 2020; Osmundsen et al., 2020; Stentiford et al., 2020; Mustafa et al., 2021; Qurani et al., 2021).

CCB FEASIB.3.2.3 Integrated coastal zone management

Salt marsh management, re-vegetation of shorelines, community-based coastal adaptation, and ecosystem-based adaptation, among other approaches implemented in coastal areas (which are considered to be part of ICZM, "soft measures") were considered in this assessment. There is robust evidence and high agreement that ICZM increases ecological and adaptive capacity to climate change (Villamizar et al., 2017; Antunes do Carmo, 2018; Hamin et al., 2018; Le Cornu et al., 2018; Propato et al., 2018; Romañach et al., 2018; Rosendo et al., 2018; Warnken and Mosadeghi, 2018; Morecroft et al., 2019; Morris et al., 2019; Alves et al., 2020; Donatti et al., 2020; Erftemeijer et al., 2020; Foti et al., 2020; Gómez Martín et al., 2020; Hanley et al., 2020b; Jones et al., 2020b; Krauss and Osland, 2020; O'Mahony et al., 2020; Perera-Valderrama et al., 2020; Cantasano et al., 2021).

Diverse socio-economic co-benefits have been identified, including integration of tourism activities, increased educational opportunities for the reduction in storm damage, maintenance of ecosystems and their services, increasing adaptive capacities of institutions (Romañach et al., 2018; Mestanza-Ramón et al., 2019; Morris et al., 2019; Donatti et al., 2020; Ellison et al., 2020; Erftemeijer et al., 2020; Gómez Martín et al., 2020; Hanley et al., 2020a; Jones et al., 2020b; Martuti et al., 2020; Perera-Valderrama et al., 2020; Telave and Chandankar, 2021); as well as environmental and geophysical co-benefits aspects, including mitigation potential and hazard risk reduction (Propato et al., 2018; Romañach et al., 2018; Ellison et al., 2020; Erftemeijer et al., 2020; Hanley et al., 2020a; Jones et al., 2020b; Martuti et al., 2020; Cantasano et al., 2021).

ICZM measures are generally more cost-effective or affordable than "hard-engineering" measures (Antunes do Carmo, 2018; Morecroft et al., 2019; Morris et al., 2019; Donatti et al., 2020; Erftemeijer et al., 2020; Hanley et al., 2020a; Jones et al., 2020b), but the costs for its implementation is a barrier, especially in low income countries (Lamari et al., 2016; Villamizar et al., 2017; Rosendo et al., 2018; Mestanza-Ramón et al., 2019; Barragán Muñoz, 2020; Botero and Zielinski, 2020; Caviedes et al., 2020; Martuti et al., 2020; Lin et al., 2021). The implementation of ICZM measures requires a strong institutional framework, where all relevant stakeholders (especially representatives of local communities) are part of the decision-making process (Pérez-Cayeiro and Chica-Ruiz, 2015; Lamari et al., 2016; Hassanali, 2017; Antunes do Carmo, 2018; Hamin et al., 2018; Phillips et al., 2018; Romañach et al., 2018; Rosendo et al., 2018; Warnken and Mosadeghi, 2018; Mestanza-Ramón et al., 2019; Morecroft et al., 2019; Morris et al., 2019; Walsh, 2019; Barragán Muñoz, 2020; Caviedes et al., 2020; Donatti et al., 2020; Ellison et al., 2020; Martuti et al., 2020; O'Mahony et al., 2020; Perera-Valderrama et al., 2020). This aspect is mentioned as a key challenge in developing countries (Pérez-Cayeiro and Chica-Ruiz, 2015; Villamizar et al., 2017; Rosendo et al., 2018; Alves et al., 2020). Similarly, incorporating gender issues explicitly into ICZM is generally recommended, also because women are key knowledge holders in coastal communities; however, this is rarely done in practice, which may lead to suboptimal or unequal outcomes (Nguyen Mai and Dang Hoang, 2018; Hoegh-Guldberg and al., 2019; Pearson et al., 2019; Barreto et al., 2020). The perception that building "hard" infrastructure (i.e. coastal defense and hardening) is a more efficient way of reducing coastal risk than the implementation of "soft" or NBS measures has been challenged in recent studies (Magnan and Duvat, 2018).

CCB FEASIB.3.2.4 Agroforestry

There is *robust evidence* and *high agreement* that agroforestry systems can increase ecological and adaptive capacity (Schoeneberger et al., 2012; Smith et al., 2013; Minang et al., 2014; Apuri et al., 2018; Kmoch et al., 2018; IPCC, 2019; Jordon et al., 2020). Benefits include preservation of ecosystems services, such as water provision and soil conservation, more efficient use of limited land, alleviation of land degradation, prevention of desertification and improved agricultural output. Agroforestry solutions also result in co-benefits in the water-energy-land-food nexus, with observed positive outcomes in soil management, crop diversification, water efficiency and alternative sources of energy (De Beenhouwer et al., 2013; Elagib and Al-Saidi, 2020). Further, they can have social and economic benefits and positive synergies between adaptation and mitigation (Section 8.6.2.2) (Coulibaly et al., 2017; Hernández-Morcillo et al., 2018; Tschora and Cherubini, 2020; Duffy et al., 2021).

When locally adapted to fine-scale ecological and social variation, agroforestry initiatives can improve household income, and provide regular employment and sustainable livelihood to local communities, thereby strengthening peoples' resilience to cope with adverse impacts of changing climate conditions (Coe et al., 2014; Ogada et al., 2020; Sharma et al., 2020; Sollen-Norrlin et al., 2020; Awazi et al., 2021). However, (Cechin et al., 2021) question the financial viability of agroforestry systems, especially in the case of smallholders in agrarian reform settlements, struggling with high upfront costs. Similarly, insufficient financial support was found to be a major constraint for the implementation of broader agroforestry initiatives in South East Asia and Africa (Sections 8.5.2 and 8.6.2.1) (Dhyani et al., 2021; Williams et al., 2021).

Over the last decade, agroforestry schemes have grown in acceptability and political support, most notably observed in their broad inclusion in countries' Nationally Determined Contributions (NDCs) and National Adaptation Plans (NAPs). Governance and institutional arrangements, however, have not been conducive to broader implementation of agroforestry initiatives at the landscape level (Dhyani et al., 2021; Williams et al., 2021). *Medium evidence* with *medium agreement* suggests that economic and cultural barriers may explain difficulties with the implementation of agroforestry systems (Coe et al., 2014; Quandt et al., 2017; Cedamon et al., 2018; Hernández-Morcillo et al., 2018; Ghosh-Jerath et al., 2021). Also, unclear land tenure and ownership issues, together with inappropriate mapping and databases for monitoring vegetation, continue to hinder the adoption of broader agroforestry strategies, particularly in remote areas and tropical forests (Martin et al., 2020).
Notably, agroforestry practices are often part of indigenous and local knowledge (Santoro et al., 2020), and so far, most literature refers to the evaluation of existing agroforestry practices or autonomous adaptation, with few studies evaluating the effects of targeted interventions, especially in low and middle income countries (Miller, 2020; Castle et al., 2021).

CCB FEASIB.3.2.5 Sustainable forest management and conservation, reforestation and afforestation
There is *robust evidence* and *medium agreement* supporting the overall feasibility of forest-based adaptation options. Regarding its economic feasibility, some studies (Nabuurs et al., 2017; Chow et al., 2019; Seddon et al., 2020a) highlight that the net benefits of measures such as reforestation, sustainable forest management and ecosystem restoration outweigh the costs of implementation and maintenance. Yet, another strand of literature observes that limited access to financial resources is a major constraint to reforestation and adaptive management initiatives, especially in the face of upfront investment costs and alternative, more profitable land uses, like agriculture (Bustamante et al., 2019; Ota et al., 2020; Seddon et al., 2020b). In countries with extensive rural areas where forests provide for local communities, government support together with private investments and long-term assurances of maintenance, are considered fundamental for the long-term viability of forest conservation strategies (Bustamante et al., 2019; Seddon et al., 2020b). In rural areas, smallholders can diversify their livelihood and increase household income as a result of improved local forest governance (Bustamante et al., 2019; Fleischman et al., 2020; Ota et al., 2020) Similarly, ecosystem restoration has been found to reduce poverty and improve social inclusion and participation, given that ecosystems can be managed jointly and in traditional ways (Woroniecki et al., 2019). *Robust evidence* (*high agreement*) links forest-based adaptation to job creation, improved health and recreational benefits, most notably for indigenous, rural and remote communities (Muricho et al., 2019; Rahman et al., 2019; Ambrosino et al., 2020; Bhattarai, 2020; Ota et al., 2020; von Holle et al., 2020; Tagliari et al., 2021). However (Chausson et al., 2020), note that still today frameworks for assessing the cost-effectiveness of adaptation strategies continue to be tailored to conventional, engineered interventions, which fail to capture the broader array of material and non-material benefits that sustainable forest management might bring.

Forest-based solutions enjoy wide local, regional and international support (Lange et al., 2019; Chausson et al., 2020; Seddon et al., 2020b), and most countries have the basic regulatory framework for environmental protection. However, lack of institutional capacity, deficient inter-agency coordination, and insufficient staff and budget continue to limit broader implementation of forest-based adaptation measures. Limited technical capacity, insufficient production and supply of seeds and seedlings, long transport distances and immature supply chains have also been identified as significant barriers that hinder the expansion of forest-based initiatives (Bustamante et al., 2019; Nunes et al., 2020).

There is *robust evidence* and *medium agreement* that forest-based solutions support ecosystems' capacity to adapt to climate change, including better regulation of microclimate, increased groundwater recharge, improved quality of air and water, reduced soil erosion, improved and climate-adapted biodiversity habitats, expansion of biomass, as well as continuous provision of renewable wood products (Nabuurs et al., 2017; Chow et al., 2019; Lochhead et al., 2019; Shannon et al., 2019; Weng et al., 2019; von Holle et al., 2020; Dooley et al., 2021; Forster et al., 2021; Tagliari et al., 2021). In well designed systems, adaptation and mitigation can then go hand in hand, as in climate smart forestry. What is more, adaptive forest management is already being tested in climate smart forestry pilots in several temperate regions (Nabuurs et al., 2017). However, large afforestation and non-native monoculture plantations may negatively impact non-forest ecosystems, such as grasslands, shrublands, and peatlands, their water resources and biodiversity (Seddon et al., 2019; Seddon et al., 2020a; Seddon et al., 2020b). Similarly, the International Resource Panel (2019) warns that restoration may also imply trade-offs with other ecological and societal goals.

Regarding risk reduction potential, reforestation and afforestation strategies are found to protect in-land infrastructure from landslides and coastal infrastructure from storm surges (Seddon et al., 2020a; Seddon et al., 2020b), together with offering a cheaper solution than engineered grey solutions (Chausson et al., 2020). Land availability is a limiting factor for expanding forest-based solutions (Morecroft et al., 2019; Ontl et al., 2020). However, there is *high agreement* and *robust evidence* that reforestation, environmental conservation and nature-based solutions result in increased carbon sinks (Griscom et al., 2017; Nabuurs et al., 2017; de Coninck et al., 2018; Fuss et al., 2018; Favretto et al., 2020; Forster et al., 2021). Some authors argue that primary ecosystems and native forests contain larger stocks of carbon than tree plantations (Seddon et al., 2019; Fleischman et al., 2020; Seddon et al., 2020a), while another strain of literature finds that net sequestration rate is lower in mature primary forests than in younger managed forests with their associated wood value chains (Cowie et al., 2021; Forster et al., 2021; Gundersen et al., 2021). There is *robust evidence* and *high agreement* that reforestation and ecosystem-based strategies result in hazard risk reduction potential. Environmental restoration can be an effective climate change adaptation alternative, reducing susceptibility to extreme events, improving ecological capacities and increasing overall ecosystems' resilience (Chapter 8, Box 9.7) (Nunes et al., 2020). However, too much reliance on reforestation and green alternatives might increase water shortages and wildfires (Seddon et al., 2019; Fleischman et al., 2020).

CCB FEASIB.3.2.6 Biodiversity management and ecosystem connectivity

There is *robust evidence* and *medium agreement* supporting the overall feasibility of biodiversity management and ecosystem connectivity as adaptation options. With respect to its economic feasibility, financial constraints continue to hinder broader implementation of biodiversity-based solutions (Lausche et al., 2013; Chausson et al., 2020; Jones et al., 2020a).(Seddon et al., 2020a) highlights that only five percent of climate finance goes towards adaptation strategies, and only one percent is destined to disaster risk management including nature-based solutions and biodiversity management. Government support via subsidies and fiscal transfers is critical for broader biodiversity management interventions. In addition, REDD+ initiatives have been promoted as a profitable mechanism to advance biodiversity conservation strategies while reducing carbon emissions. As far as ecosystem connectivity is concerned, its feasibility will strongly depend on the existence of a regulatory framework that appropriately balances property rights, environmental regulations and monetary incentives to ensure landowners' willingness to participate and maintain ecosystem corridors (Jones et al., 2020b). The demands of commodity-based economies, favouring extractive land-uses, present serious barriers to upscaling biodiversity-based adaptation interventions (Seddon et al., 2020a). In addition, integrated assessments have shown how biodiversity-based solutions can deliver jobs from landscape restoration or income from wildlife tourism and how those benefits are fairly distributed (Chausson et al., 2020).

Legal and regulatory instruments are not perceived as major barriers to biodiversity management and ecosystem connectivity projects (Lausche et al., 2013; D'Aloia et al., 2019). A challenge that biodiversity-based measures still face is less acceptance among decision-makers because their efficiency and cost-benefit ratio are difficult to determine and most of the measures are only effective in the long-term (Lange et al., 2019). Methodologies to determine cost-effectiveness vary substantially between studies, in part because these analyses must be tailored to the social-ecological context in order to be meaningful for local governance. This makes it challenging to capture and synthesize the full economic benefits of biodiversity-based solutions in comparison to alternatives (Chausson et al., 2020). In all, biodiversity and nature-based solutions have gained considerable political traction, with the greatest emphasis on the role of ecosystems as carbon sinks (Lange et al., 2019; Chausson et al., 2020; Seddon et al., 2020a).

Several social co-benefits are found to follow from biodiversity management strategies, including improved community health, recreational activities, eco-tourism, in addition to educational, spiritual and scientific benefits (Lausche et al., 2013; Worboys et al., 2016; Seddon et al., 2020a). (Lavorel et al., 2020) show how the benefits of biodiversity management are co-produced by harnessing ecological and social capital to promote resilient ecosystems with high connectivity and functional diversity. Furthermore, (Chausson et al., 2020) note how properly implemented nature-based solutions, including biodiversity management, can strengthen social networks and foster a sense of place, supporting virtuous cycles of community engagement to sustain interventions over time.

There is *high agreement* and *robust evidence* supporting the ecological capacity enhancement of biodiversity-based and ecosystem connectivity strategies (Thompson et al., 2017; Lavorel et al., 2020). Forest management that favors mixed-species rather than non-native monocultures can promote the resilience of timber production and carbon storage while also benefiting biodiversity (Chausson et al., 2020). Similarly, monocultures have been found to impoverish biodiversity and hold less resilient carbon stocks than natural and semi-natural forests (Seddon et al., 2020a).

There is a *relatively high agreement* that ecosystem connectivity has the potential to improve the adaptive capacity of both ecological systems and humans. (Krosby et al., 2010), for example, found that planting trees in short distances could increase the probability of range shifts in species that depend on the habitat those trees provide. Likewise, connectivity conservation has benefits for climate change mitigation (Lausche et al., 2013), but empirical evidence of the adaptation benefits for humans is scant. More recently, it has been found that biodiversity conservation reduces the risk of zoonotic diseases when it provides additional habitats for species and reduces the potential contact between wildlife, livestock and humans (Van Langevelde et al., 2020). Ecosystem-based approaches have been promoted to address the risk of increased zoonotic diseases, including the conservation of wildlife corridors (Gibb et al., 2020).

Despite abundant literature on the necessity to implement ecosystem connectivity strategies, many policy recommendations are mostly discursive and not supported by evidence. There is a lack of specificity when referring to the actors that should intervene in the design, implementation and evaluation of policies. What is more, most of the literature comes from the natural sciences and is concerned with co-benefits to wildlife and nature, with very little elaboration on the socio-economic co-benefits for humans.

CCB FEASIB.3.2.7 Improved cropland management

Improved cropland management, which includes agricultural adaptation strategies such as integrated soil management, no/reduced tillage, conservation agriculture, planting of stress-resistant or early maturing crop varieties, and mulching, has high economic and environmental feasibility (*robust evidence, high agreement*) (AGEGNEHU and AMEDE, 2017; Lalani et al., 2017; Schulte et al., 2017; Thierfelder et al., 2017; Aryal et al., 2018a; Mayer et al., 2018; Prestele et al., 2018; Sova et al., 2018; Gonzalez-Sanchez et al., 2019; Lunduka et al., 2019; McFadden et al., 2019; Shah and Wu, 2019; TerAvest et al., 2019; Adams et al., 2020; Aryal et al., 2020a; Debie, 2020; Mutuku et al., 2020; Somasundaram et al., 2020; Du et al., 2021). Despite higher initial costs in some cases, the economic feasibility of improved cropland management is high through improved productivity, higher net-returns, reduced input costs (Aryal, 2020 #6850}(Mottaleb et al., 2017; Keil et al., 2019; Lunduka et al., 2019; McFadden et al., 2019; Parihar et al., 2020). Self-efficacy is shown to be the most important predictor in technical and non-technical adaptation behaviour (Zobeidi et al., 2021), while subsidies, extension services, training, commercial custom-hire services and strong social connections such as farmer networks are among the factors supporting adoption among farmers (Section 8.5.2.3) (Aryal et al., 2015a; Aryal et al., 2015b; Kannan and Ramappa, 2017; Bedeke et al., 2019; Acevedo et al., 2020). In some regions and for some practices, technological feasibility is constrained by cost, and inadequate information and technical know-how on particular practices and their benefits and tradeoffs, indicating medium feasibility (Khatri-Chhetri et al., 2016; Bhatta et al., 2017; Dougill et al., 2017; Kannan and Ramappa, 2017; Aryal et al., 2018a; Sova et al., 2018; Findlater et al., 2019). Delays between actions and tangible benefits can reduce public and private acceptability and uptake of improved cropland management practices (e.g. (Dougill et al., 2017) in Malawi).

There remain institutional and financial barriers to improved cropland management such as lack of comprehensive policies, inadequate mainstreaming into national policy priorities (e.g. (Amjath-Babu et al., 2019) and (Reddy et al., 2020) in South Asia), fragmentation across different sectors (Dougill et al., 2017) in Malawi), and inadequate access to credit (Aryal et al., 2018c) in India). Adoption of improved cropland management practices is often strongly mediated by gender: structural barriers such as unequal access to land, machinery, inputs, and extension and credit services, constrain adoption by female farmers (Aryal et al., 2018b; Aryal et al., 2018c). (Mponela et al., 2016; Van Hulst and Posthumus, 2016; Ntshangase et al., 2018; Aryal et al., 2020b; Somasundaram et al., 2020). Improved cropland management practices have social and ecological co-benefits in terms of better health, education and food security (Agarwal, 2017; Farnworth et al., 2017; Hörner and Wollni, 2020) and better soil health and ecosystem functioning (AGEGNEHU and AMEDE, 2017; Mottaleb et al., 2017; Thierfelder et al., 2017; Zomer et al., 2017; Sarkar et al., 2018; Gonzalez-Sanchez et al., 2019; Shah and Wu, 2019; Du et al., 2020; Mutuku et al., 2020; Somasundaram et al., 2020).

There is *robust evidence* (*medium agreement*) that improved cropland management can have mitigation co-benefits but the exact quantity of emissions reductions and increased removals depend on agro-ecosystem type, climatic factors and cropping practices (VandenBygaart, 2016; Han et al., 2018; Mayer et al., 2018; Prestele et al., 2018; Singh et al., 2018a; Sommer et al., 2018; Gonzalez-Sanchez et al., 2019; Ogle et al., 2019; Shah and Wu, 2019; Adams et al., 2020; Aryal et al., 2020a; Li et al., 2020; Wang et al., 2020; Shang et al., 2021).

CCB FEASIB.3.2.8 Efficient livestock systems

Enhancing the production efficiency of livestock systems, through for example, improved livestock diets, enhanced animal health, breeding and manure management, can contribute to adaptation and mitigation (Ericksen and Crane, 2018; Accatino et al., 2019; Paul et al., 2020)IPCC WGIII AR6 Section 7.4.3). While the technological and ecological feasibility of improving livestock production systems is high (i.e. measures are technically well established, with different options applicable to a range of livestock production systems and ecological conditions), there are multiple context-specific barriers to adoption. These include a lack of coordinated policy support or governance, potentially high implementation costs and limited access to finance, inadequate advisory, knowledge exchange or infrastructural capacity (Escarcha et al., 2018; Paul et al., 2020), the potential land requirements and associated ecological impacts of adjusting livestock management, lack of context specific research (Pardo and del Prado, 2020), and socio-cultural barriers limiting access by women or low-income groups to better breeds or feed varieties (Luqman et al., 2018; Salmon et al., 2018) as well as women losing influence in the household in some contexts when farms intensify (Tavenner and Crane, 2018). In dryland livestock systems in Ethiopia and Kenya, (Ericksen and Crane, 2018) find that low governance capacities to implement improved grazing regimes and prevent overgrazing constrain improved grassland management.

CCB FEASIB.3.2.9 Water use efficiency and water resource management

There is high technological feasibility (*robust evidence, high agreement*) to improve water use efficiency as well as manage water resources at basin and field scales. These approaches include rainwater harvesting, drip irrigation, laser land leveling, drainage management and stubble retention (Dasgupta and Roy, 2017; Khatri-Chhetri et al., 2017; Rahman et al., 2017; Adham et al., 2018; Darzi-Naftchali and Ritzema, 2018; Terêncio et al., 2018; Velasco-Muñoz et al., 2018; Sojka et al., 2019). There is *high evidence (medium agreement*) that such measures have socio-economic co-benefits and improve adaptive capacities through improved water supply (e.g. through rainwater harvesting , increased infiltration, or integrated watershed management),, and sustainable water demand management (e.g. reduction of evaporation loss). There is *medium evidence* (*high agreement*) of the option's economic feasibility due to water and energy cost savings enhanced by low-cost monitoring systems in some cases (Kodali and Sarjerao, 2017; Viani et al., 2017). Implementation costs vary widely, with landforming and irrigation infrastructure requiring substantial up-front investment, while mulches and cover crops are low cost practices. Water management and use efficiency is currently constrained by governance and institutional factors such as inadequate institutional capacities to prepare for changing water availability, especially in the long term, unsustainable and unequal water use and sharing practices, particularly across boundaries, and fragmented, and siloed resource management approaches (Lardizabal, 2015; Margerum and Robinson, 2015; Singh et al., 2020a).

CCB FEASIB.3.2.10 Livelihood diversification

Livelihood diversification is a key coping and adaptive strategy to climatic and non-climatic risks (Gautam and Andersen, 2016; Asfaw et al., 2018)Liu, 2015 #1681}(Goulden et al., 2013; Makate et al., 2016; Orchard et al., 2016; Nyantakyi-Frimpong, 2017; Schuhbauer et al., 2017; Kihila, 2018; Radel et al., 2018; Tian and Lemos, 2018; Buechler and Lutz-Ley, 2019; Salam and Bauer, 2020). There is high evidence (medium agreement) that diversifying livelihoods improves incomes and reduces socio-economic vulnerability, but depending on livelihood type, opportunities, and local context, feasibility changes (Section 8.5.1) (Barrett, 2013; Martin and Lorenzen, 2016; Sina et al., 2019). Livelihood diversification has positive and negative outcomes for adaptive capacity, especially in ecologically and resource-stressed regions (for e.g.(Anderson et al., 2017; Woodhouse and McCabe, 2018; Rosyida et al., 2019; Ojea et al., 2020), with diversification predominantly out of rural farm-based livelihoods on the rise (Rigg and Oven, 2015; Shackleton et al., 2015; Ober and Sakdapolrak, 2020). Key barriers to livelihood diversification include socio-cultural and institutional barriers (including social networks (Goulden et al., 2013) as well as inadequate resources and livelihood opportunities that hinder the full adaptive possibilities of existing livelihood diversification practices (Shackleton et al., 2015; Nightingale, 2017; Bhowmik et al., 2021; Rahut et al., 2021). Autonomous diversification in the absence of more equitable and harmonised efforts at regional and national scales to facilitate sustainable diversification can further skew development indicators at the subnational scale in favour of local elites, increased inequality, and environmental degradation (Ford et al., 2014; Wilson, 2014; Alobo Loison, 2015; Tanner et al., 2015; Gautam and Andersen, 2016; Baird and Hartter, 2017; Torell et al., 2017; Asfaw et al., 2018; Woodhouse and McCabe, 2018; Brown et al., 2019; Rosyida et al., 2019; Sani Ibrahim et al., 2019; Ojea et al., 2020; Salam and Bauer, 2020). Livelihood diversification can be facilitated in key technical areas (Shackleton et al., 2015; Brown et al., 2017; Schuhbauer et al., 2017) including regulatory frameworks (Butler et al., 2020) (limited but robust evidence), as well institutional support through funding and more localised research on interaction among and between enablers and barriers concerning specific local diversification options (Barrett, 2013; Herrero et al., 2016; Martin and Lorenzen, 2016; Sina et al., 2019) in the case of pastoral communities).

CCB FEASIB.3.3 Urban and infrastructure system transitions

CCB FEASIB.3.3.1 Sustainable land-use & urban planning

Urban planning is a medium feasibility option to support adaptation by prioritizing it in city plans, such as land-use planning, transportation (Liang et al., 2020), and health and social services (Carter et al., 2015; Araos et al., 2016b); by procuring the design and construction of resilient infrastructure; by promoting community-based adaptation through community-based design and implementation of adaptation activities (Archer, 2016); and by protecting and integrating biodiversity and ecosystem services into city planning. Research since SR 1.5 documents the challenging high costs of infrastructure (Georgeson et al., 2016; Woodruff et al., 2018); potential loss of municipal revenue in the case of managed retreat (Shi and Varuzzo, 2020; Siders and Keenan, 2020); and the fraught causal connection between planning and the reduction of socioeconomic vulnerability (Keenan et al., 2018; Anguelovski et al., 2019a; Elliott, 2019; Paganini, 2019; Shokry et al., 2020). However, adaptation benefits could potentially outweigh costs (Carey, 2020); the financial viability of green infrastructure (Meerow, 2019; Zhang et al., 2019; Van Oijstaeijen et al., 2020; Ossola and Lin, 2021); and availability of technical expertise, although the inequitable planning processes and distribution of those resources remains a significant concern (Serre and Heinzlef, 2018; Szewrański et al., 2018; Fitzgibbons and Mitchell, 2019; Hasan et al., 2019; Heikkinen et al., 2019; Colven, 2020; Goetz et al., 2020; Goh, 2020).

Structural disincentives and institutional arrangements create challenges for planning even where political willingness may be high (Di Gregorio et al., 2019; DuPuis and Greenberg, 2019; Shi, 2019; Zen et al., 2019; Rasmussen et al., 2020). Social resistance may significantly delay or block progress entirely, as vulnerable communities have responded negatively in cases adaptive urban and land-use planning leads to perceived "resilience gentrification" (Keenan et al., 2018; Anguelovski et al., 2019a), if residents do not perceive themselves as included in the crafting of plans (Araos, 2020; Rasmussen et al., 2020), if the options such as managed retreat are perceived as culturally unacceptable (Ajibade, 2019; Koslov, 2019; Siders, 2019), or if wealthier and advantaged residents benefit from planning at the expense of socially vulnerable groups (Chu and Michael, 2018; Chu et al., 2018; Fainstein, 2018; Rosenzweig et al., 2018; Pelling and Garschagen, 2019; Ranganathan and Bratman, 2021). Nonetheless, potential social co-benefits related to health and education are high (Raymond et al., 2017; Spaans and Waterhout, 2017; Klinenberg, 2018; Keeler et al., 2019; Meerow, 2019). Finally, the option is highly feasible in relation to ecological and geophysical characteristics, as urban and land-use planning's primary tool is to manipulate the built environment and natural spaces to protect and reduce the vulnerability of residents.

CCB FEASIB.3.3.2 Green infrastructure & ecosystem services

Urban green infrastructure and ecosystem services have high feasibility to support climate adaptation and mitigation efforts in cities, for example to reduce flood exposure and attenuate the urban heat island (Perrotti and Stremke, 2018; Belčáková et al., 2019; De la Sota et al., 2019; Stefanakis, 2019). While green infrastructure options are cost-effective and provide co-benefits in terms of ecosystem services such as improved air quality or other health benefits (Depietri and McPhearson, 2017; Morris et al., 2018; Reguero et al., 2018; Escobedo et al., 2019; Filazzola et al., 2019; Hewitt et al., 2020b; Venter et al., 2020; Nieuwenhuijsen, 2021) (*robust evidence, high agreement*), there remains a need for systematically assessing co-benefits, particularly for flood risk management (Alves, 2019 (Alves et al., 2019; Stefanakis, 2019) and sustainable material flow analysis (Perrotti and Stremke, 2018). Moreover, while once neglected, rapidly increasing attention has been paid to the equity and justice dimensions of planning and implementing green infrastructure initiatives, such as inclusion of citizens in decision-making or the allocation of benefits and impacts of projects (Anguelovski et al., 2019b; Buijs et al., 2019; Langemeyer et al., 2020; Venter et al., 2020)

Institutional barriers constrain the feasibility of urban green infrastructure (medium confidence), such as policy resistance to shift priorities from grey to green infrastructure (e.g. Johns 2019 in Canada) or siloed governance structures (Willems et al., 2021). Further social and political acceptability of green infrastructure is constrained by lack of confidence in efficacy (Thorne et al., 2018) or issues of accessibility (Biernacka and Kronenberg, 2018).

For flood management, a mix of green, blue and grey infrastructures are found effective with grey infrastructure reducing the risk of flooding and green infrastructure yielding multiple co-benefits (Alves et al., 2019; Gu et al., 2019; Webber et al., 2020) but catchment-wide solutions are advocated as the best performing strategy (Webber et al., 2020). Recognising and addressing a full range of ecosystem disturbances and disasters over a larger urban spatial scale (Vargas-Hernández and Zdunek-Wielgołaska, 2021) are crucial for planning green infrastructure based solutions. In some cases, low impact development interventions yield effective flood management outcomes but are adequate only for small flood peaks (Pour et al., 2020), with the major challenge being identifying best practices. Nature-based strategies (NBS) hold significant potential to achieve mitigation and adaptation goals in comparison to traditional approaches, but more research is necessary to understand their effectiveness, distribution, implementation at scale, cost-benefit and integration with spatial dimensions of planning (Davies et al., 2019; Dorst et al., 2019; Zwierzchowska et al., 2019; Hobbie and Grimm, 2020).

CCB FEASIB.3.3.3 Sustainable urban water management (blue infrastructure interventions e.g. lake/river restoration; rainwater harvesting)

Governments across scales can support urban sustainable water management with high feasibility by undertaking projects to recycle wastewater and runoff from worsening storms, with implications for decarbonization and adaptation. Green infrastructure, for example, has shown the high potential to reduce water use footprints and to save potable water for consumption (Liu and Jensen, 2018), and contributing to a "circular" water system in cities (Oral et al., 2020). Supportive governance can yield positive outcomes such as improved water security (Jensen and Nair, 2019); and there is *medium evidence* and *high agreement* that participation, such as involving informal settlement residents in water management can improve social inclusion (Pelling et al., 2018; Williams et al., 2018; Leigh and Lee, 2019; Sletto et al., 2019). Green infrastructure can support the planning of "sponge cities," such as in China, wherein large areas of green space, permeable surfaces, and sustainable water sourcing combine to purify urban runoff, attenuate peak runoff, and conserve water for consumption (Chan et al., 2018; Nguyen et al., 2019). Similar approaches in Dutch cities focus on designing and planning for the capturing, storing, and draining of storm water (Dai et al., 2018). Nonetheless, some interventions suffer from uncertainties in design, planning, and financing (Nguyen et al., 2019). As drought becomes more severe in some regions, physical barriers in the form of reduced availability of water may become pressing (Singh et al., 2021a)}.

Deployment of decentralised water management, through effective local governance frameworks, is an important water management strategy (Herslund and Mguni, 2019; Leigh and Lee, 2019) but in general, insufficient institutional learning and capacity is a critical barrier for the uptake of sustainable urban water management practices (Krueger et al., 2019; Adem Esmail and Suleiman, 2020). Transnational networks of cities for sharing best practices in water supply and storm runoff treatment also hold the potential to scale sustainable management (Feingold et al., 2018). In rapidly growing large urban areas, sustainable water management faces challenges of institutional heterogeneity (Chu et al., 2018), scalar mismatch; particularly between river basin and city scales (van den Brandeler et al., 2019) and equity and justice concerns (Chu et al., 2018; Pelling et al., 2018). Finally, assessing the vulnerability of urban water infrastructures at city-scale remains an important knowledge gap (Dong et al., 2020).

CCB FEASIB.3.4 Overarching adaptation options

CCB FEASIB.3.4.1 Social safety nets

Social safety nets meet development goals (e.g. poverty alleviation, accessible education and health services) and are increasingly being reconfigured to build adaptive capacities of the most vulnerable (Coirolo et al., 2013; Aleksandrova, 2020; Bowen et al., 2020; Fischer, 2020; Mueller et al., 2020). They include a range of policy and market-based instruments such as public works programmes and conditional or unconditional cash transfers, in-kind transfers; and insurance schemes (Centre, 2019; Aleksandrova, 2020). While there is *high evidence (medium agreement)* that social safety nets can build adaptive capacities, reduce socio-economic vulnerability, and reduce risk linked to hazards (Fischer, 2020; Mueller et al., 2020); macroeconomic, institutional, and regulatory barriers such as limited state resources, underdeveloped credit and insurance markets, and leakages constraint feasibility (Singh et al., 2018c; Hansen et al., 2019; Aleksandrova, 2020; Lykke Strøbech and Bordon Rosa, 2020). Social safety nets have strong co-benefits with development goals such as education, poverty alleviation, gender inclusion, and food security (Section 8.6) (Castells-Quintana et al., 2018; Ulrichs et al., 2019; Mueller et al., 2020) but these positive outcomes are constrained by inadequate regional inclusiveness (e.g. limited access in certain remote, rural areas - (Singh et al., 2018b; Aleksandrova, 2020; Lykke Strøbech and Bordon Rosa, 2020); or focus on rural areas overlooks urban vulnerable groups (Coirolo et al., 2013).

CCB FEASIB.3.4.2 Risk spreading and sharing

There is high confidence on risk spreading and sharing, most commonly arranged through insurance, as an adaptation option, but high to medium feasibility depending on context (e.g. developed vs. developing countries)Technological, economic, and institutional feasibility is high, as insurance can spread risk, provide a buffer against the impact of climate-hazards, support recovery and reduce the financial burden on governments, households, and businesses (Wolfrom and Yokoi-Arai, 2015; O'Hare et al., 2016; Glaas et al., 2017; Jenkins et al., 2017; Patel et al., 2017; Kousky et al., 2021). Insurance can shift the mobilization of financial resources away from ad hoc post-event payments, where funding is often unpredictable and delayed, towards more strategic approaches that are set up in advance of disastrous events (Surminski et al., 2016). By pricing risk, insurance can provide incentives for investments and behavior that reduce vulnerability and exposure (Linnerooth-Bayer and Hochrainer-Stigler, 2015; Shapiro, 2016; Jenkins et al., 2017). Socio-cultural barriers, such as social inclusiveness, socio-cultural acceptability and gender equity, constraints feasibility (Bageant and Barrett, 2017; Budhathoki et al., 2019). Insurance can provide disincentives for reducing risk through the transfer of the risk spatially and temporally; can distort incentives for adaptation strategies if the pricing is too low (moral hazard); is often unaffordable, poorly understood, and not widely utilized in developing nations even when subsidized; and can lead to maladaptation (García Romero and Molina, 2015; Joyette et al., 2015; Lashley and Warner, 2015; Jin et al., 2016; Müller et al., 2017; Tesselaar et al., 2020). Insurance can reinforce exposure and vulnerability through underwriting a return to the 'status-quo' rather than enabling adaptive behaviour (e.g. through 'no-betterment' principles) (Collier and Cox, 2021). (Surminski et al., 2016) raise concern that for low income nations and in the absence of global support, insurance shifts responsibility to those least responsible for climate change.

CCB FEASIB.3.4.3 Disaster risk management

There is robust evidence (high agreement) that DRM aids adaptation decision-making, particularly where it is demand-driven, context-specific and supported by strong institutions, good governance, strong local engagement, and trust across actors (Hasan et al., 2019; Kim and Marcouiller, 2020; Peng et al., 2020; Smucker et al., 2020; Uddin et al., 2020; Webb, 2020; Ali et al., 2021; Anderson and Renaud, 2021; Glantz and Pierce, 2021; Ji and Lee, 2021; Villeneuve, 2021). These conditions are rarely met, and therefore DRM is often constrained by institutional factors that may even increase vulnerability (Booth et al., 2020; Islam et

al., 2020a; Islam et al., 2020b; Marchezini, 2020; Goryushina, 2021; Mena and Hilhorst, 2021). The feasibility of DRM continues to be constrained by limited coordination across levels of government lack of transparency and accountability, poor communication, and a preference for top-down DRM processes that can undermine local institutions and perpetuate uneven power relationships (Atanga, 2020; Booth et al., 2020; Bordner et al., 2020; Bronen et al., 2020; Goryushina, 2021; Mena and Hilhorst, 2021; Son et al., 2021; Yumagulova et al., 2021). However, local integration of worldviews, belief systems and Local and Indigenous Knowledge into DRM activities improves feasibility (Bordner et al., 2020; Cuaton and Su, 2020; Hosen et al., 2020; Sharma and Sharma, 2021), including disability-inclusive and gender-focused DRM (Ruszczyk et al., 2020; Crawford et al., 2021). Data access and availability continues to challenge DRM despite advances in data analytics, especially in rapidly growing informal settlements, including population estimates and limited mobility data (Goniewicz and Burkle, 2019; Marchezini, 2020).
Moves towards community-based and ecosystem-based DRM are promising but uneven (Klein et al., 2019; Seebauer et al., 2019; Almutairi et al., 2020; Bordner et al., 2020; Hosen et al., 2020; Murti et al., 2020; Sharma and Sharma, 2021), and may increase vulnerability if they fail to address underlying, structural determinants of vulnerability, particularly among marginalised groups and by gender (Sections 8.4.4 and 8.4.5) (Seleka et al., 2017; Hossen et al., 2019; Ramalho, 2019; Atanga, 2020; Cuaton and Su, 2020; Gartrell et al., 2020; Kenney and Phibbs, 2020; Khalil et al., 2020; Ngin et al., 2020; Ruszczyk et al., 2020; Webb, 2020; Ali et al., 2021; Geekiyanage et al., 2021; Villeneuve, 2021).

CCB FEASIB.3.4.4 Climate services, including EWS

There is robust evidence (high agreement) that climate services aid adaptation decision-making and build adaptive capacity, particularly where they are demand-driven and context-specific (Vaughan et al., 2018; Bruno Soares and Buontempo, 2019; Daniels et al., 2020; Hewitt et al., 2020a; Findlater et al., 2021). Climate service interventions are constrained by low capacity, inadequate institutions, difficulties in maintaining systems beyond pilot project stage (Vincent et al., 2017; Tall et al., 2018; Bruno Soares and Buontempo, 2019), and poor mapping between climate services and existing user capacities and demands (Williams et al., 2020) (robust evidence, high agreement). Metrics to assess outcomes of climate services remain project-based and insufficiently capture longer-term economic and non-economic benefits of interventions (Tall et al., 2018; Parton et al., 2019; Perrels, 2020). The technical feasibility of climate services is relatively strong and growing (Vaughan et al., 2016; Kihila, 2017; Findlater et al., 2021) but they can be made more inclusive by focussing on addressing uneven uptake based on location or gender (Amegnaglo et al., 2017; Daly and Dessai, 2018; Tall et al., 2018; Alexander and Dessai, 2019; Vaughan et al., 2019; Gumucio et al., 2020) and a more balanced focus on uptake rather than data production alone (Dorward et al., 2021; Findlater et al., 2021) that values co-production and different knowledge systems (Daniels et al., 2020; Martínez-Barón et al., 2021).

CCB FEASIB.3.4.5 Population health and health systems

Climate change will exacerbate existing health challenges. Strong health systems can protect and promote the health of a population in the face of known and unexpected stressors and pressures (Watts et al., 2021), including climate change. The building blocks of strong health systems engender climate resilience, strong leadership and governance, and effective coordination across sectors, to prioritize the needs of the most vulnerable (Ebi et al., 2020). Options for enhancing current health services include providing access to safe water and sanitation, improving food security, enhancing access to essential services such as vaccinations, developing or strengthening integrated surveillance systems, and changing the timing and location of specific vector-control measures (WHO, 2015; Haines and Ebi, 2019). These measures can reduce the health system's vulnerability to climate change, especially if combined with iterative management that incorporates monitoring of (and resilience against) climate change impacts (Hanefeld et al., 2018; Haines and Ebi, 2019; Linares et al., 2020; Rudolph et al., 2020) (medium evidence, high agreement).

Health system can provide sufficient and high quality healthcare to all where capacity is well-developed, and where options are aligned with national priorities, engage local to international communities, and address the needs of particularly vulnerable regions and population groups (Hanefeld et al., 2018; Austin et al., 2019; Nuzzo et al., 2019; Sheehan and Fox, 2020). Microeconomic feasibility and socio-economic vulnerability reduction potential are high where a system's capacity is well-developed. Macroeconomic feasibility poses a significant challenge in low income settings, with many governments projected to require international climate finance for health systems which is not currently available (WHO, 2019; Watts et al., 2021), and where adequate household-level financial security is a cross-cutting barrier (Paudel and Pant, 2020). Risk mitigation potential is high where capacity is well developed, for example through technologies to monitor and alter environmental conditions (Lock-Wah-Hoon et al., 2020; Kouis et al., 2021; Ligsay et al., 2021). Social co-benefits of mainstreaming health and climate change are also present, such as the inclusion of environmental health in medical education curricula training programmes (Kligler et al., 2021). There is growing recognition that lack of institutional capacity and low availability of resources represent major barriers to health system adaptation options, particularly for health systems struggling to manage current health risks (Ebi et al., 2018; Brooke-Sumner et al., 2019; Chersich and Wright, 2019; Gilfillan, 2019; Negev et al., 2019; Hussey and Arku, 2020), for neglected populations (Hanefeld et al., 2018; Negev et al., 2019), and where there are conflicting mandates or poor coordination across ministries (Austin et al., 2019; Fox et al., 2019; Gilfillan, 2019; Kendrovski and Schmoll, 2019; Sheehan and Fox, 2020). Barriers to adapting health systems to climate change include lack of institutional funding, staff, and data access (Austin et al., 2019; Schramm et al., 2020; Opoku et al., 2021), inadequate resources for evaluation and management of adaptation (Pascal et al., 2021), competing stakeholder goals, and costly technology (Negev et al., 2021). Within the healthcare community, surveillance systems generally lack ways to integrate climate observation data, as well as expertise to critically evaluate these data, limiting their ability to plan and prepare for climate hazards and hospital-associated vulnerabilities (Runkle et al., 2018; Chersich and Wright, 2019; Liao et al., 2019). Although understanding on health vulnerability is growing (Berry et al., 2018), knowledge on the health effects of climate change among health practitioners remains limited (Ebi et al., 2018; Brooke-Sumner et al., 2019; Chersich and Wright, 2019; Fox et al., 2019; Liao et al., 2019; Albright et al., 2020). Mechanisms to ensure transparency and accountability of implementing, monitoring, and evaluating adaptation within the health sector are lacking, across scales and contexts (Gostin and Friedman, 2017; Huynh and Stringer, 2018; Parry et al., 2019).

CCB FEASIB.3.4.6 Human migration and displacement

Much climate-related migration is associated with labour migration. Rural-urban migrant networks are important channels for remittances and knowledge that help build resilience to hazards in sending areas (Bragg et al., 2018; Obokata and Veronis, 2018; Semenza and Ebi, 2019; Maharjan et al., 2020; Porst et al., 2020). Whether migration reduces vulnerability for migrants depends on levels of control over the migration decision and assets such as wealth education of the migrant household (Thober et al., 2018; Cattaneo, 2019; Hoffmann et al., 2020; Maharjan et al., 2020; Sedova and Kalkuhl, 2020). Individuals from households of all levels of wealth migrate. However, poorer households do so with lower levels of choice and often more likely under duress, and in these cases migration can undermine wellbeing (Suckall et al., 2016; Mallick et al., 2017; Nawrotzki and DeWaard, 2018; Natarajan et al., 2019). In some cases, migration can increase poverty in sending communities (Jacobson et al., 2019).Women in the sending community can experience an increase or decrease in the vulnerability depending on context (Banerjee et al., 2018; Banerjee et al., 2019; Goodrich et al., 2019; Maharjan et al., 2020; Rao et al., 2020; Singh and Basu, 2020; Singh et al., 2020b). Migration has been highly politicised, and climate-related immigration has been conceptualised in public and media discourse as a potential threat which limit adaptation feasibility (Telford, 2018; Honarmand Ebrahimi and Ossewaarde, 2019; McLeman, 2019; Wiegel et al., 2019; Hauer et al., 2020). Existing international agreements provide potential frameworks for climate-related migration to benefit adaptive capacity and sustainable development (Warner, 2018; Kälin, 2019). However, agreements to facilitate temporary or circular migration and remittances are often informal and limited in scope (Webber and Donner, 2017; Margaret and Matias, 2020) and migrant receiving areas, particularly urban areas, can be better assisted to prepare for population change (Deshpande et al., 2019; Adger et al., 2020; Hauer et al., 2020). Policies and planning are lacking that would ensure that positive migration outcomes for sending and receiving areas and the migrants themselves (Wrathall et al., 2019; Adger et al., 2020; de Salles Cavedon-Capdeville et al., 2020; Hughes, 2020).

Investing in building in situ adaptive capacity through climate resilient development is a precondition to supporting high agency migration (). Migration only tends to occur when adaptation in situ has been exhausted and thresholds for living with risk have been crossed (Sections 8.2.2.1, 8.4.4, 8.4.5) (McLeman, 2018; Adams and Kay, 2019; Semenza and Ebi, 2019). The financial, emotional and social costs of leaving are high (Adams and Kay, 2019; McNamara et al., 2021), there are environmental, health and wellbeing risks in destination areas (Schwerdtle et al., 2018; Schwerdtle et al., 2020) and existential threats to identity and citizenship (Oakes, 2019; Piguet, 2019; Desai et al., 2021). In receiving areas, without appropriate policies to ensure equitable provision of services, there can be socio-cultural barriers to in-migration where there is the perception of a loss caused by new arrivals, although outcomes are mixed (Koubi et al., 2018; Linke et al., 2018; Spilker et al., 2020; Petrova, 2021).

CCB FEASIB.3.4.7 Planned relocation and resettlement

Few climate-related planned resettlement and relocation initiatives have taken place. However, initial findings, and experience from past development and disaster-related resettlement programmes, show that when implemented in a top-down manner and without the full participation of those affected, resettlement increases vulnerability by undermining livelihoods, negatively impacting health, community cohesion and emotional and psychological wellbeing (Wilmsen and Webber, 2015; Dannenberg et al., 2019; Piggott-McKellar et al., 2019; Tabe, 2019; Ajibade et al., 2020; Henrique and Tschakert, 2020; Desai et al., 2021). Planned relocation could also redistribute vulnerability for those who do not move (Thomas and Benjamin, 2018; Mach et al., 2019; Piggott-McKellar et al., 2019; Johnson et al., 2021; Maldonado et al., 2021) and vulnerability generally is reproduced along existing social cleavages often worsening inequality (See and Wilmsen, 2020). Approaches that foreground participation; non-material and socio-cultural factors, livelihoods, and local power dynamics can be addressed and adjusted to prevent planned relocation from reproducing inequality (See and Wilmsen, 2020; Alverio et al., 2021).

There is inadequate institutional capacity to enable movement relocation with global and national policies identified as too abstract and lacking guidance on ensuring equity (Mortreux et al., 2018; Kelman et al., 2019; Ajibade et al., 2020; Hauer et al., 2020; Alverio et al., 2021). Lack of institutional capacity can lead to resettlements being stalled indefinitely. Climate-related resettlement can be facilitated by novel institutional structures that expand the definition of disaster to include slow onset events, adaptive management frameworks that facilitate a continuum of responses from supporting communities to community relocation and approaches that incorporate existing power dynamics (Bronen and Chapin, 2013; See and Wilmsen, 2020). In 2018, the Fiji Government provided a framework for climate change related relocation and equipped communities with rights in the planned relocation process (McMichael and Katonivualiku, 2020). However, even with guidelines in place, local socio-cultural dynamics complicate planning, and relocation should take place only after cost-benefit analysis of all available adaptation options (Jolliffe, 2016).(Bronen and Chapin, 2013; Albert et al., 2017; Mortreux et al., 2018). At a local level, issues around land tenure, a lack of financial support, dedicated governance frameworks and complex planning processes delay action (Albert et al., 2017). Funding for climate-related resettlement is currently not readily available, exacerbated by a lack of appropriate mechanisms through which to deliver that funding (Boston et al., 2021). For example, planned relocation projects cannot access disaster relief funds in the US because of the slow onset nature of the impacts (Bronen and Chapin, 2013).

Without consultation relocated people can experience significant financial and emotional distress as cultural and spiritual bonds to place and livelihoods are disrupted (Neef et al., 2018; Roy et al., 2018; Piggott-McKellar et al., 2019; Bertana, 2020; McMichael and Katonivualiku, 2020; McMichael et al., 2021) - However, in some places, where climate risks are acute, political acceptance for planned relocation is high (e.g. (McNamara, 2015; Roy et al., 2018) in Kiribati). Socio-cultural feasibility can be improved by participatory approaches, and where possible, moving within ancestral lands (McNamara, 2015). In this case, voluntary planned relocation can represent the assertion of people living in an area to preserve land and community-based social, cultural and spiritual ties.

A summary of feasible options to enable four 1.5C-relevant system transitions is presented in Figure Cross-Chapter Box FEASIB.2.

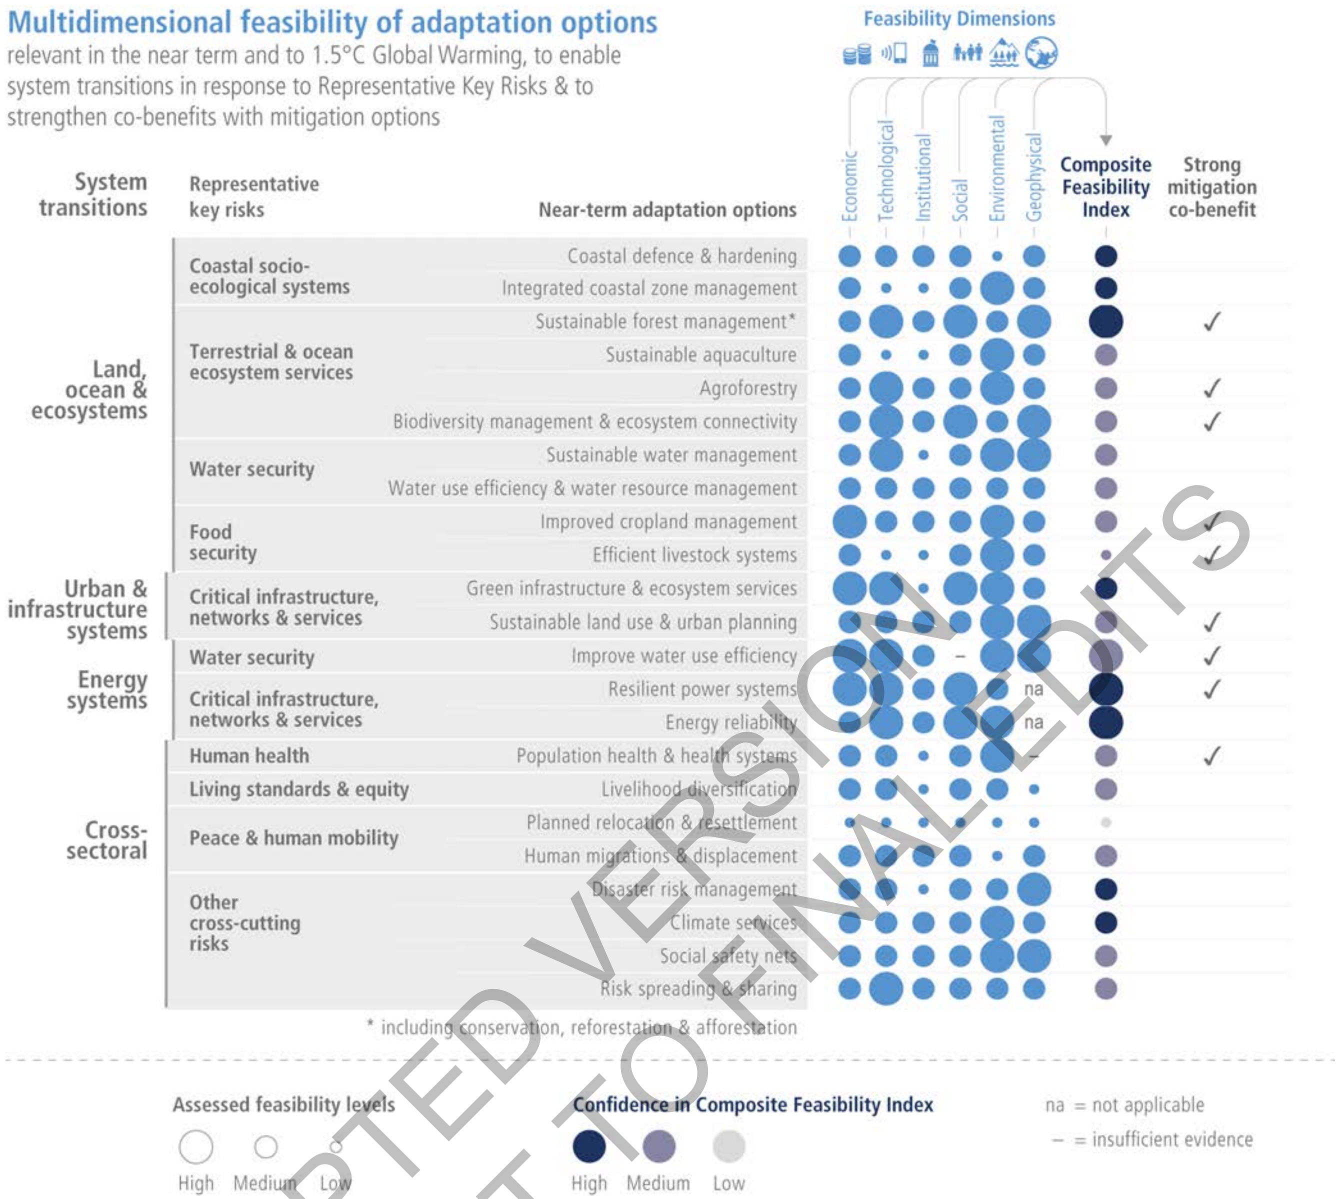

Figure Cross-Chapter Box FEASIB.2: Multi-dimensional feasibility.

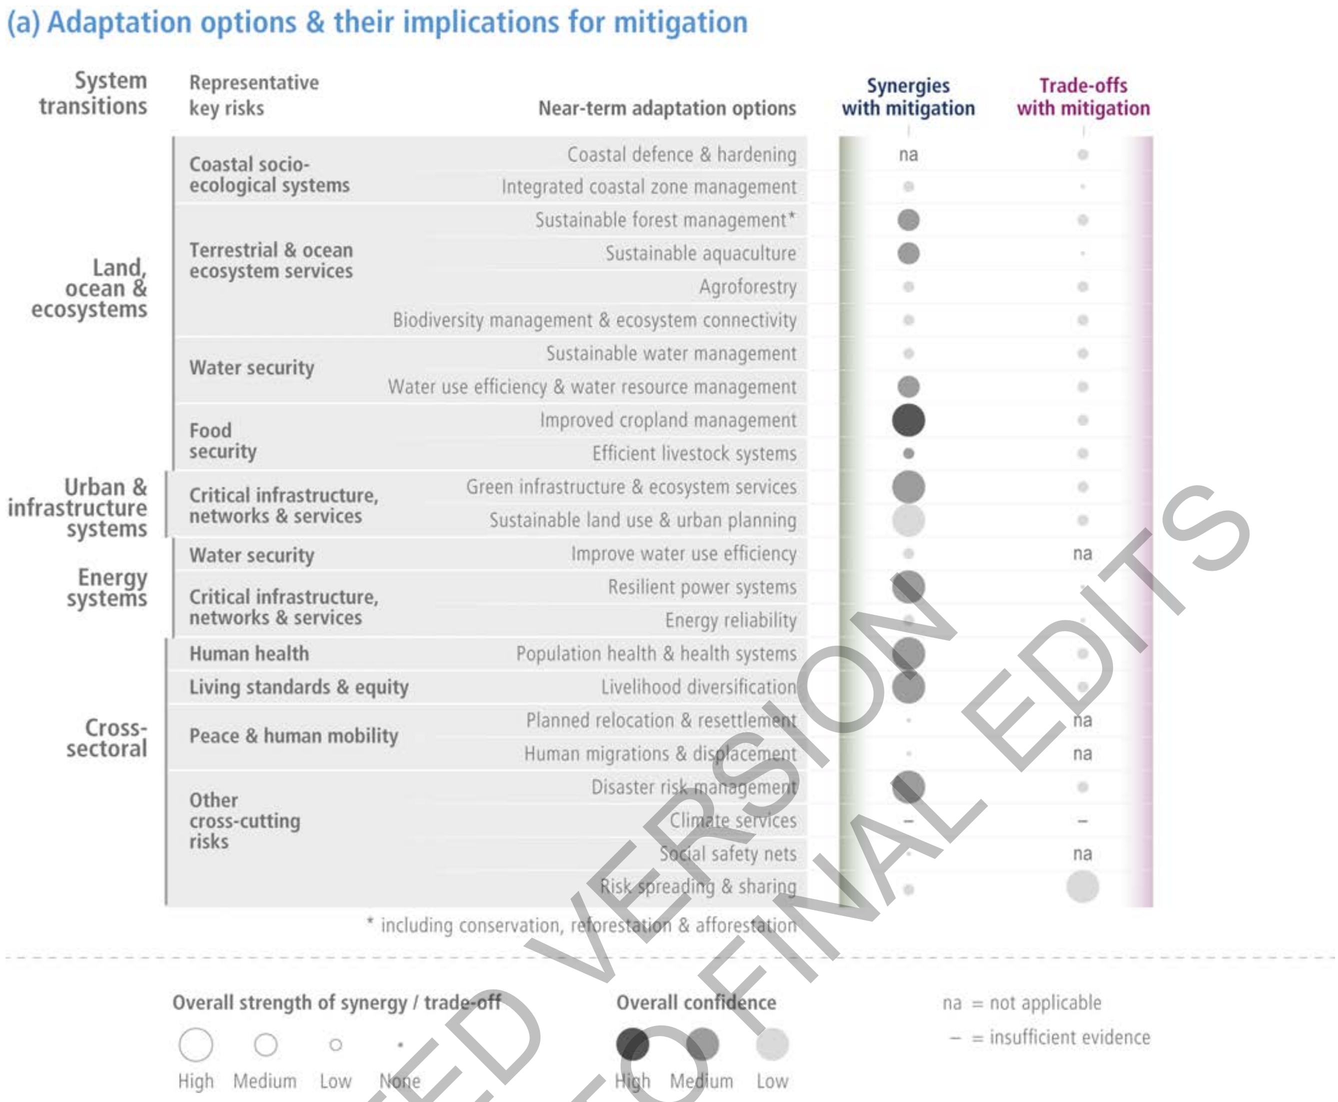
CCB FEASIB.4 Synergies and Trade-offs

The feasibility assessment focuses on individual options. However, systems transitions necessitate assessing how mitigation and adaptation options *interact* to mediate overall feasibility. To capture these linkages, this section reports synergies and trade-offs of a) adaptation options for mitigation, and b) mitigation options for adaptation (following (de Coninck et al., 2018) as outcome of an iterative assessment between WG2 and WG3 authors. Also assessed are synergies and tradeoffs of adaptation with the SDGs following (Roy et al., 2018) (which was done for mitigation alone).



(a) Adaptation options & their implications for mitigation
System transitions
Representative key risks
Near-term adaptation options
Synergies with mitigation
Trade-offs with mitigation
Land, ocean & ecosystems
Coastal socio-ecological systems
Coastal defence & hardening
Integrated coastal zone management
Terrestrial & ocean ecosystem services
Sustainable forest management*
Sustainable aquaculture
Agroforestry
Biodiversity management & ecosystem connectivity
Water security
Sustainable water management
Water use efficiency & water resource management
Food security
Improved cropland management
Efficient livestock systems
Urban & infrastructure systems
Critical infrastructure, networks & services
Green infrastructure & ecosystem services
Sustainable land use & urban planning
Energy systems
Water security
Improve water use efficiency
Critical infrastructure, networks & services
Resilient power systems
Energy reliability
Cross-sectoral
Human health
Population health & health systems
Living standards & equity
Livelihood diversification
Peace & human mobility
Planned relocation & resettlement
Human migrations & displacement
Other cross-cutting risks
Disaster risk management
Climate services
Social safety nets
Risk spreading & sharing

Figure Cross-Chapter Box FEASIB.3: Synergies and trade-offs. This figure shows a) adaptation options synergies and trade-offs with mitigation and b) mitigation options synergies and trade-offs with adaptation. The size of the circle denotes the strength of the synergy or trade-offs with big circles meaning strong synergy or trade-off and small circles denoting a weak synergy or trade-off.

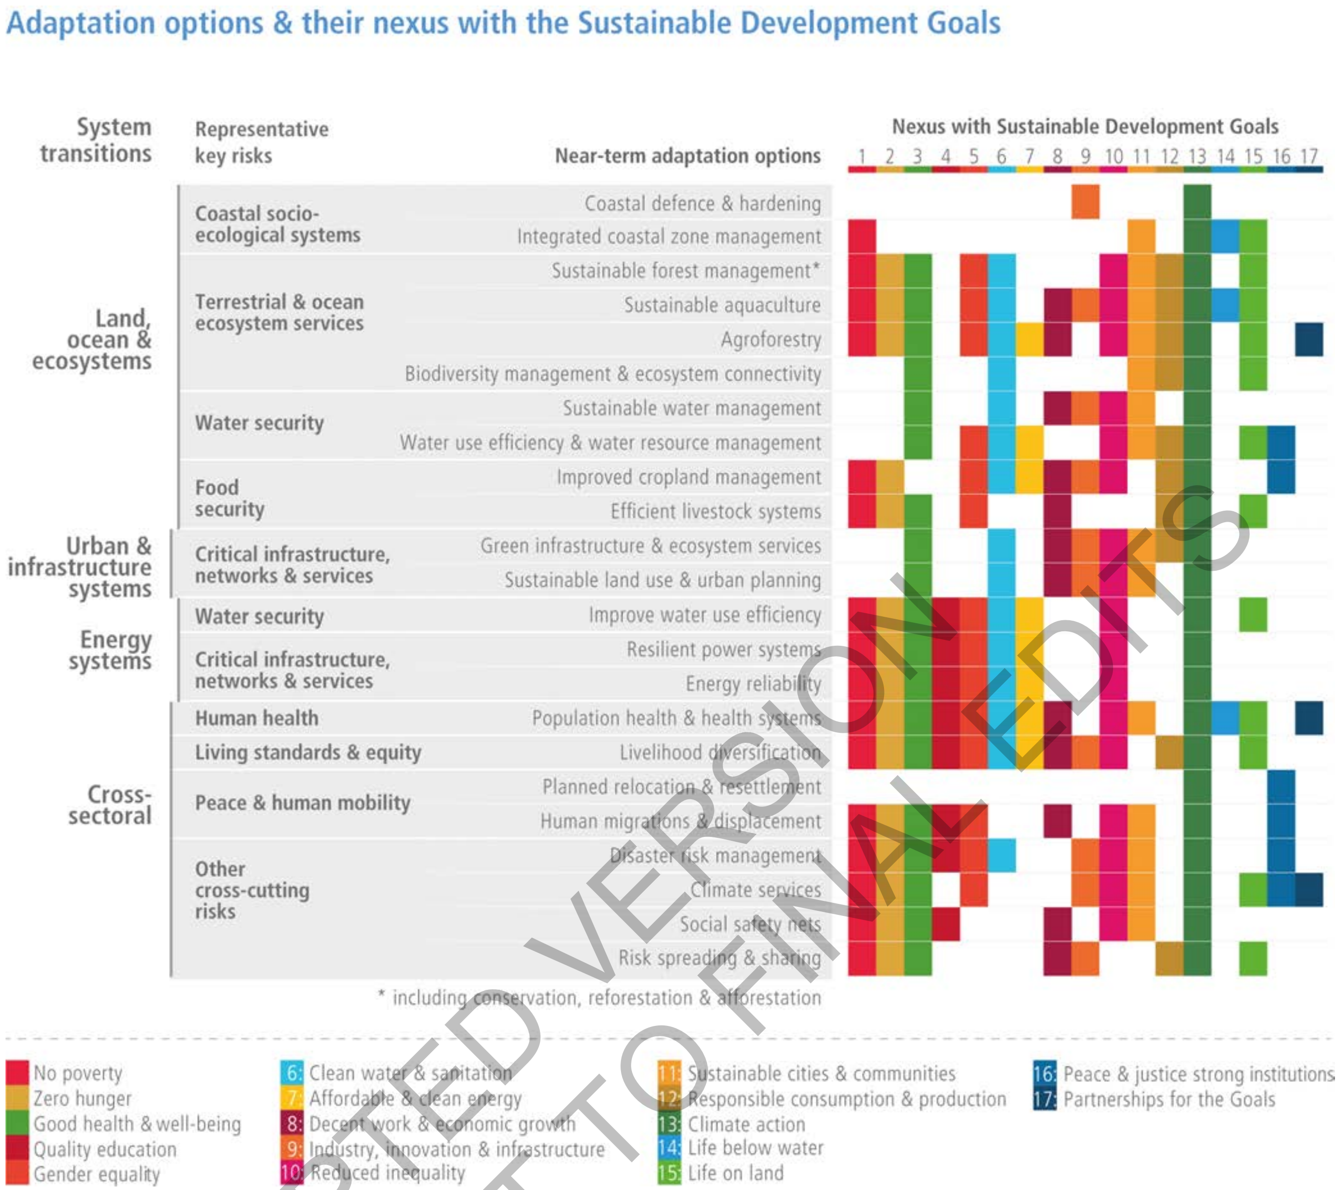

Figure Cross-Chapter Box FEASIB.4: Adaptation options and their nexus with the Sustainable Development Goals.

CCB FEASIB.5 Knowledge Gaps

Despite the progress in new evidence since the SR1.5, there remain several knowledge gaps for the assessment of adaptation and mitigation options. They are found within the Figure Cross-Chapter Box FEASIB.2 through the NE (no evidence) or LE (low evidence).

Within energy system transitions, resilient power infrastructure has knowledge gaps on indicators of transparency and accountability potential, socio-cultural acceptability, social and regional inclusiveness and intergenerational equity.

Under land and ecosystem system transitions, gaps include limited evidence for some of the institutional and socio-cultural feasibility dimensions indicators of Integrated Coastal Zone Management. Specifically, there is lack of evidence for transparency and accountability potential and for gender and intergenerational equity. For coastal defense and hardening, there is no or limited evidence on the indicators of employment and productivity enhancement, legal and regulatory acceptability, transparency and accountability potential, social and regional inclusiveness, benefits for gender equity, intergenerational equity and land use change enhancement potential. Sustainable aquaculture has knowledge gaps for the indicators of macroeconomic viability, legal and regulatory acceptability, transparency and accountability potential, social and regional inclusiveness, intergenerational equity and land use change enhancement potential. The geographical feasibility for migration and relocation is still an emerging area of research, however, there is limited evidence to assess this specific dimension.

The option of reforestation, afforestation, protection of forests and wild areas and their resources, biodiversity management and conservation has knowledge gaps for the indicators of risk mitigation potential, legal and regulatory feasibility and social and regional inclusiveness. The option of improved cropland management has no or limited evidence for the indicators of legal and regulatory feasibility, transparency and accountability potential and hazard risk reduction potential. Efficient livestock systems has no evidence for political acceptability and legal and regulatory feasibility and limited evidence for overall institutional feasibility. Agroforestry has knowledge gaps for employment and productivity enhancement, transparency and accountability potential and intergenerational equity. There is also limited evidence for the economic and technical feasibility dimensions for ecosystem connectivity.

For urban and infrastructure systems, the option of green infrastructure and ecosystem services has limited evidence for macroeconomic viability, employment and productivity enhancement and political acceptability. Sustainable water management has gaps for macroeconomic viability, employment and productivity enhancement, and transparency and accountability potential.

For overarching options, the main knowledge gaps identified are socio-cultural acceptability for social safety nets. While the evidence on resettlement, relocation and migration is large and growing, there is disagreement on several indicators, marking the need for more evidence synthesis. Geophysical feasibility for resettlement, relocation and migration has limited evidence, but is an emerging area of research.

In general, throughout most of the options, there is significantly less literature from the regions of Central and South America and West and Central Asia, as compared to other world regions.

Executive Summary

Geographic areas that are exceptionally rich in species, ecologically distinct and/or show high endemism (species occurring in that defined geographic area and nowhere else), are broadly recognised as biodiversity hotspots and prioritised for conservation. Here, we assess the impacts and vulnerability to climate change of terrestrial, freshwater and marine regions considered to be biodiversity hotspots. {CCP1.1}

Species in biodiversity hotspots already show changes in response to climate change (*high confidence*[1]). The animal and plant species assessed have been shifting their geographic ranges from low to high latitudes in response to climate warming on land and in the ocean (*very high confidence*). On land, climate change-induced shifts towards higher elevations are also common in biodiversity hotspots (*high confidence*); while in the ocean climate-induced shifts to greater water depths are little studied. In the ocean, abrupt mortality of habitat-forming species on coral reefs and kelp forests, especially following heatwaves, are increasing in frequency in biodiversity hotspots (*high confidence*). {CCP1.2.1, 1.2.2, 1.2.4}

All biodiversity hotspots are impacted, to differing degrees, by human activities (*very high confidence*), Climate change impacts are compounded by other anthropogenic impacts, including habitat loss and fragmentation, hunting, fishing and its bycatch, over-exploitation, water abstraction, nutrient enrichment, pollution, human introduction of invasive species, pests and diseases, all of which reduce climate resilience (*very high confidence*), complicating the attribution of observed changes to climate change. {CCP1.2.1}

Observed climate velocities are approximately 20% lower inside than outside of terrestrial and freshwater biodiversity hotspots, but 69% higher inside than outside marine hotspots (*high confidence*). In spite of the lower climate velocities inside terrestrial hotspots, these areas are projected not to serve as effective climate refugia from the effects of global warming, especially for endemic species (unique to a hotspot) (*medium confidence*). The greater climate velocities inside marine hotspots exposes their species to greater climate-induced pressures inside than outside hotspots (*high confidence*). The differences between temperatures inside and outside of hotspots narrow with increasing warming (*medium confidence*). {CCP1.2.2}

The risk of species extinction increases with warming in all climate change projections for native species studied in hotspots (*high confidence*), being about ten-times greater for endemic species from 1.5°C to 3°C above pre-industrial levels (*medium confidence*). Of the 6,116 projections for more than 2,700 species assessed in biodiversity hotspots, ~44% were found to be at high extinction risk, and ~24% at very high extinction risk due to climate change (*medium confidence*). Very high extinction risk in biodiversity hotspots due to climate change is more common for endemic species than other native species (*high confidence*). For these endemic species, considering all scenarios and time periods evaluated, ~100% on islands, ~84% on mountains, ~12% on continents (*high confidence*) and ~54% in the ocean (notably the Mediterranean) (*low confidence*) are projected to be threatened with extinction due to climate change. With further warming, increasingly high risks of local and global extinctions are projected in biodiversity hotspots from climate-related stressors (*high confidence*). {CCP1.2.1, Figure CCP1.7, Figure CCP1.6}

Adaptation options could enhance the persistence of biodiversity in hotspots (*high confidence*). Noting that over 3 billion people live within biodiversity hotspots, reduction of existing (non-climatic) pressures due to human activities is critical for building resilience within hotspots. Adaptation options for biodiversity (e.g., expanding fully protected areas, restoration and sustainable use practices) are as applicable inside as outside biodiversity hotspots (*high confidence*). Nevertheless, the protection of biodiversity hotspots is key to prevent a substantial global biodiversity decline from climate change {CCP 1.3, Table CCP1.2, 2.6, 3.6, Cross-Chapter Box NATURAL in Chapter 2}.

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

CCP1.1 Point of Departure

Biodiversity hotspots are geographic areas with an exceptionally high richness of species, including rare and endemic species. Such hotspots have deep evolutionary roots and are concentrated in areas where past climatic variability was moderate (Enquist et al., 2019; Brown et al., 2020; Trew and Maclean, 2021). An important limitation of the biodiversity hotspot concept is that there may be species highly threatened with extinction which do not occur within what has traditionally been classified as a hotspot (Grenyer et al., 2006). Thus, biodiversity hotspot assessments need to be paralleled by assessments of highly endangered species, and the threats they face.

Many studies have proposed biodiversity hotspots based on different criteria, taxa and geographic contexts (e.g., Myers et al., 2000; Mittermeier et al., 2004; Mittermeier et al., 2011; Williams et al., 2011; Noss et al., 2015; Asaad et al., 2017). A coherent comparative assessment of all such schemes is beyond the scope of this chapter but is provided in recent reviews (Asaad et al., 2017; Jefferson and Costello, 2019). We base this assessment on the "WWF Global 200" areas of conservation importance (Olson and Dinerstein, 2002). These 238 ecoregions have been used in a previous climate risk assessment (Warren et al., 2018b) and cover terrestrial, freshwater and marine environments (Table CCP1.1, Figures CCP1.1, CCP1.2). In addition we included the terrestrial "biodiversity hotspots" as defined by Myers et al. (2000) and extended later (Table CCP1.1; Mittermeier et al., 2011; Williams et al., 2011; Noss et al., 2015). This assessment thus covers the "Global 200" (hereafter G200) and "Myers" biodiversity hotspots rather than particular species or ecological systems such as rainforests, coral reefs or the deep sea. Such systems are assessed in Chapters 2 and 3. Chapters 2 and 3 also cover observed and projected impacts, changes in ecosystem functioning, and species extinction risks at a global level.

Biodiversity hotspots have not been explicitly covered in the Fifth Assessment Report (IPCC, 2014) (hereafter AR5). Thus, the point of departure is AR4 (Parry et al., 2007), which assessed that climate change exacerbates biodiversity risks in hotspots and that 15-40% of endemic species (species only occurring in one region) were projected to become extinct at 3.5°C global warming (Fischlin et al., 2007). Risks of extinction are assessed using the guidelines in Chapter 2, with species projected to lose 80% of its range or abundance being classified as at very high risk of extinction and those projected to lose 50% being at high risk of extinction (Chapter 2, Fig. 2.8 for definitions and a global overview).

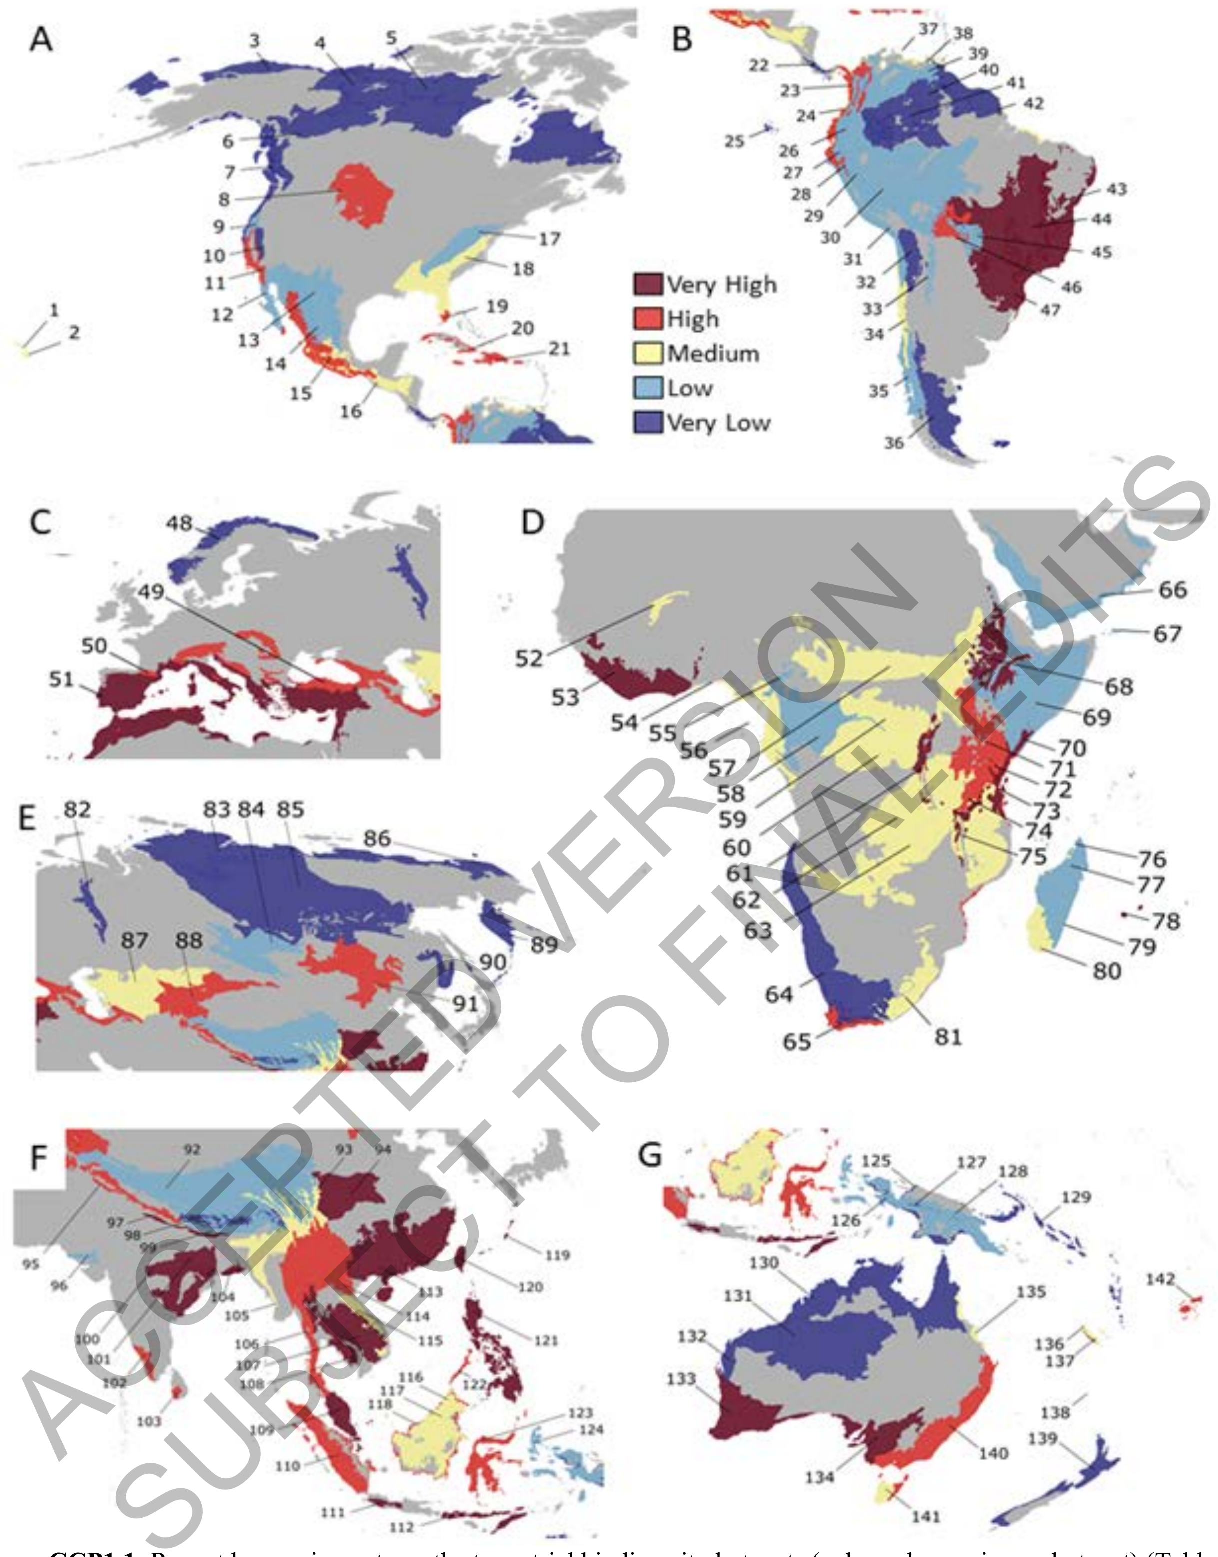

Figure CCP1.1: Recent human impacts on the terrestrial biodiversity hotspots (coloured, grey is non hotspot) (Table SMCCP1.1). Impacts are scaled in five equal 20% categories. A, North and Central America, B, South America, ,C, Europe and North Africa, ,D, Africa and Arabia, E, North Asia, ,F, Southeast Asia, G, Southeast Asian archipelagos, Australia and New Zealand. See Table CCP1.1 for key to hotspot numbers.

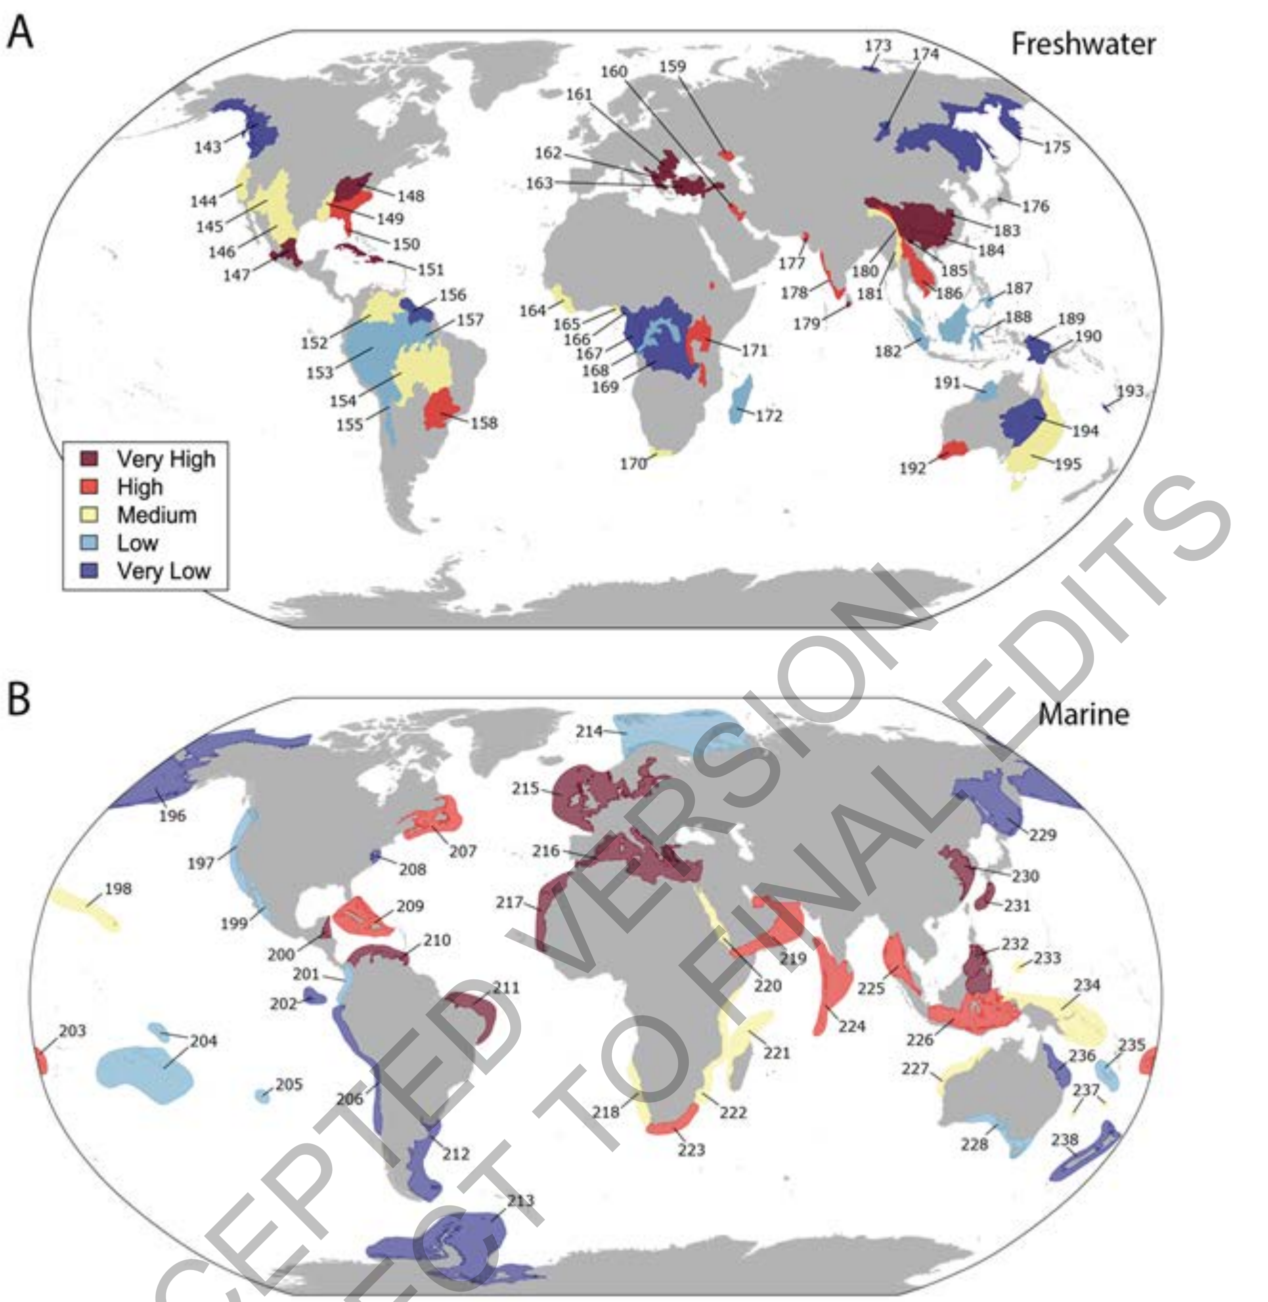

Figure CCP1.2: Recent human impacts from multiple factors on (A) freshwater hotspots since 2000 based on Janse et al. (2015) and (B) marine hotspots based on Halpern et al. (2015). Human impacts in terrestrial and freshwater habitats refer to the remaining wilderness. Marine impacts represent land-based, fishing, climate change and ocean-based stressors. Impacts are scaled into five equal 20% categories. See Table CCP1.1 for the key to hotspot numbers.

Table CCP1.1: List of biodiversity hotspots names from (Olson and Dinerstein, 2002) as mapped in Figures CCP1.1 (terrestrial, black text) and CCP1.2 (freshwater and marine in green and blue text respectively). Hotspots containing islands (> 100km2) are indicated with an asterisk.

CCP1.2 Assessment

Specific hotspot numbers (H) are indicated in this chapter text to aid their identification in Table CCP1.1 and Figures CCP1.1 and CCP1.2.

CCP1.2.1 Global Perspective

CCP1.2.1.1 Observed Impacts

CCP1.2.1.1.1 Observed climatic hazards

Terrestrial and freshwater hotspots have been warming less over the last 50 years than non-hotspot areas, whereas marine hotspots have been warming more (Kocsis et al., 2021). The warming inside terrestrial hotspots is 0.91°C (Myers) and 1.04°C (G200), respectively, while for freshwater hotspots it is 0.89°C, compared to a +1.08°C warming outside (Kocsis et al., 2021). In contrast, mean annual sea surface temperatures in the G200 marine biodiversity hotspots have warmed 41% more than the regions outside (0.53 *vs* 0.38°C) (Kocsis et al., 2021). Thus, terrestrial biodiversity hotspots have been warming slightly less, and marine hotspots considerably more than non-hotspots (*medium confidence*).

Climate velocity, the direction and pace of movement in climate variables (typically temperature) in space, is key to understanding the origin and fate of biodiversity hotspots under climate change (Loarie et al., 2009; Burrows et al., 2011). Climate trajectories generally predict the direction and pace of past and future species range shifts (Pinsky et al., 2013; Brito-Morales et al., 2018) although there are exceptions (Fuchs et al., 2020). Spatial patterns of climate trajectories show regions where species are expected to leave, pass through, and/or arrive under climate change (Burrows et al., 2014). Regions of high climate velocities are those with low topographic relief on land, particularly flooded grasslands and deserts (Loarie et al., 2009), and tropical as well as offshore and polar sea regions (Burrows et al., 2011; Burrows et al., 2014; García Molinos et al., 2016; Brito-Morales et al., 2018; Brito-Morales et al., 2020).

On millennial time scales, some areas of low climate velocity have more endemic species and can be considered climate refugia, at least on land (Sandel et al., 2011) and, for marine species, around Antarctica (H213) (Costello et al., 2010). This suggests that if these areas are subject to increased velocities they may lose species which may not be able to disperse fast enough to cope with the pace of climate change (*medium confidence*) (Sandel et al., 2011; Brito-Morales et al., 2018).

Climate velocities are 47% (Myers), 29% (G200, terrestrial) and 10% (G200, freshwater) lower inside than outside biodiversity hotspots, respectively (Kocsis et al., 2021), but are 69% higher inside marine hotspots than outside (*medium confidence*). Climate velocities from 1970 to 2019 ranged from 3-4 km/decade (terrestrial and freshwater) to ~11 km/decade in marine (Kocsis et al., 2021).

For terrestrial and freshwater hotspots, the highest climate velocities are in central South America, including the Amazon (H153, 154) (Figure CCP1.3). Terrestrial hotspots also have high velocities in the Arctic (H196, 214) and east of the Caspian Sea, while freshwater hotspots have low velocities in eastern European Mediterranean and eastern Australia.

Marine hotspots have a wider range of climate velocities than terrestrial and freshwater environments (Figure CCP1.3), being faster in equatorial, Mediterranean (H216), Baltic (H215), North and Okhotsk (H229), and Arctic hotspots (H196, 214), and slow in the Antarctic hotspot (H213). Marine species tend to follow climate velocities more closely than terrestrial species (*high confidence*) (Sunday et al., 2012; Pinsky et al., 2019; Lenoir et al., 2020). The reasons may be smaller thermal safety margins in the seas or greater human impacts on land impeding species range shifts. Climate velocities are particularly fast in equatorial seas (Figure CCP1.3; Burrows et al., 2011), which are therefore expected to be source areas for species shifting their ranges towards the subtropics (Burrows et al., 2014). The subtropics are then source areas of species that shift to temperate latitudes and so forth, such that observed impacts in marine biodiversity hotspots are largely attributable to species range shifts (*high confidence*) (Pecl et al., 2017). Because marine climate velocities are significantly greater within than outside hotspots, marine hotspots are especially prone to species redistributions (*medium confidence*) (Figure CCP1.3; Kocsis et al., 2021).

While species from lower latitudes may shift their geographic ranges into higher latitudes to adapt to changing climate, there are no species to replace low latitude species. Thus, as already observed in the oceans around the equator, the loss of species in low latitudes will continue with future climate warming (*high confidence*) (Yasuhara et al., 2020; Chaudhary et al., 2021). The issue also extends to altitudinal ranges in terrestrial environments, with species moving to higher elevations where surface area generally declines with increasing elevation, and mountaintop species may have nowhere to go (Flousek et al., 2015; Freeman et al., 2018; Kidane et al., 2019).

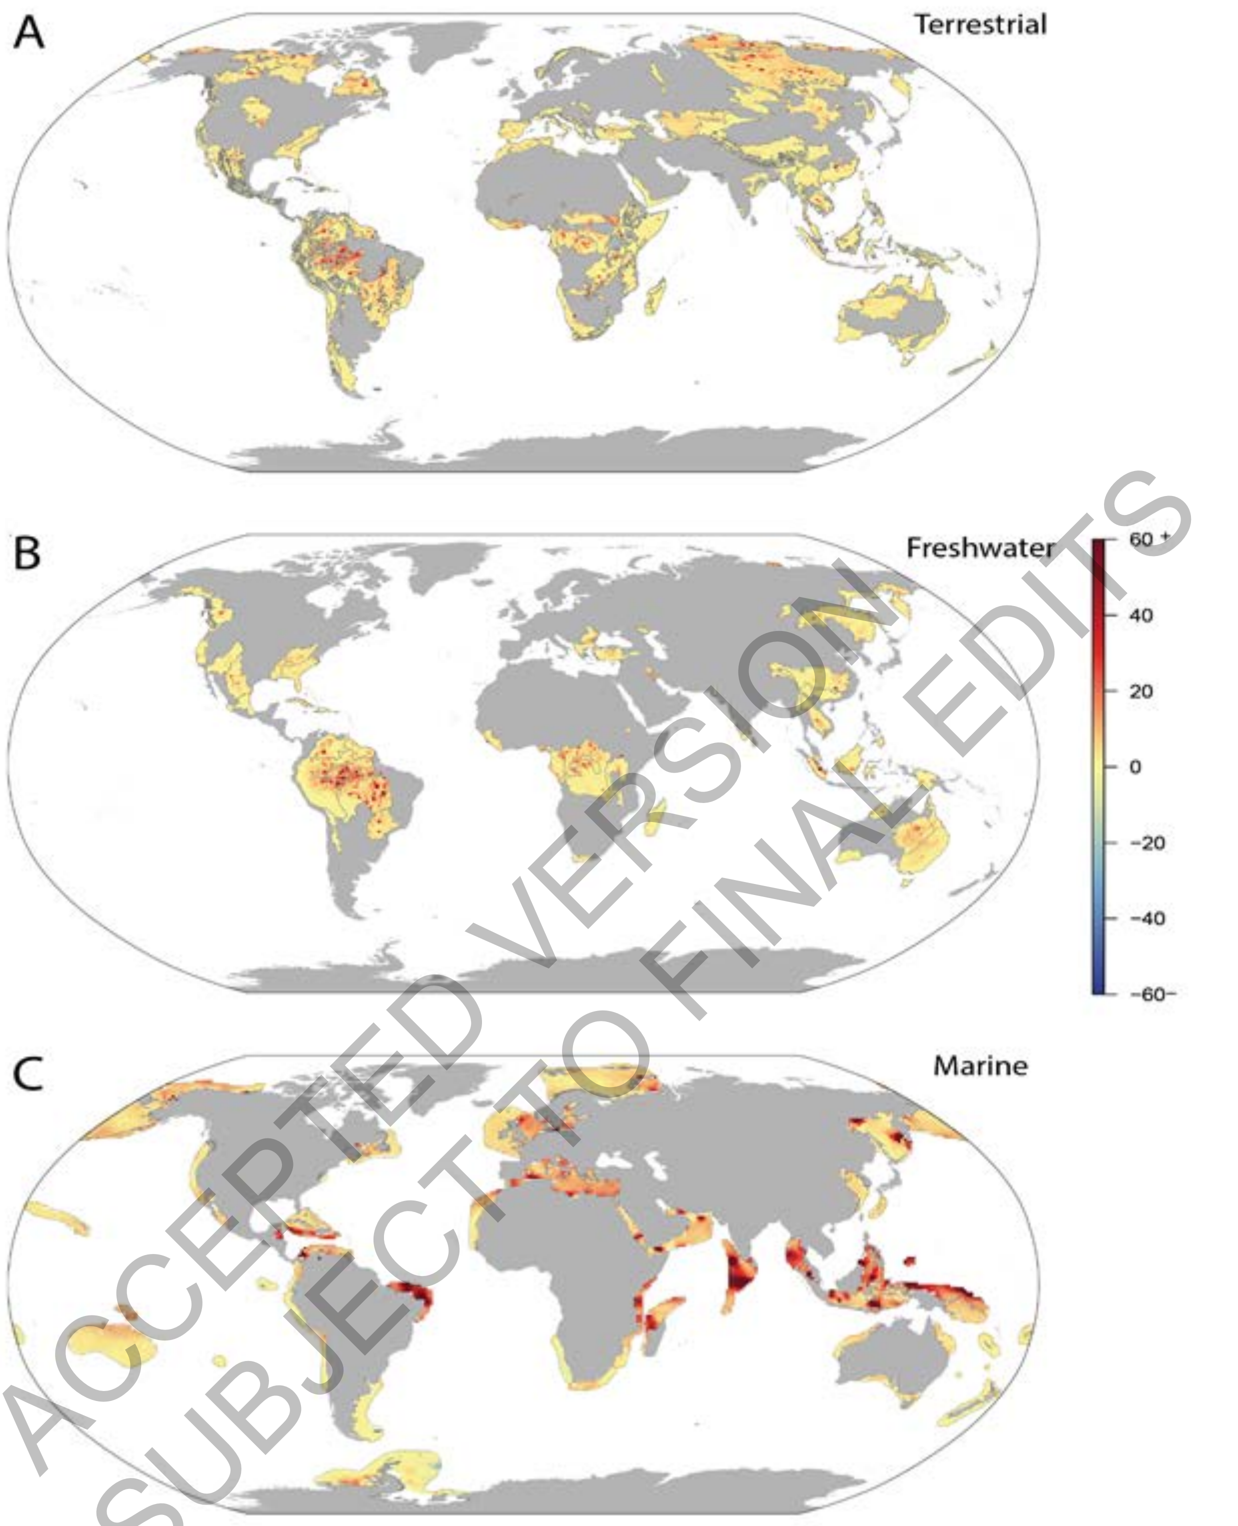

Figure CCP1.3: Climate velocities in terrestrial (A), freshwater (B) and marine (C) hotspots between 1970-2019. Values are presented in km/decade and derived using VoCC (García Molinos et al., 2019) from gridded temperature data, sea-surface temperatures for marine (Rayner et al., 2003) and near surface air temperatures on land and freshwater (Harris et al., 2020). Positive and negative velocities indicate warming and cooling, respectively.

CCP1.2.1.1.2 Observed impacts on biodiversity

Although the conservation status has only been assessed globally for about 6% of all species (Costello, 2019) and most confirmed extinctions and threatened species are terrestrial, a higher proportion of freshwater species are threatened, which is reflected in the higher proportion of freshwater hotspots impacted by humans (Collen et al., 2014; Costello, 2015; Harrison et al., 2018). The rate of species endemicity is exceptionally high in freshwater biogeographic realms (i.e., large regions of distinct species composition and endemicity), at 89-96% for fish in all but one realm, compared to 11-98% for terrestrial vertebrate groups (Leroy et al., 2019) and 17-84% for marine realms (Costello et al., 2017). Already, one third of wetlands have been lost and 9,000 freshwater species threatened with extinction without considering the effects of climate change (Darwall et al., 2018), and only 13% of world rivers were recently classified as least impacted (Su et al., 2021).

Globally, observed climate-driven changes in biodiversity are typically of species distributions shifting to higher latitudes (*virtually certain*) (Lenoir et al., 2020, Ch.2, Ch. 3.4). Since the 1950s, marine species richness has shifted poleward in the northern hemisphere, increased in mid-latitudes, and declined at the equator in concert with ocean warming (*medium confidence*) (Chaudhary et al., 2021). Climate-driven altitudinal shifts are common on land (*high confidence*) (Lenoir and Svenning, 2015; Steinbauer et al., 2018), and depth shifts in the ocean may occur but are little studied (*low confidence*) (Burrows et al., 2019; Jorda et al., 2020). While climate-induced range expansions can be viewed as opportunities for increasing regional biodiversity, range contractions adversely affect biodiversity through regional extirpations (*high confidence*) (Cahill et al., 2013; Chaudhary et al., 2021).

Both of the two climate change associated global species extinctions to date support the predictions that endemic species on mountains and islands are at the greatest risk of extinction (Manes et al., 2021). The golden toad (*Bufo periglenes*) became extinct after some years of decline associated with changes in climate warming and precipitation in the Talamancan-Isthmian Pacific Forests biodiversity hotspot (H22) (Section 2.4.2.2; Pounds et al., 1999; Cahill et al., 2013). The Bramble Cays Melomys, a rodent endemic to an island between Australia and Papua New Guinea closely related to a mainland Australian species, became extinct due to habitat loss arising from climate change related sea-level rise and cyclone activity (Chapter11; Fulton, 2017; Roycroft et al., 2021).

CCP1.2.1.2 Projected Impacts

CCP1.2.1.2.1 Projected climatic hazards

Comparison of climate warming projected for air and sea temperature shows biodiversity hotspots will continue to experience the greatest net increases in temperature at higher northern hemisphere latitudes; particularly in tundra regions (Figures CCP1.4, CCP1.5, Table CCP1.1). Generally, terrestrial and freshwater hotspots are projected to continue to warm more than marine (Figure CCP1.3). Predicted actual temperatures are projected to continue to be the highest in the tropics, indicating where there are more thermally stressful conditions for more species (*high confidence*) (Stuart-Smith et al., 2015; Stuart-Smith et al., 2017; Foster et al., 2018; Waldock et al., 2019). By the end of this century, all terrestrial biodiversity hotspots in central and south America, Africa, India and southern and eastern Asia (including the Indo-west Pacific islands) are projected to experience climates unprecedented in their species' evolutionary history (*medium confidence*) (Williams et al., 2007).

Based on WGI Atlas data (Gutiérrez et al., 2021), global warming is projected to affect terrestrial hotspots less than non-hotspot areas: 80% less for Myers and 95-96% less for G200 terrestrial and freshwater hotspots at global warming of 1.5-3°C (*medium confidence*) (Kocsis et al., 2021). In contrast, warming is projected to be 12-13% greater inside than outside marine hotspots (*medium confidence*) (Kocsis et al., 2021). Precipitation is generally projected to increase more in terrestrial and freshwater biodiversity hotspots compared to outside them (*low confidence*) (Kocsis et al., 2021). The exception is Myers hotspots, which are projected to have, on average, ~28% less precipitation at 1.5°C warming, but ~33% more at 2°C, and ~65% more at 3°C (*low confidence*). However, precipitation changes are often difficult to assess as many hotspots cover large areas, with some areas projected to be wetter and some drier with wide differences between different climate models.

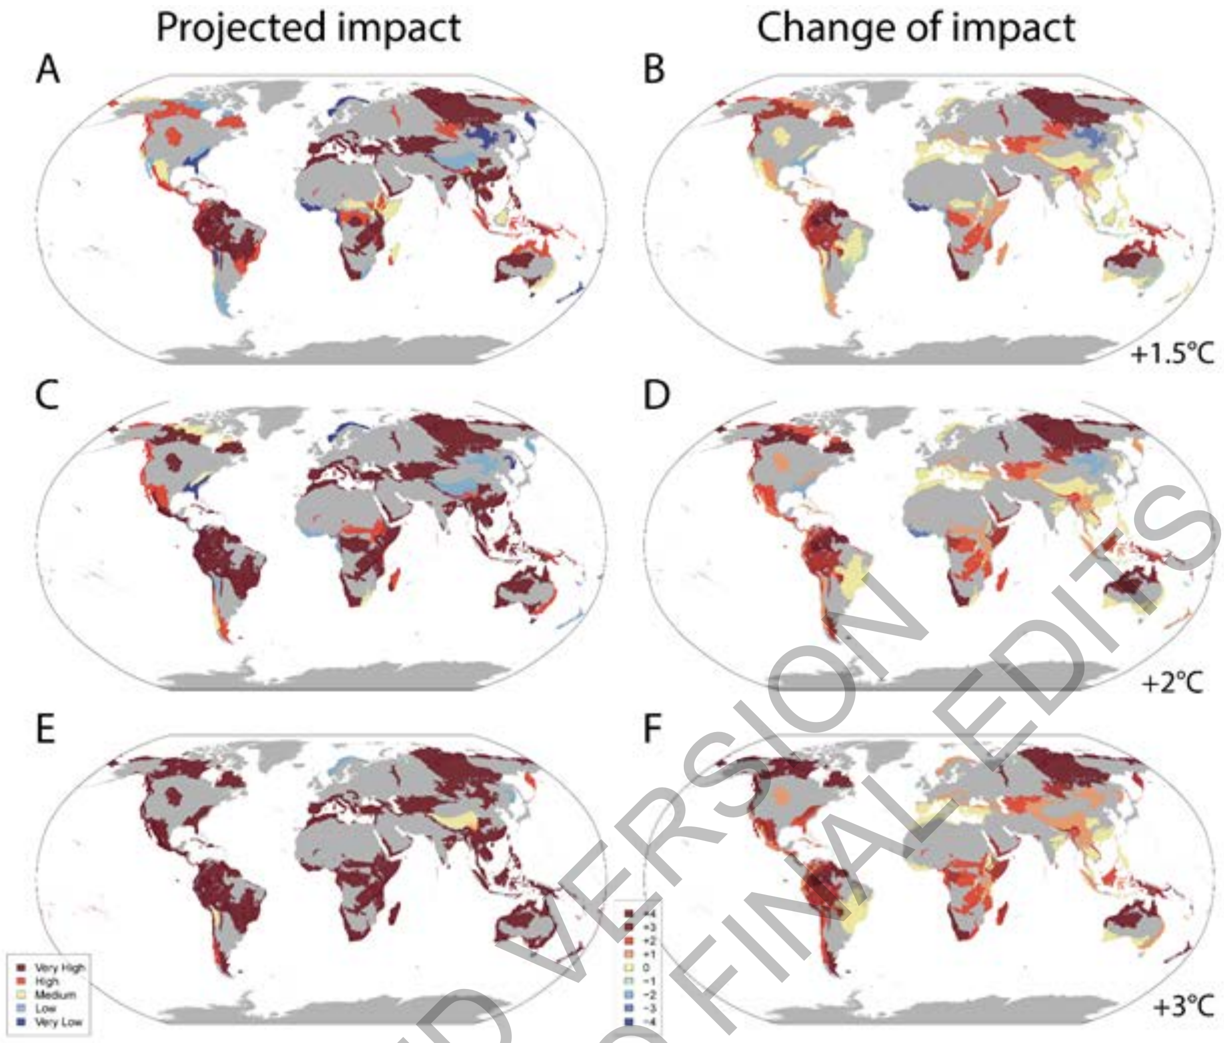

Figure CCP1.4: Projected loss of climatically suitable area in terrestrial biodiversity hotspots for a global average of 1.5°C (upper row, A-B), 2°C (middle, C-D) and 3°C (lower E-F). Left-hand column displays the projected human impact using the five equal 20% categories of present-day impact (Figure CCP1.1). The right-hand column indicates the changes of impact categories compared to present day-impact. See Table SMCCP1.1 for more details.

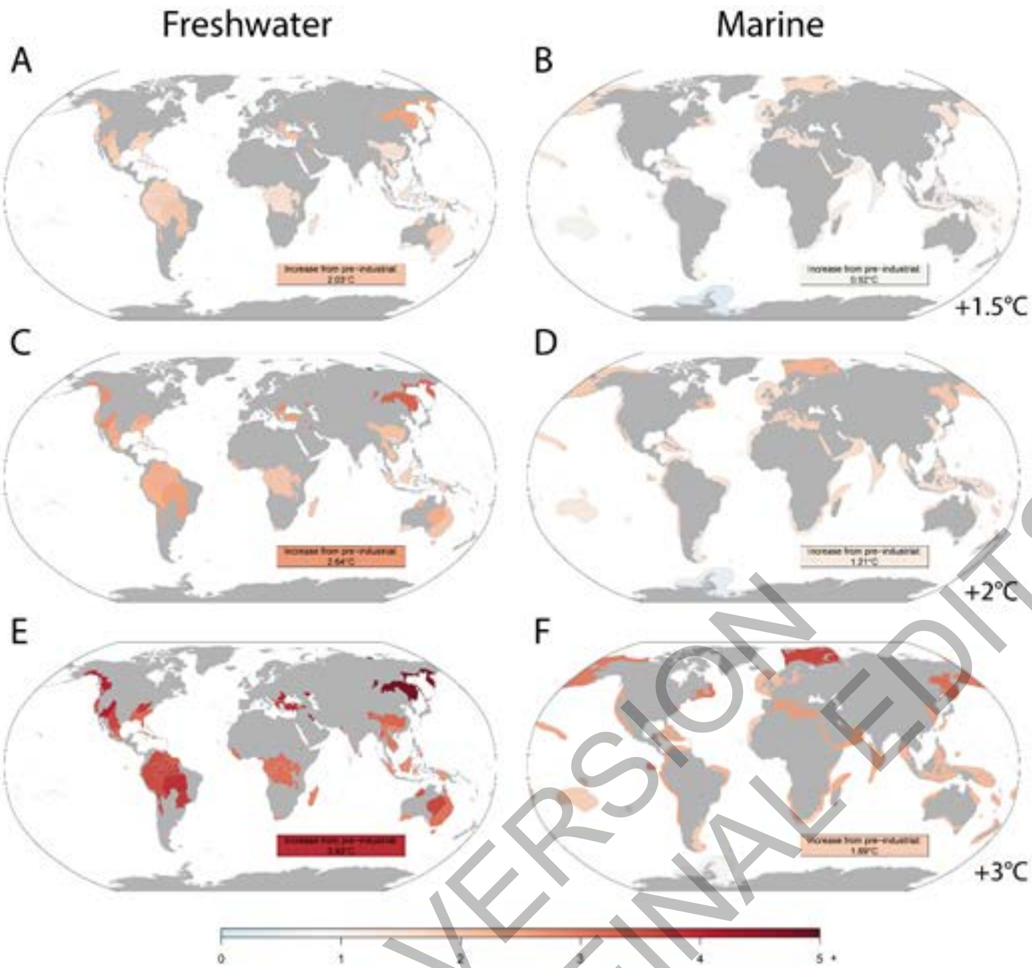

Figure CCP1.5: Projected future warming in °C for freshwater (left column, near-surface air temperature, panels A, C and E) and marine (right column as sea surface temperature, panels B, D and F) hotspots for a global average warming of +1.5°C (A, B), +2°C (C, D) and +3°C (E, F) compared to pre-industrial conditions. Values in text boxes in the Figures indicate temperature increase from present-day (2005-2014) settings. Projected temperatures were calculated with averages of multi-model, yearly means across Shared Socioeconomic Pathways (SSP) 1.26 (only for +1.5°C), SSP2-45, SSP3-70 and SSP5-85.

CCP1.2.1.2.2 Projected impacts on biodiversity

Biodiversity hotspots are expected to be especially vulnerable to climate change because their endemic species have smaller geographic ranges (*high confidence*) (Sandel et al., 2011; Brown et al., 2020; Manes et al., 2021). Manes et al. (2021) reviewed over 8,000 projections of climate change impacts on biodiversity in 232 studies, including 6,116 projections on endemic, native and introduced species in terrestrial (200 studies), freshwater (14 studies) and marine (34 studies) environments in biodiversity hotspots. Only half of the hotspots had studies on climate change impacts. All measures of biodiversity were found to be negatively impacted by projected climate change, i.e., species abundance, diversity, area, physiology, and fisheries catch potential (*medium confidence*). However, introduced species' responses were neutral to positive (*medium confidence*). Land areas were projected to be more negatively affected by climate warming than marine. Land plants, insects, birds, reptiles, and mammals were all projected to be negatively affected (*medium confidence*), as well as fish, coral reef, benthic, planktonic and other marine species (*medium confidence*).

Of the 6,116 projections for more than 2,700 species assessed in biodiversity hotspots, ~44% were found to be at high extinction risk, and ~24% at very high extinction risk due to climate change (Manes et al., 2021) (*medium confidence*). Risks of extinction were estimated based on the projections for all warming levels combined, showing that endemic species were about 2.7 times more at very high risk of extinction compared to non-endemic native species (Manes et al., 2021). Extinction risks were highest for endemic species of both land and ocean (*medium confidence*), and were higher for those living on islands (~100%, *medium confidence*) and mountains (~84%, *medium confidence*) than in the ocean (~54%, *low evidence, medium* *agreement*; *low confidence*) and on continents (~12%, *robust evidence, medium agreement*; *medium confidence*) (Figure CCP1.6). Extinction risks for non-endemic natives were ~20% for both terrestrial and marine species, with introduced species projected to become more rather than less invasive. At 1.5°C warming, ~2% of both terrestrial and marine species and at 3°C, ~20% and ~32% respectively, were projected to be at very high risk of extinction in the hotspots (Figure CCP1.6). Thus, a doubling of warming results in a roughly tenfold increase in species at very high extinction risk.

Manes et al. (2021) found that any benefits to species (e.g., range or abundance increase) were projected to be localised and transient (e.g., Arctic, H196, 214). This and previous assessments indicate that while climate change varies spatially and taxa may respond differently, a loss of biodiversity is projected across all terrestrial hotspots (*high confidence*) (Foden et al., 2013; Warren et al., 2018a; Manes et al., 2021). Abrupt changes across species assemblages may occur under all scenarios: in 9% of assemblages at 1.75°C and 35% at 4.4°C on both land and sea (Trisos et al., 2020). However, species losses may be reduced if species have thermal microclimate refugia and behavioural thermoregulation, or greater due to extreme events, such as heatwaves.

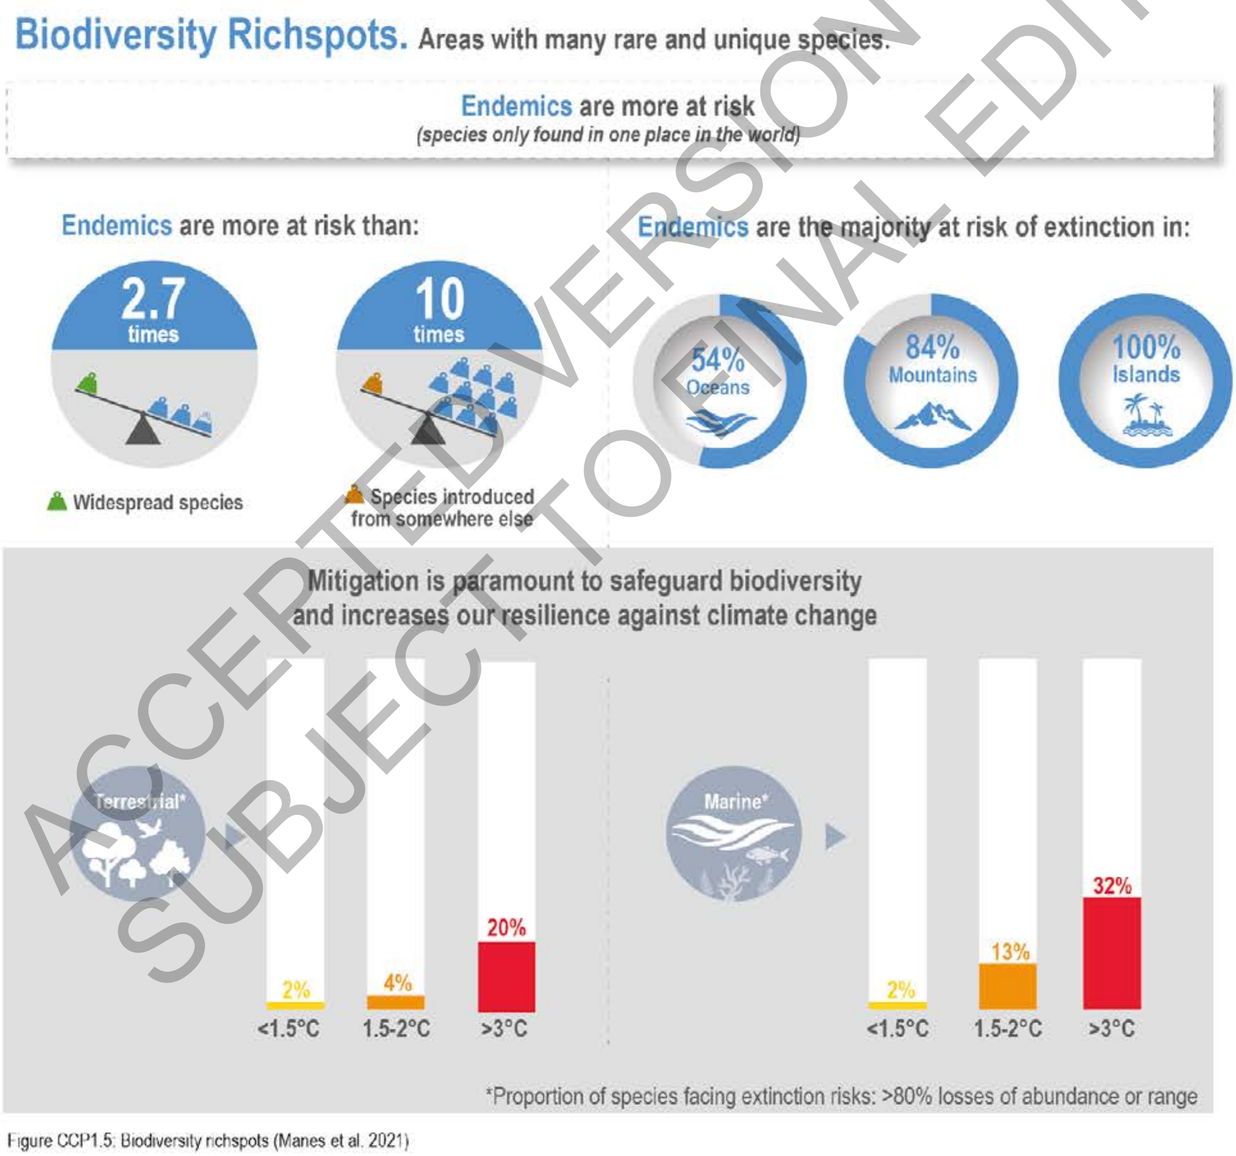

Figure CCP1.6: A summary of the projected risks of species extinction at global warming levels of < 1.5 ºC, 1.5 – 2.0 ºC, and > 3°C in terrestrial and marine biodiversity hotspots. Data from Manes et al. (2021).

CCP1.2.1.3 Compounding and Cascading Effects

All biodiversity hotspots are already impacted, to differing degrees, by human activities (*high confidence*) (Table CCP1.1, Figures CCP1.1, CCP1.2, Myers et al., 2000; Le Roux et al., 2019). At present, over three billion people live within the terrestrial and (catchments of) freshwater biodiversity hotspots, many of which border marine hotspots (WGII Atlas; Figures CCP1.1, CCP1.2; Table SMCCP1.1). Thus, climate change impacts on biodiversity hotspots are compounded by other anthropogenic impacts, increasing the vulnerability and reducing the resilience of biodiversity to climate change (*very high confidence*). Projections of changing climate alone may overestimate or underestimate the impacts on biodiversity (*medium evidence, high agreement*). The additional risk of the combined effects of climate change and other impacts (e.g., land-use change, overhunting, pollution and invasive species) on species has been raised since the Third Assessment Report. The terrestrial hotspots projected to be most affected by global warming are, in general, those already being impacted by loss of habitat due to land use change (Figure CCP1.4; Table SMCCP1.1) (Warren et al., 2018a). This remains a trend in the recent literature, although most studies still address only one stressor (Titeux et al., 2016). For example, Mantyka-Pringle et al. (2015) show that when the interaction between projected climate change and habitat loss is taken into account, the extinction risk of birds and mammals in 15–32% of terrestrial biodiversity hotspots changes. Similarly, Bellard et al. (2014b) found different results when examining the impact of climate change, invasive species and land use change independently, as opposed to synergistically. When combining those three impacts they identified the Atlantic Forest (H47), Cape Floristic Region (H65) and Polynesia-Micronesia (H1, 2, 138, 139, 142) as particularly vulnerable.

In a global assessment of the threat of climate change to river fish biodiversity, Tedesco et al. (2013) projected that current extinction rates of species may be 7% greater due to climate change (*low confidence*). The main threat is due to the effects of drought and reduced river flows, which would be 18 times greater than without climate change. However, just 20 of the 110 river basins studied would experience sufficient climate-driven water loss to cause fish extinctions by 2090. Moreover, the present rates of species loss due to present human activities are 130 times greater than those projected by likely by future climate change (*medium confidence*) (Tedesco et al., 2013).

Marine systems are also vulnerable to cumulative human impacts, which can be direct (e.g., pollution, overfishing) and indirect (altered food webs) (*very high confidence*) (Halpern et al., 2008; Halpern et al., 2015). The marine hotspots most currently threatened by non-climate related human impacts are all situated in the northern hemisphere, specifically along the northern European, Mediterranean, and Asian coasts, where the overlap of overfishing and pollution is especially large (Halpern et al., 2008; Halpern et al., 2015; Ramírez et al., 2018), part B in Figure CCP1.2). Although there is a strong overlap of non-climatic and climatic impacts in marine ecosystems (Blowes et al., 2019; Bowler et al., 2020), the effects suggest that climate change impacts are most severe in tropical and northern high latitude seas (*high confidence*) (Doney et al., 2012; Gattuso et al., 2015; Cheung et al., 2018; IPCC, 2019b). Temperature-driven range-shifts and range-expansions are projected to also lead to cascading effects on marine biodiversity through ecological interactions (*high confidence*) (Pecl et al., 2017; Vergés et al., 2019). Cascading effects may be especially pronounced in temperate reefs, where tropicalisation may lead to arrival of herbivorous fish and predators previously absent (Vergés et al., 2019). However, how these indirect effects of climate change on species may change food webs and ecosystem function, including carbon sequestration, is unknown. Direct and indirect human impacts due to fisheries and pollution can also lead to cascading effects that may be additive with climate impacts on biodiversity. Destruction of marine biogenic habitats due to trawling and dredging, and loss of large proportions of marine megafauna, particularly fish, mammals, birds and reptiles, alters food webs and reduces resilience to additional disturbances, such as due to climate change (*medium evidence, high agreement*) (Brander, 2007; Wernberg et al., 2011; Ramírez et al., 2017; Cheung et al., 2018; Bates et al., 2019; Costello, in press).

The following sections report observed and projected climate change impacts on terrestrial, freshwater and marine environments.

CCP1.2.2 Terrestrial

The 177 terrestrial hotspots assessed here (including 142 G200) cover ca. 61,000,000 km^2 (41% of global land area), with a 37% overlap with freshwater hotspots (Table CCP1.1, Figure CCP1.2). They include wet and dry forests, woodland and scrub, highlands, mangroves, deserts, steppe, savanna, grasslands, moorlands and tundra. Over 77% of publications on climate change impacts on hotspots since AR5 have been on terrestrial ecosystems, most of it on projected (as opposed to observed) impacts (Manes et al., 2021).

CCP1.2.2.1 Observed Impacts

There is *high confidence* that climate change has already had impacts in North American hotspots. Phenological and range shifts have been reported for bird and mammal species within the boreal forest hotspot (Davidson et al., 2020), and earlier egg laying in birds in tundra hotspots (H3, 5) owing to changes in snowmelt (Grabowski et al., 2013). Woody vegetation is already shifting north into the tundra (Larsen et al., 2014).

In Central and South America, observed impacts within Mesoamerica (H15, 16) and the Tropical Andes hotspots (H26, 27, 28, 32, 33) comprise upward altitudinal range shifts of birds, frogs, beetles and butterflies (Narins and Meenderink, 2014; Molina-Martínez et al., 2016; Moret et al., 2016; Freeman et al., 2018) (*medium confidence*). A shift of the Guianan-Amazon mangroves (H37) to higher grounds inland was attributed to the effects of observed sea-level rise (*low confidence*) (Cohen et al., 2018).

In Europe, the Mediterranean hotspot (H216) has seen increases in wildfires and droughts attributed to anthropogenic climate change (Gudmundsson et al., 2017; Barbero et al., 2020), and range shifts in birds have been observed at higher elevations (*medium confidence*) (Tellería, 2020).

In Africa, multiple lines of evidence suggest woody plants are increasing in area, density and cover in previously lightly wooded savanna and grassland hotspots (H65, H82) (Poulsen and Hoffman, 2015; Stevens et al., 2017). Significant vulture and cheetah range reductions in these hotspots are at least partially attributable to bush encroachment (Nghikembua et al., 2016; Wolter et al., 2016; Santangeli et al., 2018). Thus, climate-driven bush encroachment has adversely affected unique mammal and bird diversity (*robust evidence, medium agreement, medium confidence*). Warming and drying trends have historically been shown to reduce the range of the Ethiopian Wolf, and they interact with land-use pressures in the Ethiopian hotspot (H68) (Sintayehu, 2018) and plant species richness in the Cape Fynbos (H65) of southern Africa by reducing post-wildfire recruitment (*low confidence*) (Slingsby et al., 2017).

Observed impacts in Asia were mostly restricted to the Himalaya (H95, 98, 99), Sundaland (H109, 110, 111, 112, 117, 118) and Indo-Burma (H105, 106, 107, 114, 115) hotspots, showing negative impacts through increased invasion by exotic plants, decreased suitable area for endemic species and significant changes in phenology (*medium confidence*) (Telwala et al., 2013; Braby et al., 2014; Padalia et al., 2015; Lamsal et al., 2017). In the Central Asian mountain landscape (H87), studies have shown increased aridity induced by climate change impacts on several shrub species (Seim et al., 2016). Some positive effects were observed for native species in terms of an increase of suitable habitat (*limited evidence, low agreement*) (Priti et al., 2016; Tang et al., 2017; Rathore et al., 2019).

In Australia, climate change has been implicated in: drought-induced canopy dieback across a range of forest and woodland types due to decades of declining rainfall in the southwestern hotspot (H133); fires in the palaeo-endemic pencil pine forests (Tasmania H142); declines in vertebrates in the Australian Wet Tropics World Heritage Area, which overlaps with the eastern part of the Northern Australia hotspot (H131), related to warming and increased length of the dry season; and declines in grass and increases in shrubs in the Bogong High Plains (*high confidence*) (Hoffmann et al., 2019). The Australian Alps have seen increased species diversity following retreat of the snow line (Slatyer, 2010), replacement of long-lived trees by short-lived shrubs following multiple wildfires (Zylstra, 2018), and changing ecological interactions due to climate-related snow loss, drought and fires (*high confidence*) (Hoffmann et al., 2019). While warming is allowing mangroves to expand their range in coastal hotspots of Asia and Australia (Ward et al., 2016; Hughes et al., 2019a), drought and associated salinity stress has killed mangroves in northern Australia hotspots (Chapter 11, Babcock et al., 2019).

Approximately 76% of biodiversity hotspots within this assessment either contain, or, are comprised of islands >100 km^2 (Table CCP1.1). However, just 0.08% of these hotspots were represented in post-AR5 literature examining climate change impacts on terrestrial biodiversity. Most observed impacts were assessed with *low evidence*, but *high agreement*, and focus on plants and insects. Impacts described included abundance changes and extirpations (Jenouvrier et al., 2014), altitudinal range shifts (Koide et al., 2017), increased invasive alien species' abundance and extent in Madagascar (H76, 77), Balearic (H51) and Pacific Islands (Ghulam, 2014; Silva-Rocha et al., 2015; Goulding et al., 2016; Dawson et al., 2017), increased temperature affecting physiology, body size and behaviour of frogs in the Caribbean (H20) (Narins and Meenderink, 2014) and phenological alterations (Fontúrbel et al., 2018). One positive observation was the high resilience to recovery of intact forest ecosystems to tropical cyclones within Caribbean (H20) and Pacific islands (*medium confidence*) (Keppel et al., 2014; Marler, 2014; Shiels et al., 2014).

CCP1.2.2.2 Projected Impacts

Most terrestrial species in biodiversity hotspots in North America have been projected to be negatively impacted by climate change (*medium evidence, medium agreement*, *medium confidence*). About ~80% of projections for assessed species showed a negative impact of climate change climate change, with ~25% at very high risk of extinction (Figure CCP1.7; Manes et al., 2021). Alterations to vegetation that would have ecosystem-wide impacts, such as a shift from oak-dominated forests to predominantly hickory and maple species in the Appalachian Forests (H17) (Ma et al., 2016) or the continued shrinking of tundra ecosystems, have also been projected. Range shifts have been projected for a variety of plants (Beltrán et al., 2014; Riordan and Rundel, 2014) and vertebrate taxa (Warren et al., 2014; Stralberg et al., 2015; McKelvy and Burbrink, 2017). Sizeable range loss, which particularly affects endemic species, is projected with higher levels of climate change. Adaptation in the agricultural sector poses an additional risk to remaining wildlife habitat (e.g., wine in California: Roehrdanz and Hannah, 2016; Figure CCP1.9, CCP1.8).

In Central and South America, risks have been assessed in at least twenty-four terrestrial hotspots, especially within the Atlantic Forest, Cerrado, Mesoamerica and the Caribbean, the most studied hotspots in the world in terms of climate change impacts (H47, 44, 15, 16, 20, respectively) (Manes et al., 2021). About 85% of projections for assessed species showed a negative impact of climate change (*high confidence*), with ~26% of projections predicting species extinctions (Figure CCP1.7; Manes et al., 2021). Projected impacts include contraction or loss of species' geographic range, loss of diversity and high species turnover (*high confidence*). Most studies had focused on vertebrates and plants in the Atlantic Forest (H47) and Cerrado (H44) (Loyola et al., 2014; de Oliveira et al., 2015; Vale et al., 2018; Vasconcelos et al., 2018; Hidasi-Neto et al., 2019; Lima et al., 2019; Lourenço-de-Moraes et al., 2019; Vasconcelos and Prado, 2019; Velazco et al., 2019). Several insect species are projected to lose suitable climatic conditions, including Cerrado (H44) moths (Khormi and Kumar, 2014). There were projected negative impacts on vegetation such as rupestrian grasslands in Cerrado (H44) (Fernandes et al., 2018) and tropical and temperate forests in hotspots in Mesoamerica (H15, H16) (Mendoza-Ponce et al., 2018; Mendoza-Ponce et al., 2019). Endemic species face consistent risks of decrease in suitable habitat in the Atlantic Forest (H47) (Vale et al., 2018), Cerrado (H44) (Vasconcelos, 2014), Tumbes-Chocó-Magdalena (H28, H23) (Hermes et al., 2018), and Mesoamerica (H15, H16) (Garcia et al., 2014; Ramírez-Amezcua et al., 2016). Climate change may also benefit invasive plant species in terms of range expansion (Wang et al., 2017) and physiology (de Faria et al., 2018) in the region (Figure CCP1.8).

In European biodiversity hotspots, about 75% of projections for assessed species showed a negative impact of climate change, with ~30% at very high risk of extinction (*medium confidence*) (Figure CCP1.7; Manes et al., 2021). These threats are projected to be worse under higher levels of warming. Increased wildfire size and frequency is projected to have a strong effect on, the Mediterranean basin (H216) ecosystems (*medium confidence*) (Lozano et al., 2017). Range reductions have been projected for endemic plants (Pérez-García et al., 2013; Casazza et al., 2014), reptiles (Ahmadi et al., 2019), birds (Abolafya et al., 2013) and insects (Sánchez-Guillén et al., 2013) (*medium confidence*).

In African biodiversity hotspots, about 80% of projections for assessed species showed a negative impact of climate change, with ~10% at very high risk of extinction, especially of endemic species including birds, plants, bees across several taxa and hotspots if warming exceeds 2°C (*high confidence*) (Figure CCP1.7;

Figure CCP1.10; Huntley and Barnard, 2012; Kuhlmann et al., 2012; Baker et al., 2015; Lee and Barnard, 2016; Young et al., 2016; Hannah et al., 2020; Manes et al., 2021).

In Asia, there is a bias in studies towards Indo-Burma (H105, 106, 107, 114, 115), followed by Himalaya (H95, 98, 99) and South-East Asian montane tropical and temperate forests. About ~70% of projections for assessed species showed a negative impact of climate change, with ~30% at very high risk of extinction (*medium confidence*) (Figure CCP1.7; Manes et al., 2021) (). Impacts include species' range changes, habitat loss for endemic plants, expansion of invasive species, decreased connectivity and overall species richness decline (*high confidence*) (DasGupta and Shaw, 2013; Telwala et al., 2013; Sridhar et al., 2014; Zomer et al., 2014; Ali and Begum, 2015; Aryal et al., 2016). A projected decrease in habitat suitability for large species like the Asiatic Black Bear is of concern as alternative habitats are outside protected areas, and may lead to human-wildlife conflicts (Farashi and Erfani, 2018). The few positive impacts of climate change were projected as increases in suitable habitat and distribution range for a few endangered plants and mammals (*medium confidence*) (Banag et al., 2015; Shrestha et al., 2018). Animals benefiting from increased fruit and seed production in Southeast Asian forests during warm El Nino cycles were also projected to increase with climate warming (Figure CCP1.8; Corlett, 2011).

All projections for assessed species in Australia and New Zealand terrestrial biodiversity hotspots showed a negative impact of climate change, with half at very high risk of extinction (*low confidence*) (Figure CCP1.7; Manes et al., 2021) (). Observed impacts in the Australian Alps were projected to continue under future climate change (Zylstra, 2018). The Northern Australia savanna (H131) may experience increased rainfall and carbon dioxide due to climate change (Scheiter et al., 2015), and exotic grasses are projected to reduce their range under climate warming (Gallagher et al., 2009). In Australian tropical wet forests, ground-living vertebrates may be more sensitive than arboreal species to unstable climates (Scheffers et al., 2017). Bellard et al. (2016) projected losses of land due to sea-level rise in the East Australian Forest hotspot (H140), and González-Orozco et al. (2016) projected the contraction of eucalyptus species towards the coast of the Southwest Australia hotspot (H134), exposing them to sea-level rise. In New Zealand forests (H139), native plants may be replaced by more fire-resistant introduced species following climate-change related fires (*low confidence*) (Perry et al., 2014). While forest growth is projected to potentially increase due to carbon dioxide fertilization, this may be compromised by drought (*low confidence*) (Ausseil et al., 2013). Seed production in native New Zealand beech forests is projected to increase due to climate warming, fuelling the abundance of invasive rats and stoats, which then predate native species and lead to loss of endemic fauna and flora (*medium confidence*) (Figure CCP1.8; Tompkins et al., 2013, Ch. 11).

About 80% of projections for assessed terrestrial species within insular biodiversity hotspots showed a negative impact of climate change, with ~50% at very high risk of extinction, including 100% of endemic species (*medium confidence*) (Figure CCP1.7; Manes et al., 2021). In addition to habitat loss and species range reductions, changes in precipitation may be a major driver impacting tropical and subtropical island species (*medium confidence*) (Maharaj and New, 2013; Harter et al., 2015; Struebig et al., 2015; Vogiatzakis et al., 2016; Maharaj et al., 2018). Compared to continents, island species are projected to undergo greater impacts from spatial change, especially birds and amphibians (*high confidence*) (Box CCP1.1; Fortini et al., 2015; Holmes et al., 2015; Manes et al., 2021,). Of all biodiversity hotspots, island species face the highest proportion of extirpation risk at high elevations due to decreasing habitat area (e.g., Brown et al., 2015) and at low elevations from sea-level rise, habitat loss and introduced species (*medium confidence*) (Figure CCP1.11; Bellard et al., 2014a).

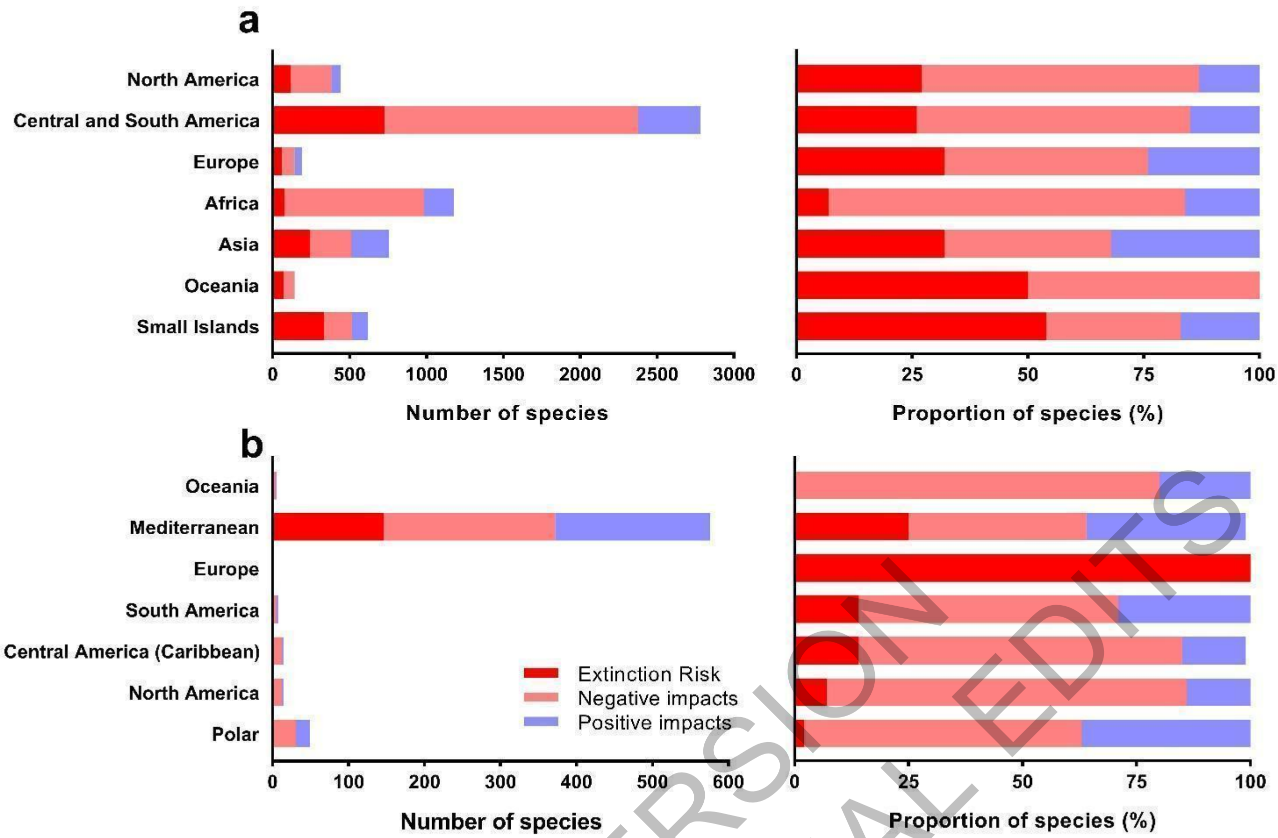

Figure CCP1.7: The projected impacts of climate change on species in 232 studies (a) terrestrial and (b) marine hotspots (adapted from Manes et al., 2021), showing the number and percentage of species showing positive and negative responses to climate change, and threatened with extinction. Note Oceania includes Australia, New Zealand, Wallacea, New Guinea, New Caledonia, Polynesia and Micronesia and overlaps with the global Small Islands category, which excludes Australia. The "small Islands" category represents oceanic and continent associated small islands, and thus overlaps with Oceania and continental data.

Figure CCP1.10: African biodiversity hotspots. Photos by Denis Costello (top two), Mark Costello (with elephant), Frank Zachos (lower four).

Figure CCP1.11: Island biodiversity hotspots. Photos by Galice Hormeau (top two) and Mark Costello (other four).

CCP1.2.3 Freshwater

The 53 hotspots in freshwater ecosystems assessed here cover ca. 32,830,000 km^2 (17% of global freshwater habitats and 22% of the global land area), with a 68% overlap with terrestrial ecosystems (Table CCP1.1, Figure CCP.2). They include lakes, rivers, and streams (Figure CCP1.12).

CCP1.2.3.1 Observed Impacts

An analysis of trends in 190 river basins in Australia found that stream-flows have been declining, including in the Central Australian (H194) and Kimberley (H191) hotspots, due to greater terrestrial plant uptake of water in response to climate-related increases in carbon dioxide (*low confidence*) (Ukkola et al., 2016). We did not find any other publications providing evidence of impacts of climate change on freshwater biodiversity within the hotspots. Whether this is because freshwater temperatures tend to be cooler due to inputs from groundwater and/or mountain streams (Knouft and Ficklin, 2017), resilience of freshwater species, or lack of research is unclear.

CCP1.2.3.2 Projected Impacts

Cold-water species are projected to lose habitat in Canada and this may apply in the Alaskan river (H143) and Russian Far East Lake Inle (H181) hotspots (*medium confidence*) (Comte et al., 2013). Water abstraction is significant in the Colorado river hotspot (H145) and reduces its resilience to climate change effects on flow rates (Grafton et al., 2013).

In South America, in the Brazilian Amazon hotspot (H153, 154, 157) half the assessed fish species were considered sensitive to increased temperatures and reduced oxygen due to climate change (*low confidence*) (Frederico et al., 2016), and the use of protected areas was recommended to reduce the impacts of deforestation and water pollution (Jézéquel et al., 2020). El Nino related floods have led to declines in numbers of caiman, a top predator in the Brazilian Paraná river hotspot (H158), which indicates that increased floods due to climate change may reduce its population and alter food webs (*low confidence*) (Herrera et al., 2015).

In Europe, including the Mediterranean freshwater hotspots, climate change is projected to result in reduced river flow, low oxygen in summer, salinity incursions, further eutrophication and spread of invasive species, compromising the survival of native biodiversity (*medium confidence*) (Moss et al., 2009). The longer growth season in the boreal and Arctic latitudes is projected to aid the invasion of exotic species, and increase lake stratification resulting in lower oxygen below the hypolimnion (*medium confidence*). In addition, strict cold-water species are projected to lose suitable habitat (Moss et al., 2009). An analysis of 1,648 species of freshwater fish, amphibians, turtles, plants, molluscs, crayfish and dragonflies, projected ~6% of common and ~77% of rare species would lose 90% of their geographic range (*low confidence*) (Markovic et al., 2014). Even if some species may be able to spread to other areas and follow the climate, Markovic et al. (2014) projected a loss of species, especially molluscs, from the south-eastern Mediterranean, including the Balkan biodiversity hotspot (H162) (*medium confidence*). Similarly, within Europe, Mediterranean fish (Jarić et al., 2019) and insects (Conti et al., 2014) are the most threatened by climate warming, droughts and floods. The fish species of the Danube river delta hotspot (H161) are less susceptible to climate change than in the Balkans (H162) and Anatolian (H163) hotspots. The rest of Europe, from the Iberian Peninsula to Scandinavia is not classified as a biodiversity hotspot. Thus, the areas where freshwater biodiversity is most threatened by climate change in Europe are in two of the three hotspots (*high confidence*).

The African Rift Valley Lakes (H171), including Lakes Tanganyika and Turkana, are suffering from climate change influenced drought, potentially impacting freshwater biodiversity (*medium confidence*) (Dudgeon et al., 2006). Africa and Madagascar (H172) are projected to see a climate-driven 10% reduction in freshwater flow that is projected to threaten the survival of ~9% of freshwater dependent fish and birds (*low confidence*) (Thieme et al., 2010). Climate change is projected to increase the extinction vulnerability of most freshwater fish in the western South Africa Cape hotspot (H170) (*low confidence*) (Shelton et al., 2018).

In Asia, although climate change impacts on the Yangtze (H183) and Mekong river (H186) biodiversity hotspots have not been reported, they are subject to the range of human impacts of over-exploitation, pollution, water abstraction, altered flow regimes, habitat loss, and spread of invasive species which makes them more vulnerable to climate effects (*medium confidence*) (Dudgeon et al., 2006). The release of water from shrinking glaciers in Asia to some extent protects downstream freshwaters against drought, but half of these glaciers are projected to disappear by 2100 (*medium confidence*) (Pritchard, 2019).

In Australia, the Murray-Darling river basin occupies much of the Eastern Rivers hotspot (H195) and climate related drought exacerbated by water abstraction is projected to drive declines in freshwater birds, fish and invertebrates (*high confidence*) (Grafton et al., 2013). However, a national scale analysis projected that climate change would cause freshwater species range shifts, but no losses of species in this hotspot (*low confidence*) (James et al., 2017, Chapter 11).

Figure CCP1.12: Photographs of freshwater biodiversity hotspots. Photos by Will Darwall, Pablo Tedesco, and Mark Costello (bottom row).

CCP1.2.4 Marine

The 43 hotspots in marine ecosystems cover 46,600,000 km^2, representing 9% of the ocean area (Table CCP1.1, Figure CCP1.2). They include coral reef ecosystems, kelp forests, seagrass meadows, polar, and upwelling zones (Figures CCP1.13, CCP1.14).

CCP1.2.4.1 Observed Impacts

Observed impacts attributable to climate change are strongly biased geographically, with most data from the temperate Northern Hemisphere, followed by subtropical to temperate Australia and few long-term data in the tropics (Poloczanska et al., 2013; Poloczanska et al., 2016). Marine heatwaves have increased over the past century, causing mass mortalities in the hotspots of the Mediterranean (H216), Great Barrier Reef (H236), western and southern Australia (H227, 228), north-west Atlantic (H207), and north-east Pacific (H197) (*high confidence*) (Hobday et al., 2018; Oliver et al., 2018). The shift of thousands of species from equatorial latitudes since the 1950s has been attributed to climate warming (*medium confidence*) (Chaudhary et al., 2021).

Climate-change related hazards, particularly marine heat events, have caused widespread coral bleaching and mass mortalities as the time between consecutive bleaching events decreases (*high confidence*) (IPCC, 2018; Bindoff et al., 2019; IPCC, 2019b). Coral reefs in some Indian Ocean hotspots (H230, 234) already exhibit net loss of coral reefs (*low confidence*) (Perry et al., 2018). While coral bleaching is a visible symptom of heat stress, warming has also induced restructuring of associated fish and invertebrate communities in the Great Barrier Reef (H236) (*medium confidence*) (Stuart-Smith et al., 2018).

Although the number of coral species that are both exposed and vulnerable to climate hazards is greatest in the central Indo-Pacific, the proportion of corals at risk is greater in the lower diversity Caribbean hotspots (H209) (*medium confidence*) (Foden et al., 2013). Some reef corals may acclimate to heatwaves (*low confidence*) (DeCarlo et al., 2019), and some have expanded their latitudinal ranges polewards (*high confidence*), up to 14 km/yr in the northwest Pacific (Yamano et al., 2011). Although future latitudinal expansions may be limited by winter light availability (Muir et al., 2015) new coral reefs are already emerging in Japan (Kumagai et al., 2018).

The Mediterranean Sea hotspot (H216) is negatively affected by climate change (*high confidence*) (Cross-Chapter Paper 4). Species entering via the Suez Canal from the Red Sea (H220) are facilitated by warming and lead to profound community changes (*high confidence*) (Yeruham et al., 2015; Rilov, 2016; Vasilakopoulos et al., 2017; Givan et al., 2018; Bianchi et al., 2019). In contrast, the more open coastal seas of both coasts of North America have had increasing species richness since the 1970s (Batt et al., 2017).

Kelp forests are in decline in mid-latitudes due to warming and associated increased herbivory (*medium confidence*) (Section 3.4.2.3, Chapter 11). South and south-eastern (H228), and south-western (H227) Australia have experienced a climate-related decline of kelp forests (Wernberg et al., 2011; Vergés et al., 2016; Wernberg et al., 2016). West Australia (H227) has been affected by extreme climate events leading to tropicalisation characterised by the replacement of kelp and sessile invertebrates by algal turfs and warm-water fish species (Wernberg et al., 2013; Wernberg et al., 2016). Australia's Great Barrier Reef (H236), kelp forests, seagrass meadows, and mangroves (due to drought), have suffered mortalities due to climate change (*medium confidence*) (Babcock et al., 2019). Climate warming driven changes in seaweed assemblages have been reported not only in Australia, but in the marine biodiversity hotspots of Atlantic Canada, Japan, Mediterranean, New Zealand (Laffoley and Baxter, 2016; Thomsen et al., 2019; Thomsen and South, 2019), and California (H207, 231, 216, 238, 199) (Arafeh-Dalmau et al., 2019; McPherson et al., 2021). However, while climate change is having measurable effects on kelp, the dominant effects on kelp projected to 2025 are fishing, through its effects on herbivores and predators (*medium confidence*) (Steneck et al., 2002). Although fishing affected Atlantic cod in the Barents Sea (H214) and Gulf of Maine (H207) biodiversity hotspots, so did climate change, but negatively and positively, respectively (Kjesbu et al., 2014; Pershing et al., 2015).

Range expansions out of the Nansei Shoto (H231) hotspot south of Japan led to the replacement of temperate kelp forests by tropical coral and herbivorous fishes on Japanese coasts (Kumagai et al., 2018). The Yellow Sea (H230) is one of the most exploited marine hotspots, with decreasing ecosystem services compounded by climate change but *low confidence* for climate change contributing substantially to ecological degradation (Wang et al., 2016; Song and Duan, 2019).

Upwelling systems are best known for bringing nutrients to the surface that stimulate phytoplankton blooms, which in turn support important fisheries (Section 3.4.2.11). However, this deep water also tends to be low in oxygen, which can be further depleted by respiration and surface warming. Prolonged marine heatwaves in this Californian hotspot (H197) drove major shifts in the geographic range of birds, mammals, fish, crustaceans, molluscs and other species, and toxic algal blooms (Sanford et al., 2019).

In both the Antarctic (H213) and Arctic (H196, 214), the loss of ice impacts on the behaviour and foraging ability of marine mammals and birds (Doney et al., 2012). The retreat of sea-ice in the Bering Sea (H196) hotspot has been followed by a reorganisation of the seabed and fish communities, a northward shift in species, and greater species' biomass and richness (Mueter and Litzow, 2008; Grebmeier et al., 2018). In the Eurasian Arctic (H214), species richness has similarly been increasing (Węsławski et al., 2011; Kortsch et al., 2012; Certain and Planque, 2015; Fossheim et al., 2015; Węsławski et al., 2018) as has phytoplankton productivity (Arrigo et al., 2008). The distribution of krill has already contracted with ocean warming in the Southern Ocean (*medium confidence*) (Cox et al., 2018; Atkinson et al., 2019).

CCP1.2.4.2 Projected Impacts

Tropical extirpations, as already underway (CCP1.2.4.1), are projected to reduce hotspot diversity especially in the Coral Triangle (H226, 232, 234), Maldives (H224), and to a lesser extent in the Caribbean (H200, H210) (Jones and Cheung, 2015; García Molinos et al., 2016), and Persian Gulf (H219) (Wabnitz et al., 2018). Paleo evidence supports projections of tropical biodiversity loss under high global warming (*high confidence*) (Kiessling et al., 2012; Yasuhara et al., 2020).

Warm-water coral reefs are expected to decline with 1.5ºC warming (*very high confidence*) (King et al., 2017; Bindoff et al., 2019) leading to systems with reduced biodiversity and structural complexity (*high confidence*) (Chapters 3 and 11, Box 11.2). In the Coral Triangle, marine heatwaves are projected to have the same effect as an added mean annual 0.5°C SST increase (McManus et al., 2020). While some corals may survive in deep 'mesophotic' reefs (Laverick and Rogers, 2019), the shallow coral reefs of today appear unlikely to last the century if climate warming continues without mitigation (*high confidence*) (Hughes et al., 2018a; Hughes et al., 2018b; IPCC, 2018; Bindoff et al., 2019; Hughes et al., 2019b).

In temperate shelf seas, ocean acidification may lead to increases of fleshy algae at the expense of calcifying algae (*low confidence*) (Zunino et al., 2017). However, seagrass has been projected to decline (Chefaoui et al., 2018) and increase (Zunino et al., 2017) in the Mediterranean Sea hotspot (H216). Kelp forests are expected to decline in the northwest Atlantic (Grand Banks, H207), whereas gains and losses are approximately balanced in the Northeast Atlantic Shelf (H215) under RCP 8.5 (Assis et al., 2018; Wilson et al., 2019), but leading to impoverished benthic assemblages (*medium confidence*) (Teagle and Smale, 2018).

Projected climate caused changes in biodiversity in coastal upwelling regions are uncertain. While productivity in the California Current (H197) system is projected to increase with future climate change, non-linear plankton responses and uncertain interactions with food-web dynamics hinder predictions of ecosystem responses (Xiu et al., 2018). In addition, this hotspot is projected to suffer from ocean acidification by 2050 (Gruber et al., 2012).

Around Antarctica (H213), almost half of all species are endemic (Costello et al., 2010), and warming during this century is projected to cause a reduction in suitable thermal environment for 79% of its species given continued warming (RCP8.5) (*low confidence*) (Basher and Costello, 2016; Griffiths et al., 2017). The previously mentioned declines in Southern Ocean krill due to climate change contribute to projected declines in baleen whales there (Tulloch et al., 2019).

Species richness in the northern polar hotspots is expected to increase substantially (*high confidence*) (Cheung et al., 2015). However, population sizes of presently occurring native species are expected to decline, especially in the Barents Sea (H214) (Koenigstein et al., 2018). Ocean acidification is projected to continue globally, and while its impact is uncertain and projected to be less than the effect of warming, it may lead to changes in marine food webs due to varying effects on marine species (Terhaar et al., 2020). Hotspots in temperate latitudes are projected to have assemblages modified by immigration from the tropics and emigration to polar waters. Where land barriers and other geographical limits to range shifts occur, limited dispersal and habitat fragmentation may also limit the capacity of species to track climate velocities such as in the Baltic Sea (H215) (Jonsson et al., 2018), Mediterranean Sea (H216) (Burrows et al., 2014; Arafeh-Dalmau et al., 2021), and Antarctica (H213) (*medium confidence*) (Cristofari et al., 2018).

CCP1.3 Adaptation and Solutions

Terrestrial, freshwater and coastal marine ecosystems are impacted by the three billion people that currently live in in biodiversity hotspots (WGII Atlas). At the same time, biodiversity in hotspots supports the livelihoods of the local communities. The suite of adaptation options for biodiversity are as applicable inside as outside hotspots (Table CCP1.2). However, autonomous adaptation options are more limited in hotspots, due to, for example, high endemism within hotspots, the fact that hotspots have evolved in isolation, their species often have narrow thermal tolerances, or lack connectivity (e.g., mountaintops and islands) (*high confidence*). In addition, many of these hotspots are now faced with widespread fragmentation and habitat degradation (*high confidence*) (Table SMCCP1.1).

Because projected changes in biodiversity increase disproportionately with warming, climate change mitigation is the primary action to conserve biodiversity within hotspots. If global warming is kept within the 1.5°C limit of the Paris Agreement, just ~4% of endemic species in biodiversity hotspots would be threatened with extinction from climate change. However, at the current commitments there is projected to be ~3°C warming by 2100 and ~20% and ~32% for terrestrial and marine species, respectively, fall into the category of very high extinction risk (Figure CCP1.6; Manes et al., 2021).

Although mitigation can sharply reduce extinction risk associated with climate change (*high confidence*), it cannot reduce all of the risk, nor the risk associated with other drivers that can have a compound effect with climate change. Thus, in addition to mitigation, the literature consistently calls for reducing current non-climate impacts (e.g., habitat conversion, over-exploitation, hunting, fishing, wildfire, pollution, human introduced invasive species) in order to increase biodiversity resilience to climate change (*very high confidence*) (e.g., Mantyka-Pringle et al., 2015; Warren et al., 2018a; Costello, in press). The main strategies to increase resilience rely on the combination of well-planned protected areas, restoration of degraded areas, and the sustainable use of biodiversity (*high confidence*) (Chapter 2; Section 3.6; Table CCP1.2; IPCC, 2019a; Pörtner et al., 2021) . On land, creating corridors for species is key for facilitating species movements (*high confidence*) (McGuire et al., 2016; Heikkinen et al., 2020; Pörtner et al., 2021). Habitat protection has numerous co-benefits, including potential climate mitigation through carbon storage and sequestration, in addition to climatic regulation (Alkama and Cescatti, 2016; Mackey et al., 2020), and pandemic prevention (Cross-Chapter Box COVID in Chapter 7; Allen et al., 2017; Dobson et al., 2020,).

Active relocation of endangered species to areas where they may be safer from predation and human impacts, as already practised for a few charismatic fauna, is expensive and fraught with complex regulations and concerns over impacts on native species (Brodie et al., 2021). Therefore, managed relocation of species threatened by climate change is questionable for most species.

Healthier marine ecosystems are more resilient to additional stressors, such as storms and climate change (*high confidence*) (Isbell et al., 2015; Duffy et al., 2016; Roberts et al., 2017; Bates et al., 2019; Mariani et al., 2020; Donovan et al., 2021; Costello, in press). Extinction risk is lower when populations are larger and more genetically diverse, individuals are larger and older, and seabed habitats (e.g., coral, kelp, seagrass) are flourishing as occurs in marine reserves (*high confidence*) (Costello, 2014; Roberts et al., 2017; Bates et al., 2019; Costello, in press). Similarly, global fish biomass may be less affected from climate change if biodiversity is greater (Duffy et al., 2016). Thus, a network of reserves representative of global biodiversity, helps attenuate the effects of climate change (*medium confidence*), e.g. by having more abundant fish and top predator populations (Roberts et al., 2017; Beyer et al., 2018; Carter et al., 2020; Sala et al., 2021). However, the impacts of marine heatwaves on corals across marine reserves illustrates that enhanced resilience is not enough to protect against extreme and future climate change conditions (*high confidence*) (Bruno et al., 2018; Hughes et al., 2018a; Kleypas et al., 2021).

Mangroves occupy the interface of terrestrial, freshwater and marine environments, dominate in eight hotspots (Table CCP1.1) and are connected to or integral habitats within one-third of all terrestrial and freshwater, and two-thirds of marine, hotspots (Figures CCP1.1, 2). A global analysis of sediment cores from mangroves indicated that mangroves seem to be able to accrete sediment at levels of sea-level rise projected under low emission scenarios, but may decline at their seaward edge under high emission scenarios (*high confidence*) (Saintilan et al., 2020, Section 3.4.2, Cross-Chapter Box SLR in Chapter 3). However, even if this seaward erosion occurs, the expansion of mangroves inland due to sea-level rise will increase carbon sequestration, because they capture carbon from seawater and freshwater runoff, in addition to photosynthesis, into their underlying sediments. If coastal management permits the expansion of mangroves inland with rising sea level, this will increase carbon sequestration because mangroves capture and preserve more carbon in their sediments than other terrestrial and marine forests and biomes (*high confidence*) (Table CCP1.2; Alongi, 2020; Goldstein et al., 2020; Lovelock and Reef, 2020; Saintilan et al., 2020).

On land, fragmentation and habitat degradation are particularly pervasive, imposing hard limits to adaptation of terrestrial and freshwater ecosystems (Ibisch et al., 2016; Lenoir et al., 2020; Mechler et al., 2020). Thus, the protection of existing natural habitats coupled with the restoration of the surrounding non-protected habitat can increase the effectiveness of adaptation strategies in terrestrial and freshwater hotspots (*very high confidence*) (Table CCP1.2; IPCC, 2019a; Jung et al., 2021) . Additionally, strategic allocation of new protected areas within gaps across elevational and climatic gradients could enhance biodiversity conservation across hotspots. This would align with target 3 of the Convention on Biological Diversity's post-2020 global biodiversity framework, and could include underrepresented climate and elevation spaces as well as potential climate refugia currently not under protection (Pörtner et al., 2021). In terrestrial ecosystems, restoration initiatives can help sustain biodiversity, improve resilience in a changing climate, and avoid maladaptation by selecting appropriate native species to be planted (Cross-Chapter Box BIOECONOMY in Chapter 5; Gann et al., 2019). In freshwater ecosystems, conservation needs catchment level management of human activities (Saunders et al., 2002; Dudgeon et al., 2006) (Chapter 11, Box 11.6) especially as 37% of the terrestrial biodiversity hotspots overlap with freshwater (Figure CCP1.2), and 23% border marine hotspots (Olson and Dinerstein, 2002).

Protecting biodiversity hotspots is a pragmatic way to conserve biodiversity that is representative of a substantive fraction of genetic and species diversity on Earth (Mittermeier et al., 2011) while achieving co-benefits (Bonan, 2016; Sala et al., 2021). Protecting hotspots also helps protect important ecosystem services. In a global ranking of areas that combine biodiversity conservation while maximizing carbon retention and water quality regulation, for example, the terrestrial and freshwater hotspots assessed here ranked high (41st and 34th on average, respectively, on a scale of 100) (Jung et al., 2021). The solutions needed to reverse biodiversity decline are well known and articulated in numerous international agreements and goals, such as the Convention of Biological Diversity Aichi Targets, the United Nations' Sustainable Development Goals, the Nationally Determined Contributions under the Paris Agreement, the International Union for Nature Conservation's Bonn Restoration Challenge, and the Ramsar Convention on Wetland Conservation. Thus, expanding and enhancing protection of a worldwide network of fully protected areas and protection and restoration of non-protected areas representative of the biodiversity hotspots — inclusive of marine, freshwater and terrestrial environments, is a highly recommended adaptation strategy to increase resilience of biodiversity to climate change (Brito-Morales et al., 2018). However, adaptation strategies alone cannot protect biodiversity from climate impacts without complementary and concomitant reduction of greenhouse gas emissions.

Table CCP1.2: Examples of adaptation actions that benefit the conservation of biodiversity and climate change mitigation.

Actions	Terrestrial	Freshwater	Marine
Protect biodiversity hotspots	Protect native forests, bush, and grasslands	Stop pollution and sedimentation into streams, rivers, ponds, lakes	Ban seabed trawling and dredging
	Control introduction and spread of invasive species and pests		
Increase connectivity	Use riverbank and hedgerow corridors to connect protected native habitats		Already connected
	Reduce habitat and species loss outside protected areas to add species dispersal (corridors)		
Outside biodiversity hotspots	Environmentally sustainable agriculture, tourism, and other land and freshwater uses		Environmentally sustainable aquaculture, fisheries, tourism
Restoration and recovery	Actively rehabilitate old mines, quarries and industrial lands	Stabilise riverbanks. Remove weirs and artificial barriers to fish migration.	Ban removal of marine life and habitat, and fishing in selected areas to allow passive recovery of habitats,

	Reintroduce extirpated native species		natural population structure, and food webs
Reduce erosion, soil loss, and flooding	Preserve, reduce degradation, and restore habitats to enable uplands to absorb rainfall and reduce flash floods. Protect sand-dune systems from erosion due to human and farm animal trampling. Set aside land for salt marshes and mangroves to buffer against river and seawater flooding. Link estuarine and upriver protected areas to provide more wildlife habitat and absorb storm surges and floods.		
Urban development	Concentrate development to more cost efficiently manage transport and waste management infrastructure	Limit upland development where it may affect freshwater quality	Avoid construction in areas at risk of sea level rise and associated storm surges.
Greenhouse gas mitigation	Prevent deforestation; Reforestation (especially mangroves); Revegetation; Fewer farm mammals. Minimise release of greenhouse gases from soils.	Expand wetlands to capture and deposit carbon in soils.	Limit seabed disturbance by trawling and dredging that releases CO_2 and CH_4. Eliminate fishery subsidies, and remove tax breaks on fuel for fishing boats.
Carbon sequestration and preservation	Allow biodiversity to flourish and capture CO_2 from the air and sequester it in biomass, soils and sediments.		
	Manage forestry to maximise in situ food web biomass.	Manage fisheries to maximise in situ food web biomass.	
Social	Communicate information on the benefits of adaptation measures to the public		
Political and economic	Provide leadership and governance of mitigation and adaptation measures, including through regulations and economic incentives that guide the transition to a low carbon emissions economy		
Scientific	Address data gaps and make monitoring data and its meaning rapidly available to society so that the public and policy makers are informed of trends in biodiversity and related factors, including climate variables, extreme weather related events, threatened and invasive species, natural habitats, and their relationships.		
	Conduct research to improve understanding of cause-effect relationships regarding environmental factors and biodiversity trends, including in nature conservation, forestry, agriculture, fisheries and food production sectors, and improve projections of consequences of management action and inaction		

[START BOX CCP1.1 HERE]

Box CCP1.1: Climate Change and Terrestrial Biodiversity Hotspots on Small Islands

Despite covering approximately 2% of the Earth's land area, islands harbour more than 20% of extant terrestrial species (Wetzel et al., 2013). Islands have disproportionately higher rates of endemism and threat when compared to continents, with 80% of historical extinctions (since 1500 AD) having occurred on islands (*high confidence*) (Taylor and Kumar, 2016; Spatz et al., 2017; Dueñas et al., 2021). Current climate change projections suggest that insular species are particularly sensitive, and even at mild warming levels, substantial losses are expected (*high confidence*) (Pouteau and Birnbaum, 2016; Taylor and Kumar, 2016; Dawson et al., 2017; Manes et al., 2021). Given islands' characteristic high endemicity, current high threat levels and the fact that islands host almost half of all species currently considered to be at risk of extinction, at especially higher warming levels (*high confidence*) (Taylor and Kumar, 2016; Spatz et al., 2017) — further losses could contribute disproportionately to global biodiversity decline (*medium evidence, high agreement*) (Harter et al., 2015; Pouteau and Birnbaum, 2016; Manes et al., 2021).

The high vulnerability of terrestrial biodiversity on islands to global change can be explained by a number of limitations, characteristic of both islands and insular species. Older, isolated islands tend to have fewer species and lower functional redundancy but higher proportion of endemism (Pouteau and Birnbaum, 2016; Médail, 2017). Many of these islands contain species with inherently high sensitivity to environmental change (narrow habitat ranges, small population sizes, low genetic diversity and poor adaptive, dispersal and defensive capabilities) (Harter et al., 2015). Unlike continental environments, insular species often have limited opportunities for autonomous adaptation from not having enough geographic space to shift their ranges to track suitable climatic conditions (*high confidence*) (Fortini et al., 2015; Manes et al., 2021). Local extinction risks are amplified by even small losses of habitat due to global change including human-induced disturbances, extreme events, sea-level rise (Chapter 15; Cross-Chapter Box SLR in Chapter 3) and invasive species.

However, some insular species may be resilient to climate change (*low confidence*). Intact island forests, for example, have shown rapid recovery rates after tropical cyclones, despite high levels of initial damage, especially in the Caribbean (*medium confidence*) (Luke et al., 2016; Richardson et al., 2018). Additionally, many Mediterranean islands are 'disturbance adapted', with continued persistence of some single-island endemic plants, despite exposure to multiple threats (Vogiatzakis et al., 2016). This continued persistence has been attributed, at least partially, to climate refugia, oceanic buffering, and high habitat heterogeneity within topographically complex mountainous regions (Chapter 15, Table 15.1; Pouteau and Birnbaum, 2016; Médail, 2017). However, this climate resilience may not be sustained under climate change, especially when coupled with habitat degradation (*high confidence*) (Wiens, 2016).

Adaptation strategies depend on the ability to project future impacts from climate change, but this is hampered by lack of fine-scale climate data especially for developing small island nations. There is a paucity of robust impacts-based modelling output for terrestrial biodiversity from these islands due to the wide, chronic unavailability of Regional Climate Model (RCM) data premised on the most recent suite of scenarios (RCPs and especially SSPs) *(medium evidence*, *high agreement*) (Gutiérrez et al., 2021, Ch.15.8; Pörtner et al., 2021; WMO, 2021). Additionally, realistic assessments of changing climate on such small ecosystems require further RCM downscaling and verification to sub-island resolutions of < 5 km. Furthermore, widely used statistically (bias-corrected) downscaled data at sub-5 km resolutions such as WorldClim are often unsuitable due to limited spatial and temporal resolutions of observation station data from small islands (Maharaj and New, 2013; Gutiérrez et al., 2021), and higher errors associated with statistical downscaling and locations with complex topography and coastlines (Fick and Hijmans, 2017; Lanzante et al., 2018). Widespread unavailability of such data constrains accurate simulations of climatic variation within the small-scale mountainous and coastal regions of islands, associated with climate refugia and high habitat heterogeneity (*high confidence*) (Balzan et al., 2018). This is a key element contributing to the continued delay in development of robust adaptation strategies towards not only biodiversity conservation but other important cross-sectoral issues (*medium confidence*) (Robinson, 2020b).

Due to islands' limited size and isolation, conventional conservation measures focused on expanding protected areas, dispersal corridors and buffer zones are of limited effectiveness on islands (*high confidence*) (Vogiatzakis et al., 2016). Instead, multifaceted, locally-driven holistic climate-smart strategies across mosaics of human-impacted, often heavily degraded and fragmented landscapes are required. These should ideally be long-term, flexible and sustainable solutions that incorporate social and biocultural knowledge as well as economic co-benefits to island communities in order to 'buy time' (Betzold, 2015; Robinson, 2020a). Examples include ecosystem-based approaches such as ridge-to-reef management (Table CCP1.2.4; Struebig et al., 2015; Ferreira et al., 2019), which incorporates conservation partnerships among lands inside and outside protected areas to increase connectivity and reduce land-use impacts, while building on the interconnections among terrestrial, freshwater, coastal and marine ecosystems. Such strategies require raising awareness of biodiversity values among local communities, and cross-sectoral planning and policy at both island, regional and trans-boundary scales. These lend to private-public partnerships, increasing the potential of solutions reaching beyond protected areas boundaries and affecting socio-political change (*high confidence*) (Scobie, 2016).

Limited terrain, natural, economic and data resources across small developing-nation islands mean that unconstrained habitat destruction and degradation cannot be sustained, as this harms both people and the biodiversity upon which they depend. This limitation of resources compromises climate adaptation — which is often further complicated by varying governance and states of economic development (Petzold and Magnan, 2019). With changing climate conditions, there is an increased urgency to re-think how progress can be measured, and to create opportunities building on synergies between disaster risk reduction, food security and social justice – so that islands can most benefit from their natural resources and biodiversity in a sustained manner (Box 15.2; Section 15.3.4.4).

[END BOX CCP1.1 HERE]

[START FAQCCP1.! HERE]

FAQ CCP1.1: Why are biodiversity hotspots important?

Biodiversity hotspots are regions that are exceptionally rich in species, ecologically unique and which may contain geographically restricted species. They are thus priority targets for nature conservation.

Recognizing that the Convention on Biological Diversity definition of biodiversity includes the variation within and between species and of ecosystems, different schemes have been applied to define hotspots, leading to hundreds of different areas being proposed as hotspots. However, all identify a set of priority areas that cover a small portion of the Earth, but house an exceptionally high proportion of its biodiversity. Because biodiversity underpins all life on Earth, these hotspots have significant global value as they contain species and habitats that are found nowhere else. Their loss would mean loss of species and habitats that provide wild and farmed food, medicine and other materials, and services such as climate regulation, pollination and water purification, all of which maintain the health of the ecosystems we depend upon.

Healthy ecosystems, with flourishing biodiversity in natural conditions, are more resilient to disturbances, whether natural or human in origin. Environmentally sustainable development inside and outside hotspots could help reverse human impacts on biodiversity. The hotspots also capture and store carbon, thereby helping to mitigate climate change. Prioritization of protecting biodiversity in hotspots thus benefits nature conservation and helps mitigate climate change. A global network of protected areas and restoration initiatives inside biodiversity hotspots can also help increase resilience to the effects of climate change on biodiversity.

[END FAQ CCP1.1 HERE]

[START FAQ CCP1.2 HERE]

FAQ CCP1.2: How can society ensure conservation of biodiversity in climate policies?

To reduce the effects of climate change on biodiversity it is first essential to address direct human impacts that are already leading to a loss of biodiversity. This can be achieved by protecting biodiversity in conservation areas, restoring biodiversity everywhere possible and promoting sustainable development. Climate policies should thus integrate with policies to protect and restore nature.

Avoiding further loss of biodiversity is implicit in sustainable development. This needs to happen on land, rivers, lakes and in the oceans. It is especially important in "biodiversity hotspots" (FAQ-CCP1.1) and protected areas. Hence calls by the International Union for the Conservation of Nature (IUCN), Convention on Biological Diversity, United Nations Sustainable Development Goals and scientific community to increase the size and connectivity of fully protected areas (which aim to have biodiversity in a near natural condition) and include in them the biodiversity hotspots, need to be immediately implemented.

Five of the Sustainable Development Goals (SDGs) are life on land, life below water, good health and well-being, food security, and climate action. They underpin and interact with many other SDGs. Healthy ecosystems play a role in mitigating greenhouse gas emissions, not only protecting areas to prevent the release of carbon through land conversion activities but also restoring otherwise degraded land. The United Nations has declared 2021- 2030 as the Decade of Restoration, and the Decade of the Oceans. Restoration means actively or passively allowing habitat to return to its natural state (e.g., grassland, forest, peatland, oyster beds), including replanting native vegetation. This can benefit the recovery of biodiversity, help remove carbon dioxide from the atmosphere, and improve the delivery of nature's contributions to people such as climate regulation, water purification, pollination and pest and disease control. Thus, protecting biodiversity helps to meet two SDGs directly, and three indirectly.

On land, the loss of natural forests and grasslands not only means a loss of carbon and many of their associated species, but exposes soils to erosion, affecting food production, and can affect the climate by altering the water-cycle. Sustainable development, even within hotspots, involves active restoration of natural biodiversity, reducing poaching and trafficking of wildlife (UN SDG 15), and needs to include agriculture. This includes working to ensure biodiverse soils, and supporting healthy pollinator populations. Biodiversity includes not only wild species but also the genetic diversity, including crops and wild crop relatives. These wild relatives may contain important genes that could help farmed crops survive better in a changed climate. At least some of these wild relatives come from areas designated as hotspots. In the ocean, sustainable development means reducing pollution, carefully managed aquaculture development, increased protected areas (from the present 2.5% of the ocean area), enforcement of fisheries regulations, and removal of fishery subsidies that perpetuate over-fishing within Exclusive Economic Zones and on the High Seas (UN SDG 14). Generally, the use of freshwaters, both rivers, lakes and groundwaters, has not been sustainable and needs to restore biodiversity and water quality by eliminating pollution, and better management of abstraction, river flows, fishing and invasive species. Thus, as is the case with land and oceans, climate policies must prioritize the restoration of freshwater biodiversity, and reduction of the current negative impacts of human activities.

Cross-Chapter Paper 2: Cities and Settlements by the Sea

Cross-Chapter Paper Leads: Bruce Glavovic (New Zealand/South Africa), Richard Dawson (United Kingdom), Winston Chow (Singapore)

Cross-Chapter Paper Authors: Matthias Garschagen (Germany), Marjolijn Haasnoot (The Netherlands), Chandni Singh (India), Adelle Thomas (Bahamas)

Cross-Chapter Paper Contributing Authors: Jeroen Aerts (The Netherlands), Sophie Blackburn (United Kingdom), David Catt (USA), Eric Chu (USA), William Solecki (USA), Stijn-Temmerman (Belgium), Gundula Winter (Germany)

Cross-Chapter Paper Review Editor: Soojeong Myeong (Republic of Korea)

Cross-Chapter Paper Scientist: David Catt (USA)

Date of Draft: 1 October 2021

Notes: TSU Compiled Version

Table of Contents

Executive Summary

Cities and settlements by the sea (C&S) are on the frontline of climate change – they face amongst the highest climate-compounded risks but are a key source of innovations in climate resilient development (*high confidence*[1]) {Sections 6.1, 6.2; Chapter 7, Box 15.2; Cross-Chapter Box –COVID in Chapter 7; Cross-Chapter Box –SLR in Chapter 3; CCP2.2; SMCCP2.1; WGI Section 12.4.10.2}.

Much of the world's population, economic activities and critical infrastructure are concentrated near the sea (*high confidence*), with nearly 11% of the global population, or 896 million people, already living on low-lying coasts directly exposed to interacting climate- and non-climate coastal hazards (*very high confidence*) {CCP2.1}. Low-lying C&S are experiencing adverse climate impacts that are superimposed on extensive and accelerating anthropogenic coastal change (*very high confidence*) {WGI Section 12.4.10.2; Sections 6.1, 6.2; CCP2.2, SMCCP2.1}. Depending on coastal C&S characteristics, continuing existing patterns of coastal development will worsen exposure and vulnerability (*high confidence*) {CCP2.1}. With accelerating sea level rise (SLR) and worsening climate-driven risks in a warming world, prospects for achieving the Sustainable Development Goals (SDGs) and charting Climate Resilient Development (CRD) pathways are dismal (*high confidence*) {CCP2.3, CCP2.4; Chapter 16, 18}. However, coastal C&S are also the source of SDG and CRD solutions because they are centres of innovation with long histories of place-based livelihoods, many of which are globally connected through maritime trade and exchange (*medium confidence*) {CCP2.4}.

Regardless of climate and socio-economic scenarios, many C&S face severe disruption to coastal ecosystems and livelihoods by 2050 – and across all C&S by 2100 and beyond – caused by compound and cascading risks, including submergence of some low-lying island states (*very high confidence*) {CCP2.1; CCP2.2; SROCC SPM, Chapter 4; Section 6.2}.

There is *high confidence* that projected climate risks will increase with (i) exposure to climate- and ocean-driven hazards manifest at the coast, such as heat waves, droughts, pluvial floods, and impacts due to SLR, tropical cyclones, marine and land heatwaves, and ocean acidification; (ii) with increasing vulnerability driven by inequity, and (iii) increasing exposure driven by urban growth in at-risk locations. Compounded and cascading climate risks, such as to coastal C&S infrastructure and supply chain networks, are also expected to increase {Section 6.2.7; CCP2.2}. These risks are acute for C&S on subsiding and/or low-lying small islands, the Arctic, and open, estuarine and deltaic coasts (*high confidence*) {CCP2.2; Table SMCCP2.1}. By 2050, more than a billion people located in low-lying C&S will be at risk from coast-specific climate hazards, influenced by coastal geomorphology, geographical location and adaptation action (*high confidence*). Between US$7-14 trillion of coastal infrastructure assets will be exposed by 2100, depending on warming levels and socio-economic development trajectories (*medium confidence*) {CCP2.1}. Historically rare extreme sea level events will occur annually by 2100, with some atolls being uninhabitable by 2050. Coastal flood risk rapidly increases in coming decades, and could increase by 2–3 orders of magnitude by 2100 in the absence of effective adaptation and mitigation, with severe impacts on coast-dependent livelihoods and socio-ecological systems (*high confidence*) {SROCC SPM; Chapter 4}. Impacts reach far beyond C&S e.g., damage to ports severely compromising global supply chains and maritime trade with local-global geo-political and economic ramifications. Global investment costs to accommodate port growth and adapt to SLR amount to USD223-768 billion before 2050, presenting opportunities for C&S by the sea to build climate resilience (*medium evidence, high agreement*) {CCP2.1; CCP2.2; Cross-Chapter Box SLR in Chapter 3}. Severely accelerated SLR resulting from rapid continental ice mass-loss would bring impacts forward by decades, and adaptation would need to occur much faster and at much greater scale than ever done in the past (*medium confidence*).

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

A mix of interventions is necessary to manage coastal risks and build resilience over time. An adaptation pathways approach sets out near-term 'low-regret' actions that align with societal goals, and facilitates implementation of a locally appropriate sequence of interventions in the face of uncertain climate and development futures, and enables necessary transformation (*high confidence*) {CCP2.3; Cross-Chapter Box DEEP in Chapter 17, Cross-Chapter Box SLR in Chapter 3}

A mix of infrastructural, nature-based, institutional and socio-cultural interventions are needed to reduce the multifaceted risk facing C&S, including vulnerability reducing measures, avoidance (i.e., disincentivising developments in high-risk areas), hard- and soft-protection, accommodation, advance (i.e., building up and out to sea) and retreat (i.e., landward movement of people and development) (*very high confidence*) {CCP2.3}. Depending on the C&S archetype, technical limits for hard protection may be reached beyond 2100 under high emission scenarios, with socio-economic and governance barriers reached before then (*medium confidence*). Hard protection can, however, set up lock-in of assets and people to risks and, in some cases, may reach limits, due to technical and financial constraints, by 2100 or sooner depending on the scenario, local SLR effects and community tolerance thresholds (*medium confidence*). Where sufficient space and adequate habitats are available, nature-based solutions can help to reduce coastal hazard risks and provide other benefits, but biophysical limits may be reached before end-century (*medium confidence*). Accommodation is easier, faster and cheaper to implement than hard protection, but limits may be reached by 2100, or sooner in some settings. An adaptation pathways planning approach demonstrates how the solution space can expand or shrink depending on the type and timing of adaptation interventions {CCP1.3.1.2}. As SLR is relentless on human timescales, the solution space will shrink without adoption of an adaptation pathways planning approach (*high confidence*). Due to long implementation lead times and the need to avoid maladaptive lock-in, especially in localities facing rapid SLR and climate-compounded risk, adaptation will be more successful if timely action is taken accounting for long-term (committed) SLR; and if this is underpinned by sustained and ambitious mitigation to slow greenhouse gas emission rates (*high confidence*) {CCP2.3; CCP2.4; Cross-Chapter Box SLR in Chapter 3}.

Individual and collective choices founded on public-centred values and norms, as well as pro-social behaviour, help to foster climate resilient coastal development in C&S (*high confidence*) {CCP2.4.1}.

The effectiveness of different approaches (e.g., awareness and education, market-based and legal strategies) is mediated by how well they address contextual and psycho-social factors influencing adaptation choices in coastal C&S (*medium confidence*). Adaptation options accounting for risk perceptions and aligning with public values are more likely to be socio-culturally acceptable, and consequently facilitate pro-social behavioural change {CCP2.4.1}.

Locally appropriate institutional capabilities, including regulatory provisions and finances dedicated to maintaining healthy coastal social-ecological systems, build adaptive capacity in C&S by the sea (*high confidence*) {CCP2.4}.

Implementing integrated multi-level coastal zone governance, pre-emptive planning, enabling behavioural change, and alignment of financial resources with a wide set of values, will provide C&S with greater flexibility to open up the solution space to adapt to climate change (*high confidence*) {CCP2.4.4}. Insufficient financial resources are a key constraint for coastal adaptation, particularly in the Global South (*high confidence*). Engaging the private sector in coastal adaptation action with a range of financial tools is crucial to address the coastal adaptation funding gap (*high confidence*). Considering the full range of economic and non-economic values will improve adaptation effectiveness and equity across C&S archetypes (*high confidence*). Aligning adaptation in C&S with socio-economic development, infrastructure maintenance, and COVID-19 recovery investments will provide additional co-benefits {CCP2.4.2}. Urgency is also driven by the need to avoid lock-in to new and additional risk, e.g., avoid C&S sprawl into fragile ecosystems and the most exposed coastal localities {CCP2.3}.

Realising global aspirations for climate resilient development depend on the extent to which coastal C&S institutionalise key enabling conditions and chart place-based adaptation pathways to close the coastal adaptation gap, and take urgent action to mitigate greenhouse gas emissions (*medium confidence*) {CCP2.4, Table CCP2.1}.

Since AR5, extensive adaptation planning has been undertaken, but there has not been widespread effective implementation - giving rise to a ‘coastal adaptation gap’ (*high confidence*). To date, most interventions have been reactive, reliant on protective works alone (*high confidence*). Effectiveness of alternative interventions differs among C&S archetypes, while their feasibility is influenced by geomorphology, socio-economic conditions as well cultural, political and institutional considerations (*very high confidence*). Mismatches between adaptation needs and patterns of physical development are commonplace in many coastal C&S, with especially adverse impacts on poor and marginalised communities in the global North and South (*high confidence*). Overcoming this gap is key to transitioning towards CRD (*medium confidence*). Under higher warming levels and higher SLR, increasingly dichotomous coastal futures will become more entrenched (*medium confidence*), with stark differences between more urbanised, resource-rich coastal C&S dependent on hard protection, and more rural, resource-poor C&S facing displacement and migration {CCP2.3; CCP2.4, Chapter 18}.

Coastal adaptation innovators adopt more flexible, anticipatory and integrative strategies, combining technical and non-technical interventions that account for uncertainties, and facilitate effective resolution of conflicting interests and worldviews (*limited evidence, high agreement*) {CCP2.3; CCP2.4; Chapter 17, 18; Cross-Chapter Box DEEP in Chapter 17}. Moreover, a core set of critical enablers is foundational for C&S to chart CRD pathways. These include building and strengthening governance capabilities to tackle complex problems; taking a long-term perspective in making short-term decisions; enabling more effective coordination across scales, sectors and policy domains; reducing injustice, inequity, and social vulnerability; and unlocking the productive potential of coastal conflict while strengthening local democracy (*medium evidence, high agreement*) {Table CCP2.1, Table CCP2.2}.

C&S play a pivotal role in global aspirations to implement the Paris Agreement, advance the SDGs, and foster CRD. Progress towards these ends depends on the extent to which C&S mobilise urgent and transformational changes to institutionalise enabling conditions; close the coastal adaptation gap by addressing the drivers and root causes of exposure and vulnerability to climate-compounded coastal hazard risks; and drastically reduce greenhouse gas emissions (*medium confidence*) {CCP2.4; Chapter 18}

CCP2.1 Context of Cities and Settlements by the Sea

CCP2.1.1 Introduction and Context

This CCP examines the distinctive roles played by Cities and Settlements (C&S) by the sea in vulnerability and coastal hazard risk reduction, adaptation, resilience, and sustainability in a changing climate. The paper builds upon evidence from AR5 (Wong et al., 2014), the Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC) (Magnan et al., 2019; Oppenheimer et al., 2019) and draws material from across WGII AR6 (especially Chapters 3, 6, 9-15). It differs from the sea level rise (SLR) focused analysis of urban areas in SROCC (Section 4.3) through a more integrated assessment that distinguishes between archetypal coastal C&S (CCP2.1.2); sectoral risks to C&S by the sea, (CCP2.2); responses to address these risks (CCP2.3); and enabling conditions and lessons learned (CCP2.4).

We define 'cities and settlements' as concentrated human habitation centres, whether small or large, rural or urban (Chapter 6.1.3). We highlight the unique exposure and vulnerability of coastal C&S resulting from rapid urbanisation at the narrow land-sea interface, concentration of economic activity and at-risk people, many with long-standing cultural ties to the coast and dependence on coastal ecosystems that are prone to climate change impacts (*high confidence*) (He and Silliman, 2019; Lau et al., 2019; Oppenheimer et al., 2019; Sterzel et al., 2020).

Presently, coastal C&S population exposure to ocean-driven impacts from SLR, and other climate-driven impacts is considerable by any measure (Buddemeier et al., 2008; Barragán and de Andrés, 2015; Kay and Alder, 2017; Haasnoot et al., 2019; McMichael et al., 2020; Sterzel et al., 2020). In 2020, almost 11% of global population – 896 million people – resided in C&S within the Low Elevation Coastal Zone (LECZ, coastal areas below 10 m of elevation above sea level that are hydrologically connected to the sea) (Haasnoot et al., 2021b), and potentially increases beyond 1 billion by 2050 (Oppenheimer et al., 2019). Infrastructural and economic assets worth US$6,500-US$11,000 billion are also exposed in the 1-in-100-year floodplain for C&S of all sizes (Neumann et al., 2015; Muis et al., 2016; Brown et al., 2018; Andrew et al., 2019; Kulp and Strauss, 2019; Kirezci et al., 2020; Thomas et al., 2020; Haasnoot et al., 2021b; Hooijer and Vernimmen, 2021).

Further, coastal cities located at higher elevations (e.g., São Paulo, Brazil), or distantly located inland along tidal-influenced rivers (e.g., the Recife Metropolitan Region, Brazil) also have populations and infrastructure exposed to climate impacts. As such, the inclusion of C&S beyond the LECZ is warranted when assessing climate impacts and associated exposure, vulnerabilities and risks. The coastal zone includes some of the world's largest, most densely populated megacities, as well as the fastest-growing urban areas. However, vast coastal areas are sparsely populated, with population in these regions concentrated in smaller C&S, including along subsiding shorelines and in deltas (Nicholls and Small, 2002; McGranahan et al., 2007; Merkens et al., 2018; Edmonds et al., 2020; Nicholls et al., 2021). From this wider perspective, climate change impacts on the coast directly or indirectly affect a large portion of the global population, economic activity and associated critical infrastructure. Some estimates suggest 23-37% of the global population lives within 100 km of the shoreline (Nicholls and Small, 2002; Shi and Singh, 2003; Christopher Small and Joel E. Cohen, 2004; McMichael et al., 2020).

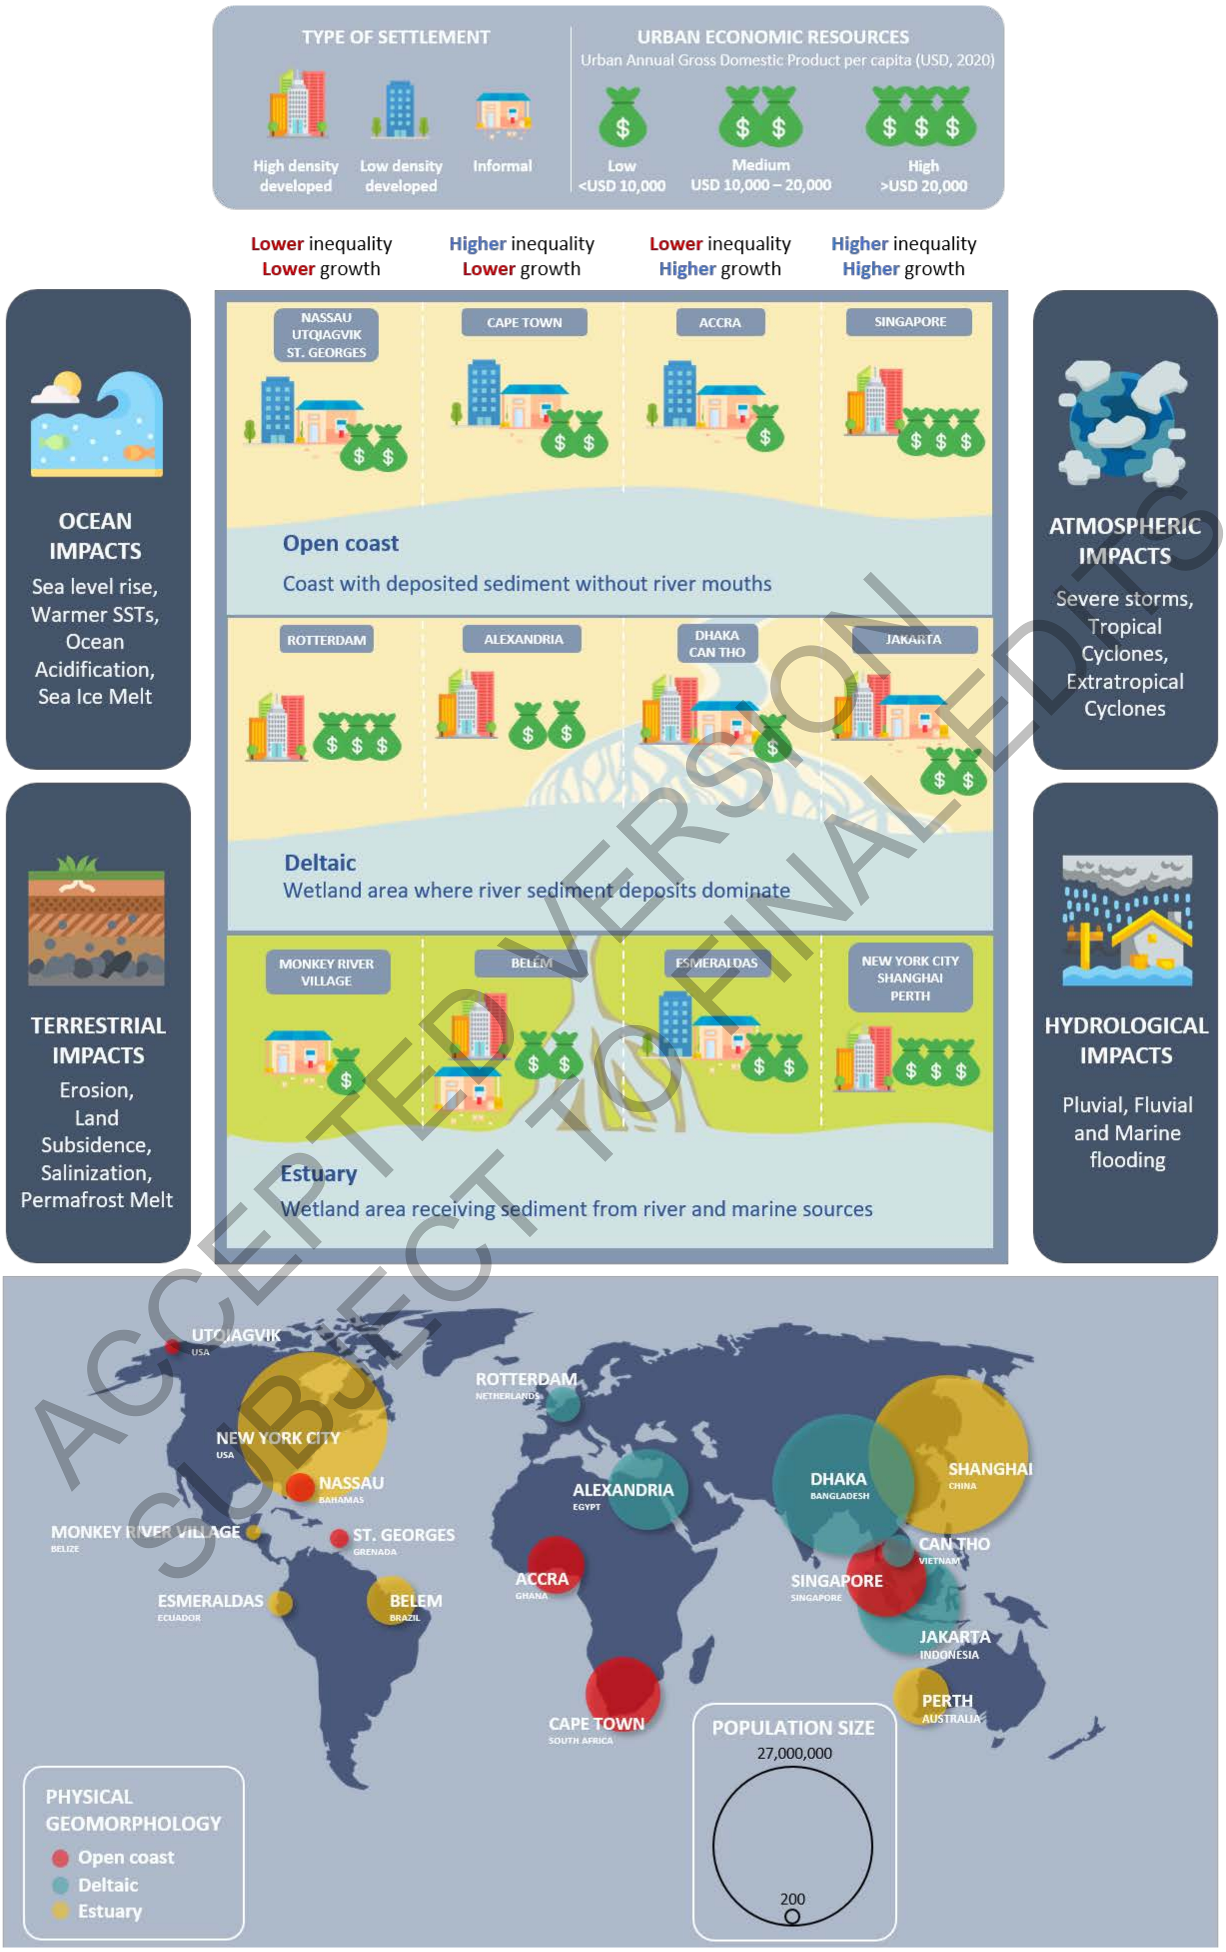
C&S by the sea are thus on the 'frontline' of action to adapt to climate change, mitigate greenhouse gas emissions, and chart climate resilient development (CRD) pathways for several distinct reasons. First, home to a concentrated (and growing) portion of the world's population, many coastal C&S are simultaneously exposed and vulnerable to climate-compounded hazards as well as being centres of creativity and innovation (Glavovic, 2013; Crescenzi and Rodríguez-Pose, 2017; Druzhinin et al., 2021; Mariano et al., 2021; Storbjörk and Hjerpe, 2021). Second, people in C&S by the sea rely on coastal ecosystems, many of which are highly sensitive to climate change impacts that compound non-climate risks and increase the precarity of coastal livelihoods (Lu et al., 2018; He and Silliman, 2019; Thrush et al., 2021). Third, coastal C&S are linked together through a network of ports and harbours that underpin global trade and exchange but are prone to climate change impacts, especially SLR, with significant implications for global CRD prospects (Becker et al., 2018; Christodoulou et al., 2019; Walsh et al., 2019; Hanson and Nicholls, 2020). For these reasons, this paper assesses responses, enabling conditions and lessons learned for addressing climate change in C&S by the sea.

CCP2.1.2 Urbanisation in Coastal Systems: Coastal City and Settlement Archetypes

This assessment uses an archetype framework categorizing coastal C&S according to geomorphological characteristics, urban growth, economic resources, and inequalities (Figure CCP2.1). We use three broadly defined coastal settlement geomorphologies in each row: open coasts (a coast with sediment without river mouths), and two transitional coastal zones with river mouths: estuaries (a wetland receiving sediment from both fluvial and marine sources, which is affected by tide, wave, and river processes), and deltas (a wetland where fluvial sediment is supplied and deposited more rapidly than it can be redistributed by basin processes such as waves and tides) (Bhattacharya, 1978; Barragán and de Andrés, 2015; Kay and Alder, 2017; Haasnoot et al., 2019; Sterzel et al., 2020). Small island C&S are not singled out in this typology because their coastlines often include the geomorphic features listed above, or require a different adaptation approach at larger spatial scales (Haasnoot et al., 2019). Several coastal C&S have a combination of two typologies e.g., Maputo-Matola, Mozambique, and Mumbai, India, having both open and transitional riverine coasts, and can be classed as mixed. We also acknowledge several coastal C&S may have areas sited in mountainous topography that abruptly rise from the coast (e.g., along the Mediterranean), but generally these cities have narrow densely populated coastal shelfs exhibiting these three archetypal categories (Blackburn et al., 2019). Arctic settlements are addressed separately in this CCP.

Coastal C&S within these geomorphological categories are further distinguished according to higher or lower rates of urban growth and inequality – which can be estimated through population growth from national census data, or areal extent of urban development (CEIC); as well as relative urban inequalities estimated by Gini Coefficient data and urban-rural poverty rates (OECD, 2018; OECD, 2020). Combining geomorphological and socio-economic data accounts for urban-rural interconnections and differences; with levels of capital generation, diversity of economic functions and human development indices having previously been used to discern cultural, economic, administrative and political differences between cities and their hinterland (Blackburn et al., 2019; Rocle et al., 2020). For instance, the ecological, cultural and economic footprint of tertiary sectors e.g., coastal tourism associated with the Australian Great Barrier Reef stretches far beyond the nearest onshore settlement of Cairns (Bohnet and Pert, 2010; Brodie and Pearson, 2016).

Some caveats are warranted. First, locating a specific city or settlement in a particular archetype does not account for future reclassification due to growth or shifts in development trajectories. Second, significant socio-economic, political and governance variations exist within many C&S, c.f., impoverished informal settlements alongside wealthy neighbourhoods in cities like Cape Town and São Paulo (also see Table SMCCP2.1). Third, this archetype framework does not explicitly reveal important interconnections between coastal C&S and their hinterlands, or between particular C&S through maritime trade or other economic, socio-cultural and geopolitical inter-dependencies. Notwithstanding these caveats, these archetypes reveal differentiated physical impacts and socio-economic conditions, as well as the variable challenges and opportunities arising for addressing climate change impacts and projected risk, which, depending on coastal type, C&S size, and resource availability, help to inform efforts to adapt and chart CRD for each archetype (Sánchez-Arcilla et al., 2016; Rocle et al., 2020; Sterzel et al., 2020).



TYPE OF SETTLEMENT
High density developed
Low density developed
Informal
URBAN ECONOMIC RESOURCES
Urban Annual Gross Domestic Product per capita (USD, 2020)
Low <USD 10,000

Figure CCP2.1: Archetypal C&S affected by ocean, terrestrial, geological, atmospheric and hydrological hazards driven by climate change. Coastal C&S are grouped by physical geomorphology along estuary, deltaic, or open coasts (Barragán and de Andrés, 2015; Kay and Alder, 2017; Haasnoot et al., 2019). C&S are also classified according to relative inequality (e.g., urban Gini coefficient or poverty rates) and growth rates (e.g., recent population growth and increasing density of urban form or built-up area over the past decade) (OECD, 2018; CEIC; OECD, 2020). Settlement types (e.g., informal, low-density or high-density developments) and economic resources (e.g., urban per capita GDP) are also reflected in their respective categories. The bottom map shows the location, 2020 population size, and geomorphological types.

CCP2.2 Climate Change Risks to Cities and Settlements by the Sea

Coastal C&S are at the forefront of climate risk (FAQ CCP2.1). The dynamic interaction between ocean- and climate-drivers and varied coastal geographies influences the character of coastal risks, including many that are unique to C&S by the sea. The interaction of coastal hazards with exposure and vulnerability is differentiated by coastal archetypes, leading to distinct climate change-compounded risks, and associated responses (Figure CCP2.2; Section 1.3.1.2; Simpson et al. (2021)).

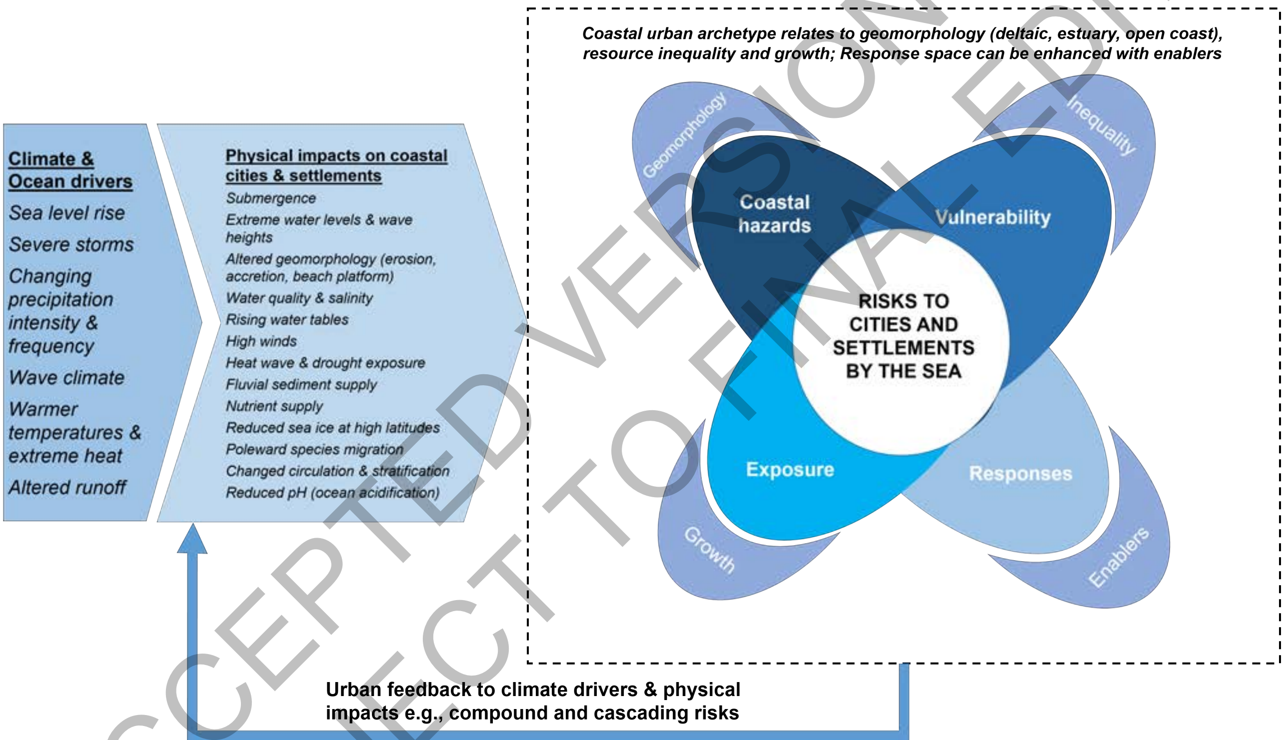

Figure CCP2.2: Schematic of how climate- and ocean-drivers (from WGI Chapter 12.4.10.2) and consequential physical impacts on coastal C&S influence risks assessed in (CCP2.2; Figure based on Simpson et al. (2021) and Section 1.3.1.2). These risks to C&S by the sea are shaped and mediated by adaptation interventions aimed at reducing vulnerability and exposure to coastal hazards given settlement archetypes, as well as by expanding the space for responses to risk via enabling conditions assessed in (CCP2.4). Note that exposure to coastal hazard is controlled chiefly by underlying coastal C&S geomorphology, and changes in coastal hazards and urban growth, including population and infrastructure growth; vulnerability is controlled, for example, by socio-economic development and inequality; and responses that shape risks assessed in (CCP2.3) can be enhanced by enabling conditions, including behavioural change, conducive finance, and prudent governance.

Overall, interactions between climatic and non-climatic drivers of coastal change are increasing the frequency and intensity of many coastal hazards, with settlement archetypes and the wider coastal zone subject to escalating risk (*high confidence*) (Figure CCP2.2; Table SMCCP2.1 for examples of selected coastal C&S). Risks can vary markedly between different archetypes. C&S sited on deltaic and estuarine coasts face additional risks of pluvial flooding compared to open coasts; while greater vulnerabilities arise in coastal settlements with higher inequalities.

Risks to C&S by the sea were extensively covered in SROCC (Oppenheimer et al., 2019) and also in WGII Chapter 3, 6 and regional chapters; in this paper, specific risks to livelihoods, activities, built environment, and ecosystems are assessed in detail in Supplementary Material SMCCP2.1. The ocean- and climate-impact drivers influencing these risks are assessed in WG1 (Section 12.4.10.2), which include extreme heat, pluvial floods from increasing rainfall intensity, coastal erosion and coastal flood driven by increasing SLR, and tropical cyclone storm surges (*high confidence*). Further, Arctic coastal settlements are particularly exposed to climate change due to sea ice retreat as well as from permafrost melt (*high confidence*).

Without adaptation, risks to land and people in coastal C&S from pluvial- and coastal-flooding will *very likely*[2] increase substantially by 2100 and *likely* beyond as a result of SLR, with significant impacts even under RCP2.6 (Neumann et al., 2015; Muis et al., 2016; Brown et al., 2018; Nicholls et al., 2018; Kulp and Strauss, 2019; Oppenheimer et al., 2019; Kirezci et al., 2020; Haasnoot et al., 2021b). Across these studies, by 2100, 158-510 million people and US$7,919-US$12,739 billion assets under RCP4.5, and 176-880 million people and US$8,813-US$14,178 billion assets under RCP8.5, will be within the 1-in-100-year floodplain (*very high confidence*). There is *medium confidence* that accelerated SLR will increase shoreline erosion globally, although biophysical feedbacks will allow many coastlines to maintain relatively stable morphology if room exists to accommodate mangroves in estuarine and deltaic coasts, and beach movement along open coasts (Kench et al., 2015; McLean and Kench, 2015; Perkins et al., 2015; Richards and Friess, 2016; CCC, 2017; Duncan et al., 2018; Luijendijk et al., 2018; Mentaschi et al., 2018; Schuerch et al., 2018; Ghosh et al., 2019; Masselink et al., 2020; Toimil et al., 2020; Vousdoukas et al., 2020b). Limiting emissions to RCP2.6 (corresponding to a mean post-industrial global temperature increase of 1.5-2C) significantly reduces future SLR risks (Hinkel et al., 2014; Brown et al., 2018; Nicholls et al., 2018; Schinko et al., 2020). For example, by 2100 the population at risk of permanent submergence increases by 26% under RCP2.6 compared with 53% under RCP8.5 (median values from Kulp and Strauss (2019).

There is *high confidence* about regionally differentiated but considerable global sectoral impacts in coastal C&S arising from exposure to hazards. Tangible impacts include damage, loss of life, loss of livelihoods, especially fisheries and tourism (Tessler et al., 2015; Avelino et al., 2018; Hoegh-Guldberg et al., 2018; Seekamp et al., 2019; Arabadzhyan et al., 2020); negative impacts on health and wellbeing, especially under extreme events (McIver et al., 2016; Bakkensen and Mendelsohn, 2019; Bindoff et al., 2019; Pugatch, 2019); and involuntary displacement and migration (Hauer, 2017; Davis et al., 2018; Neef et al., 2018; Boas et al., 2019; McLeman et al., 2021). Intangible impacts include psychological impacts due to extreme events, such as heat-waves, flooding, droughts, and tropical cyclones; heightened inequality in coastal archetypes with systematic gender/ethnicity/structural vulnerabilities; and loss of things of personal or cultural value, and sense of place or connection, including existential risk of the demise of nations due to submergence (Allison and Bassett, 2015; Barnett, 2017; Schmutter et al., 2017; Weir et al., 2017; Farbotko et al., 2020; Hauer et al., 2020; Hoffmann et al., 2020; Bell et al., 2021). Impacts extend beyond the coastal zone, for example disruption to ports and supply chains, with major geopolitical and economic ramifications from the C&S to global scale (*very high confidence*) (Becker et al., 2018; Camus et al., 2019; Christodoulou et al., 2019; Walsh et al., 2019; Hanson and Nicholls, 2020; Yang and Ge, 2020; Izaguirre et al., 2021; León-Mateos et al., 2021; Ribeiro et al., 2021).

Many coastal C&S have densely built physical infrastructure and assets that are exposed and vulnerable to climate change-compounded coastal hazards. There is *high confidence* that SLR, land subsidence, poorly regulated coastal development, and the rise of asset values are major drivers of future risk in all coastal archetypes and, without adaptation, built environment risks, especially in archetypes with high exposure due to rapid growth, are expected to rise considerably in this century across all RCPs (Koks et al., 2019; Magnan et al., 2019; Oppenheimer et al., 2019; Abadie et al., 2020; Nicholls et al., 2021). Archetypes with more

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

informal settlements are often disproportionally exposed to coastal risks (Roy et al., 2016; Hallegatte et al., 2017; Bangalore et al., 2019).

There is *high confidence* that loss of coastal ecosystem services will increase risks to all coastal C&S archetypes that include reduced provisioning of materials and food (e.g., wood, fishery habitat) (Kok et al., 2021), amelioration of coastal hazards (e.g., attenuation of storm surges, waves, and containing erosion) (Section 2.3.2.3; Godfroy et al., 2019; Schoutens et al., 2019; Zhu et al., 2020b), climate change mitigation (through carbon sequestration) (Macreadie et al., 2017; Rovai et al., 2018; Ward, 2020), water quality regulation (nutrient, pollutant and sediment retention and cycling) (Wilson et al., 2018; Zhao et al., 2018), and recreation and tourism (Pueyo-Ros et al., 2018).

Most studies of coastal C&S focus on adaptation to a single or limited set of risks, but there is *high confidence* that compound and cascading risks significantly alter C&S risk profiles (Nicholls et al., 2015; Estrada et al., 2017; Edmonds et al., 2020; Eilander et al., 2020; Yin et al., 2020; Ghanbari et al., 2021). Extreme events can lead to cascading infrastructure failures that cause damage and economic losses well beyond the coastal zone (Haraguchi and Kim, 2016; Kishore et al., 2018; Rey et al., 2019; So et al., 2019), and have forced evacuation of C&S and small islands (Look et al., 2019; Thomas and Benjamin, 2020). These risks are exacerbated by non-climate drivers, e.g., compound and cascading impacts arising from exposure to tropical cyclones and COVID-19 that threaten population health and hamper pandemic responses (Salas et al., 2020; Shultz et al., 2020a; Shultz et al., 2020b). There is emerging evidence (*low confidence*) from individual coastal C&S, and regional case studies (e.g., in Europe, Australia, and the U.S.), illustrating the increasing influence of compound risks on vulnerability due to accelerating climate change (Wahl et al., 2015; Xu et al., 2019; Kirezci et al., 2020).

Figure CCP2.3 shows that ocean-driven coastal risks to people, land, and infrastructure in East and Southeast Asia are highest compared to other regions, even for low levels of projected SLR. However, risks facing coastal C&S are high across the globe, especially under higher SLR projections (*high confidence*). Without adaptation, the population at-risk to a 100-year coastal flood increases by ~20% if current global mean sea level rises by 0.15m relative to current levels; this at-risk population doubles at 0.75m rise in mean sea level, and triples at 1.4m. Simultaneously, coastal C&S are projected to experience shoreline retreat, with coastlines having more than 100 m retreat increasing ~165% if current mean sea levels rise between 0.23-0.53 m. Ocean-driven flooding in coastal C&S is also projected to disrupt flights by up to three orders of magnitude per year in selected coastal C&S as mean sea level increases. Typically, larger risks correspond with archetypes associated with higher inequality and high growth rates, especially in deltas, leading to larger vulnerability and exposure respectively under higher warming levels.

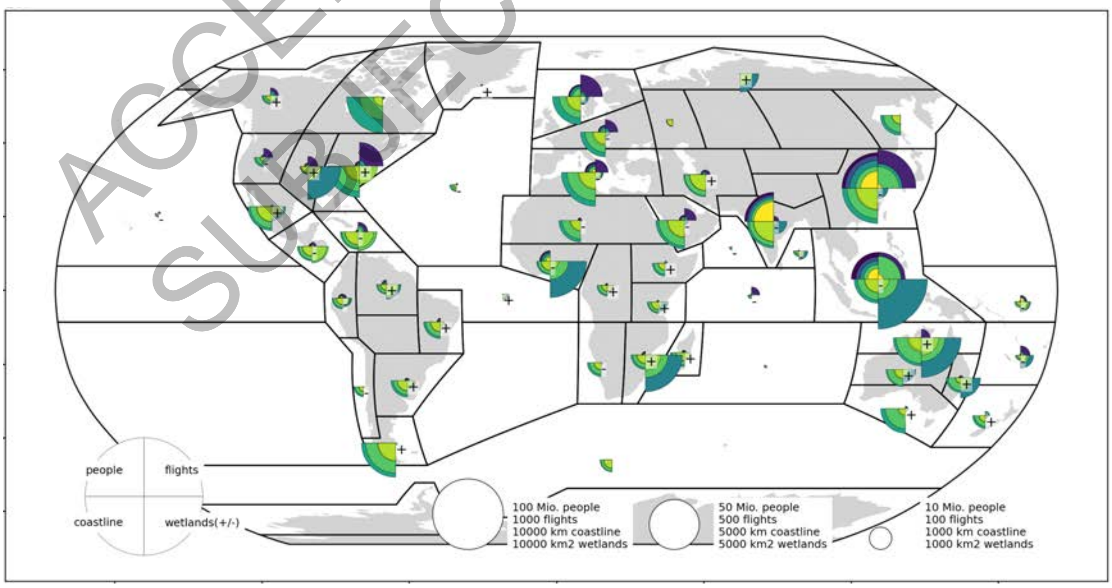

Figure CCP2.3: Map of coastal C&S risks according to IPCC regions, showing risks to people from a 100-year coastal flood event (*100.000) (Haasnoot et al., 2021b), risks to loss of coastal land (length of coast with more than 100 m retreat) (Vousdoukas et al., 2020b), risks to the built environment (airports at risk indicated by number of flights disrupted (Yesudian and Dawson, 2021)) and risk to wetlands (± indicates positive or negative area change) (Schuerch et al., 2018). Risks are reported against global mean sea level rise relative to 2020, depending on data availability.

CCP2.3 Adaptation in Cities and Settlements by the Sea

CCP2.3.1 Introduction

This section extends SROCC Chapter 4 (Oppenheimer et al., 2019), which focused on SLR, and draws from Chapters 6 and 9-15 to cover all C&S archetypes. Adaptation interventions span psycho-social (e.g., awareness raising), economic (e.g., insurance), physical (e.g., retreat), technical (e.g., sea walls) and natural dimensions (e.g., wetland restoration) (Nicholls et al., 2015). Adaptation strategies for coastal C&S are typically classified in terms of protect, accommodate, advance, and retreat, which are used below.

Some coastal cities have adapted to meters of SLR in the past, indicating that adaptation is feasible (Esteban et al., 2020a), but future adaptation options are influenced by variations in projected socio-economic conditions and rates of SLR (Cross-Chapter Box SLR in Chapter 3). To date, interventions are typically implemented reactively in response to extreme events (*high confidence*); but leading adaptors are increasingly proactive (*medium confidence*) (Araos et al., 2016; Dulal, 2019; Dedekorkut-Howes et al., 2020), and those that move from previously rigid to more adaptive and flexible solutions, using an adaptation pathways approach that keeps options open in the face of uncertainty, have improved climate risk management (*high confidence*) (Sections 9.9.4; 10.5; 11.7; 12.5.5; 13.2; 14.7; 15.5; Cross-Chapter Box DEEP in Chapter 17; Walker et al., 2013; Marchau et al., 2019).

The effectiveness of different strategies and interventions is mediated by physical coastal features for hard adaptation measures, and by the scope and depth of soft adaptation measures, e.g., the coverage extent of social safety nets for urban poor (Section 6.3). Their feasibility is also shaped by socio-economic, cultural, political and institutional factors, e.g., social acceptance of measures (CCP2.2, SMCCP2.2.4). Together, response effectiveness and feasibility shape the solution space for mediating risks (Section 1.3.1.2; Figure CCP2.3; Simpson et al., 2021;), which is achieved chiefly through governance interventions e.g., laws and regulations (Haasnoot et al., 2020). Access to financial resources expands the solution space, most notably for some resource-rich coastal archetypes (CCP2.4.2; Table SMCCP2.1; Sections 3.6, 14.7), but rapid population growth and unfolding climate-driven impacts can increase risks (Haasnoot et al., 2021a) especially for small island and poorer C&S (*high confidence*) (Section 15.3; Magnan and Duvat (2020).

CCP2.3.2 Protection of Coastal Cities and Settlements

CCP2.3.2.1 Hard Engineering Measures

Hard engineering protection measures are commonly used to reduce coastal flooding, and to drain or store excess water from intense precipitation. Many coastal cities, in particular densely populated and high resource archetypes, have planned and are planning to continue a protection-based strategy, comprising e.g., breakwaters, sea walls and/or dikes, which could be raised or complemented with large barriers or with 'super-levees' enabling construction on top of them (*high confidence*) (Table SMCCP2.1; Takagi et al., 2016; Haasnoot et al., 2019; Hall et al., 2019; Esteban et al., 2020b)).

Protection is effective in the short- to medium-term for many coastal cities, and can be cost-effective in the 21st Century (section CCP2.4.2), but residual risk remains because protection can fail. Even under RCP8.5, technical limits to hard protection may only be reached after 2100 in many regions, but socio-economic and institutional barriers may be reached before then (Hinkel et al., 2018). With progressive SLR, protection eventually becomes unaffordable and impractical (Strauss et al., 2021). Combining hard engineering measures with nature-based solutions, spatial planning and early warning systems, can help to contain residual risk (Du et al., 2020). Protective works do not prevent salinisation and higher groundwater levels (Alves et al., 2020), and can lead to loss of coastal habitat (Cross-Chapter Box SLR in Chapter 3; Achete et al. (2017); Cooper et al. (2020)). Hard protection measures also create long-term path-dependency as they last for decades and attract new development, locking in impact and exposure as C&S grow, with the expectation of ongoing protection (Chapter 3; Di Baldassarre et al., 2015; Gibbs, 2016; Griggs and Patsch, 2019; Siders, 2019a).

CCP2.3.2.2 Soft Engineering and Sediment-based Measures

Sediment-based interventions e.g., beach nourishment, aim to limit coastal erosion and flood risk and have become a widely applied strategy especially in open coast archetypal C&S; in part because there is less impact on adjacent beaches and coastal ecology, and lower construction and maintenance costs compared to hard protection (*high confidence*) (Parkinson and Ogurcak, 2018). In addition, it is considered a flexible strategy under more rapid SLR conditions (Kabat et al., 2009; Stive et al., 2013), and can be applied in the form of a mega-nourishment strategy wherein natural currents distribute sand along the coast (Stive et al., 2013; de Schipper et al., 2021). However, there are limits to this strategy due to environmental impacts, costs, and the availability of potential and permitted sand reserves which may be unable to keep up with higher rates of SLR (Parkinson and Ogurcak, 2018; Haasnoot et al., 2019; Harris et al., 2021; Staudt et al., 2021). Simultaneously, other socio-economic needs (e.g., damming rivers, or for building and transport infrastructure) may compete for sand as a limited resource (Torres et al., 2017; Bendixen et al., 2019). Regional and global governance provisions (e.g., spatial reservations for sand mining; international frameworks for distribution) could improve long-term feasibility (Torres et al., 2017; Parkinson and Ogurcak, 2018; Bendixen et al., 2019; Haasnoot et al., 2019).

CCP2.3.2.3 Nature-based Measures

Nature-based measures, such as retaining mangroves and marshes, have been successful in reducing deaths and damage due to storm surges (*high agreement, medium evidence*) (Das and Vincent, 2009; Saleh and Weinstein, 2016; Narayan et al., 2017; Triyanti et al., 2017; Hochard et al., 2019; del Valle et al., 2020), and across the USA reportedly provide USD23.2 billion yr-1 in storm protection services (Saleh and Weinstein, 2016). They are also a cost-effective strategy (*medium confidence*) that provide C&S with additional co-benefits through ecosystem services (*high confidence*) (Cross-Chapter Box NATURAL in Chapter 2; Section 2.2.4; Narayan et al., 2016; Depietri and McPhearson, 2017; Morris et al., 2018; Reguero et al., 2018; Chausson et al., 2020; Du et al., 2020; NIES and ISME, 2020; Reguero et al., 2020; Sudmeier-Rieux et al., 2021).

Nature-based measures can reduce inland propagation of extreme sea levels (high tides, storm surges) (*high agreement*) (Godfroy et al., 2019; James et al., 2020; Zhu et al., 2020b), with vertical reduction in water levels ranging from 5-50cm/km behind large mangroves and marshes (Stark et al., 2015; Van Coppenolle and Temmerman, 2020). They also attenuate wind-driven waves and reduce shoreline erosion (*high agreement*), and this can be as much as 90% over stretches of 10-100 meters for dense mangrove and marsh vegetation (*medium evidence*) (Li et al., 2014; Möller et al., 2014; Vuik et al., 2016; Vuik et al., 2018; Godfroy et al., 2019; Zhu et al., 2020a) and up to 40% for dunes (Feagin et al., 2019). Coral reefs on average reduce wave energy by 97% (Ferrario et al., 2014). Seagrass meadows attenuate wind waves to a lesser extent, and are only effective in water <0.2 m deep (Ondiviela et al., 2014; Narayan et al., 2016; Morris et al., 2019).

Within limits, coastal ecosystems can respond to rising sea-level through sediment accretion and lateral inland movement (Kirwan et al., 2016; Schuerch et al., 2018). Nature-based measures have greatest potential in coastal deltas and estuaries, where human populations are exposed but large ecosystems, like mangroves and marshes, can be conserved and restored (Menéndez et al., 2020; Van Coppenolle and Temmerman, 2020). Their feasibility depends on physical, ecological, institutional, and socio-economic conditions that are typically locality-dependent (Temmerman and Kirwan, 2015; Arkema et al., 2017); space may not be available in certain places (e.g., intensive urbanization on the shoreline), or these measures may conflict with other human demands for scarce land (Tian et al., 2016). Successful nature-based measures require site-specific knowledge and science-based design, pilot monitoring, and adaptive upscaling (Evans et al., 2017; Nesshöver et al., 2017), and more rigorous understanding of long-term performance, maintenance and costs (Kumar et al., 2021).

Nature-based measures are increasingly implemented in combination with hard protection measures (Hu et al., 2019; Schoonees et al., 2019; Morris et al., 2020; Oanh et al., 2020). They can reduce dike failure and increase design life where sediment accretion allows wetlands to respond to SLR (Jongman, 2018; Vuik et al., 2019; Zhu et al., 2020a). There is *high agreement* that a hybrid strategy combining hard and soft protect strategies is more effective and less costly under many circumstances; and there is *limited evidence* that technical limits will be encountered with such a strategy for low-lying C&S built on soft or permeable soil or with high exposure to monsoons and river discharges (Spalding et al., 2014; Sutton-Grier et al., 2015; Pontee et al., 2016; Morris et al., 2018; Reguero et al., 2018; Du et al., 2020; Morris et al., 2020; Seddon et al., 2020; Waryszak et al., 2021).

CCP2.3.3 Accommodation of the Built Environment

The most effective solution for limiting the growth of climate risks in C&S by the sea is to avoid new development in coastal locations prone to major flooding and/or SLR impacts (*very high confidence*) (Cross-Chapter Box SLR in Chapter 3; Oppenheimer et al., 2019; Doberstein et al., 2019). For existing C&S accommodation includes biophysical and institutional responses to reduce exposure and/or vulnerability of coastal residents, human activities, ecosystems and the built environment, enabling continued habitation of coastal C&S (Oppenheimer et al., 2019). Next to hard protection, accommodation is the most widely used adaptation strategy across all archetypes to date (*high confidence*) (Sayers et al., 2015; Olazabal et al., 2019; Le, 2020). Measures include elevation or flood-proofing of houses and other infrastructure (Garschagen, 2015; Aerts et al., 2018; Buchori et al., 2018; Jamero et al., 2018; Tamura et al., 2019), spatial planning (e.g. Duy et al. (2018)), amphibious building designs (Nilubon et al., 2016), increasing water storage and/or drainage capacity within C&S (Chan et al., 2018), early warning systems and disaster responses (Hissel et al., 2014), and slum upgrading (Jain et al., 2017; Olthuis et al., 2020).

Raising land, or individual buildings, can avert flooding and can be done artificially or as nature-based interventions through river diversion and control in estuarine and deltaic archetypes (Nittrouer et al., 2012; Auerbach et al., 2015; Day et al., 2016; Sánchez-Arcilla et al., 2016; Hiatt et al., 2019; Cornwall, 2021). Nature-based land elevation is limited by sediment supply and can address SLR rates of up to 10mm/yr (Kleinhans et al., 2010; Kirwan et al., 2016; IPCC, 2019). It also assumes that existing land-use patterns permit land raising (e.g., in rural or newly developed areas (Scussolini et al., 2017). Artificial land raising can achieve significant elevations and be implemented over a large spatial scale (Esteban et al., 2015; Esteban et al., 2019). Raising land can be cost beneficial for small areas, or where lower safety levels are satisfactory, but protection is usually more economical for larger areas, though both strategies are often combined (Lendering et al., 2020).

Accommodation measures can be very effective for current conditions and small changes in SLR (Laurice Jamero et al., 2017; Scussolini et al., 2017; Oppenheimer et al., 2019; Du et al., 2020; Haasnoot et al., 2021a), and buy time to prepare for more significant changes in sea level and other climate compounded coastal hazards. However, limits to this strategy occur comparatively soon in some locations, possibly requiring protection in the medium-term, and retreat in the long run and beyond 2100, particularly in scenarios of dramatic SLR (Oppenheimer et al., 2019). For the foreseeable future, accommodation can play an important role in combination with protective measures, to form hybrid interventions, with higher effectiveness than either approach in isolation (Du et al., 2020). Accommodation can play an increasingly important role where hard protection is neither technically nor financially viable; but detailed studies about expected trends of accommodation are lacking (Oppenheimer et al., 2019).

CCP2.3.4 Advance

An advance strategy creates new land by building seaward, which can reduce risk for the hinterland and the newly elevated land, either by land reclamation through land-filling or polderisation through planting of vegetation to support natural land accretion (Wang et al., 2014; Sengupta et al., 2018). Advance has occurred in all archetypes (*high confidence*); from open coasts (e.g., Singapore) and small atolls (e.g., Hulhumalé in the Maldives) (Hinkel et al., 2018; Brown et al., 2020) to cities on estuaries (e.g., Rotterdam) and deltas (e.g., Shanghai Sengupta et al. (2020)), and mountainous coasts (e.g., Hong Kong SAR, China). Earth observations show between 14,000-33,700 km^2 of land has been gained in coastal areas over the past 30 years, the dominant drivers being urban development and activities like fish farming (Donchyts et al., 2016; Zhang et al., 2017; Mentaschi et al., 2018). Advancing seawards through large floating structures may be a viable option in future (Wang et al., 2019; Setiadi et al., 2020; Wang and Wang, 2020), but is at an experimental stage, and, so far, only applied in calm water within a city as part of an accommodate strategy (Scussolini et al., 2017; Penning-Rowsell, 2020; Storbjörk and Hjerpe, 2021).

Advance is seen as an attractive option to adapt to SLR in growing cities that are already densely populated and have limited available land for safe development, with a moderate to high adaptive capacity. But advance can have significant negative impacts on coastal ecosystems and livelihoods, requires substantial financial and material resources and time to build, and may be subject to land subsidence (Jeuken et al., 2014; Garschagen et al., 2018; Brown et al., 2019; NYCEDC, 2019; Oppenheimer et al., 2019; Sengupta et al., 2020; Bendixen et al., 2021).

CCP2.3.5 Retreat

Retreat is a strategy to reduce exposure and eventually risks facing coastal C&S by moving people, assets and activities out of coastal hazard zones (Oppenheimer et al., 2019). This includes adaptive migration, involuntary displacement, and planned relocation of population and assets from the coast (Section 7.2.6; Cross-Chapter Box CB-MIGRATE in Chapter 7).

Planned relocation in coastal C&S with high hazard exposure and climate impacts is already occurring and has been increasing in frequency (*medium confidence*) (Hino et al., 2017; Mortreux et al., 2018), with some small islands purchasing land in other countries to facilitate movement (Klepp, 2018). In the Arctic, the pressure to relocate away from the coast is expected to rise given the interacting effects of permafrost thaw and coastal erosion. Native villages in Alaska are already relocating (Ristroph, 2017; Ristroph, 2019). Involuntary resettlement may be a secondary effect of large-scale hard coastal protection projects, or inner-city river and canal regulation. In Jakarta, for example, a new giant seawall project involves resettling coastal households along large parts of the coastline (Garschagen et al., 2018).

Increased migration is to be expected across different climate scenarios, but there is *limited evidence* and *medium agreement* about the scale of climate-induced migration at the coast (Oppenheimer et al., 2019) (Chapter 16, RKR on peace). Planned relocation is expected to rise in C&S in response to SLR and other coastal hazards (*high agreement, medium evidence*) (Siders et al., 2019). Relocation has predominantly been reactive to date, but increased attention is being given to pre-emptive resettlement and the potential pathways and necessary governance, finance and institutional arrangements to support this strategy (Ramm et al., 2018; Lawrence et al., 2020; Haasnoot et al., 2021a). There is *limited evidence* about the costs of planned relocation and retreat more generally (Oppenheimer et al., 2019).

Retreat can effectively reduce the exposure of urban residents to coastal hazards and provide opportunity for re-establishment of ecosystems services (*very high confidence*) (Song et al., 2018; Carey, 2020; Hindsley and Yoskowitz, 2020; Lincke et al., 2020; Lincke and Hinkel, 2021). But there is *high confidence* that it can sever cultural ties to the coast (Reimann et al., 2018) and can lead to negative and inequitable socio-economic effects for resettled communities if not planned and implemented in ways that are inclusive, just and address cultural, place-attachment and livelihood considerations (Ajibade, 2019; Adger et al., 2020; Carey, 2020; Jain et al., 2021; Johnson et al., 2021), and the rights and practices of Indigenous People (Nakashima et al., 2018; Ristroph, 2019; Mohamed Shaffril et al., 2020). If planned well ahead and aligned with social goals, pathways to managed retreat can achieve positive outcomes and provide opportunities for transformation of coastal C&S (Haasnoot et al., 2021a; Mach and Siders, 2021). There is *medium confidence* that the availability of suitable and affordable land, and appropriate financing, is a major bottleneck for planned relocation (Alexander et al., 2012; Ong et al., 2016; Hino et al., 2017; Fisher and Goodliffe, 2019; Hanna et al., 2019; Buser, 2020; Doberstein et al., 2020), particularly in very dense mega-urban areas (Ajibade, 2019) and crowded small islands (Neise and Revilla Diez, 2019; Weber et al., 2019; Kool et al., 2020; Lincke et al., 2020)

CCP2.3.6 Adaptation Pathways

No single adaptation intervention comprehensively addresses coastal risks and enables CRD. An adaptation pathways approach can facilitate long-term thinking, foresee maladaptive consequences and lock-ins, and address dynamic risk in the face of relentless and potentially high SLR; and frame adaptation as a series of manageable steps over time (Cross-Chapter Box DEEP in Chapter 17; Figure CCP2.4; Haasnoot et al.

(2019)). A portfolio of hard, soft and nature-based interventions can be used to implement strategies to protect, accommodate, retreat, and advance, individually or in combination.

The strategy, and portfolio of interventions, can be adjusted in response to new information about SLR and other climate risks according to economic, environmental, social, institutional, technical or other objectives. In cases of rapid SLR, it may be necessary to implement a short-term protection strategy to buy time to implement more transformative and enduring strategies (*high confidence*) (Du et al., 2020; Lawrence et al., 2020; Morris et al., 2020; Haasnoot et al., 2021a). There is *high agreement* that combining and sequencing adaptation interventions can reduce risk over time (Du et al., 2020; Morris et al., 2020). Phasing interventions can help to spread costs and minimise regret (de Ruig et al., 2019), provided that options are kept open to adjust to changing conditions (Buurman and Babovic, 2016; Haasnoot et al., 2019; Hall et al., 2019).

Many megacities plan to continue a protection strategy (Table SMCCP2.1). This becomes increasingly costly, institutionally challenging, and requires space possibly facilitated through local relocation. There is *high agreement* that many C&S are locked-in to a self-reinforcing pathway: coastal defences have a long lifetime and attract people and assets that require further protection (Gralepois et al., 2016; Bubeck et al., 2017; Welch et al., 2017; Di Baldassarre et al., 2018; Jongman, 2018). Transitioning to alternative pathways may involve major transfer and sunk costs (e.g., Gralepois et al. (2016)), but these may prove to be less costly in the long-term. Because of considerable inertia in the built form of cities, such transitions are more likely to be successful and aligned with societal goals if embedded early into C&S planning and development processes that enable transformational change and CRD (Sections 6.4.8; 11.7; 13.11; Box 18.1; Ürge-Vorsatz et al., 2018; Siders 2019b).

In islands, hybrid options of nature-based (where space and environmental conditions allow) and protect measures (on wealthy, already densely populated islands) could reduce risk for low SLR in the next few decades (Section 15.5). Where feasible, retreat is a compelling option to reduce risk (Figure CCP2.4). With higher rates and levels of SLR in the medium- to long-term, financial, governance and material barriers may differentiate resource-rich islands and more rural islands, leading to a dichotomy between which islands retreat or can rely on protection for a period of time.

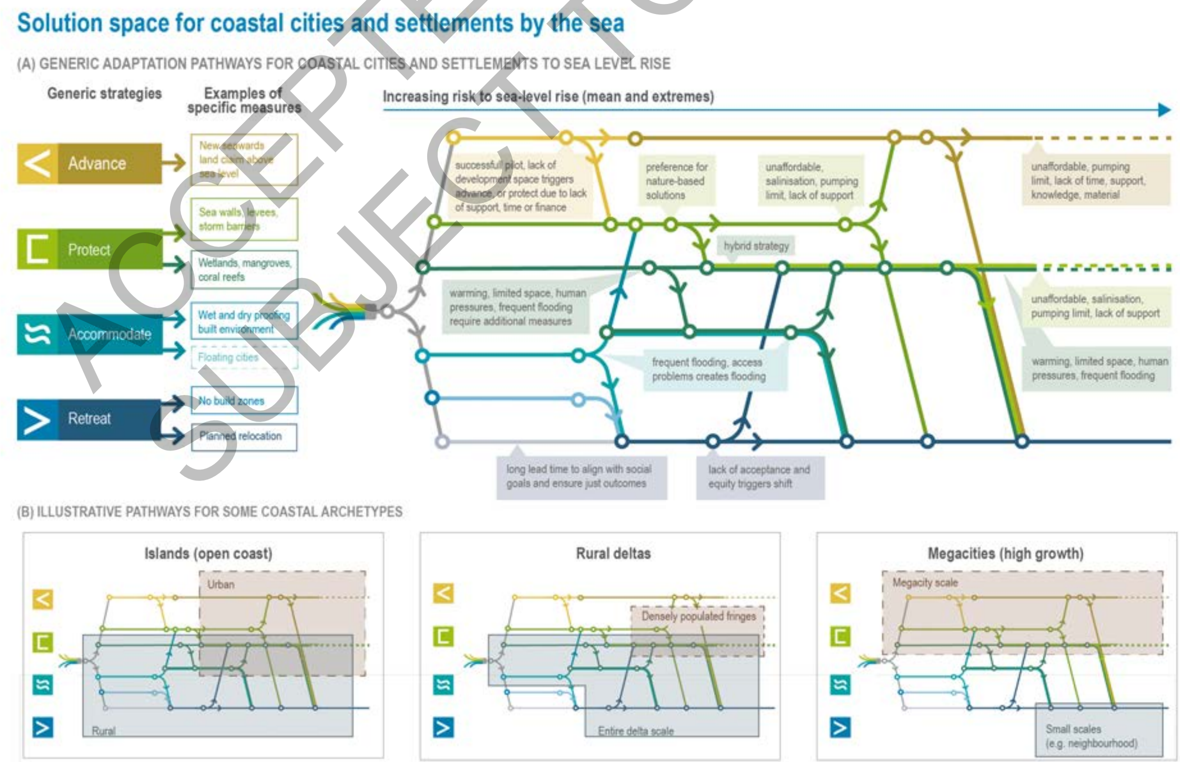

Figure CCP2.4: Generic adaptation pathways for coastal C&S (a) and the typical solution space with illustrative pathways for three coastal archetypes (b). As risk increases under rising sea levels, solutions need to be combined or sequenced in order contain risk. Pathways involve different trade-offs. Based on Table SMCCP2.1 - 2.3; Chapters 11 and 13, Magnan and Duvat (2020); Lawrence et al. (2020); Haasnoot et al. (2019). Depending on local conditions, archetype and risk tolerance, alternative pathways are needed and possible to contain risk. Dashed lines indicate uncertainty in pathway (a). Dashed and plain borders are used for illustrating various local situations within each archetype (b).

CCP2.4 Enabling Conditions and Lessons Learned

Here we distil enabling conditions and lessons learned from C&S archetypes adapting to coastal risk (Table SMCCP2.1; Table SMCCP2.2; Sections 6.4; 9.9.4; 10.5; 10.6; 11.7; 11.8; 12.5.5; 13.6.2; 14.7.2; 15.6).

CCP2.4.1 Enabling Behavioural Change

Changing behaviours and practices are a critical enabler of adaptation in coastal C&S. Behavioural enablers include using economic, informational, socio-cultural, and psychological incentives to motivate adaptation actions (van Valkengoed and Steg, 2019; Gibbs, 2020): e.g., leveraging Indigenous Knowledge and Local Knowledge (IKLK) and religious beliefs to incentivise adaptation (Hiwasaki et al., 2014; Ford et al., 2015); implementing subsidies/bans to incentivise sustainable aquaculture (Condie et al., 2014; Krause et al., 2020); providing localized flood warnings and forecasts to inform individual risk perceptions and risk management (Bruine de Bruin et al., 2014; Gibbs, 2020), or incentivise risk insurance (Bradt, 2019).

There is *high evidence* with *medium agreement* that public attitudes and perceptions of climate risks significantly influence individual adaptation behaviour across all coastal archetypes (Bradt, 2019; Buchanan et al., 2019; Javeline et al., 2019). Information on climate risks and impacts (e.g., flood warnings, SLR projections) strongly shapes public perceptions of climate risks. It is most effective at incentivising and enabling adaptation behaviour if provided at meaningful spatial and temporal scales, with guidance about how to interpret the information (*medium evidence, high agreement*) (Gibbs (2020); Cools et al. (2016)). Further, there is *medium evidence, high agreement* that integrating climate information with existing knowledge systems, such as local norms and beliefs and IKLK, is critical to improve public acceptability and develop context-specific solutions (Ford et al., 2015).

A second key enabler of coastal adaptation behaviour is self-efficacy or belief in one's capacity to undertake adaptation. There is *medium evidence, high agreement* that high risk perception is in itself insufficient to motivate people to undertake adaptation (Fox-Rogers et al., 2016; Roder et al., 2019; Gibbs, 2020) and needs to be supplemented with supportive policy and financial provisions to enable adaptation Fox-Rogers et al. (2016).

Third, there is *medium evidence* on how trust in state-led, planned adaptation measures can hinder or enable individual adaptation (van Valkengoed and Steg, 2019; Schneider et al., 2020). As an enabler, trust in early warnings can mitigate flood risk by incentivising evacuation (Binh et al., 2020) and high trust can help overcome uncertainty attached to projected climate impacts and/or adaptation decisions (Frederiksen, 2014). As a barrier, low trust can disincentivise adaptation, e.g., willingness to pay for flood insurance (Roder et al., 2019) or public support for managed retreat (Hanna et al., 2020). Paradoxically, high trust in existing adaptation measures can reduce people's perceived need for ongoing adaptation (e.g., levees potentially reducing individual flood-proofing actions). Adaptation decisions also manifest 'single-action bias' with modest-cost adaptation actions in the present disincentivising further adaptation (Buchanan et al., 2019).

Several tools to incentivise adaptation behaviour are being tested around the world – e.g., nudges and boosts[2] are being experimented with to shape individual risk beliefs and demand for flood insurance (Bradt, 2019); ordinances are being used to ban, authorise or limit certain activities (Herrick, 2018); subsidies and financial support being used to incentivise adaptation such as subsidised beach nourishment (McNamara et al., 2015); and zoning restrictions and building codes restrict or guide climate-resilient infrastructural development Schneider et al. (2020). Overall, the literature affirms that behavioural interventions are more readily taken up if they are: aligned with cultural practices, norms, and beliefs; on temporal scales within peoples' planning horizons; and build upon relationships of trust and legitimacy (Donner and Webber, 2014; Herrick, 2018; Schneider et al., 2020).

CCP2.4.2 Finance

Lack of financial resources is a key constraint affecting all coastal archetypes (*high confidence*) (Table SMCCP2.2). Adaptation to coastal hazards is costly – the global costs of protecting coastal areas with levees (annual investment and maintenance costs) are estimated at US$12–71 billion in 2100 with SLR up to 1.2m (Hinkel et al., 2014). Broadly speaking, it is cost-effective to contain coastal hazard risk in the short- to medium-term in densely populated wealthy localities by using protective works but such measures are unaffordable in dispersed poorer coastal C&S (Lincke and Hinkel, 2018).

Archetypes with high adaptive capacity may currently have financial resources to meet adaptation needs, but such funding may be unsustainable in the long-term. In Catalonia, while public funds are currently used to finance beach nourishment, these costs will increase with SLR and it is unclear if public finance will remain a feasible source (Hinkel et al., 2018). Even in relatively richer municipalities, financing adaptation is constrained by other urban priorities (Bisaro and Hinkel, 2018). In Europe, shifting responsibilities from national governments to transnational and local actors has resulted in reduced national budgets for coastal adaptation investment and increased pressure on local authorities to raise public funds for adaptation without alienating electoral bases (Bisaro and Hinkel, 2018).

Locations in the Global South have limited public budgets allocated to coastal adaptation and may rely on international donor aid (Donner et al., 2016; Araos et al., 2017). Such aid is often inconsistent and short-term, which limits long-term maintenance of knowledge, equipment and infrastructure needed to sustain adaptation measures beyond initial funding periods (Weiler et al., 2018; Thomas et al., 2020), with resultant negative consequences in places as different as Kiribati (Donner and Webber, 2014) and Bangladesh (Hinkel et al., 2018). Donor-funded adaptation programs aimed at promoting behavioural change, e.g., through coastal planning or new decision-making systems, require enduring training and institutional capacity, which is difficult to upkeep after aid is depleted. Donor funding is often project-based and there are few avenues available to fund additional permanent and long-term staff needed to bolster climate change institutions. Without funding to support additional staff, existing institutions often lack the human capacity and resources needed for coastal adaptation (Ziervogel and Parnell, 2014).

C&S in the Global South also face financial challenges in addressing loss and damage due to climate-induced slow-onset and extreme events. Financial support to address both quantifiable damages and non-economic losses through measures such as climate resilient reconstruction after extreme weather events, and national and local level emergency contingency funds, is lacking and has been an issue of contention in international policy arenas (Bahinipati et al., 2017; Wewerinke-Singh and Salili, 2020; Martyr-Koller et al., 2021).

While coastal adaptation has largely been viewed as the responsibility of governments, private finance is increasingly recognized as necessary to help close the coastal adaptation funding gap (Ware and Banhalmi-Zakar, 2020). Financial arrangements for coastal adaptation measures that align public actor and private investor interests are suitable for a range of budgets, from US$10,000-100 million (Bisaro and Hinkel, 2018). Private equity instruments that involve real estate development companies have already been successfully implemented and are most effective in urban areas with high-value real estate development (Chiang and Ling, 2017). Public-private partnership equity instruments that engage construction and real estate developers have been successful for small- to medium-scale infrastructural projects. While public-private partnership bonds and public bonds have potential to align public actors and private investors, such instruments require de-risking of coastal adaptation through enabling economic policy instruments, such as concessional loans (Bisaro and Hinkel, 2018).

Explicitly identifying the benefits, or goods and services, that are provided by coastal adaptation is critical to supplement limited government funds and engage a broader set of financial tools and actors (Woodruff et al., 2020). Matching goods and services provided by particular adaptation strategies to specific beneficiaries helps identify the range of fair and equitable financial tools. In the Netherlands, public funding through state, regional and local entities have independent tax revenue systems to provide the funding needed to maintain flooding infrastructure (Hinkel et al., 2018).

Given the high costs of coastal adaptation, benefit to cost ratios (BCR) are often used to determine the value of investing in adaptation. BCR are high for urbanized coastal areas with high concentrations of assets (13% of the world's coastline), covering 90% of global coastal floodplain population and 96% of assets in the global coastal floodplain (Lincke and Hinkel, 2018). A global assessment shows BCR for investing in flood protection up to ~120 (Tiggeloven et al., 2020). For Europe, at least 83% of flood damages could be avoided by elevating dikes along ~23-32% of Europe's coastline and BCR vary from 8.3 to 14.9, with higher ratios for higher concentration pathways (Section 13.2) (Vousdoukas et al., 2020a). Globally 40% of damages can be reduced with levees of 1m and costs lower than avoided damage (Tamura et al., 2019). For a mix of expensive storm surge barriers, nature-based solutions and flood proofing measures for New York City, Aerts et al. (2014) found BCRs <1 for the current situation, but >2 for a SLR scenario of +1m.

However, BCR values may be low and adaptation investment may not be financially viable for small coastal settlements, less densely populated poorer coasts, or isolated communities *(medium confidence).* Considering BCR of protection and coastal migration across a range of SLR and SSP scenarios for the 21st century, a higher BCR was found for protection of only 3% of the global coastline protecting 78% of the coastal population and 92% of global coastal floodplain assets, while for the remaining coasts, coastal migration was estimated to be optimal in terms of economic costs (Lincke and Hinkel, 2021). Considering coastal migration as part of the solution space could lower global costs in investment and maintenance for SLR protection by a factor of 2-4 in the 21st century but would result in large land losses and high levels of migration for South and South-east Asia in particular and, in relative terms, small island nations would suffer most. The need to consider place attachment, community relationships, livelihoods and the spiritual and cultural significance of settlements limit the application of BCR as a tool for coastal adaptation decisions in these contexts (Thomas and Benjamin, 2020). Moreover, there is limited knowledge on trade-offs, including BCR, of alternative adaptation options and pathways at global to regional scale, in particular over the long-term (beyond 2100).

Even where BCR is high, finance may be inaccessible as it is challenging to convert the long-term benefits of adaptation into the revenue streams that may be needed to initially finance adaptation investments (Hinkel et al., 2018). For example, in Ho Chi Minh City, Vietnam, despite high BCR, high costs of flood protection (US$1.4-2.6 billion) have prevented such adaptation measures from being implemented (Hinkel et al., 2018; Cao et al., 2021). Moreover, drawing from places as distinct as small communities in Fiji (Neef et al., 2018) and Belize (Karlsson and Hovelsrud, 2015), and megacities like New York City and Shanghai (Oppenheimer et al., 2019), BCR provides only a limited view and consideration of feasibility, effectiveness, efficiency, equity, culture, politics and power, and attachment to place, is more likely to foster CRD (*high confidence*).

CCP2.4.3 Governance

An array of climate and non-climate perils (Le Cozannet et al., 2017), present coastal communities and their governing authorities with immense governance and institutional challenges that will get progressively more difficult as sea level rises (*high confidence*) (Wallace, 2017; Leal Filho et al., 2018; Oppenheimer et al., 2019). Yet a study of public provisions for coastal adaptation in 136 of the largest coastal port-urban agglomerations across 68 countries found no policy implementation in 50% of the cases; in 85% of cases, adaptation actions are not framed by current impacts or future risks; and formal efforts are recent and concentrated in more developed settings (Olazabal et al., 2019; Olazabal and Ruiz De Gopegui, 2021) - underscoring a persistent coastal adaptation gap. Translating these challenges into enabling governance conditions is difficult but instructive lessons are being learned, and summarized (from Table SMCCP2.4) for archetypal C&S in Tables CCP2.1, 2.2.

We start with a synopsis of governance settings within which coastal adaptation and CRD choices are made, and spotlight factors hindering and enabling translation of adaptation into practice. Then, building upon and extending the SROCC analysis of enablers and lessons learned in responding to SLR (Oppenheimer et al., 2019), we assess key governance challenges, related enablers and lessons learned (Tables CCP2.1, CCP2.2).

Governance arrangements and practices are embedded in the socio-political and institutional fabric of coastal C&S. Consequently, barriers and enablers for adapting to climate change at the coast, and charting pathways for CRD, reflect more general constraints and opportunities (*high confidence*) (Meerow, 2017; Rocle and Salles, 2018; Rosendo et al., 2018; Di Giulio et al., 2019; Hölscher et al., 2019; Van Assche et al., 2020; Williams et al., 2020). Local level action is often constrained; 231 cities in the USA report weak leadership, lack of funding and staffing, and low political will (Fu, 2020). A meta-analysis of coastal municipal planning documents in Australia shows few localities have moved beyond risk assessment (Bradley et al., 2015). Coastal C&S tend to prefer strategies that protect and accommodate existing coastline assets, i.e., a 'fix and forget' approach (Gibbs, 2015), rather than enduring proactive adaptation (Cooper and Pile, 2014).

Many C&S, especially in the Global South, already face high exposure to coastal risks, and development constraints associated with poverty and socioeconomic inequality, lack of transparent resource allocation mechanisms, and low political will (*high confidence*) (Di Giulio et al., 2019; Nagy et al., 2019; Pasquini, 2020; Lehmann et al., 2021). Research from across South America notes inadequate regulatory frameworks, missing data and information, widespread coastal ecosystem degradation, and complex interactions between natural disasters and civil conflict (Villamizar et al., 2017; Nagy et al., 2019). Coastal climate risks in the Global South are often compounded by ongoing land-use management conflicts and other pressures including informal land uses, unregulated and/or inadequate infrastructure/building development, public health priorities such as combating Dengue Fever, inadequate income diversification, low education levels, and political marginalization of communities historically not represented in the urban development process (Barbi and Ferreira, 2014; Salik et al., 2015; Cabral et al., 2017; Goh, 2019). There are also entrenched socio-economic inequalities leading to the maldistribution of adaptation actions and benefits in the Global North (Gould and Lewis, 2018; Keenan et al., 2018; Ranganathan and Bratman, 2019; Yumagulova, 2020; Long et al., 2021).

To address the myriad governance challenges attributed to low awareness, low skills, scalar mismatches, and high socioeconomic inequality and coastal vulnerability, post-AR5 research highlights enablers of more innovative approaches to bridge capacity, policy, and financial deficits (Reiblich et al., 2019) and facilitate more proactive implementation of coastal adaptation actions (Table SMCCP2.2; Fu, 2020). A survey of NGOs, state and local government across Alaska, Florida, and Maryland in the USA found that perceived risk, uncertainty, and trust in support for climate adaptation varied across two stages of adaptation – support for the development of plans and willingness to allocate human and financial resources to implement plans (Kettle and Dow, 2016). To bridge this gap, Cinner et al. (2018) suggest the need to build capacity across five domains: the assets that people can draw upon in times of need; the flexibility to change strategies and interventions; the ability to organize and act collectively; learning to recognize and respond to change (especially as important thresholds are approached); and the agency to determine whether to change or not, and then take prudent action).

Effective and accountable local leadership can help to mobilize capacities, resources, and climate awareness within coastal C&S. Strong leadership is associated with agenda-setting authorities and the ability to navigate complex institutional interests towards more strategic planning efforts (*high confidence*) (Ferguson et al., 2013; Anguelovski et al., 2014; Chu et al., 2017; Valdivieso and Andersson, 2018; Fink, 2019; Ndebele-Murisa et al., 2020). Policy leadership can positively influence the motivation and initiative of municipal officers (Lassa and Nugraha, 2014; Wijaya et al., 2020); whilst local leadership is needed integrate coastal management, disaster management and climate adaptation mandates (Rosendo et al., 2018).

Inclusive decision-making arrangements can enable participation, local ownership, and further equity in crafting coastal adaptation plans and policies (Chu et al., 2016). Inclusion of diverse stakeholders can help improve awareness of adaptation needs; help to bridge existing social inequalities in decision-making about adaption needs, options and outcomes; close the gap between formal and informal institutions, and engage Indigenous forms of decision-making, which often associate climate risks with livelihood, housing, and employment stressors (Ziervogel et al., 2016; Fayombo, 2020). For example, research from Pacific Island States (Nunn et al., 2017) and coastal Arctic zones (Romero Manrique et al., 2018) highlight the need to engage with Indigenous environmental knowledge. Case studies from Indonesia, Philippines, and Timor-Leste show that IKLK and customary laws can support environmental awareness, strengthen social cohesion, and help communities to better respond to climate impacts (Hiwasaki et al., 2015). Research from coastal Cambodia shows that inclusive governance arrangements can target empowerment of the most vulnerable groups to facilitate better adaptation behavior and mainstream adaption knowledge through both formal and informal education at the community level (Ung et al., 2016).

The law is key to governing climate risks in C&S, including regulating exposure to coastal hazards; facilitating accountable decision-making, funding arrangements, liabilities, and resolving disputes; and securing human rights (*high confidence*) (Setzer and Vanhala, 2019; Averill, 2020). But it has limits and can be an adaptation enabler and barrier (Green et al., 2015; Cosens et al., 2017; Craig et al., 2017; DeCaro et al., 2017). Contemporary legal practice has not enabled effective adaptation in part because SLR affects compensable property rights that are secured by the law and which generally trump concerns about public safety, resilience and sustainability (Reiblich et al., 2019). Private property rights can be used as both a sword and a shield to privilege dominant interests, by undermining land use policies, plans and implementation efforts intended to promote integrated coastal management and risk reduction (O'Donnell et al., 2019; Reiblich et al., 2019). Climate change litigation has proliferated over the last decade (Setzer and Vanhala, 2019), addressing, among other things, failures to prepare for or adapt to climate change, and to secure human rights (Peel and Osofsky, 2018). Reflexive and adaptive law that accounts for the distinctive features of coastal hazard risk, and associated governance imperatives, builds coastal C&S adaptive capacity and resilience (*high confidence*) (Garmestani and Benson, 2013; Cosens et al., 2017; DeCaro et al., 2017). Procedural justice, due process, and use of substantive standards instead of rules, provide legal stability and enable adaptation (Craig et al., 2017). Coastal adaptation efforts are ultimately implemented through C&S actions that are enabled or constrained by prevailing legislative, executive and judicial provisions and practices, which differ significantly across jurisdictions (He, 2018). In practice, the 'coastal lawscape' is made up of interconnected cultural-normative, political and legal systems that need to be understood holistically to enable coastal adaptation in C&S (O'Donnell, 2021).

Tables CCP2.1 and CCP2.2 summarise key insights about key governance challenges facing archetypal coastal C&S around the world, and associated critical enablers and lessons learned to address climate change-compounded coastal hazard risk (based on synthesis of Table SMCCP2.3).

Table CCP2.1: Governance challenges and critical enablers for addressing coastal hazard risk in C&S

Key governance challenges	Critical enablers for C&S to address coastal hazard risk
Complexity: Climate change compounds non-climatic hazard risks facing coastal C&S in interconnected, dynamic and emergent ways for which there are no simple solutions.	Draw on **multiple knowledge systems** to co-design and co-produce more acceptable, effective and enduring responses.
	Build **governance capacity** to tackle complex problems.
Time horizon and uncertainty: The future is uncertain, but climate change will continue for generations and cannot be addressed by short-term (e.g., 1-10 years) responses alone.	Adopt a **long-term view** but take action now. **Keep options open** to adjust responses as climate risk escalates and circumstances change
	Avoid new development commitments in exposed locations. Enable managed retreat in most at-risk locations by **anticipatory actions**, e.g., secure funds, legal provisions for buy-outs, resettlement, etc.
Cross-scale and cross-domain coordination: Decisions bound by jurisdictional and sectoral boundaries fail to address linkages within and between coastal ecosystems and C&S facing interconnected climate change compounded impacts and risk.	Develop networks and linkages within and between different governance scales and levels, and across policy domains and sectors, to improve **coordination**, build trust and legitimise decisions.
	Build **shared understanding** and enable locally appropriate responses through experimentation, innovation and social learning.
Equity and social vulnerability: Climate change compounds everyday inequity and vulnerability in coastal C&S, making it difficult to disentangle and address social drivers and root causes of risk.	Recognise political realities and **prioritise vulnerability**, justice and equity concerns to enable just, impactful and enduring outcomes.
	Strengthen **community capabilities** to respond to coastal hazard risk, using external assistance and government support if necessary.
Social conflict: Coastal C&S will be the focal point of contending views about appropriate climate responses; and face the challenge of avoiding destructive conflict and realising its productive potential.	Design and facilitate **tailor-made participation processes**, involving stakeholders early and consistently from negotiating responses to implementation.
	Create **safe arenas of engagement** for inclusive, informed and meaningful deliberation and collaborative problem-solving.

Table CCP2.2: Lessons learned from efforts to address coastal hazard risk

Lessons to address governance challenges and unlock enablers	**Archetypal C&S initiatives, constraints aside**
Complexity: Multiple knowledge systems – Reveal dynamic complexity drawing on multiple sources of locally relevant evidence – Use and integrate local, Indigenous and scientific knowledge – Include marginalised voices and knowledges of vulnerable groups, women, young people, etc. – Build shared understanding through storytelling – Bridge gaps between science, policy and practice by experimenting with novel approaches and working across organisational, sectoral and institutional boundaries	**Seychelles (0.1mill; open coast):** Science-policy-local knowledge partnerships to co-produce usable information for decision-making. **Dhaka, Bangladesh (21mill; delta):** Climate change is national priority. Partnering with Netherlands to develop long-term data plans. **Jakarta, Indonesia (10.8mill; delta):** Community-based efforts to foster mutual assistance and self-organisation. **Utqiagvik (formerly Barrow) Alaska, USA (0.04 mill; Arctic, open coast):** Using local knowledge and historical precedent of transformative change to integrate local and scientific knowledge.
Complexity: Governance capacity – Joined-up visionary leadership is key, e.g., cabinet- and C&S-level commitments to long-term implementation – Translate political will into substantial dedicated budgets to build government capacity to tackle complex problems – Use flexible approaches to build resilience, e.g., independent agency alongside traditional administrative bodies – Counter deadlocks due to short-term priorities and vested interests with long-term perspective, considering plausible scenarios and incentivising novel solutions – Translate national requirements into local action with enabling provisions for tailored local policy and practice – Tackle emergent problems by setting up enduring monitoring and lesson-learning processes – Governance arrangements reconcile competing interests in inclusive, timely and legitimate manner – Make visible and reflect on underlying reasons for policy actions / inaction, including values, attitudes and taken for granted habits influencing problem-solving capability	**Singapore (5.6mill; open coast):** Integrated approach across Ministries committing to long-term adaptation (and mitigation goals) by 2030. **Rotterdam, Netherlands (0.65mill; delta):** Delta Programme, supported by law, administrative arrangements, and €1bill pa budget to 2029. **Florianopolis, Santa Catarina island, Brazil (1.2mill; mixed):** Building knowledge hub via public-private-civil society partnerships. **Nassau, Bahamas (0.275mill; open coast, small island):** Identifying responsibilities, accessing funding, and preparing adaptation plans drawing on evidence-based studies. **Shanghai (27mill; estuary), China:** Contain risk by combining long-term planning, political will, and national and municipal provisions, and technical capability. **Can Tho City, Vietnam (0.4 mill; delta):** Engage international donors and research community.
Time horizon and uncertainty: Long-term view – Establish national policies and guidance with long-term view (e.g., 100 years) that enables action now – Develop shared medium- (10-50 years) to long-term vision (100+ years) – Use adaptation pathways approach to make short-term decisions consistent with long-term goals – Meaningfully involve stakeholders, e.g., involve representatives in decision-making – Address power imbalances and human development needs, e.g., in goal-setting and process design – Reconcile divergent perspectives through tailored responses	**Napier (65k), Hawkes Bay (178.6k; open coast), New Zealand:** National law compels local authorities to take 100-year perspective; 2100 Strategy accounts for dynamic complexity and uncertain future through adaptation pathways. **Shanghai, China (27mill; estuary):** Plans up to 2100, strong national and municipal focus on climate change, and access to technical expertise. **Dhaka, Bangladesh (21mill; delta):** Long term adaptation plans through to 2100.
Time horizon and uncertainty: Avoidance and anticipatory action – Avoid development in exposed localities using spatial plans – Use window of opportunity created by extreme events – Prepare pre-event plans and tailor risk reduction and resilience building post-disaster – Reveal political pressures and opposition that hamper efforts to address intolerable risk and unacceptable impacts	**Rotterdam, Netherlands (0.65mill; delta):** Delta Programme promotes 'living with water', allowing and managing urban flooding. **Napier (65k), Hawkes Bay, New Zealand (178.6k, open coast):** Regulatory provisions discourage new development in high-risk locations; strategy sequences adaptation interventions. **Florianopolis, Santa Catarina island, Brazil (1.2mill; mixed):** Research reveals unregulated ad hoc development in at-risk locations preventing effective adaptation.
Cross-scale and cross-domain coordination: Coordination – Collaborative projects involve state and non-state actors	**Seychelles (0.1mill; open coast, small island):** Cross-sectoral and institutional collaboration to improve use of limited financial resources; and

– Multi-lateral agreements, e.g., between neighbouring countries, coastal regions and C&S – Connect people, organizations and communities through boundary spanning organizations – Leadership by central actors with capable teams is key – Mobilise the capabilities of communities and non-state actors – Address policy inconsistencies and clarify roles and responsibilities – Secure national and regional resources to support local efforts – Use measures to promote interaction, deliberation and coordination to manage spill-over effects – Strengthen linkages between formal (e.g., regulatory) and informal (e.g., traditions and rituals) institutions, e.g., through information sharing – Use spatial coordination mechanisms, e.g., land-use planning, to translate national and regional provisions into local competencies	community-based and ecosystem-based adaptation to bridge adaptation and mitigation and improve coordination. **Florianopolis, Santa Catarina island, Brazil (1.2mill; mixed):** Effective local climate action hampered by governance constraints and weak federal leadership. **Cape Town, South Africa (4.6mill; mixed):** Multi-level climate governance advanced at local-provincial level, but political turf-battles hamper national-provincial-local progress.
Cross-scale and cross-domain coordination: Shared understanding – Prioritise social learning and shared understanding, e.g., accessible information to all, irrespective of education, language, etc. – Account for local history, culture and politics through engagement, experimentation and innovation – Generate socio-economic, livelihood and climate-development co-benefits – Leverage national and trans-national community and local authority networks	**Cape Town, South Africa (4.6mill; mixed):** Capable local leaders collaborate with researchers in municipality-initiated community-based adaptation. Translating plans into action challenging given 'everyday' vulnerability exacerbated by climate change impacts. **New York City, USA (23.5mill; mixed):** State and city government work with communities to build adaptive capacity and resilience, drawing on technical capabilities but many challenges.
Equity and social vulnerability: Address vulnerability – Expose drivers and root causes of injustice, structural inequity and vulnerability – Link human development concerns, risk reduction, resilience and adaptation – Raise awareness and public support for actions that are just and equitable – Understand discriminatory drivers (e.g., on racial grounds) of coastal land-use patterns and risk – Address barriers facing marginalised groups – Use inclusive planning, decision-making and implementation processes that give voice to vulnerable people	**Cape Town, South Africa (4.6mill; mixed):** Adaptation framed by apartheid legacy; focus on reducing vulnerability, public safety and securing critical infrastructure and community assets. **Maputo-Matola, Mozambique (3mill; mixed):** Livelihood opportunities compromised by ecological degradation compelling community DIY coping in face of severe poverty and vulnerability, and weak governance and institutional capacity, and reliance on donors. **New York City, USA (23.5mill; estuary):** Hurricane Sandy (2012) focused attention on climate risk and plight of exposed and vulnerable people, and sparked adaptation action.
Equity and social vulnerability: Community capabilities – Raise vulnerability and risk awareness and understanding, build community capability and leverage external support by working with professionals, academics, local NGOs, journalists and activists – Secure rights of vulnerable groups through court action where necessary – Integrate traditional community responses with local government efforts – Ensure gender equity, e.g., representation on planning and decision-making bodies	**Monkey River village, Belize (200 people; estuary):** Remote Indigenous community capacity to tackle erosion enabled by interventions by researchers, journalists and local NGOs to secure media and political attention after hurricane damage. **Accra, Ghana (2.5mill; delta):** Household adaptation mediated by local government flood mitigation efforts; need better early warning and maintain local stormwater to prevent flooding. **Lagos, Nigeria (14 mill; open coast):** Building adaptive capacity to overcome 'everyday' vulnerability and poverty severely challenging.
Social conflict: Tailor-made participation – Create opportunities for integrative and inclusive solutions – Use conflict resolution mechanisms	**Napier (65k), Hawkes Bay, New Zealand (178.6k people, open coast):** Collaboration between local authorities and Indigenous People (Māori), involving stakeholders, led to co-designed

– Appoint independent facilitators / mediators and involve officials as 'bureaucratic activists' to improve inclusivity and iterative and reflexive engagement – Align informal participatory processes with statutory processes and government practices – Sustain engagement by securing resources for local use, and aligning activities with political and bureaucratic cycles – Involve historically disadvantaged and socially vulnerable groups, e.g., accessible meeting locations / venues, local languages and culturally appropriate meeting protocols – Involve local leaders who will champion adaptation and help mainstream findings into C&S decision-making – Inclusive processes help address conflict and drivers of vulnerability, and promote just adaptation	long-term strategy with implementation commitment. **Manila, Philippines (14mill; open coast):** Metro-wide planning and infrastructure provisions that foster climate justice and resilience explored; with community-based actions.
Social conflict: Safe arenas of engagement – Use flexible and enabling processes based in local institutions that are robust and fair, supported by governing authorities – Attend to local social dynamics and reduce elite domination – Use local and Indigenous knowledge and science – Use institutional improvisation to address local concerns – Use trusted independent facilitators – Incentivise participation by disadvantaged groups – Focus on improving risk literacy, optimism and capacity for joint problem-solving – Use joint, collaborative activities to facilitate public dialogue, and secure institutional support for action – Enable ongoing deliberation and social learning – Make continual adjustments as circumstances change, e.g., build shared understanding about locally relevant thresholds beyond which alternative courses of action need to be actioned.	**Napier (65k), Hawkes Bay, New Zealand (178.6k people, open coast):** Active involvement of local communities, Indigenous People (Māori) and research community to co-produce fit-for-purpose long-term coastal hazard risk strategy. **Rotterdam, Netherlands (0.65mill; delta):** Delta Programme institutionalised multi-level adaptation governance with strong accountability mechanisms. **Greater London, UK (8.9mill; estuary):** Long-term provisions for at-risk Thames Estuary, including major protective works, embedded in Greater London Spatial Development Plan and London Climate Change Partnership championed by strategic leadership, and supported by the public and strong technical capability.

In sum, prospects for addressing climate risk in archetypal coastal C&S around the world depend on the extent to which societal choices, and associated governance processes and practices, address the drivers and root causes of exposure and social vulnerability (*very high confidence*). Coastal C&S are more able to address these challenges when authorities work with local communities, and vulnerable groups in particular, and with stakeholders from the local to national level and beyond, to chart adaptation pathways that enable sustained reduction in the exposure and vulnerability of those most at risk *(very high confidence)* (Cross-Chapter Box SLR in Chapter 3; Magnan et al., 2019; Oppenheimer et al., 2019). Unlocking potential enablers for locally appropriate and effective adaptation is difficult because many drivers and root causes of coastal risk are historically and institutionally embedded *(high confidence)* (Thomas et al., 2019). Charting credible, salient and legitimate adaptation pathways is consequently a struggle in reconciling divergent worldviews, values and interests (Sovacool, 2018; Mendenhall et al., 2020; Bowden et al., 2021a; Bowden et al., 2021b). Unlocking the productive potential of conflict is foundational for transitioning towards pathways that foster CRD *(high confidence)* (Abrahams and Carr, 2017; Harris et al., 2018; Sharifi, 2020). But this can be especially challenging for low-lying coastal C&S characterised by degraded coastal ecosystems susceptible to climate change impacts as well as pronounced inequity and governance constraints *(high confidence)* (Esteban et al., 2017; Jones et al., 2020).

CCP2.4.4 Enabling Climate Resilient Development for Cities and Settlements by the Sea

The above critical enablers, and lessons learned from around the world, establish a strong foundation for charting pathways for CRD in coastal C&S. These pathways will necessarily vary in different C&S, and synergies and commonalities within different coastal archetypes can be leveraged. Pivotal is recognition of the narrow window of time remaining to translate embryonic risk assessment and adaptation planning into concerted implementation efforts. C&S by the sea could be the centres of innovation that lead the way to advancing SDGs through to 2030, and CRD beyond this decade (see Section 2.1.1).

This CCP shows that a range of adaptation solutions; hard and soft protection, nature-based measures, accommodate, advance, retreat, and behavioural change will need to be implemented as an integrated and sequenced portfolio of responses if coastal C&S are to contain the adverse risks of climate change (*high confidence*). The effectiveness and feasibility of any intervention, at a given moment, to reduce a particular climate-compounded coastal hazard risk, or combination of risks, depend upon the settlement archetype; including its geomorphological, cultural, economic, technical, institutional, and political features, and historical development trajectory. Coastal C&S will benefit from developing flexible adaptation pathways - sequences of adaptation strategies and intervention options - to navigate a dynamic solution space that changes in response to climate and other drivers of change, and is also shaped by human development choices, and socio-economic, technological and institutional change.

There is no silver bullet or panacea. But developing locally appropriate, yet flexible, pathways for CRD will help coastal communities address escalating risks and uncertainty (Cross-Chapter Box DEEP in Chapter 17). Effective pathways are based on robust integrated information about dynamic coastal hazard risk and plausible interventions. However, their successful implementation requires multi-scale governance arrangements and practices able to bridge different administrative and sectoral capacities in the coastal zone; effective and accountable leadership; and inclusive decision-making arrangements to enable participation, manage conflicts and trade-offs; engender local ownership, and promote equity and justice in coastal adaptation plans and policies. Further, the feasibility of adaptation strategies and interventions, especially those entailing changing behaviours and practices, is increased by recognising and incorporating peoples' values and beliefs and Indigenous and Local knowledge systems, as well as the voices of women and vulnerable groups.

Coastal C&S are on the frontline of observed climate change impacts and future risk (*high confidence*). Difficult choices will be made as climate- and ocean-driven extremes become more frequent. In the next few decades, many coastal regions and C&S will have the opportunity to take actions to avoid and reduce risk, through incremental as well as more transformative interventions. Under higher levels of global warming, decisions will need to be made faster or respond to higher levels of SLR (*high confidence*) (Cross-Chapter Box SLR in Chapter 3). This is particularly challenging in coastal C&S characterised by inertia and path-dependency of development choices, with long lead times for adaptation planning and implementation, and the long design life and societal impact of many interventions. Given the risks assessed in coastal C&S, the scale of climate impacts globally will depend to a large extent on whether coastal settlements develop and implement pre-emptive and flexible adaptation pathways, and whether significant and timely reduction in greenhouse gas emissions is achieved in C&S and globally *(high confidence).*

[START FAQ CCP2.1 HERE]

FAQ CCP2.1: Why are coastal cities and settlements by the sea especially at risk in a changing climate, and which cities are most at risk?

Coastal cities and settlements (C&S) by the sea face much greater risk than comparable inland C&S because they concentrate a large portion of global population and economic activity whilst being exposed and vulnerable to a range of climate- and ocean-compounded hazard risk driven by climate change. Coastal C&S range from small settlements along waterways and estuaries, to small island states with maritime populations and/or beaches and atolls that are major tourist attractions, to large cities that are major transport and financial hubs in coastal deltas, and mega-cities and even mega-regions with several coastal mega-cities.

The concentration of people, economic activity and infrastructure dynamically interact with coast-specific hazards magnifying the exposure of these C&S to climate risks. While large inland cities and coastal settlements can be exposed to climate-driven hazards, such as urban heat islands and air pollution, the latter are also subject to distinctive ocean-driven hazards, such as rising sea levels, exposure to tropical cyclones and storm surges, flooding from extreme tides, and land subsidence from decreased sediment deposition along coastal deltas and estuaries. With climate change increasing the intensity and frequency of hazards under all future warming levels, the risks to lives, livelihoods and property are especially acute in C&S by the sea.

Coastal cities are diverse in shape, size, growth patterns and trajectories, and access to cultural, financial, and ecosystem resources and services. Along deltaic and estuarine archetypes, cities most vulnerable to a changing climate have relatively high levels of poverty and inequality, in terms access to resources and ecosystem services, and large populations and dense built environments translating into higher exposure to coastal climate risks.

These climate risks at the coast can also be magnified by compounding and cascading effects due to non-climate drivers directly affecting vulnerable peri- and ex-urban areas inland. These risks include disruption to transport supply chains and energy infrastructure from airports and power plants sited along coastal areas, as occurred in New York City, USA, during Hurricane Sandy in 2012. The impacts can be felt around the world through globalized economic and geopolitical linkages, e.g., through maritime trade and port linkages.

For open coasts, settlements on low-lying small island states and the Arctic are especially vulnerable to climate change, and sea level rise impacts in particular, well before 2100. While the economic risks may not compare to the scale of those faced in coastal megacities with high per capita GDP, the existential risks to some nations and an array of distinctive livelihoods, cultural heritage, and ways-of-life in these settlements are great, even with modest sea level rise.

[END FAQ CCP2.1 HERE]

[START FAQ CCP2.2 HERE]

FAQ CCP2.2: What actions can be taken by coastal cities and settlements to reduce climate change risk?

Sea level rise responds to climate change over long timeframes and will continue even after successful mitigation. However, rapid global mitigation of greenhouse gases significantly reduces risks to coastal C&S, and crucially buys time for adaptation.

Appropriate actions to reduce climate change risks on coastal C&S depend on the scale and speed of coastal change interacting with unfolding local circumstances – reflecting the hazards, exposure, vulnerability, and response to risks.

'Hard' protection, like dikes and seawalls, can reduce risks of flooding for several metres of sea-level rise in some coastal C&S. These are most cost-effective for densely populated cities and some islands but may be unaffordable for poorer regions. Although these measures reduce the likelihood of coastal flooding, residual risk remains, and hard protection typically has negative consequences for natural systems. In low-lying protected coastal zones, draining river and excess water will increasingly be hampered, requiring pumping eventually or transferring to alternative strategies.

Whereas structures can disrupt natural beach morphology processes, sediment-based protection replenishes beaches. These have lower impact on adjacent beaches and coastal ecology and lower costs for construction and maintenance compared to hard structures. Another form of 'soft' protection involves establishing, rehabilitating and preserving coastal ecosystems, like marshes, mangroves, seagrass, coral reefs and dunes, providing 'soft' protection against storm surges, reducing coastal erosion, and offering additional benefits including food, materials, and carbon sequestration. However, these are less effective where there is limited space in the coastal zone, limited sediment supply, and under higher rates of sea level rise.

Coastal settlements can 'avoid' new flood and erosion risk by preventing development in areas exposed to current and future coastal hazards. Where development already exists, settlements can 'accommodate' climate change impacts through, among other things, land use zoning, raising ground or buildings above storm surge levels, installing flood proofing measures within and outside properties, and early warning systems. Improving the capacity of urban drainage, incorporating nature-based solutions within urban areas, and managing land upstream of settlements to reduce runoff from the hinterland, reduces the risk of compound flood events. More radically, land can also be reclaimed from the sea, which offers opportunities for further development but has impacts on the natural system and wider implications for the trajectory of development.

Coastal risks and impacts such as floods, loss of fisheries or tourism, or salinization of groundwater, require people to change behaviour to adapt, such as diversifying livelihoods or moving away from low-lying areas. Currently most of these practices are reactive and help people adjust to/cope with current impacts. While a critical part of coastal adaptation, changing behaviour is most likely when enabled by supportive policies and financial structures, and alignment with socio-cultural values and worldviews.

Where risks are very high, or resources are insufficient to manage risks, submergence or erosion of coastal C&S will be inevitable, requiring 'retreat' from the coastline. This is the outlook for millions of people in coming decades, including those living in river deltas, Arctic communities, small islands, and low-lying small settlements in poor and wealthy nations. Whilst the impacts of retreat on communities can be devastating, the prospect of many C&S and even whole nations being permanently inundated in coming centuries underscores the imperative for urgent action.

Crucial to making choices about how to mitigate greenhouse gas emissions, and adapt to climate change in coastal C&S, is to establish institutions and governance practices supporting climate resilient development – a mix and sequence of mitigation and adaptation actions - that are fair, just, and inclusive as well as technically and economically effective across successive generations.

[END FAQ CCP2.2 HERE]

[START FAQ CCP2.3 HERE]

FAQ CCP2.3: Considering the wide-ranging and interconnected climate and development challenges coastal cities and settlements face, how can more climate resilient development pathways be enabled?

Coastal C&S are on the frontline of the climate change challenge. They are the interface of three interconnected realities. First, they are critical nodes of global trade, economic activity and coast-dependent livelihoods, all of which are highly and increasingly exposed to climate- and ocean-driven hazards (FAQ CCP2.1). Second, coastal C&S are also sites where some of the most pressing development challenges are at play (e.g., trade-offs between expanding critical built infrastructure while protecting coastal ecosystems, high economic growth coupled with high inequality in some coastal megacities). Third, coastal C&S are also centres of innovation and creativity, thus presenting a tremendous opportunity for climate action through a range of infrastructural, nature-based, institutional, and behavioural solutions (FAQ CCP2.2). Given these three realities of high climate change risks, rapid but contested and unequal development trajectories, and high potential for innovative climate action, C&S are key to charting pathways for Climate Resilient Development.

Three key levers can enable pathways that are climate-resilient and meet goals of inclusive, sustainable development. One is to enable climate resilient development is flexible, proactive, and transparent governance systems, built on a bedrock of accountable local leadership, evidence-based decision-making, even under uncertainty, and inclusive institutions that consider different stakeholder voices and knowledge systems. Another key enabler is acknowledging the socio-cultural and psychological barriers to climate action and incentivising people to change lifestyles and behaviours that are pro-climate and aligned with community-oriented values and norms. In practice, coastal C&S are experimenting with different strategies to change practices and behaviours, such as using subsidies and zoning policies, tax rebates and public awareness campaigns, to promote individual and collective action. Finally, enabling climate resilient development needs dedicated, short- and long-term financing to reorient current trajectories of unsustainable and unequal development towards climate mitigation and adaptation action that reduces current and predicted losses and damages, especially in highly vulnerable coasts, such as the small island states, the

Arctic and low-lying C&S. Currently, adaptation finance is concentrated in coastal megacities and tends to be deployed in risk-proofing high-value waterfront properties or key infrastructures. Addressing these finance imbalances (globally, regionally, and sub-nationally) remains a critical barrier to inclusive climate resilient coastal development.

Notwithstanding the many interconnected challenges faced, from more frequent and intense extreme events to the COVID-19 pandemic, many coastal C&S are experimenting with ways to pivot towards climate resilient development. Critical enablers have been identified and lesson learned which, if translated into practice, will enhance the prospects for advancing the SDGs and charting pathways for Climate Resilient Development that are appropriate to local contexts and foster human well-being and planetary health.

Executive Summary

Introduction

This cross-chapter paper on "Deserts, semi-arid areas and desertification" updates and extends Chapter 3 on "Desertification" in the IPCC Special Report on Climate Change and Land (SRCCL). It assesses new information and links it to the findings across the chapters of Working Group 2's contribution as well as relevant chapters of Working Group 1's contribution to the IPCC Sixth Assessment Report (AR6), with an added focus on deserts which were outside the scope of the SRCCL.

Where are we now: Observed impacts and adaptation responses

Deserts and semi-arid areas have already been affected by climate change, with some areas experiencing increases in aridity. Mixed trends of decreases and increases in vegetation productivity have been observed, depending on the time period, geographic region, detection methods used and vegetation type under consideration (*high confidence*[1]). These changes have had varying and location-specific impacts on biodiversity, and have altered ecosystem carbon balance, water availability and the provision of ecosystem services (*high confidence*). There is no evidence, however, of a global trend in dryland expansion based on analyses of vegetation patterns, precipitation and soil moisture, with overall, more greening than drying in drylands since the 1980s (*medium confidence*). Deserts and semi-arid areas host unique biodiversity, rich cultural heritage and provide globally valuable ecosystem services. They are also highly vulnerable to climate change. The vitality of natural ecosystems in arid and semi-arid regions greatly depends on water availability, as they are highly sensitive to changes in precipitation and potential evapotranspiration {3.1.2; 3.2.1}, as well as to land management practices. Multiple lines of evidence from 1920-2015 indicate that surface warming of 1.2ºC-1.3ºC over global drylands (Section 1.1.1) exceeded the 0.8ºC-1.0ºC warming over humid lands. From 1982 to 2015, unsustainable land use and climate change combined caused desertification of 6% of the global dryland area, while 41% showed significant increases in vegetation productivity (greening) and 53% of the area had no notable change, although greening rates are slowing or declining in some locations. Greening may cause biodiversity loss and ecosystem service degradation in relation to livelihood systems {3.2.2}. Observed trends in deserts and semi-arid areas have led to varying impacts on flora, fauna, soil, nutrient cycling, the carbon cycle and water resources. Ecological changes in dryland ecosystems detected and attributed primarily to climate change include tree mortality and losses of mesic tree species at specific sites in the African Sahel particularly during the droughts of the 1970s and 80s, and in North Africa from 1970 to 2007 (CCP4.3.2); and losses of bird species in the Mojave Desert of North America from 1908 to 2016 (CCP4.3.2). In contrast, growth in herbaceous vegetation production has increased in some drylands since the 1980s. Widespread woody encroachment has occurred in many shrublands and savannas in Africa, Australia, North America and South America, due to a combination of land use change, changes in rainfall, fire suppression, and CO_2 fertilization {3.2.1, 3.2.2} which, together with unsustainable management, alters biodiversity and reduces ecosystem services such as water availability and grazing potential.

The impacts of climate change have affected the ecosystem services that humans can harness from drylands, with largely negative implications for livelihoods, human health and wellbeing, particularly in deserts and semi-arid areas with lower adaptive capacities (*high confidence*). Ecosystem degradation (Section 16.5.2.3.1) and desertification threaten the abilities of both natural and human systems to adapt to climate change (*high confidence*) {3.1.1}. Changes in desert and semi-arid ecosystem services most acutely affect people who are directly dependent on naatural resources for their livelihoods and survival. These groups also often have lower capacities to adapt, particularly given structural limitations of some drylands where healthcare, sanitation, infrastructure and efficient markets are lacking, reinforcing existing inequalities (*high confidence*) {3.2.1, 3.2.2}. In rural drylands in tropical and Mediterranean areas, human populations are steadily expanding with mixed implications for ecosystem services under climate change, while rapid

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

urbanisation in new and existing dryland megacities put additional pressure on water ecosystem services (*high confidence*). Impacts resulting from consumption of dryland ecosystem services elsewhere, alongside other teleconnections associated with health, trade, conflict and migration, mean that dryland adaptive capacities have far reaching implications for other locations, while other locations affect dryland adaptation options {3.1.1; 3.4}.

Where are we going? Risks and adaptation under warming pathways

Some drylands will expand by 2100, while others will shrink (*high confidence*). Climate change affects drylands through increased temperatures and more irregular rainfall, with important differences between areas with different rainfall distributions linked to the dominant climate systems in each location (Chapter 9). Projections are nevertheless uncertain and not well supported by observed trends, while different methodological approaches and indices exhibit different strengths and weaknesses (*medium confidence*). A fundamental methodological challenge is how to attribute projected impacts to climate change when background climate variability in drylands is so high. Some projections show aridity (as measured by the aridity index) to expand substantially on all continents except Antarctica. Expansion of arid regions is probable in southwest North America, the northern fringe of Africa, southern Africa and Australia. The main areas of semi-arid expansion are *likely*[2] to occur on the north side of the Mediterranean, southern Africa and North and South America. India, parts of northern China, eastern equatorial Africa and the southern Saharan regions are projected to have shrinking drylands. Under RCP 8.5, aridity zones could expand by one-quarter of the 1990 area by 2100, increasing to over half the global terrestrial area. Lower greenhouse gas emissions, under RCP 4.5, could limit expansion to one-tenth of the 1990 area by 2100. Nevertheless, the utility of the aridity index in delineating dryland biomes is limited under an increasing CO_2 environment (*medium confidence*) and how well the index fits observed trends has been questioned in recent research. The impacts of climate change on sand and dust storm activity are projected to be substantial, however, there is large regional variability in terms of rainfall seasonality, land management practices, as well as differences in rates of change and the scales at which the projections are undertaken. The characteristics and speed of human responses and adaptations also affect future risks and impacts (*high confidence*). Increased temperature and rainfall variability will significantly change the inter-annual variability in the global carbon cycle which is strongly influenced by the world's drylands and the ways they are managed (*medium confidence*). Increased variability of precipitation would generally contribute to increased vulnerability for people in drylands, intensifying the challenges that people living in deserts and semi-arid areas will face for their sustainable development (*medium confidence*) {3.3.1, 3.3.2}.

Contributions of adaptation measures to climate resilient development

Drivers of desert expansion and greening are numerous, are attributed to environmental and human processes and differ across dryland types, yet a suite of adaptations can help to address human drivers of change, support resilience and build the adaptive capacity of dryland people (*medium confidence*). Deserts and semi-arid areas have a rich cultural heritage, Indigenous knowledge, and local knowledge which enrich and influence sustainability and land use globally. Growing research evidence and experience highlight the necessary features of an enabling environment for dryland adaptation (Section 8.5.2). Key enablers include supportive policies, institutions and governance approaches that strengthen the adaptive capacities of dryland farmers, pastoralists and other dryland resource users (*high confidence*), addressing drivers (proximate and underlying) as well as symptoms of desertification. For instance, the skills and capacities held by the mobile and adaptive approach of pastoralists may provide lessons for society at large in adapting to climate change and dealing with increased uncertainty. Such a policy would stand in contrast to previous attempts at settling pastoralists. There is a persistent gap in terms of scaling-up already known good practices, combining nature-based, land-based, and ecosystem-based approaches that facilitate sustainable land management, with contextually appropriate and responsible governance systems (e.g., including those supporting communal land tenure arrangements and Indigenous knowledge) (*medium*

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range

confidence). Land based adaptations can help manage dryland changes including sand and dust storms and desertification (*high confidence*), while technological options linked to water management draw from both traditional practices and new innovations. Adequate financing and investment is required to harness multiple benefits for managing the impacts of climate change and desertification whilst accelerating progress towards sustainable development in deserts and semi-arid areas {3.4}.

CCP3.1 Introduction

CCP3.1.1 Concepts, Definitions and Scope

Deserts and semi-arid areas are in 'drylands', which comprise hyper-arid, arid, semi-arid and dry sub-humid areas (Figure CCP3.1). Drylands cover about 45-47% of the global land area (Prăvălie, 2016; Koutroulis, 2019) and are home to about 3 billion people residing primarily in semi-arid and dry sub-humid areas (van der Esch et al., 2017). Drylands host unique, rich biodiversity (Maestre et al., 2015) and provide important ecosystem services (Bidak et al., 2015; Lu et al., 2018), while dryland people have a rich cultural and historical heritage. Rural human populations are growing in some Mediterranean and tropical drylands, while many are rapidly urbanizing (Guengant Jean-Pierre, 2003; Tabutin and Schoumaker, 2004; Denis and Moriconi-Ebrard, 2009), with varying impacts on ecosystem services and adaptive capacities. In recent decades, 6% of global megacities have been established in arid areas and 2% in hyper-arid desert areas (Cherlet et al., 2018), with many of these areas suffering from severe water security challenges (Stringer et al., 2021). Dryland inhabitants in many developing countries are also experiencing poverty (Section 16.1.4.3), hunger, poor health, land degradation, and economic and political marginalisation (Mbow et al., 2019; Mirzabaev et al., 2019), which sometimes limits their access to common pool resources. These challenges, together with a weak enabling environment, threaten opportunities to adapt to climate change.

The terms "desert" and "desertification" are subject to various interpretations due to the diverse components, processes and states they denote. Recognizing "land degradation" as a contested and perceptual term (Blaikie and Brookfield, 1987; Behnke and Mortimore, 2016; Robbins, 2020), this cross-chapter paper, defines land degradation as "a negative trend in land condition, caused by direct or indirect human-induced processes including climate change, expressed as long-term reduction or loss of at least one of the following: biological productivity, ecological integrity or value to humans" (Olsson et al., 2019). Desertification is land degradation in arid, semi-arid, and dry sub-humid areas (UNCCD, 1994). Following the above definitions, desertification is more common in arid and semi-arid climates than in hyper-arid climates. When desertification does occur in arid and hyper-arid ecosystems it is often in oases and irrigated cultivated lands (Ezcurra, 2006; Dilshat et al., 2015). Hyper-arid areas, except wetlands such as oases, wadis and riverbanks, are excluded in the United Nations Convention to Combat Desertification (UNCCD) definition of desertification used here, yet many of the world's deserts are in hyper-arid areas. Hyper-arid areas are therefore included when discussing deserts but not when discussing desertification. Deserts are not the end point in a desertification process (Ezcurra, 2006), and there is robust evidence of desertification in deserts, mostly driven by human activities and climate variability, expressed as loss of biological productivity, ecological integrity or value to humans to below their natural levels (Moridnejad et al., 2015).

Interactions between climate change and desertification in drylands create challenges for both ecosystem and human resilience, affecting ecosystem services, biodiversity, food security, human health and wellbeing (Reed and Stringer, 2016). Dryland livelihoods that heavily rely on natural ecosystems face pressures including high population growth rates, weak or poor governance, low investment, unemployment and poverty, market distortions and underestimates of the value of drylands (Stringer et al., 2017; Bawden, 2018). These pressures intersect with broader societal challenges such as conflict and civil unrest (Okpara et al., 2015; Almer et al., 2017), which together, can contribute to human displacement (Section 16.2.3.8) in some drylands (Warner, 2010; Abel et al., 2019). Nevertheless, evidence linking conflict with climate change and desertification is weak (Benjaminsen et al., 2012) and data are insufficient to draw robust conclusions.

Drylands yield important opportunities for adapting to and mitigating climate change. They offer abundant solar energy which could support mitigation efforts, opportunities for cultural and nature-based tourism, rich plant biodiversity in some areas (e.g. Namibia), and extensive Indigenous knowledge and experience of adapting to dynamic climates (Christie et al., 2014; Stringer et al., 2017), e.g. across West Asia and North Africa (Louhaichi and Tastad, 2010; Hussein, 2011). Improved understanding of challenges and opportunities in drylands can be achieved by transdisciplinary, multi-scale and inter-sectoral approaches encompassing links between physical, biological and socioeconomic, and institutional systems (Reynolds et al., 2007; Stringer et al., 2017).

Chapter 3 of the IPCC Special Report on Climate Change and Land (SRCCL) focused on desertification, but links between climate change and deserts, desertification and semi-arid areas have not been extensively considered in recent IPCC assessment cycles. AR5 noted that desertification contributes to atmospheric dust production, identifying desertification as needing consideration within climate change mitigation and adaptation governance and decision-making (Boucher et al., 2013; Myhre et al., 2013). This cross-chapter paper focuses on environmental and human aspects, finding that climate change impacts will intensify the challenges faced by dryland populations in advancing sustainable development. However, viable options exist for adapting to climate change, reducing desertification and supporting progress towards the Sustainable Development Goals (SDGs), particularly by combining modern science, Indigenous knowledge, and local knowledge, as well as livelihood and land management strategies that enable land-based adaptation, mitigation and nature-based solutions (Section 16.3.2.3).

CCP3.1.2 Key Measurement Challenges and Observed Dryland Dynamics

Maps of dryland extent commonly employ a climate-based approach measured using the aridity index (AI), or consider the extent of dryland vegetation. The two approaches sometimes do not demarcate the same geographical areas as being drylands, particularly when projecting future changes (Stringer et al., 2021). Dryland dynamics therefore need to be viewed specifically in relation to the definitions and measurements being used. From 1982 to 2015, unsustainable land use and climate change combined caused desertification of 6% of the global dryland area, while 41% showed significant greening (i.e. increased vegetation productivity), and 53% of the area had no notable change (Figure CCP3.1; Burrell et al., 2020);). In contrast Yuan et al. (2019) conclude that during 1999-2015, trends of vegetation production reversed globally and in drylands, showing extensive declines. Thus, while overall greening has occurred, this trend now appears to be declining. Analyses of vegetation, soil, and physical characteristics of over 50 000 sample points in drylands around the world indicate that aridification causes ecological degradation at three successive thresholds: vegetation decline at aridity index = 0.56, soil disruption at aridity index = 0.3, and loss of plant cover at aridity index = 0.2 (Berdugo et al., 2020). Drylands nevertheless show different dynamics depending on the index used and the variables assessed.

Based on the AI, some drylands are projected to expand and others to contract due to climate change. However, there is no evidence of a global trend in dryland expansion based on vegetation patterns, precipitation and soil moisture, based on the satellite record from the 1980s to the present (*medium confidence*). The AI will also be of limited use under a changing CO_2 environment due to higher water use efficiency by some plants (Mirzabaev et al., 2019), and it overvalues the role of potential evapotranspiration (PET) relative to rainfall. It also does not account for CO_2 impacts on evapotranspiration, and seasonality in rainfall and evapotranspiration. Higher annual PET because of increased temperatures will have little impact if temperature and actual evapotranspiration are not rising during the period of vegetation growth (Stringer et al., 2021).

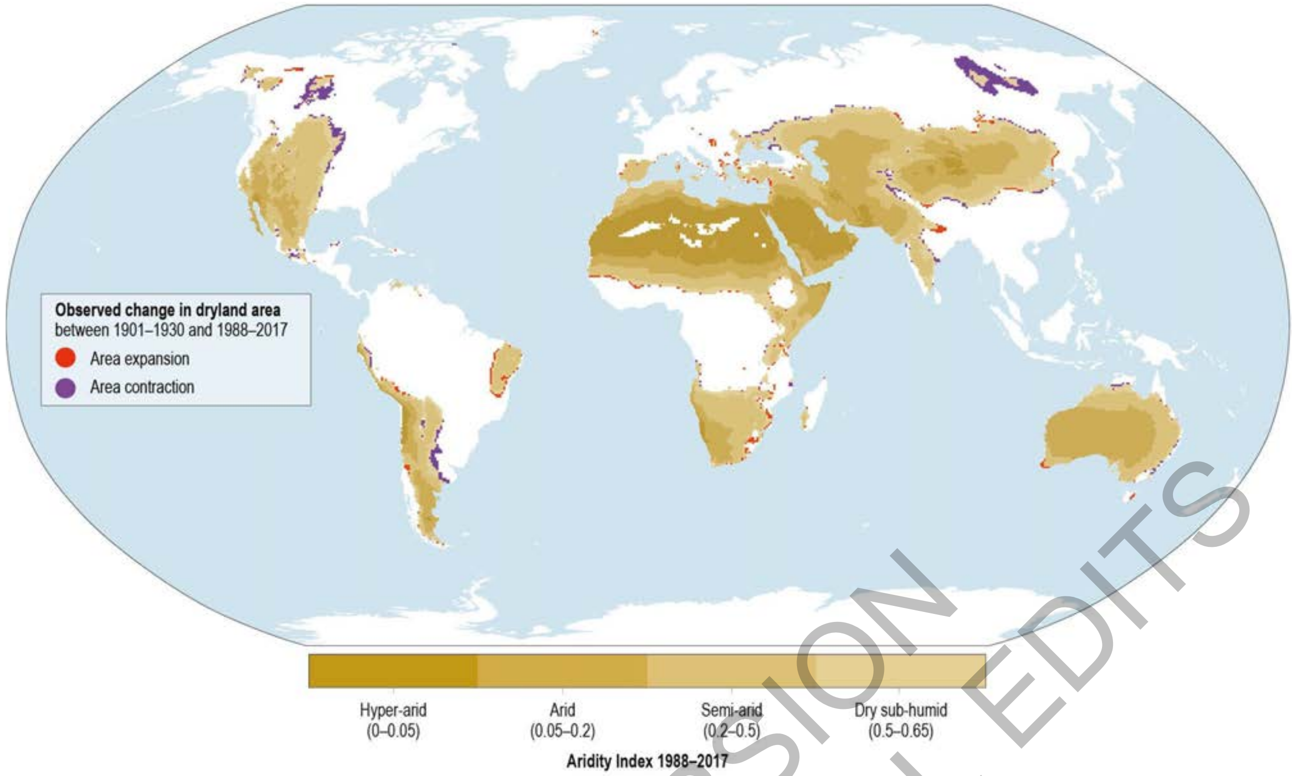

Figure CCP3.1: Aridity zone extent and observed changes in dryland areas as defined by the Aridity Index. Aridity zones, according to UNESCO (1979) and UNEP (1992) classifications, defined by the aridity index (AI), consider the ratio of average annual precipitation to potential evapotranspiration: (i) dry sub-humid ($0.5 \leq AI < 0.65$), (ii) semi-arid ($0.2 \leq AI < 0.5$), (iii) arid ($0.05 \leq AI < 0.2$) and (iv) hyper-arid ($AI < 0.05$). Drylands include land with AI < 0.65, humid lands are those with AI >0.6. Drylands include land with AI < 0.65, humid lands are those with AI >0.65 (UNEP, 1992). Deserts represent a major part of the hyper-arid and arid zones. The aridity zones are shown for climate in the period 1988-2017 and changes in dryland area (combined area of four aridity zones) are shown between the periods 1901-1930 and 1988-2017, based on climate time series at 50 km spatial resolution (Harris et al., 2020). The AI has various limitations in assessing dryland expansion and different indices highlight different areas and different changes. This is known as the aridity paradox (Greve et al., 2019). See SRCCL Section 3.2.1 (Mirzabaev et al., 2019) for an in-depth analysis of limitations, and Stringer et al. (2021) for a summary of different measures and indices used in the literature.

CCP3.2 Observed Impacts of Climate Change Across Sectors and Regions

CCP3.2.1 Observed Impacts on Natural Systems in Arid and Semi-arid Areas

CCP3.2.1.1 Temperature and Rainfall

Significant warming has occurred across drylands globally (WGI, 2021). Surface warming (from 1920-2015) of 1.2ºC-1.3ºC in global drylands has exceeded the 0.8ºC-1.0ºC warming over humid lands (Huang et al., 2017). As measured by the AI, this has expanded the area of drylands by ~4% from 1948-2004 (Ji et al., 2015; Spinoni et al., 2015; Huang et al., 2016). However, as mentioned in Figure CCP3.1, the AI has various limitations in assessing drylands expansion. Increases in potential evapotranspiration have exceeded increases in precipitation in the last half of the period 1901-2017 (Pan et al., 2021). Observations from the Sahel demonstrated that temperature seasonality changes differ from rainfall seasonality changes (Guichard et al., 2015), and there has been an increase in surface water and groundwater recharge in the Sahel since the 1980s, referred to as "the Sahel paradox" (Favreau et al., 2009; Gardelle et al., 2010; Descroix et al., 2013; Wendling et al., 2019). Research from the USA suggests that historical soil moisture levels can contribute to such variability (Heisler-White et al., 2009). Studies from the Middle East show rising temperatures and declining rainfall trends (ESCWA, 2017), with most decreasing aridity trends in north Sudan and most increasing aridity trends in eastern Arabia over the period 1948-2018 (Sahour et al., 2020).

CCP3.2.1.2 Ecosystem Processes

Semi-arid ecosystems have a disproportionately large role in the global carbon cycle, driving trends and inter-annual variability of the global carbon sink (Alstrom et al., 2015). These systems are highly sensitive to annual precipitation and temperature variations (*high confidence*) (Alstrom et al., 2015, Poulter et al., 2014). The positive trend in semi-arid regions is consistent with widespread woody encroachment and increased vegetation greenness (Andela et al., 2013; Piao et al., 2019; Piao et al., 2020) driven by CO_2 fertilisation and rainfall increases (Sitch et al., 2015; Piao et al., 2020), although some trends are complicated by irrigation practices (He et al., 2019). Increases in temperature and drought diminish this trend through reduced vegetation productivity and increased vegetation mortality (Brandt et al., 2016; Ma et al., 2016; Fernández-Martínez et al., 2019; Maurer et al., 2020) with indications that this trend is declining or reversing in some locations (Yuan et al., 2019; Wang et al., 2020).

Changed climates have increased water constraints of vegetation growth most notably in the Mediterranean (CCP1.2.3.2, CCP4.2.1) and west and central Asia (Jiao et al., 2021). Climate change and elevated CO_2 have both increased and decreased vegetation sensitivity to rainfall throughout drylands, with the degree of variation shaped by region, land-use and vegetation traits (Haverd et al., 2017; Abel et al., 2021). Mineral nitrogen production in drylands may become increasingly decoupled from consumption by plants over prolonged dry periods, and more extreme hydrological events can drive multiple changes to nutrient cycling (Manzoni et al., 2019). Soil biocrusts (composed of lichens, bryophytes and soil microorganisms) which contribute to dryland ecosystem function including carbon uptake and soil stabilisation (Reed et al., 2019), are sensitive to warming and altered rainfall in a shift in biocrust communities of mosses and lichens in favour of early successional cyanobacteria-dominated biocrusts (Escolar et al., 2012; Reed et al., 2012), which can increase surface albedo (Rutherford et al., 2017).

CCP3.2.1.3 Vegetation Changes

CCP3.2.1.4 Woody Cover Increase

Dryland ecosystems have shown mixed trends of decreases and increases in vegetation and biodiversity, depending on the time period, geographic region, and vegetation type assessed (see Table CCP3.1 for examples of observed environmental changes and impacts in drylands and the role of climate change and non-climatic factors in causing these changes).

Increases in shrub cover in arid deserts and shrublands have been recorded in the North American drylands (Caracciolo et al., 2016; Archer et al., 2017; Chambers et al., 2019), the Namib desert (Rohde et al., 2019), the Karoo (Ward et al., 2014; Masubelele et al., 2015b), north and central Mexico (Pérez-Sánchez et al., 2011; Báez et al., 2013; Castillón et al., 2015; Sosa et al., 2019), large parts of the West African Sahel with some local exceptions (Brandt et al., 2016), and in Central Asia (Jia et al., 2015; Li et al., 2015; Deng et al., 2016; Jiao et al., 2016; Wang et al., 2016). Increasing woodiness in the Namib is consistent with an increase in rainfall extremes and westward expansion of convective rainfall (Haensler et al., 2010; Rohde et al., 2019). Increasing rainfall and rising CO_2 concentrations (which improves water use efficiency) benefits some shrubs (Polley et al., 1997; Morgan et al., 2004; Donohue et al., 2013). Together with changes in land use (Hoffman et al., 2018), improved land management (Reij et al., 2005) and improved irrigation (He et al., 2019) this contributes to woody cover increases. Extensive woody encroachment has been recorded in savannas (measured between 1920-2015, over the past century) in Africa (2.4% woody cover increase/decade), Australia (1% increase/decade), and South America (8% increase/decade) (O'Connor et al., 2014; Stevens et al., 2016; Skowno et al., 2017; Venter et al., 2018; Zhang et al., 2019). Following drought in the Sahel (1968-1973 and 1982-1984), a rainfall increase since the mid-1990s has been linked to increases of woody cover between 1992-2011/2012 (Brandt et al., 2016; Brandt et al., 2017; Brandt et al., 2019). See SRCCL section 3.2.1.1 for an evaluation of NDVI and remote sensing approaches used in these studies. Tree regeneration by farmers has also increased woody cover, particularly next to villages (*high confidence*) (Reij et al., 2005; Reij and Garrity, 2016; Brandt et al., 2018). Otherwise, savanna encroachment has been attributed to combinations of increased rainfall (Venter et al., 2018; Zhang et al., 2019), warming (Venter et al., 2018) and CO_2 fertilisation (Kgope et al., 2010; Bond and Midgley, 2012; Buitenwerf et al., 2012; Stevens et al., 2016; Quirk et al., 2019) interacting with changing land use (Archer et al., 2017; Venter et al., 2018) where herbivory and fire regimes are altered (O'Connor et al., 2014; Archer et al., 2017;see also discussion on fire and herbivory in Section 2.4.3.1.2). In some cases, woody increase has been balanced locally by changes in runoff (Trichon et al., 2018), or by land clearing and fuel wood harvesting, as seen in western Niger, northern Nigeria, and at the periphery of major towns (Montagné et al., 2016).

CCP3.2.1.5 Tree Death and Woody Cover Decline

Field measurements have also detected tree mortality and loss of mesic tree species at some Sahel sites during drought periods (Gonzalez et al., 2012; Kusserow, 2017; Brandt et al., 2018; Ibrahim et al., 2018; Trichon et al., 2018; Zwarts et al., 2018; Bernardino et al., 2020; Zida et al., 2020) and a reduction of mesic species in favour of drought-tolerant species (*high confidence*) (Hänke et al., 2016; Kusserow, 2017; Ibrahim et al., 2018; Trichon et al., 2018; Dendoncker et al., 2020; Zida et al., 2020b), with attribution to climate change (Gonzalez et al., 2012). Furthermore, vegetation productivity per unit of rainfall showed a net decline of 4% in the period 2000-2015 across drylands globally, with the greatest net declines in Africa (16%) and Asia (33%) (Abel et al., 2021), but with location-specific increases in vegetation-rainfall sensitivity, e.g. in southern and eastern Africa and parts of the Sahel. Furthermore, NDVI declines were reported across the Sahel from 1999 to 2015 (Yuan et al., 2019; Zida et al., 2020a). However, field site monitoring showed a strong regeneration of the decimated woody populations except on shallow soil where the runoff system had evolved towards a web of gullies (Hiernaux et al., 2009a; Trichon et al., 2018; Wendling et al., 2019) .

Other site-specific impacts include tree mortality in south-western Morocco (Le Polain de Waroux and Lambin, 2012), mortality of *Austrocedrus* and *Nothofagus* forests in the dry Patagonia forest-steppe (Rodríguez-Catón et al., 2019), and a tree range contraction of *Aloidendron dichotmum* in Southern Africa (Foden et al., 2007b). In Morocco, tree mortality was most highly correlated to an increase in aridity, measured by the Palmer Drought Severity Index (PDSI), which showed a statistically significant increase since 1900 due to climate change (Dai et al., 2004; Esper et al., 2007; Dai, 2011).

In deserts of the south-western United States, a drought since 2000, mainly due to climate change (Williams et al., 2020), together with land use change, invasive plant species, and wildfire (Syphard et al., 2017), has led to reductions in native desert plant species (Defalco et al., 2010; Conver et al., 2017) and perennial vegetation cover (Munson et al., 2016a; Munson et al., 2016b). An increase in invasive exotic grasses has increased wildfires in these desert ecosystems in which fire had been rare (Brooks and Matchett, 2006; Abatzoglou and Kolden, 2011; Hegeman et al., 2014; Horn and St. Clair, 2017). In the Mojave Desert in the United States, a loss of bird biodiversity has also been detected and attributed to increased aridity caused by climate change (Iknayan and Beissinger, 2018; Riddell et al., 2019).

CCP3.2.1.6 Change in Herbaceous Cover

Changes in aridity (Rudgers et al., 2018) have caused some expansion of dominant grasses (often invasive) into desert shrublands. The spread of invasive *Bromus tectorum* may be enhanced by altered precipitation and freeze-thaw cycles (*low confidence*) (Collins and Xia, 2015; Rudgers et al., 2018). Arid grassland has expanded (between 10-100 km) into the eastern Karoo, South Africa (*high confidence*) (du Toit et al., 2015; Masubelele et al., 2015a; Masubelele et al., 2015b). Observations from 100-year-old grazing trials demonstrate that the increase in grassiness is a product of shift in rainfall seasonality and an increase in rainfall (Du Toit and O'Connor, 2014; du Toit et al., 2015; Masubelele et al., 2015a; Masubelele et al., 2015b; du Toit et al., 2018). These changes are causing an increase in fire frequency in these seldom burnt areas (du Toit et al., 2015). The Sahara Desert was suggested to have expanded 10% from 1902 to 2013 (Thomas and Nigam, 2018), although herbaceous vegetation production has increased in general in the Sahel since the dry 1980s (Eklundh and Olsson, 2003; Anyamba and Tucker, 2005; Herrmann et al., 2005; Hutchinson et al., 2005; Olsson et al., 2005; Fensholt et al., 2006; Dardel et al., 2014; Hiernaux et al., 2016; Stith et al., 2016; Benjaminsen and Hiernaux, 2019; Hiernaux and Assouma, 2020).

Trends of land degradation (Section 16.4.1.2) and desertification (as demonstrated by loss of cover or reduced vegetation productivity) as an impact of changing climatic trends have been reported in Burkina Faso (Zida et al., 2020), the north-western regions of China during 1975-1990 (Zhang et al., 2020) in Afghanistan (Savage et al., 2009), Iran (Mahmoudi et al., 2011; Kamali et al., 2017), Argentina (Barbosa et al., 2015) and India (Javed et al., 2012). Encroachment, re-greening and an increase of unpalatable plant species into rangeland areas (e.g. in East Africa and southern Africa's Kalahari) all contribute to dryland degradation through the loss of open ecosystems and their services (Reed et al., 2015; Le et al., 2016; Chen et al., 2019b).

Table CCP3.1: Observed ecological changes in drylands.
[INSERT TABLE CCP3.1 HERE]

CCP3.2.1.7 Sand and Dust Storms

Soil dust emissions are highly sensitive to changing climate conditions but also to changing land use and management practices (*high confidence*). Distinguishing between the effects of these drivers is not straightforward, even in well-documented locations (Middleton, 2019). There is *limited evidence and low agreement* about the impacts of climate change on sand and dust storms (SDS), with studies pointing to either substantial increases (+300%) or decreases (-60%) (Boucher et al., 2013). Current climate models cannot adequately model the impact of climate change on SDS activity (Mirzabaev et al., 2019). However, there is *high confidence* that land degradation, loss of vegetative cover, and drying of water bodies in semi-arid and arid areas will contribute to sand and dust activity (Mirzabaev et al., 2019).

Sand and dust storms remain a major concern for desert areas under conditions of climate change and desertification (Middleton, 2017). Only about 20% of deserts are covered by sand, but desert sand and dust storms provide an important feedback mechanism to climate (Pu and Ginoux, 2017), with literature showing that some areas have very frequent dust days (Figure CCP3.2; Ginoux et al., 2012). In some locations such as the USA, desert dust can be deposited downwind on snowpacks, hastening snowmelt and altering river hydrology (Painter et al., 2010). Deserts and other natural dryland surfaces produced 75-90% of atmospheric dust globally in the early 21st century, with the remainder from agricultural and other land dominated by human land use (Ginoux et al., 2012; Stanelle et al., 2014).

Recent changes in dust emissions and their attributions vary geographically. Warming in Iran over the period 1951–2013 has been associated with an increased frequency of dust events (Alizadeh-Choobari and Najafi, 2018) and a trend (2000–2014) towards increased fine atmospheric mineral dust concentrations in the US southwest has been linked to increasing aridity (Hand et al., 2017). Conversely, increases in rainfall, soil moisture, and vegetation linked to changes in circulation strength of the Indian summer monsoon since 2002 have led to a substantial reduction of dust in the Thar Desert and surrounding region, showing agreement with findings from the Sahel and the West African Monsoon (Kergoat et al., 2017). A decreasing trend in the number and intensity of SDS in spring (2007-2016) in East Asia has also responded to higher precipitation and soil moisture, related to a decrease in the intensity of the polar vortex, favouring higher vegetation cover during the period studied (An et al., 2018). Global climate change, transboundary movement of aeolian material by atmospheric flows from Central Asia, dynamics of the Caspian Sea regime, erosion, salinization, as well as the loss of land as a result of the placement of industrial facilities have expanded the land area prone to desertification in Russia. Desertification has been observed to some extent in 27 sub-regions of the Russian Federation on territory of more than 100 million hectares (Kust et al., 2011; also recently confirmed by National Report, 2019). Eastern and south-eastern regions of Kalmykia, Russia, serve as dust sources, while dust and sand masses from the areas of the Black Land sometimes move far beyond to parts of Rostov, Astrakhan, Volgograd, and Stavropol regions. Agricultural land in these areas can become covered with dust and sand 10 cm or more thick, with negative impacts on yields (Tsymbarovich et al., 2020). High dust day frequency is occurring also in the High Latitude Dust (HLD) source areas not reported in Figure CCP3.2 such as in Iceland, Patagonia, Canada, Alaska, and based on *in situ* measurements in Antarctica (Dagsson-Waldhauserová et al., 2014; Bullard et al., 2016; Dagsson-Waldhauserova and Meinander, 2019; Bachelder et al., 2020). Active HLD dust sources cover at least 500,000 km^2 and produce at least 5% of global dust budget (Bullard et al., 2016). HLD has negative impacts on the cryosphere via albedo changes and snow/ice melting (Boy, 2019; Dagsson-Waldhauserova and Meinander, 2019).

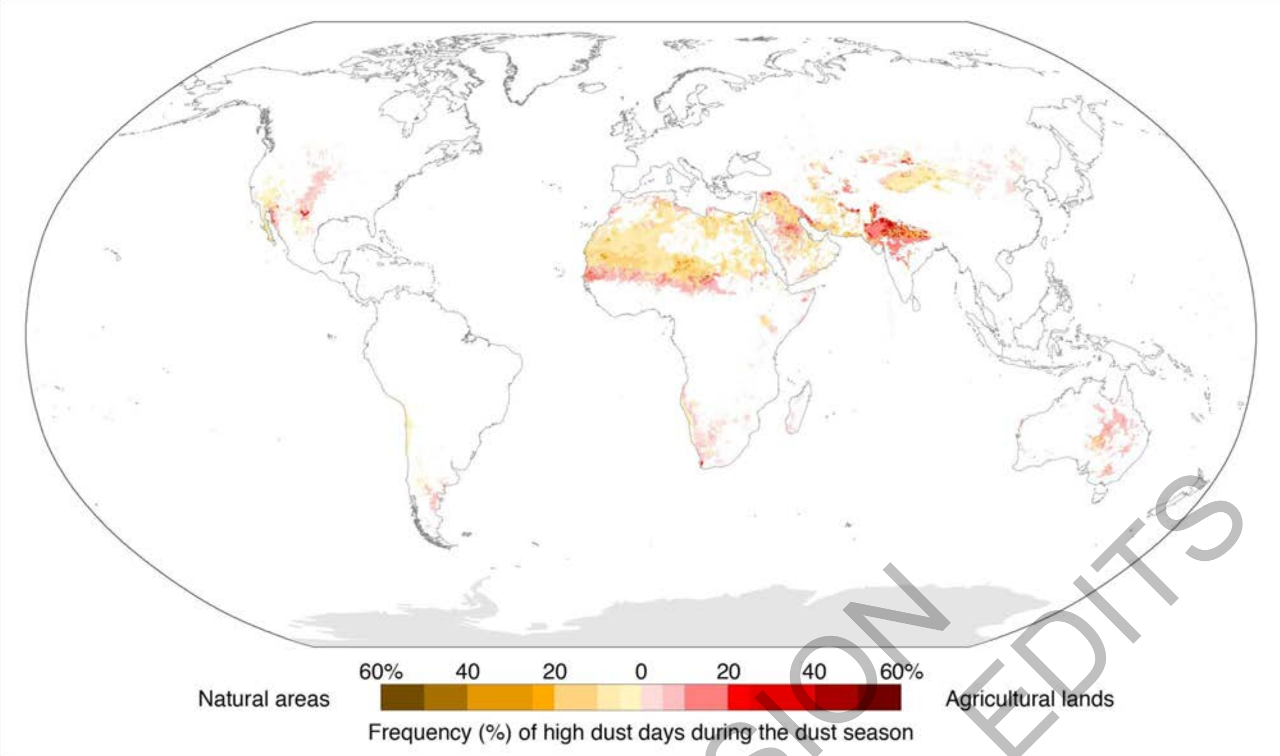

Figure CCP3.2: Frequency of high dust days (dust optical depth >0.2) during the dust season, based on 2003-2009 remote sensing, the most recent data analysed, and divided into areas primarily in agriculture and areas dominated by natural land cover (Ginoux et al., 2012). Dust seasons: Africa (North), Year-round; Africa (South), September-February; America (North), March-May; America (South), December-February), Asia, March-May; Australia, September-February.

CCP3.2.1.8 Water Scarcity

Climate change and desertification have been linked to water loss (Bayram and Öztürk, 2014; Schwilch et al., 2014; Mohamed et al., 2016), decreases in water quantity for irrigation, and contamination of surface water bodies (Middleton, 2017). Increased runoff in areas in the Sahel with shallow soils increased water flows to lakes and the recharge of water tables (Favreau et al., 2009; Gardelle et al., 2010; Descroix et al., 2013; Kaptué et al., 2015; Gal et al., 2017). Water scarcity (Section 16.5.2.3.7) was among the first impacts of climate change recognized in North African countries such as Morocco which have extensive dryland areas, with countries such as Turkey, Libya, USA and China carrying out large-scale water transfer projects (Sternberg, 2016; Stringer et al., 2021). The decrease in water availability in Morocco was substantial in terms of both surface water supply (Rochdane et al., 2012; Choukri et al., 2020) and groundwater (Bahir et al., 2020), threatening agricultural production.

CCP3.2.2 Observed Impacts of Climate Change on Human Systems in Desert and Semi-Arid Areas

Climate change and desertification, alongside other drivers of degradation, reduce dryland ecosystem services, leading to losses of biodiversity, water, food, and impacts on human health (CCP4.2.3, WG2) and well-being *(high confidence*) (Mirzabaev et al., 2019) resulting in disruption to the economic structures and cultural practices of affected communities (Elhadary, 2014; Middleton, 2017).

CCP3.2.2.1 Sand and Dust Storms

Desertification and SDS can cause substantial socioeconomic damage in drylands (UNEP, 1992; Opp et al., 2021) over both the short and long term. Short-term impacts occur on health, food production systems, infrastructure (damaging buildings, energy systems, and communications), transport and related economic productivity, air and road traffic, and costs are incurred in clearing sand and dust from deposition areas (Mirzabaev et al., 2019). In the Arab region increasing frequency of SDS events is projected to further exacerbate water scarcity and drought (ESCWA, 2017). Longer-term costs include loss of ecosystem services, biodiversity and habitat, chronic health problems, soil erosion and reduced soil quality (particularly through nutrient losses and deposition of pollutants), and disruption of global climate regulation (Middleton, 2018; Allahbakhshi et al., 2019). Dust deposition nevertheless can offer environmental and economic benefits, bringing important nutrients that improve and sustain soil fertility (Marticorena et al., 2017). Preventing and reducing SDS entails upfront investment costs but full cost-benefit analyses of different measures compared to the costs of inaction are scarce and need to consider the likely frequency and magnitude of SDS events (Tozer and Leys, 2013).

CCP3.2.2.2 Human Health

Potential impacts of climate change, recurrent droughts and desertification on human health in drylands include: higher risks from water scarcity (linked to deteriorating surface and ground water quality and water-borne diseases; Stringer et al., 2021), food insecurity and malnutrition (Section 16.2.3.3) in the absence of sufficient imports; respiratory, cardiovascular and infectious diseases caused by SDS (Mirzabaev et al., 2019), potential displacement and migration and mental health consequences (Chapter 7; Stringer et al., 2021) and heat stress (Dunne et al., 2013; Zhao et al., 2015; Russo et al., 2016). SDS negatively impact human health through various pathways, causing respiratory, cardiovascular diseases and facilitating infections (*high confidence*) (Díaz et al., 2017; Goudarzi et al., 2017; Allahbakhshi et al., 2019; Münzel et al., 2019). SDS can cause mortality and injuries related to transport accidents (Goudie, 2014). Research from China suggests that prenatal exposure to SDS can affect children's cognitive function (Li et al., 2018). The pollutants that are entrained and ingested or inhaled closely link to the land management strategies in source areas.

Droughts (TS.2.6 L, AR6, WGI) are among the natural hazards with the highest adverse impacts on human populations (Mishra and Singh, 2010). Although droughts just represented 4% of hazard events, their impacts amounted to 31% of affected people (29 million) (Louvain, 2019). Drought exposure relates to a higher risk of undernutrition (Section 16.5.2.3.6), among vulnerable populations (Kumar, 2016), particularly children (IFPRI, 2016) for whom the impacts can lead to lifelong consequences through stunted growth, impaired cognitive ability and reduced future educational and work performance (UNICEF/WHO/WBG, 2019). The corresponding costs of children stunting in terms of lost economic growth can be of the order of 7% of per capita income in developing countries (Galasso and Wagstaff, 2018).

CCP3.2.2.3 Agro-ecological Food Systems, Livelihoods and Food Security

Rising temperatures, variation in rainfall patterns and frequent extreme weather events associated with climate change have adversely affected agro-ecological food systems and pastoral systems in some drylands (Section 16.3.2.6Zhu et al., 2013; Amin et al., 2018), especially in developing countries (Haider and Adnan, 2014; Ahmed et al., 2016; ur Rahman et al., 2018) where desertification is a key challenge to agricultural livelihoods. Recurrent droughts in recent decades, coupled with wind erosion (particularly of fine sediment which gives soil its water holding capacity and nutrients), affected vast areas in Argentina, leading to land abandonment and agricultural fields being covered by sand and invasive plants (Abraham et al., 2016). Temperature increases have contributed to reduced wheat yields in arid, semi-arid and dry sub-humid zones of Pakistan (Sultana et al., 2019). Agricultural production in the drylands of South Punjab is experiencing irreversible impacts since the grain formation phase has become swifter with a warmer climate, leading to improper growth and reduced yields (Rasul et al., 2011).

Aslam et al. (2018) regard climate change impacts to be particularly threatening to the livestock sector, water and food security and the economy beyond agriculture in South Punjab, particularly as yields decrease. In the livestock sector across global drylands (TS.4.3.2.10, AR 6, WGI), observed impacts include reduction of plant cover in rangelands, reduced livestock and crop yields, loss of biodiversity and increased land degradation and soil nutrient loss (Van de Steeg, 2012; Mganga et al., 2015; Ahmed et al., 2016; Mohamed et al., 2016; Eldridge and Beecham, 2018) as well as injury and livestock death due to SDS. This is particularly worrisome for traditional pastoralists who find themselves with fewer safety nets and limited adaptive capacities than in the past, particularly where mobility, access and tenure rights are becoming restricted (Section 16.3.2.6; Box CCP3.1) and where use of technologies such as mobile phones can result in mixed effects, as found in Morocco (Vidal-González and Nahhass, 2018). Observed SDS impacts can increase food production costs and threaten sustainability more generally (Middleton, 2017).

Woody-plant encroachment and greening may be masking underlying land degradation processes and losses of ecosystem services, livelihood and adaptation options in pastoral livelihood systems (Reed et al., 2015; Chen et al., 2019a). Woody encroachment alters ecosystem services, particularly in rangelands, resulting in reduction of grass cover, hindering livestock production (Anadón et al. 2014), reducing water availability (Honda and Durigan 2016, Stringer et al., 2021) but increasing availability of wood (Mograbi et al., 2019).

[START BOX CCP3.1 HERE]

Box CCP3.1: Pastoralism and Climate Change

Pastoralism is a livestock keeping system based on the herding of animals. Migrations often take place over long distances to track variable and unpredictable plant growth that tends to be patchy in space and variable in time (Homewood, 2018). Pastoralism has a considerably lower carbon budget than other livestock-keeping systems, with research on pastoralism in the Sahel concluding that this system may be carbon neutral (Assouma et al., 2019), despite contributing directly to greenhouse gas emissions via methane enteric emissions and indirectly through faeces-driven CO_2, CH_4 and N_2O emissions during mineralisation (Assouma et al., 2017). Efforts to sedentarize and villagize pastoralists can lead to land degradation and higher overall emissions from the sector (Section 16.3.2.6).

Pastoralists migrate with their animals in some of the most remote and marginal environments on the planet. Globally, mobile pastoralists number about 200 million households and use about 25% of the Earth's landmass (Dong, 2016). Many pastoralists operate in non-equilibrial environments that are unstable, fluctuating and generally uncertain, and driven more by climatic variation than livestock numbers and grazing pressure (Behnke et al., 1993). Examples of such systems are grazing areas in the dry tropics (Sandford, 1983; Turner, 1993; Sullivan and Rohde, 2002; Benjaminsen et al., 2006; Hiernaux et al., 2016), and rangelands in the Arctic (Behnke, 2000; Tyler et al., 2008; Benjaminsen et al., 2015; Marin et al., 2020).

Over many generations, pastoralists have accumulated practical experience and knowledge to cope with uncertainty and value variability (Krätli and Schareika, 2010), mainly through a mobile and flexible approach. While pastoralists are also at risk of climate change impacts, they may be better able to adapt to a changing climate than other land users (Davies and Nori, 2008; Krätli and Schareika, 2010; Jones and Gutzler, 2016).

While pastoralists possess substantial adaptive capacity as a result of their Indigenous knowledge, this has been under pressure during the last few decades through continued loss of livestock corridors (essential to mobility) and pastures in general due to competing land-uses such as farming, mining, crop expansion and the establishment or extension of protected areas (Thébaud and Batterbury, 2001; Brockington, 2002; Benjaminsen and Ba, 2009; Upton, 2014; Johnsen, 2016; Tappan, 2016; Homewood, 2018; Weldemichel and Lein, 2019; Bergius et al., 2020). Many of these competing land uses erect fences and exclude other uses, while property rights often privilege sedentary farming.

Modern states have typically tried to settle pastoralists and confine their movements within clearly defined boundaries, claiming that pastoral land-use is neither ecologically sustainable nor economically productive. Based on such negative and often flawed views, stall-feeding and ranching are often presented by policymakers as successful models of livestock keeping in contrast to the pastoral way of life (Steinfeld et al., 2006; Chatty, 2007).

Current pressures and processes of pastoral change are spatially variable and complex, and tend to result in further economic and political marginalization of pastoralists, with adverse effects on livelihoods and landscapes. With climate change, which is projected to lead to higher temperatures and more frequent fluctuations in precipitation, maintaining flexibility and resilience in pastoral land use is essential. However, current processes of marginalization, in addition to increased insecurity in some drylands (e.g. the Sahel), make pastoralists more vulnerable, and constrain them from fully employing their adaptive capacities

(Davies and Nori, 2008). The skills and capacities held by pastoralists may, however, offer lessons for society at large in its struggle to adapt to climate change and deal with increased uncertainty (Davies and Nori, 2008; Scoones, 2009; Nori and Scoones, 2019).

[END BOX CCP3.1 HERE]

CCP3.2.2.4 Gender Differentiated Impacts

Impacts of desertification, climate change, and environmental degradation, as well as vulnerability and capacity to adapt, are gendered. Differences are determined by socially structured gender-specific roles and responsibilities, ownership of, access to and control over natural resources and technology, decision making, and capacity to cope and adapt to long-term changes (Mirzabaev et al., 2019; Cross-Chapter Box GENDER in Chapter 18). Assessments of the gender dimension of desertification and climate change impacts and responses are scarce, and highly context specific. For example, in many lower income countries, rural women produce most of the household food, and are responsible for food preparation and collecting fuelwood and water from increasingly distant sources (Mekonnen et al., 2017; Droy, 2020). Drought and water scarcity particularly affect women and girls in drylands because they need to spend more time and energy collecting water and fuelwood, have less time for education or income generating activities, and may be more exposed to violence (Sommer et al., 2014) and less able to migrate as an adaptation option. Women are also commonly excluded from family and community decision making on actions to address desertification and climate change, yet their engagement in climate adaptation is critical. International policy efforts are currently seeking to better recognise and address this challenge (Okpara et al., 2019).

CCP3.2.2.5 Climate Change, Migration and Conflict

Dryland populations pursuing traditional land-based livelihood options are generally mobile due to a highly fluctuating resource base (Box CCP3.1). Many rural dwellers in drylands also move to urban areas for seasonal work which can have positive impacts in terms of remittances. While reasons for migration vary and can be positive or negative, oppression and human rights abuses, lack of livelihood opportunities and food insecurity tend to be among the main push factors, while emerging opportunities at the rural-urban nexus present lucrative pull factors (Cross-Chapter Box MIGRATE in Chapter 7). In a survey in Libya in 2016, 80% of migrants interviewed said they had left home because of economic hardship (Hochleithner and Exner, 2018), which in drylands under water scarcity linked to climate change, would be exacerbated.

Causes of migration and violent conflict need to be seen in a wider historical, agrarian, political, economic and environmental context, in a multi-scalar perspective integrating levels of analysis from the local to the global (Glick Schiller, 2015). Quantitative studies tend to conclude that climate change has so far not significantly impacted migration including in drylands (Owain and Maslin, 2018), although with some disagreement (Lima et al., 2016; Missirian and Schlenker, 2017). In a study of the climate change-migration-conflict interface, Abel et al. (2019) found limited empirical evidence supporting a link between climatic shocks, conflict and asylum-seeking for the period 2006–2015 from 157 countries. The authors found evidence of such a link for the period 2010–2012 relating to some countries affected by the Arab Spring and concluded that the impact of climate on conflict and migration is limited to specific time periods and contexts.

The same lack of general causality is largely concluded on the specific link between climate change and conflict (Buhaug et al., 2014; Buhaug et al., 2015; von Uexkull et al., 2016; Koubi, 2019), but a minority of quantitative studies argue for a stronger causal association (Hsiang et al., 2013). Mach et al. (2019) found considerable agreement among experts that climate variability and change have influenced the risk of organized armed conflict within countries, but they also agreed that other factors, such as state capacity and level of socioeconomic development, played a much larger role. These factors also play a role in determining adaptation possibilities and in shaping the enabling environment (Section 8.5.2).

Qualitative case studies tend to frame conflict and migration within a larger political, economic and historical context. A number of studies from African drylands find that land dispossession is a key driver of both migration and conflict resulting from large-scale resource extraction or land encroachment often associated with processes of elite capture and marginalization (Benjaminsen and Ba, 2009; Benjaminsen et al., 2009; Cross, 2013; Glick Schiller, 2015; Nyantakyi-Frimpong and Bezner Kerr, 2017; Obeng-Odoom, 2017; Bergius et al., 2020). By undermining livelihoods, exacerbating poverty, and setting rural population groups adrift, land dispossession in the Sahel may lead to increased migration to urban areas, to rural sites of non-farm employment (e.g. mines) (Chevrillon-Guibert et al., 2019) or out of the country. In addition, it may lead to other types of reactions including violent resistance (Oliver-Smith, 2010; Cavanagh and Benjaminsen, 2015; Hall et al., 2015) as already seen in the Sahel in terms of the emergence of jihadist armed groups (Benjaminsen and Ba, 2019). Major drivers of the current crisis in Mali include decades of bureaucratic mismanagement and widespread corruption, the spill-over of jihadist groups from Algeria after the civil war there in the 1990s and the current civil war in Libya. Climate change has played a marginal role as a driver of conflicts in the Sahel (Benjaminsen et al., 2012; Benjaminsen and Hiernaux, 2019) but has potential to exacerbate the situation in the future with regards to migration and conflict (Owain and Maslin, 2018).

CCP3.3 Future Projections

CCP3.3.1 Projected Changes and Risks in Natural Systems

CCP3.3.1.1 Temperature

Globally, warming rates have been twice as high in drylands compared to humid lands, because the sparse vegetation cover and lower soil moisture of dryland ecosystems amplify temperature and aridity increases (Huang et al., 2016). This enhanced warming is expected to continue in the future. Surface warming over drylands is projected to reach ~6.5°C (~3.5°C) under the high RCP8.5 (low-moderate RCP4.5) emissions scenario by the end of this century, relative to the historical period (1961-1990) (Huang et al., 2016; Huang et al., 2017). Exploring the spatial variations between the aeolian desertification response in selected climate change scenarios, Wang et al. (2017) reported that temperature rise could trigger aeolian desertification in West Asia, Central China and Mongolia. The number of extremely hot days with temperatures above 40°C is projected to increase considerably across the Arab region by the end of the 21st century (ESCWA, 2017).

CCP3.3.1.2 Rainfall, Evaporation and Drought

Drylands are highly sensitive to changes in precipitation and evapotranspiration. Potential evapotranspiration (PET) is projected to increase in all regions globally, under all RCPs, as a result of increasing temperatures and surface water vapour deficit (Mirzabaev et al., 2019). Simulations based on coupled land surface, energy and water and vegetation models in the Central Sahel showed a strong response of the water budget. Under +2°C and +4°C warming scenarios, decreased evapotranspiration, runoff and drainage were found for all scenarios except those with the highest precipitation (Léauthaud et al., 2015).

Globally, soil moisture declined over the 20th century (Gu et al., 2019), a trend that is projected to continue under all emissions scenarios (WGI AR6). Projected drier soils can further amplify aridity through feedbacks with land surface temperature, relative humidity and precipitation (Berg et al., 2016).

Drought conditions (frequency, severity and duration) are expected to substantially worsen in global drylands, driven by a higher saturation threshold and more intense and frequent dry spells under rising temperatures (Liu et al., 2019a; Liu et al., 2019b). In a +1.5°C world, historical 50-year droughts (based on the Standardised Precipitation-Evapotranspiration Index (SPEI)) could occur twice as frequently across 58% of global landmasses relative to the 1976–2005 period, an area that increases to 67% under 2°C warming (Gu et al., 2020). Multi-year drought events of magnitudes exceeding historical baselines will increase by 2050 in countries with drylands including Australia, Brazil, Spain, Portugal, and the USA (Jenkins and Warren, 2015). The magnitude of drought stress in different regions differs depending on the metric used. Projections based on the Palmer Drought Severity Index (PDSI) suggest drought stress will increase by more than 70% globally, while a substantially lower estimate of 37% is found when precipitation minus evapotranspiration (P-E) is used (Swann et al., 2016). However, the two metrics agree on increasing drought stress in regions with more robust decreases in precipitation, such as southern North America (Section 14.4.3.1), north-eastern South America (Section 12.3.1.1) and southern Europe (Section 13.1.3; Swann et al., 2016).

CCP3.3.1.3 Aridity

Studies based on the AI (the ratio of annual potential evapotranspiration to precipitation), almost always project conditions of increasing aridity under climate change, and associated widespread expansion of drylands (Huang et al., 2016). The limitations of the AI are widely reported (Mirzabaev et al., 2019), with alternative indices that consider different variables including the Ecohydrological Index, PDSI, Standardised Precipitation Index and SPEI (Stringer et al., 2021). AI projections indicate potentially severe aridification in the Amazon, Australia, Chile, the Mediterranean region, northern, southern and west Africa, south-western United States, and South America (*medium confidence*) (Feng and Fu, 2013; Greve and Seneviratne, 2015; Jones and Gutzler, 2016; Park et al., 2018). However, the AI does not incorporate potential changes to plant transpiration under increasing CO_2 concentration and therefore overestimates drought conditions and aridity. Additionally, it does not reflect seasonality in rainfall and evapotranspiration, which is important in regions where temperature and actual evapotranspiration are not increasing during the wet season when vegetation growth is occurring. Mirzabaev et al. (2019) concluded that while aridity will increase in some places (*high confidence*), there is insufficient evidence to suggest a global change in dryland aridity (*medium confidence*). Nevertheless, a comparison of several metrics of aridity showed robust aridity increases are projected for several hotspots such as the Mediterranean region and South Africa (Greve et al., 2019). Under RCP8.5, aridity zones could expand by one-quarter of the 1990 area by 2100, increasing to over half of the global terrestrial area (Huang et al., 2016; Lickley and Solomon, 2018). Lower greenhouse gas emissions, under RCP4.5, could limit expansion to one-tenth of the 1990 area by 2100 (Huang et al., 2016). Aridity could expand substantially on all continents except Antarctica (Huang et al., 2016), with expansion first manifesting in the Mediterranean region, southern Africa, southern South America, and western Australia (Lickley and Solomon, 2018). In the Northern Hemisphere, aridity zones could expand poleward as much as 11 degrees of latitude (Rajaud and Noblet-Ducoudré, 2017). By 2100, the population of dryland areas could increase by 700 million people and, under RCP8.5, three billion people might live in areas with a 25% or greater increase in aridity (Lickley and Solomon, 2018). Many studies point to an increasing dryland area based on the AI, but there is low agreement on the actual amount and area of change (Feng and Fu, 2013; Scheff and Frierson, 2015; Huang et al., 2017). The inconsistency between studies is largely due to the substantial internal climate variability in regional precipitation. Changes in annual precipitation have been shown to range from -30% to 25% over drylands. Consistent changes in precipitation are only found at high latitudes, while total PET is projected to increase over most land areas (Feng and Fu, 2013). This leads to more consistent, widespread drying in the tropics, subtropics and mid-latitudes in most models (Feng and Fu, 2013; Cook et al., 2014; Scheff and Frierson, 2015; Zhao and Dai, 2015).

CCP3.3.1.4 Dryland Extent

Global dryland area (based on the AI) is projected to expand by ~10% by 2100 compared to 1961-1990 under a high emission scenario (Chapter 12, WGI). However, there are significant regional differences in the drivers of dryland expansion and subsequent estimates of change in dryland extent. Subtropical drylands are projected to expand as the climate in these regions shifts from temperate to subtropical and aridity increases in currently sub-humid subtropical regions, resulting in the loss of temperature-controlled seasonal cycles (Schlaepfer et al., 2017). Observed and projected warming and drying trends are most severe in transitional climate regions between dry and wet climates, with some exceptions (Nkrumah et al., 2019), which are often highly populated agricultural regions with fragile ecosystems (Cheng and Huang, 2016). In contrast, P-E predicts decreasing drought stress across temperate Asia and central Africa (Swann et al., 2016). Expansion of arid regions is anticipated in southwest North America, the northern fringe of Africa, southern Africa and Australia. The main areas of semi-arid expansion are expected to occur in the north side of the Mediterranean, southern Africa and North and South America. In contrast, India, eastern equatorial Africa and other areas of the southern Saharan regions are projected to have shrinking drylands (Biasutti and Giannini, 2006; Biasutti, 2013; Rowell et al., 2016). Future projections may underestimate dryland expansion, since the Coupled Model Intercomparison Project (CMIP) 5 models underestimate historical warming (Huang et al., 2016) and overestimate precipitation over drylands, particularly in the semi-arid and dry sub-humid regions (Ji et al., 2015). However, estimates vary depending on the metric used (Swann et al., 2016; Berg et al., 2017b). Studies based on off-line aridity and drought metrics (calculated from model output of precipitation, evapotranspiration or temperature) project strong surface drying trends (Cook et al., 2014; Scheff and Frierson, 2015; Zhao and Dai, 2015), while projections based on total soil water availability from CMIP5 models show weaker and less extensive drying (Berg et al., 2017a). In contrast, projections in southern Africa may overestimate future drying, with systematic rainfall biases being found in the present-day climatology in models that simulate extreme future drying (Munday and Washington, 2019). Improvements in projections of future changes in aridity require better understanding of seasonality, land hydrology, and the feedbacks between projected soil moisture decrease on land surface temperature, relative humidity and precipitation (Huang et al., 2016).

Higher dust emissions are consistent with climate change projections indicating an expansion in the global area of drylands (Feng and Fu, 2013; Huang et al., 2016) and increased drought risk (Cook et al., 2014; Xu et al., 2019), but future trends in dust event frequency and intensity as a result of climate change are uncertain and will vary geographically (Jia, 2019). Combined effects of climate change and anthropogenic activities are projected to increase sand encroachment and extreme dust storms (Omar Asem and Roy, 2010; Sharratt et al., 2015; Pu and Ginoux, 2017) as a result of increased aridity, accelerating soil erosion (Section 4.4.8; Sharratt et al., 2015) and loss of biomass (Sharratt et al., 2015; Middleton and Kang, 2017). Shifts in dust storm timings are also projected in some regions (Hand et al., 2016). Dustiness is projected to increase in the southern US Great Plains in the late 21st century under the RCP8.5 climate change scenario but decrease over the northern Great Plains (Pu and Ginoux, 2017). A declining trend in dust emission and transport from the Sahara under RCP8.5 was detected by Evan et al. (2016) but regional climate model experiments conducted by Ji et al. (2018) under the same scenario indicated that overall dust loadings would increase by the end of the 21st century over West Africa. New dust sources may emerge with changing climate conditions, as Bhattachan et al. (2012) indicate for the Kalahari Desert in southern Africa, due to vegetation loss and dune remobilization. There is overall *low confidence* on future atmospheric dust loads at the global and regional scale. Models of future dust emissions are limited by the low accuracy of models of present anthropogenic dust emissions, which range from 10% and 60% of the total atmospheric dust load (Webb and Pierre, 2018). A global compilation of data from sedimentary archives (ice cores), remote sensing, airborne sediment sampling and meteorological station data estimated that anthropogenic dust emissions have at least doubled over the past 250 years (Hooper and Marx, 2018). While future emissions of natural dust sources are projected to decrease (Mahowald et al., 2006) or remain stable (Ashkenazy et al., 2012), when sources of human emissions are included, projections of future atmospheric dust loads suggest that emissions may increase (Stanelle et al., 2014).

The relative contribution of albedo and evapotranspiration to regional trends in surface temperature (Charney, 1975) remains unresolved, and may be determined by different mechanisms in different systems, depending on site-specific conditions such as snow coverage, vegetation and soil moisture (Yu et al., 2017). For example, the vegetation-albedo feedback mechanism may dominate in the Arctic (Blok et al., 2011; te Beest et al., 2016), while the vegetation-evaporation feedback may drive change in other regions. Actions that increase forest cover across Africa could thus, theoretically, moderate projected future temperature increases (Wu et al., 2016; Diba et al., 2018), but with potentially negative effects on biodiversity (Chapter 2). Soil drying exacerbates atmospheric aridity, which causes more soil drying in a self-reinforcing land–atmosphere feedback that could intensify under RCP8.5 (Zhou et al., 2019).

Changes to the composition, structure and functioning of natural communities in deserts and dryland ecosystems are key risks resulting from water stress, drought intensity and continued habitat degradation, greater frequency of wildfire, biodiversity loss and the spread of invasive species (Hurlbert et al., 2019). Not all these stresses occur at the same time in a particular environment, with some areas more exposed to e.g. wildfire than others, especially in areas with high amounts of dry herbaceous biomass. Grassland composition may shift as C3 plants are replaced by C4 species, which have higher optimal temperatures and higher water use efficiency (although seasonality of precipitation also plays a role) (Knapp et al., 2020). Many desert species have morphological, physiological and/or behavioural adaptations to cope with climatic extremes, including rapid regeneration following droughts (Boudet, 1977; Hiernaux and Le Houérou, 2006), leaf dropping during the dry season to reduce water loss (Santos et al., 2014), alongside long histories of adaptation to climate change (Brooks et al., 2005; Ballouche and Rasse, 2007), while many animals live near their physiological limits (Vale and Brito, 2015). Substantial ecological effects may occur when extreme events such as heatwaves or droughts are superimposed on the warming trend, pushing species beyond their physiological and mortality thresholds (Hoover et al., 2015; Harris et al., 2018).

Climate change increases risks of continued range retractions of Karoo succulents in South Africa (Young et al., 2016), dry argan woodlands in Morocco (Alba-Sánchez et al., 2015), epiphytic cacti in Brazil (Cavalcante and Duarte, 2019; Cavalcante et al., 2020) and other plant species exposed to higher aridity. Projected increases in heat and aridity could increase mortality of trees and shrubs in Sonoran Desert ecosystems in the United States (Munson et al., 2012; Munson et al., 2016b), reduce sagebrush in arid ecosystems of the western United States (Renwick et al., 2018), and contribute to the replacement of perennial grasses with xeric shrubs in the south-western United States (Bestelmeyer et al., 2018). CO_2 fertilization and warmer conditions, combined with changes in timing and availability of moisture, could increase invasive grasses and wildfire in desert ecosystems of Australia and the south-western United States where wildfire has historically been absent or infrequent (Abatzoglou and Kolden, 2011; Horn and St. Clair, 2017; Klinger and Brooks, 2017; Syphard et al., 2017). Trends of woody encroachment may continue in some North American and African drylands or at least not reverse (Higgins and Scheiter, 2012; Caracciolo et al., 2016). Impacts of woody encroachment on drylands may show a slight increase in carbon, but a decline in water and huge negative impacts on biodiversity, with a tendency for open ecosystem species to be most affected (Archer et al., 2017). Expansion of grasses into these arid shrublands has the potential to transform them rapidly, especially through the acceleration of the fire cycle (Bradley et al., 2016). While the impact of increased aridity may be offset by changing water use efficiency by plants under high CO_2 concentrations, limiting the expansion of dryland ecosystems (Swann et al., 2016; Mirzabaev et al., 2019), increased plant growth in response to elevated CO_2, which results in increased water consumption, may counteract this. Increased water use efficiency is therefore not expected to counterbalance increased evaporative demand (Chapter 8). There is *medium confidence* that succulent species will be particularly vulnerable to increased heat and aridity due to reduced physiological performance, loss of seed banks, lower germination rates and increased mortality (Table CCP3.1; Musil et al., 2005; Aragón-Gastélum et al., 2014; Shryock et al., 2014; Martorell et al., 2015; Carrillo-Angeles et al., 2016; Aragón-Gastélum et al., 2017; Koźmińska et al., 2019).

CCP3.3.2 Projected Impacts on Human Systems

Across many drylands, human-induced causes of desertification, SDS, climate change and unsustainable land use, are projected to become more pronounced over the next several decades with global consequences. Future climate changes with increasing frequency, intensity and scales of droughts and heatwaves, are projected to further exacerbate the vulnerability and risk to humans from desertification (Hurlbert et al., 2019).

Sand and dust storms exert a wide range of impacts on people, within deserts and semi-deserts but also outside dryland environments because of long-range dust transport (Middleton, 2017). Research on the economic impacts of SDS is lacking, while studies that have been conducted lack consistency in data collection methods and analysis (Middleton, 2019). Although projections are rarely modelled, estimated economic damages of increased dust-related health impacts and mortality under RCP8.5 could total $47 billion/year additional to the 1986-2005 value of $13 billion/year in southwest USA (Allahbakhshi et al., 2019).

Projected impacts of climate change on the risk of food insecurity are a particular concern for the developing world drylands (Chapter 16, WGI; Mirzabaev et al., 2019), potentially leading to breakdown of food production systems, including crops, livestock, and fisheries, as well as disruptions in food supply chains and distribution (Myers et al., 2017; Lewis and Mallela, 2018). Developing country drylands are particularly vulnerable due to a higher share of populations with lower income, lower physical access to nutritious food, social discrimination as well as other environmental factors that link to climate change. For example, countries such as Somalia, Yemen and Sudan faced recent and resurging challenges from an increase in desert locusts, the effects of which in 2020 extended from East Africa through the Arabian Peninsula and Iran as far as India and Pakistan. Meynard et al. (2020) note that under climate change, some areas suffering from previous outbreaks may see changes in formation of swarms of *Schistocerca gregaria*. Salih et al. (2020) recognise that attributing the 2020 swarms as a single event to climate change remains challenging, but highlight that projected temperature and rainfall increases in deserts and strong tropical cycles can create conditions conducive to the development, aggregation, outbreak and survival of locusts. Mandumbu et al. (2017) highlight how crop parasites such as *Striga spp.* in southern Africa may benefit from higher temperatures and rainfall activating dormant seeds, while high winds aid their dispersal. Combined with increasing risks of erosion and soil fertility losses (*Striga* is able to tolerate drought and a low nitrogen environment), this can have important impacts on the yields of key dryland crops such as maize and pearl millet.

Human responses can exacerbate desertification processes under climate change conditions, even in deserts. Exploitation of mineral resources (e.g. lithium mining in Chile's Atacama Desert) can cause human population changes as people flock to the area for work (Liu et al., 2019), increasing vulnerability due to e.g. soil erosion and salinisation, as well as increasing pressure on potable water for human consumption (Stringer et al., 2021) and exhausting aquifers. Salinisation is projected to increase in the drylands due to climate change impacts in future (Mirzabaev et al., 2019). For example, in India, about 7 million ha arable land area is currently salt-affected (Sharma et al., 2015; Sharma and Singh, 2015). It is projected that unsustainable use of marginal quality waters in irrigation and neglect of drainage, combined with climate change impacts, will accelerate land salinization in India, rendering another 9 million ha area salty and less productive by 2050 (ICAR-CSSRI, 2015). This has important cost implications given that annually, 16.84 million tonnes of farm production valued at INR 230.19 billion is already lost in India due to salinity and associated problems (Sharma and Singh, 2015). The literature further shows evidence of desertification of oases and irrigated lands in parts of northern China's drylands (Wang et al., 2020), the Indian subcontinent's deserts, as well as the Mesopotamian Arabian Desert (Ezcurra, 2006; Dilshat et al., 2015).

CCP3.4 Adaptations and Responses

Adaptations to climate change impacts in human systems vary depending on exposure to risks, types of risks and responses, underlying social vulnerabilities and adaptive capacities, including access to resources, the extent of adaptation responses and the potential of these responses to reduce risk/vulnerability (Chapter 16 ; Singh and Chudasama 2021). Adaptations tend to be applied locally, tackling symptoms of the problem and proximate drivers (e.g. of desertification), rather than distant or external drivers (Morris et al., 2016; Adenle and Ifejika Speranza, 2021). Different groups require different kinds of supports and levers to enable them to follow adaptive pathways (Stringer et al., 2020; Møller et al., 2017) and face different barriers and limits to adaptation (Chapter 18, WG2). What constitutes an incremental adaptation in one location may be transformational in another. Spatial patterns of dryland resilience and adaptive capacity can be partly explained by access to livelihood capitals (Mazhar et al., 2021) and are shaped by prevailing structures and power dynamics. Supportive policies, institutions and good governance approaches can strengthen the adaptive capacities of dryland farmers, pastoralists and other resource users (*high confidence*) (Stringer et al., 2017). Table CCP3.2 provides examples of illustrative adaptation options responding to major challenges of climate change and desertification in deserts and semi-arid areas. Some adaptations present no-regrets options while others tackle desertification and/ or climate changes to different extents.

Table CCP3.2: Synthesis of adaptation measures and responses to risks in deserts and semi-arid areas. Appropriateness of measures is context dependent and some adaptations will be incremental or even maladaptive in some dryland contexts while being transformational in other locations.
[INSERT TABLE CCP3.2 HERE]

Adaptations to climate change, desertification, drought management (Section 17.2.2.2) and sustainable development activities largely overlap in drylands, pointing to synergies between them (Reichhuber et al., 2019). For example, support for communal and flexible land tenure could bring about benefits across multiple dimensions, while attention to water as a limiting factor in drylands can link to multiple SDGs (Stringer et al., 2021) as well as adaptations in natural systems, where improved forecasting and anticipatory science and management can be appropriate (Bradford et al., 2018). Currently, more than 125 countries around the world, particularly in drylands, are setting land degradation neutrality (LDN) targets. LDN and its hierarchical response mechanisms of avoiding, reducing and reversing land degradation, can provide an overarching resilience-based framework for adaptation at the national level (Mirzabaev et al., 2019; Orr et al., 2017b; Cowie et al., 2018) and support biodiversity conservation (Akhtar-Schuster et al., 2017). However, achieving LDN will require a transparent decision and prioritisation process (Dallimer and Stringer, 2018), anchored in a socio-ecological systems approach (Okpara et al., 2018), with investment in all dimensions of an enabling environment, including inclusive policies and regulations, sustainable institutions, accessible finance and effective science-policy communications and interactions (Verburg et al., 2019; Allen et al., 2020). LDN calls for integrated land use planning to ensure land uses are optimized at a landscape scale to help balance competition for limited land resources and harness multiple benefits (Cowie et al., 2018, Verburg et al., 2019), recognising that adaptations present synergies and trade-offs along various dimensions of sustainable development such as poverty reduction, enhancing food security and human health or providing improved access to clean energy, land water, and finance (see Section 8.6). Distributional effects of adaptation options also may vary between different socio-economic groups within countries or locally among communities, pushing social justice concerns to the fore (Section 8.4). Measures promoting particular adaptations need to take into account such consequences as well as the potential for some adaptations to become maladaptive at scale.

Natural systems are also able to adapt to climate change, be adapted and become more resilient to desertification. For example, the root network architecture of the hyper-arid Negev Desert acacia trees has enabled them to withstand intensive cultivation and climate-change driven desertification (Winter et al., 2015) while vegetation-induced sand mounds ("coppice dunes") in the Arabian Desert have reduced desertification through reducing wind erosion and enriching sand desert land with water and nutrients (Quets et al., 2017). Vegetation cover of psammophyte shrub species (in the "desert oasis transitional area") surrounding the Dunhuang Oasis (northwest China) reduces oasis land degradation risk by reducing sand grain size and velocity of winds from the aeolian desert (Zhang et al., 2007); while land use planning in Israel's Negev Desert taking a 'sharing' approach between cultivation and urbanization has helped to minimise the external degrading effects of adjacent desert land ecosystems (Portnov and Safriel, 2004). Scholars are nevertheless questioning the wider suitability of tree planting in drylands, given concerns for water availability and other ecosystem services (Veldman et al., 2015; Bond et al., 2019; Veldman et al., 2019). How natural dryland systems are managed following disturbances such as wildfire is important too. van den Elsen et al. (2020) found that establishing vegetation and mulch cover after a fire in a Mediterranean dryland ecosystem reduced soil erosion, helping maintain soil fertility and nutrients. However, different management objectives require different adaptations. For example, adaptation measures that reduce land degradation through reforestation could increase vulnerability to fire if they exclude ecologically sound fire management or are based on plant species that are fire prone. Combinations of different land management practices and governance approaches tackling a range of different stresses appear to best support sustainability and adaptation over the long term (van den Elsen et al., 2020).

Collective action can facilitate the implementation of adaptation responses and help tackle challenges associated with upscaling of successful land-based adaptations (Thomas et al., 2018). However, a lack of coordination between stakeholders and across sectors can be problematic (Amiraslani et al., 2018), showing the importance of multi-stakeholder engagement (De Vente et al., 2016). Multi-stakeholder engagement is recognized as an essential part of desertification control, as well as vital in tackling climate change (Reed and Stringer, 2016), with participation taking place to different extents in different drylands according to the prevailing governance system. In China, the Grain for Green programme is an example of a large-scale ecological restoration programme securing local engagement through payments for ecosystem services (Kong et al., 2021), while transdisciplinary stakeholder engagement involving researchers and central and local governments in the Heihe River Basin in China's arid and semi-arid northwest, using an interdisciplinary 'web' approach, enabled basin restoration. Multi-stakeholder efforts saw improvement in the condition of Juyan Lake and the surrounding catchment, increasing both the lake surface area and groundwater in downstream locations (Liu et al., 2019).

In the short- to medium-term, monitoring, prediction and early warning can support adaptation and e.g. help reduce negative impacts of SDS by mobilising emergency responses. Daily dust forecasts enable preparation to minimise risks from sand/dust storms to both human and natural systems (e.g. the WMO Sand and Dust Storm Warning Advisory and Assessment System: https://sds-was.aemet.es/forecast-products/dust-forecasts). Preparedness and emergency response procedures benefit from covering diverse sectors, such as public health surveillance, hospital services, air and ground transportation services, water and sanitation, food production systems and public awareness, suggesting the need for a coherent, multi-sector governance approach. Longer-term actions include prioritizing sustainable land management (Middleton and Kang, 2017), based on Indigenous knowledge and local knowledge, and modern science (Verner, 2012), along with the investment of financial and human capital in supporting these measures. Devolved adaptation finance in dryland areas of e.g. Kenya (Nyangena and Roba, 2017) and Mali (Hesse, 2016) has yielded promising insights, highlighting the importance of climate information services and local government support for community prioritisation of adaptation activities. Such actions can enable substantial benefits for poor and marginalised men and women. Among international institutional measures, a global coalition to combat SDS was launched at the United Nations Convention to Combat Desertification Conference of Parties (UNCCD COP14) in 2019, which could help to better mobilize a global response to SDS. Similarly, there have been calls for increased investment in regional institutions such as the Desert Locust Control Organisation for Eastern Africa to both pre-empt and tackle locust plagues (Salih et al., 2020), requiring trans-boundary cooperation.

There is *high agreement* and *robust evidence* that shifting emphasis to proactive risk mitigation, including solutions for drought, flooding erosion and dust management, instead of exclusive focus on disaster management, reduces vulnerability and improves adaptive capacity (Section 16.4.3.2 and 16.5.2.3.4; Sivakumar, 2005; Grobicki et al., 2015; Wieriks and Vlaanderen, 2015; Aguilar-Barajas et al., 2016; Runhaar et al., 2016; Wilhite and Pulwarty, 2018; Wilhite, 2019). It also underscores the LDN response hierarchy avoid > reduce > reverse (Orr et al., 2017a). Nevertheless, *ex ante* drought and flood risk mitigation has been adopted in limited dryland settings, despite that it is preferable to increase preparedness before it happens, provide incentives for adaptation instead of insurance, provide insurance instead of relief, and provide relief instead of regulation (Sivakumar, 2005). Yet, providing disaster relief is often more publicly visible and politically expedient, despite its social, economic and environmental challenges. The absence of proactive risk mitigation and resulting crisis management increases vulnerability, increases reliance on government support, reduces self-reliance and increases costs (Grobicki et al., 2015; Wilhite, 2019), as well as hindering progress towards the SDGs. In the case of drought and flooding, major obstacles for the transition from reactive management to proactive drought risk mitigation include path dependencies and lack of knowledge about relative costs and benefits of reactive versus proactive approaches. This lack of information can deter large-scale and long-term investments into proactive approaches (Mirzabaev, 2016).

A range of risk mitigation and adaptation measures can be taken, to address drought, desertification and other climate change-related challenges in deserts and semi-arid areas, some of which can be both proactive and reactive. These include *inter alia*:

i) Policies, public advocacy, and social media campaigns that improve water use efficiency, especially in agriculture and industry, which can foster behavioural changes and reduce water consumption (Yusa et al., 2015; Tsakiris, 2017; Booysen et al., 2019),

ii) Integrating access to insurance, financial services, savings programs, and cash transfers into policies to increase the effectiveness of e.g. drought responses. Such efforts can result in significant cost savings (Berhane et al., 2014; Bazza et al., 2018 ; Guimarães Nobre et al., 2019),

iii) Development of robust early warning systems that provide information and improve knowledge surrounding drought and SDS to enable early recovery (Wilhite, 2019), considering also vulnerability and impact assessments (i.e. who is at greatest risk),

iv) Water management and storage, including using methods that draw on Indigenous knowledge (Stringer et al., 2021), water transfers, and trade, all of which can reduce costs and provide timely adaptations to drought, supporting agricultural productivity and rural livelihoods (Harou et al., 2010; Hurlbert, 2018),

v) Restoration, reclamation, and landscape heterogeneity strategies, promoting ecosystem resilience to wind erosion and dust abatement (Duniway et al., 2019) as well as restoring important ecosystem services at a catchment scale,

vi) Prevention of soil erosion, provision of dust abatement and enhanced biodiversity by changing grazing techniques (e.g. rotational grazing), facilitating herd mobility, protecting rangeland areas from fragmentation, promoting common tenure and access rights on grazing land, enabling rapid post fire restoration efforts, minimum tillage, sustainable land management, integrated landscape management, planting and caring for non-irrigated indigenous trees and other vegetation (Middleton and Kang, 2017); and

vii) Creation of drought tolerant food crops through participatory plant breeding (Grobicki et al., 2015) and investment in research and development of drought resistant varieties (Basu et al., 2017; Mottaleb et al., 2017; Dar et al., 2020), alongside adjusted planting and harvesting periods (Frischen et al., 2020). Similar to other adaptations, the net economic benefits of *ex ante* resilient plant development far outweigh the research investment (Basu et al., 2017; Mottaleb et al., 2017; Dar et al., 2020).

Many of these measures can also support climate change mitigation efforts in drylands. Uptake of adaptation measures is often grounded in clear communications and information provision to support behavioural changes, taking into account local risk aversion and risk perceptions (Zeweld et al., 2018; Jellason et al., 2019). Building capacity by improving the knowledge base and access to information as well as to financial and other resources, encourages vulnerable economic sectors and people to adopt more self-reliant measures that promote more integrated and sustainable use of natural resources *(high confidence*) (Sivakumar, 2005; Wieriks and Vlaanderen, 2015; Aguilar-Barajas et al., 2016; Middleton and Kang, 2017; Wilhite, 2019). Engaging natural resource users as active participants in planning and technology adoption using extension services, financial grants and services geared to the local area, can build resilience and drive changes in practices (Webb and Pierre, 2018), while approaches such as Integrated Water Resources Management (IWRM) can support adaptation and drought risk management, including in dryland urban megacities (Stringer et al., 2021) and in deserts and semi-arid areas where precipitation trends remain stable yet other pressures on water are growing (Reichhuber et al., 2019).

[START FAQ CCP3.1 HERE]

FAQ CCP3.1: How has climate change already affected drylands and why are they so vulnerable?

Human-caused climate change has so far had mixed effects across the drylands, leading to fewer trees and less biodiversity in some areas and increased grass and tree cover in others. In those dryland areas with increasing aridity, millions of people face difficulties in maintaining their livelihoods particularly where there is water scarcity.

Drylands include the hottest and most arid areas on Earth. Human-caused climate change has been intensifying this heat and aridity in some places, increasing temperatures more across global drylands than in humid areas. In areas which are hotter and drier, tree death has occurred and in some locations bird species have been lost. Climate change has reduced rainfall in some dryland areas and increased rainfall in other areas. Increased rainfall, combined with the plant-fertilizing effect of more carbon dioxide in the atmosphere, can increase grass and shrub production in dryland areas. Because water is scarce in drylands and aridity limits the productivity of agriculture, millions of people living in drylands have faced severe difficulties in maintaining their livelihoods. This challenge is exacerbated by non-climate change factors, such as low levels of infrastructure, remoteness, and limited livelihood options that are less dependent on scarce natural resources. High temperatures in drylands increase the vulnerability of people to potential heat-related illnesses and deaths from heat under continued climate change.

[END FAQ CCP3.1 HERE]

[START FAQ CCP3.2 HERE]

FAQ CCP3.2: How will climate change impact the world's drylands and their people?

Climate change is projected to lead to higher temperatures across global drylands. Many drylands also risk more irregular rainfall leading to increased irregularity in crop yields, and increased water insecurity where less rainfall is projected, which may have profound implications for both dryland ecosystems and their human inhabitants.

There is, however, considerable uncertainty about the changes that may occur in drylands in the future and how people and ecosystems will be affected. In some drylands, higher temperatures and declining rainfall have increased aridity. However, this is not a global trend as many drylands are experiencing increases in vegetation cover and rainfall. Both the amount of rainfall and its seasonality have changed in many dryland areas, associated with natural variability and warming.

Most climate models project increased rainfall in tropical drylands, but more variability. High natural climatic variability in drylands makes predictions uncertain. Understanding future impacts is further complicated by many interacting factors such as land use change and urbanisation that affect the condition of drylands. Future trends in sand and dust storm activity are also uncertain and will not be the same everywhere, but there will likely be increases in some regions (e.g. the United States) in the long-term. The impacts of climate change in deserts and semi-arid areas may have substantial implications globally: for agriculture, biodiversity, health, trade and poverty, as well as potentially, for conflicts and migration. Increasing temperatures and more irregular rainfall are expected to affect soil and water and contribute to tree death and loss of biodiversity. In other places, woody encroachment onto savannas may increase, in response to the combination of land use change, changes in rainfall, fire suppression, and CO_2 fertilization. Crop yields are projected to decline in some areas, with adverse impacts on food security. The potential for conflicts and migration is primarily associated with socioeconomic development, while links to climate change remain uncertain and lack evidence.

[END FAQ CCP3.2 HERE]

[START FAQ CCP3.3 HERE]

FAQ CCP3.3: What can be done to support sustainable development in desert and semi-arid areas, given projected climate changes?

Water is a major limiting factor in drylands. Many efforts to support sustainable development aim to improve water availability, access and quality, ranging from large engineering solutions that move or desalinise water; to herders' migrations with their animals to locations that have water; to land management and water harvesting practices that conserve water and support land cover. These solutions draw on Indigenous knowledge, local knowledge and innovative science, and can help to address multiple Sustainable Development Goals.

Different desert and semi-arid areas can benefit from different incremental and transformational solutions to move toward sustainable development under climate change. In some dryland areas facing critical water shortages, transformational adaptations may be needed - for example, large-scale water desalination when they have access to sea water, despite high energy use and negative environmental impacts of waste brine. In dryland agricultural areas across the world, incremental adaptations include water conservation measures, use of improved crop varieties or increasing herd mobility. What counts as a transformational change in some places may be incremental in others. Often solutions can target multiple development goals. For example, water harvesting can make water available during drought, buffering water scarcity impacts, while also supporting food production, agricultural livelihoods and human health. Land based approaches, e.g. restoration of grassland, shrubland, and savanna ecosystems, are important for ensuring ecological integrity, soil protection and preventing livelihoods from being undermined as a result of growing extreme weather events. It is important that policies, investments and interventions that aim to support sustainable development take into account which groups are likely to be most affected by climate change. Those people directly dependent on natural resources for their survival are generally most vulnerable but least able to adapt. The capacity to translate local and Indigenous knowledge and experience into actions can require external support. Governments and other stakeholders can help by investing in early warning systems, providing climate information, realigning policies and incentives for sustainable management, investing in supporting infrastructures, alongside developing alternative livelihood options that are less exposed and sensitive to climate change. Involving all relevant stakeholders is important. For example, in China the Grain for Green programme secured local engagement by paying people to manage the environment more sustainably. At a global level important groups have emerged to cooperate and offer solutions around issues such as sand and dust storms, and integrated drought management. Efforts are needed across all scales from local to global to support sustainable development in desert and semi-arid areas, given projected climate changes.

Large Tables

Table CCP3.1: Observed ecological changes in drylands.

Region	**Observed change**	**Climate change factors**	**Attribution to climate change**	**Non-climate change factors**	**Confidence in observed change**	**References**
Hyper arid						
Asian hyper arid regions (Gobi)	Loss of shallow rooted desert plants	Increase in extreme warm temperatures			*Medium*	Li et al. (2015)
North America - Mojave Desert	Loss of mesic bird species	Decreased rainfall	Yes. Analyses of causal factors find decreased rainfall more important than non-climate factors.	Livestock, human-ignited fires	*Medium*	Iknayan and Beissinger (2018); Riddell et al. (2019)
	Decline of desert tortoise (*Gopherus agassizii*) population 90% from 1993 to 2012 at one site in the Mojave	Decreased rainfall				Lovich et al. (2014)
	Reduced perennial vegetation cover, including trees and cacti, in the Mojave and Sonoran deserts of the southwestern United States	Increased temperature, decreased rainfall, wildfire		Land use change, invasive plant species	*High*	Defalco et al. (2010); Munson et al. (2016b); Conver et al. (2017)
Arid						
African Sahel	Woody cover increase in parts of the Sahel	Increase in rainfall since the mid-1990s (compared to 1968-1993)and increased CO_2		Restoration planting Agroforestry	*High*	

	Increase in grass production across Sahel	Increases in rainfall since the mid-1990s (compared to 1968-1993) and increased CO_2			*Medium*	Hiernaux et al. (2009a); Hiernaux et al. (2009b); Dardel et al. (2014); Venter et al. (2018); Zhang et al. (2018); Brandt et al. (2019); Bernardino et al. (2020)
	Decline of mesic tree species at field sites across the Sahel	Decreased rainfall from 1901 to 2002 increased temperature	Yes. multivariate statistical analyses find climate factors more important than non-climate factors.	Land clearing for cropland expansion, Increase pressure on wood resources (rural demography, urbanization)	*High*	Gonzalez (2001); Wezel and Lykke (2006); Maranz (2009); Gonzalez et al. (2012); Hänke et al. (2016); Kusserow (2017); Ibrahim et al. (2018); Zida et al. (2020b)
	Increased tree mortality at field sites across the Sahel	Decreased rainfall from 1901 to 2002, increased temperature	Yes. multivariate statistical analyses find climate factors more important than non-climate factors.	Agricultural expansion, modified runoff on shallow soils	*High*	Helldén (1984); Gonzalez, (2001); Wezel and Lykke (2006); Maranz (2009); Vincke et al. (2010); Hänke et al. (2016); Trichon et al. (2018); Zwarts et al. (2018); Wendling et al. (2019); Bernardino et al. (2020); Zida et al. (2020a)
	Latitudinal biome shift of the Sahel	Decreased rainfall, increased temperature	Yes. multivariate statistical analyses find climate factors more important than non-climate factors.		*High*	Boudet (1977); Tucker and Nicholson (1999); Gonzalez, (2001); Hiernaux and Le Houérou (2006); Hiernaux et al. (2009a); Maranz (2009); Gonzalez et al. (2012)
Namib desert	Increase in woody plant cover and a shift of mesic	Increase in amount of fog from westward			*Medium*	Morgan et al. (2004); Haensler et al. (2010); Donohue et al. (2013); Rohde et al. (2019)

	species into more arid regions	expansion of convective rainfall and increase in number of extreme rainfall events. Elevated CO2 and warming effects on the Bengula upwelling system				
Southern Africa - Nama-Karoo		Shifting rainfall seasonality (debate if its cyclical or directional); elevated CO2			*Medium*	Du Toit and O'Connor (2014); du Toit et al. (2015); Masubelele et al. (2015a); Masubelele et al. (2015b)
	Eastern Karoo has experienced a significant increase in the end of the growing season length	Shift in rainfall seasonality and increase in MAP			*Low*	Davis-Reddy (2018)
	Woody encroachment has been observed throughout the Nama-Karoo in valley bottoms, ephemeral stream banks and the slopes of Karoo hills.	Rising concentration of CO_2		Changing land use and herbivore management	*Medium*	Polley et al. (1997); Morgan et al. (2004); Donohue et al. (2013); Ward et al. (2014); Masubelele et al. (2015a); Hoffman et al. (2018)
Southern Africa - Succulent Karoo	*Succulent Karoo*: Range shift in tree aloe *Aloidendron dichotomum* with mortality in the warmer and drier range and increase in recruitment in the cooler southern range, populations have positive growth rates, possibly due to warming, although this finding has been challenged	Warming and drying			*Medium*	Foden et al. (2007a); Jack et al. (2016)
Northern Africa - Morocco	Increased vulnerability of oasis's, and reduced ecosystem service provision	High temperature and reduced precipitation		Agricultural growth, high population growth	*Medium*	Karmaoui et al. (2014)

		causing soil and water salinization, drying up of surface water. Hot winds and sandstorms.		and unregulated and indiscriminate land development		
	Reduced surface water availability	Increased temperature and reduced precipitation		High demand (population growth) and landuse change	*Medium*	Rochdane et al. (2012); Choukri et al. (2020)
	Reduction of resilience of *Abies pinasapo- Cedrus atlantica* forests to subsequent droughts	Successive droughts			*Medium*	Navarro-Cerrillo et al. (2020)
North American drylands	Drought adapted species are increasing in Chihuahuan deserts	Increase in aridity and increased inter-annual variation in climate trends			*Medium*	Collins and Xia (2015); Rudgers et al. (2018)
	Widespread woody plant encroachment. *Prosopis sp* encroachment in arid desert regions (Chihuahuan and Sonoran Desert) at a rate of ~3% per decade.	Increasing temperature, elevated CO_2 and changing rainfall		Fire suppression and altered grazing/browsing regimes,	*High*	Caracciolo et al. (2016); Archer et al. (2017)
	Plant desert community shift changes the albedo through the reduction in dark biocrusts	Warming and drought			*Medium*	Rutherford et al. (2000)
South Chihuahuan Desert - North and central Mexico	Shrub encroachment of grassland (*Berberis trifoliolata, Ephedra aspera, Larrea tridentata*) changes on dominant species in shrub areas loss of less resistant shrubby species (*Leucophyllum laevigatum, Lindleya mespiloides, Setchellanthus caeruleu*). Shrub encroachment of mesic and temperate areas	Decreased rainfall, increase in temperature and increase CO_2		Urban growth, mechanized agriculture, and changes in land use	*High*	Pérez-Sánchez et al. (2011); Castillón et al. (2015); Sosa et al. (2019)

	Shifts on soil microbial community to more abundant in fungi (Ascomycota and Pleosporales)	decreased rainfall and increase in temperature		changes in land use	*Low*	Vargas-Gastélum et al. (2015)
	Limited ecological connectivity of shrubby populations	decreased rainfall + increase in temperature			*Medium*	Sosa et al. (2019)
	Loss of Cacti species (*Echinocactus platyacanthus, Pediocactus bradyi, Coryphantha werdermannii, Astrophytum*) due to decline in physiological performance, loss of seed banks and lower germination rates	decreased rainfall + increase in temperature		Cattle grazing, looting	*High*	Aragón-Gastélum et al. (2014); Shryock et al. (2014); Martorell et al. (2015); Carrillo-Angeles et al. (2016); Aragón-Gastélum et al. (2018)
Arid and semi-arid territories in Argentina	Decreases in vegetation indexes	Decreased rainfall		human-induced land degradation	*Low*	Barbosa et al. (2015)
Argentina Chaco Region	Dryland salinity	changes in rainfall		Land use change Overexploitation of water resources	*Medium*	Amdan et al. (2013); Marchesini et al. (2017)
South America Arid Diagonal	Marked reduction in streamflow from the Andes mountain "water towers" due to the persistent reduction in precipitation."	Decrease in precipitation in the upper Andes. The unprecedented 10-year extreme dry period has been called the "Mega-drought			*High*	Bianchi et al. (2017); Rivera and Penalba (2018); Masiokas et al. (2019); Rodríguez-Morales et al. (2019)
South American Andes	Extensive glacier retreat across the Andes	Increasing sub-continental temperature and regional reduction in snow precipitation			*High*	Dussaillant et al. (2019); Falaschi et al. (2019); Masiokas et al. (2019)

Patagonian Andes	Widespread tree mortality of *Austrocedrus* and *Nothofagus* forests in the dry ecotone forest-steppe across Patagonia	Increase in extreme drought events			*High*	Rodríguez-Catón et al. (2019)
	Increase in elevation of the upper-forest *Nothofagus* treeline across Patagonia	Increase in temperature and duration of the growing season at high elevation in the Patagonian Andes			*High*	(Srur et al. (2016); Srur et al. (2018)
Central Asian arid lands	Shrub encroachment into arid grasslands within the past 10 years	Temperature of central Asian arid regions experienced a sharp increase since 1997 and has been in a state of high variability since then			*Medium*	Li et al. (2015)
Loess Plateau, China	Widespread vegetation greening in the Loess Plateau region; soil moisture declining widely, and deficit in forests and orchards. The runoff of the Yellow River is declining	Significant warming, slight increase in precipitation.		The land use and cover change, ecological restoration, mainly induced by Grain for Green Project	*High*	Jia et al. (2015); Wang et al. (2015); Deng et al. (2016); Jiao et al. (2016)
The Three-River Source Region of the Tibetan Plateau, China	The runoff increases, the total water storage and groundwater increasing. NPP increase	The precipitation increasing and evapotranspiration (ET) slight decreasing		Grassland protection	*High*	Xu et al. (2019)
Semi-arid						
Australian arid lands	Widespread greening	Elevated CO2			*Medium*	Donohue et al. (2013)
African savanna	Doubling of tree cover from 1940 – 2010 in South Africa changing land use), and 20% increase in spread of woody	Warming, elevated CO_2, altered rainfall regimes		Removal of mega-herbivores, fire suppression,	*High*	Skowno et al. (2017); Stevens et al. (2017); Venter et al. (2018); García Criado et al. 2020)

	areas into previously open areas in the last 20 years			changed herbivore regime		
African savanna	Widespread increase in tree cover across Africa with only 3 countries across continent experiencing a net decline in tree cover	Warming, changing rainfall, mention of CO_2		Fire suppression	*High*	Venter et al. (2018)
African savanna	Biodiversity responses to changes in vegetation structure (woody encroachment) causing declines in functional groups that are open area specialists. Records in birds, rodents, termites, mammals, insects.	Woody encroachment			*Medium*	Blaum et al. (2007); Blaum et al. (2009); Sirami and Monadjem (2012); Gray and Bond (2013); Péron and Altwegg (2015); Smit and Prins (2015)
African semi-arid regions (savanna)	Reduced tourism experience due to woody encroachment	Woody encroachment			*Low*	Gray and Bond (2013)
North American drylands – sagebrush steppes	Sagebrush steppes are being invaded by non-native grasses	Increase in temperature and favourable climates			*High*	Bradley et al. (2016); Hufft and Zelikova (2016); Chambers (2018)
	Shrub encroachment,(*Prosopis glandulosa, Juniper ashei* and *Juniper pinchotti)* is occurring in the semi-arid grasslands of the southern great plains at a rate of ~8% per decade	Increasing temperature, elevated CO2 and changing rainfall		Fire suppression and altered grazing/browsing regimes	*High*	Caracciolo et al. (2016); Archer et al. (2017)
	Woody encroachment in sagebrush steppes (cold deserts) (*Juniper occidentalis*) at a rate of 2% per decade	a) Warming and associated decline in snowpack b) Less precipitation falling as snow and an increase in the rain fraction in winter.			*High*	Chambers et al. (2014); Mote et al. (2018)

Central Mexico	Desertification (as decreases in vegetation indexes).	decreased rainfall + increase in temperature		Land use change and intensification	*Medium*	Becerril-Pina et al. (2015); Noyola-Medrano and Martínez-Sías (2017)
Chinese drylands	Widespread greening trend of vegetation in China over the last three decades; regional difference	Warming, CO_2 increase. 1) Rising atmospheric CO2 concentration and nitrogen deposition are identified as the most likely causes of the greening trend in China, explaining 85% and 41% of the average growing-season LAI trend. 2) Negative impacts of climate change in north China and Inner Mongolia and the positive impact in the Qinghai-Xizang plateau		Ecological protection	*Medium*	Piao et al. (2015)
Dry sub-humid						
African mesic savannas	Forest expansion into mesic savannas	Increases rainfall, elevated CO_2		Fire suppression	*Medium*	Baccini et al. (2017); Aleman et al. (2018)
South American cerrado	8% rate of woody cover increase	Elevated Co2		Fire exclusion	*High*	Stevens et al. (2017); Rosan et al. (2019)
South American cerrado	Expansion of forest into cerrado	Elevated CO2		Fire exclusion	*High*	Passos et al. (2018); Rosan et al. (2019)
Australian savannas	2% rate of woody cover increase and greening of drylands				*High*	Donohue et al. (2013); Stevens et al. (2017); Bernardino et al. (2020)

Table CCP3.2: Synthesis of adaptation measures and responses to risks in deserts and semi-arid areas. Appropriateness of measures is context dependent and some adaptations will be incremental or even maladaptive in some dryland contexts while being transformational in other locations.

Challenge	**Adaptation Measures and Responses**	**References**
Soil erosion	Rainwater harvesting and soil conservation, grass reseeding, agroforestry. Use of different breeds of grazing animals, altered livestock rotation systems, use of new crop varieties, development of management strategies that reduce the risk of wildfire.	Eldridge and Beecham (2018)
Overgrazing	Modification of production and management systems that involve diversification of livestock animals and crops, integration of livestock systems with forestry and crop production, and changing the timing and locations of farm operations. Improved breeds and feeding strategies and adoption of improved breeds for households without cows (both economic & environmental gain).	Kattumuri et al. (2015), Shikuku et al. (2017)
Clearing of natural vegetation	Carbon sequestration through decreasing vegetation clearing rates, reversal through revegetation, targeting for higher-yielding crops with better climate change adapted varieties, and improvement of land and water management Agroforestry role in addressing various on-farm adaptation needs besides fulfilling many roles in AFOLU-related mitigation pathways (assets and income from carbon, wood energy, improved soil fertility and enhancement of local climate conditions; it provides ecosystem services and reduces human impacts on natural forests). Implementation of co-benefits strategies including provision of incentives across multiple scales and time frames, fostering multidimensional communication networks and promoting long-term integrated impact assessment. Achievement of triple-wins in SSA through provision of development benefits by making payments for forest services to smallholder farmers, mitigation benefits by increasing carbon storage, and adaptation benefits by creating opportunities for livelihood diversification.	Kattumuri et al. (2017), Mbow et al. (2014), Suckall et al. (2014)
Invasive species and woody encroachment	Cliamte change is projected to facilitate the spread of invasive species. Invaive species can have profound impacts on dryland ecosystems functioning leading to the loss of biodiversity. Biomass harvesting and selective clearing; utilising intense fires to manage encroachment, combined browsing and fire management. Rewilding in open ecosystems and reintroduction of mega-herbivores (e.g. in parts of Africa) to counter negative impact of woody encroachment. Chemical removal of undesirable encroached woody species	Mirzabaev et al. (2019); Davies and Nori (2008); Stafford et al. (2017); Cromsigt et al. (2018); Ding and Eldridge (2019)
Droughts	Pro-active drought risk mitigation vs reactive crisis management approaches. Promoting collective action in livestock management, optimizing livestock policies and feed subsidies. interventions in livestock markets during drought onset. Expanding sustainable irrigation and shifting to drought-resistant crops and crop varieties. Environmentally sustainable sea water desalination. Promoting behavioural changes for more efficient residential water use. Moving away from water-intensive agricultural practices in arid areas. Harvesting rainwater by local communities; empowering women and engagement in local climate adaptation planning, community	Morton and Barton (2002); Abebe et al. (2008); Alary et al. (2014); Catley et al. (2014); Mohamed et al. (2016)

	based early warning systems, IRWM, water governance benchmarking, and exploration of palaeo channels as freshwater sources using remote sensing	
Grassland and savanna degradation	Prescribed fire and tree cutting, invasive plant removal, grazing management, reintroduction of grasses and forbs, restoration of soil disturbance.	For review see Buisson et al. (2019)
Rangeland degradation (decreasing fodder quality or yield, invasion by fodder poor value species/refusals)	Promote herd local and regional mobility during the growing season to avoid intense grazing pressure on growing annual herbaceous vegetation of rangelands near settlements, water points, market. Moderate grazing facilitates grass tillering and herbaceous flora diversity. Ecological restoration of grazing ecosystems by sowing a mixture of zone-typical dominant species and life forms of plants on severely degraded land. Clearance of invasives. Ecological restoration of arid ecosystems by sowing a mixture of zone-typical dominant species and life forms of fodder plants with partial (ribbon) treatment of pasture lands. Ecological restoration of secondary salted irrigated soils using halophytes.	De Vries and Djitèye (1982); Hiernaux et al. (1994); Hiernaux and Le Houérou (2006); Reed et al. (2015)
Poor livestock productivity (reproduction/dairy/meat) in relation with poor seasonal nutrition	Promote seasonal-regional herd mobility to optimise the use of complementary fodder resources (rangelands, browses, crop residues). Implies institutionalized communal access, community agreements and infrastructures (water points, livestock path, grazing reserves, access to education, health care, markets for transhumant population). Cross state boundary mobility implies international agreements such as promoted by N'djamena meeting (Declaration 2013)	Turner (1993); Schlecht et al. (2004); Fernández-Rivera et al. (2005); Bonnet and Herault (2011); Hiernaux et al. (2016)
	Promote strategic supplementation of reproductive and young animals by the end of dry and early wet season. Secondary effect on excretion quantity/ quality to manure croplands.	Many trials in research stations and on farm: for example Sangaré et al. (2002a); Sangaré et al. (2002b); Osbahr et al. (2011); Sanogo (2011)
Decrease trend in cropland soil fertility	Rotational corralling of livestock in field during the dry season (and on cleared fallow the following year in the wet season) to ensure maximum retrieval of organic matter and nutrients from faeces and urine deposited. Application or mineral N and P fertilisers as placed (per poquet) microdoses (50-80 kg/ha) to intensify staple crop production. Impact on soil fertility, rain use efficiency, vegetation cover, organic matter production and recycling. Legume association with cereals (millet-cowpea; Sorghum-groundnut). Adapting cultivars and cropping techniques (calendar, fertilisation)	Pieri (1989); Breman et al. (2001); Gandah et al. (2003); Manlay et al. (2004); Abdoulaye and Sanders (2005); Reij et al. (2005); Akponikpe (2008); Bagayoko et al. (2011); Bationo et al. (2011); Hiernaux et al. (2009b); Sendzimir et al. (2011); Turner and Hiernaux (2015); Weston et al. (2015; Reij and Garrity (2016)
Salinisation and groundwater depletion	Indigenous and scientific adaptive practices to cope with salinity. Farmers in waterlogged saline areas harness sub-surface drainage, salt tolerant crop varieties, land-shaping techniques and agroforestry to adapt to salinity and waterlogging risks. Locally adapted crops and landraces, and the traditional tree- and animal-based means to sustain livelihoods	Sengupta (2002); Buechler and Mekala (2005); Wassmann et al. (2009); Singh (2010); Jnandabhiram and Sailen Prasad

	in face of salinisation. Climate change is projected to increase the salinization of groundwaters. Current unsustainable use of groundwaters is already leading to their depletion in some dryland areas.	(2012); Manga et al. (2015); Sharma and Singh (2015); Gupta and Dagar (2016); Nikam et al. (2016); Bundela et al. (2017); Sharma and Singh (2017); Patel et al. (2020); Singh et al. (2020b); Sharma, (2016); Mirzabaev et al. (2019)
Sand and dust storms	Use of live windbreaks or shelterbelts, protection of the loose soil particles through the use of crop residues or plastic sheets or chemical adhesives, increasing the cohesion of soil particles by mechanical tillage operations or soil mulching. Use of perennial plant species that have the ability to trap sediments (sand and fallen dust) and form sandy mound around it, such as *Haloxylon salicornicum*, *Cyperus conglomerates*, *Lycium shawii*, and *Nitraria retusa*. In Sahel: promote herbaceous (not woody plants) to trap sand annuals such as Colocynthis vulgaris, Chrozophora senegalensis, Farsetia ramosissima, perennials such as Cyperus conglomeratus, Leptadenia hastate. In Sahel: leaving at least part of the crop residues (stalks) laid down on the soil during the dry season (100kg dry matter per hectare has already significant effect on wind erosion, many trials on Millet in Niger). Trampling by grazing livestock improves the partial burying of the residues. Improve monitoring, prediction and early warning. Monitoring, prediction and early warning to mobilize emergency responses for human systems & prioritize long-term sustainable land management measures. Establishment of a Global Dust-Health Early Warning System (building on the SDS-WAS initiative). Multi-sectoral preparedness and response including public health, hospital services, air and ground transportation and communication services	Ahmed et al. (2016); Al-Hemoud et al. (2017); Sivakumar (2005); Hiernaux et al. (2009a); Hiernaux et al. (2016); Pierre et al. (2018); Lamers et al. (1995); Michels et al. (1998); Bielders et al. (2004),UNEP (2016); UNEP (1992)

Executive Summary

The Mediterranean Region hosts exceptional biological diversity and socio-cultural richness originating from three continents. The nature of the semi-enclosed Mediterranean Sea and the complex topography imply unique physiographic and ecological features. The region has undergone continuous change in human activities during several millennia, and it now hosts more than 500 million people with a high concentration of urban settlements and industrial infrast`ructure close to sea level. The region is the world's leading tourist destination and one of its busiest shipping routes. Climate change strongly interacts with other environmental problems in the Mediterranean Basin, resulting from urbanisation, land use change, overfishing, pollution, biodiversity loss and degradation of land and marine ecosystems. {CCP4.1.1}

Previous IPCC reports have never assessed the Mediterranean region as an entity – but they have nevertheless shown that virtually all parts of it are vulnerable and face significant risks due to climate change. Identified regional key risks include increased water scarcity (notably in the South and East) and droughts (in the North), coastal risks due to flooding, erosion and saltwater intrusions, wildfire, terrestrial and marine ecosystem losses, as well as risks to food production and security, human health, well-being and the cultural heritage. {CCP4.1.2}

Surface temperature in the Mediterranean region is now 1.5°C above pre-industrial level, with a corresponding increase in high-temperature extreme events (*high confidence*[1]). Trends in precipitation are variable across the basin (*low confidence*). Droughts have become more frequent and intense, especially in the North Mediterranean (*high confidence*). The sea surface has warmed by 0.29-0.44°C per decade since the early 1980s with stronger trends in the Eastern Basin. Sea level has risen by 1.4±0.2 mm yr^{-1} during the 20th century (2.8±0.1 mm yr^{-1} over 1993-2018) (*high confidence*). Ocean acidity is increasing (*medium confidence*). {CCP4.1.3}

A growing number of observed impacts across the entire basin are now being attributed to climate change, along with major roles of other forcings of environmental change (*medium to high confidence*). These impacts include multiple consequences of longer and/or more intensive heat waves, droughts, floods, ocean acidification and sea-level rise, such as cascading impacts on marine and terrestrial ecosystems as well as on land and sea use (agriculture, forestry, fisheries, tourism, recreation etc.) and human health. {CCP4.1.4}

During the 21st century, climate change is projected to intensify throughout the region. Air and sea temperature and their extremes (notably heat waves) are *likely*[2] to continue to increase more than the global average (*high confidence*). The projected annual mean warming on land at the end of the century is in the range from 0.9 to 5.6°C compared to the last two decades of the 20th century, depending on the emission scenario (*high confidence*). Precipitation will *likely* decrease in most areas by 4% to 22%, depending on the emission scenario (*medium confidence*). Rainfall extremes will *likely* increase in the northern part of the region (*high confidence*). Droughts will become more prevalent in many areas (*high confidence*). {CCP4.1.3}

Mediterranean sea-level is projected to rise further during the coming decades and centuries (*high confidence*), *likely* reaching 0.15 to 0.33 m in 2050, and 0.3 to 0.6 m for SSP1-1.9 and 0.6 to 1.1 m for SSP5-8.5 in 2100 (relative to 1995-2014) (*medium confidence*). Higher values cannot be excluded (*low confidence*) and the process is irreversible at the scale of centuries to millennia (*high confidence*).

---

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

Coastal flood risks will increase in low-lying areas along 37% of the Mediterranean coastline that currently host 42 million people. The number of people exposed to sea-level rise is projected to increase up to 2050, especially in the Southern and Eastern Mediterranean region, and may reach up to 130% compared to present in 2100 (*medium confidence*). Coastal settlements, world heritage sites and ecosystems are at longer-term risk from sustained sea-level rise over at least the coming three centuries (*high confidence*). {CCP4.1.3, CCP4.2, CCP4.3, SMCCP4.4}

Due to its particular combination of multiple strong climate hazards and high vulnerability, the Mediterranean region is a hotspot for highly interconnected climate risks. The main economic sectors in the region (agriculture, fisheries, forestry, tourism) are highly vulnerable to climatic hazards, while socio-economic vulnerability is also considerable. The low-lying areas are the most vulnerable areas for coastal climate-related risks (e.g. sea level rise, floods, erosion) and other consequent risks (e.g. saltwater intrusion and agriculture damage) (*high confidence*). Climate change threatens water availability, reducing river low flows and annual runoff by 5-70%, reducing hydropower capacity (*high confidence*). Yields of rain-fed crops may decrease by 64% in some locations (*high confidence*). Ocean warming and acidification will impact marine ecosystems, with uncertain consequences on fisheries (*low confidence*). Desertification will affect additional areas, notably in the South and South-East (*medium confidence*). Burnt area of forests may increase by 96-187% under 3°C, depending on fire management (*low confidence*). Beyond 3°C, 13-30% of the Natura 2000 protected area and 15-23% of Natura 2000 sites could be lost due to climate-driven habitat change (*medium confidence*). {CCP4.2, CCP4.3}

The adaptive capacity of ecosystems and human systems is expected to encounter hard limits due to the interacting, cumulative and cascading effects of droughts, heat waves, sea-level rise, ocean warming and acidification (*high confidence*). Coastal protection can reduce risks from sea-level rise in some regions, but the costs of such interventions and their consequences for coastal ecosystems are high (*medium confidence*) {CCP4.4.1}. There is *low confidence* in the feasibility of adaptation options to sea-level rise beyond 2100 or for large Antarctic ice melting. {CCP4.4.5}

Progress towards achievement of the UN Sustainable Development Goals differs strongly between Mediterranean sub-regions, with north-western countries having stronger resilience than southern and eastern countries (*high confidence*). To equitably enhance regional adaptive capacity and sustainable development, while safeguarding the rights of the most vulnerable people, regional cooperation can be strengthened with a focus on the link between adaptation, costs and financial limitation and climate justice (*high confidence*). Cooperative policies across multiple various sectors, involving all user groups and considering all regional and sectorial differences may enhance sustainable resource use in the region (*high confidence*). {CCP4.4.6}

Sharing and co-production of knowledge can support climate adaptation practices and enhance sustainability in the Mediterranean region (*medium* to *high confidence*). Currently incomplete knowledge of climate impacts and risks in the southern and eastern part of the basin hinders the implementation of adaptation measures, creating a need for implementable plans with enhanced and cooperative research and monitoring capacities between the north and south/east countries (*high agreement*). {CCP4.4}

CCP4.1 Climate Change in the Mediterranean Basin

CCP4.1.1 The Mediterranean Sea, Land and People

The Mediterranean Basin, known for its exceptional environmental and socio-cultural richness, comprises the semi-enclosed Mediterranean Sea and the countries and regions bordering it[3], which belong to Europe, Asia and Africa (Figure CCP4.1). The region has a unique historical and environmental identity (Abulafia, 2011), despite undeniable variations in the environment, socio-economic conditions and cultural traditions. The countries in the Mediterranean Basin hosted approx. 542 million people in 2020, a number which is expected to increase to 657 million in 2050 and 694 million in 2100. In 1950, only 23.7% of the Mediterranean population lived in countries of the South, this number has increased to 41.2% in 2000, 46.3% in 2020, and is projected to reach 55.5% in 2050 and 64.6% in 2100 (UN DESA, 2019).

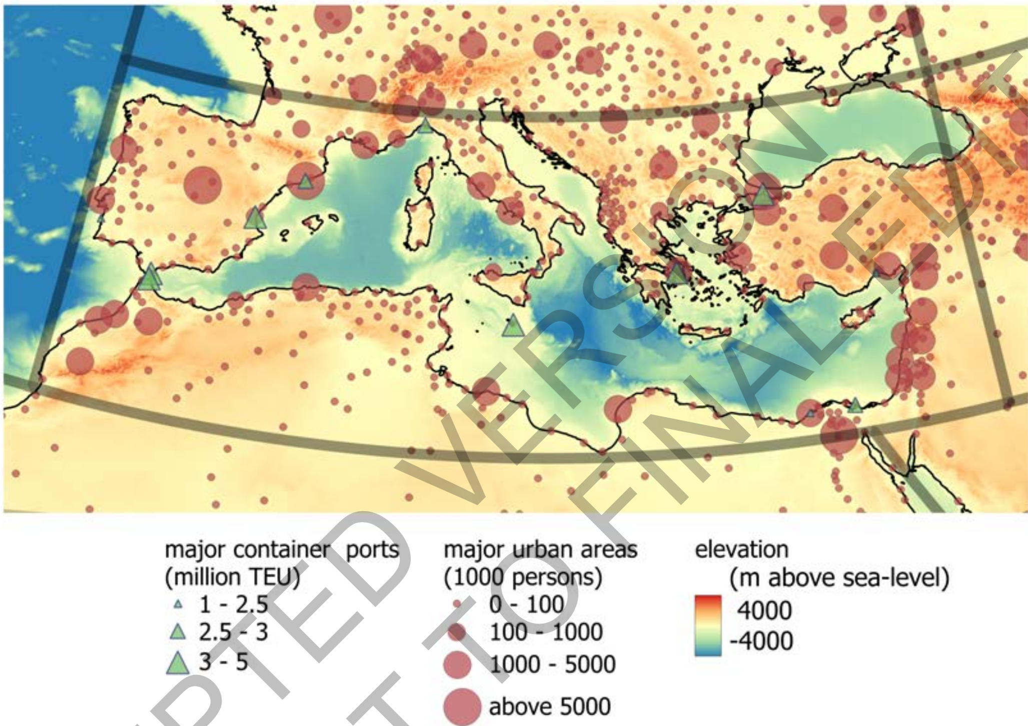

Figure CCP4.1: The Mediterranean region: Topography and bathymetry (colour bar in meters), main urban areas (population in thousands for 2020 from www.naturalearthdata.com), container ports (millions of TEU twenty-foot container equivalent units in 2017, from International Association of Ports and Harbours) and borders of the AR6-WGI Mediterranean region.

CCP4.1.2 Main Findings from Previous Assessments

All previous assessments of climate change for the Mediterranean Basin and its sub-regions indicate ongoing warming of the atmosphere and the sea, as well as projected warming and changes in rainfall (Stocker et al., 2013; Cherif et al., 2020). The projected increase in climate hazards, in combination with high regional vulnerability and exposure make it a prominent 'climate change hotspot' (Giorgi, 2006), with a large number of vulnerable natural systems and socio-economic sectors (Field et al., 2014; MedECC, 2020). In addition to high temperatures, the main risk factor identified is drought, generally expected to increase in the region, significant already at global warming of only 1.5°C, reaching, for higher warming levels, intensities unprecedented during the past 10ka (Hoegh-Guldberg et al., 2018). In southern Europe and North Africa, groundwater recharge and soil water content consequently decline, especially during summer (Kovats et al., 2014; Niang et al., 2014).

[3] By tradition, also Portugal and Jordan are considered Mediterranean countries, despite having no Mediterranean coastline

With the changing climate, marine ecosystems have already undergone changes in structure, including the spread of tropical species from the Atlantic Ocean and the Red Sea (*high confidence*) and mass mortality in at least 25 invertebrate species, threatening, along with ocean acidification, marine ecosystems, including seagrass meadows (Hoegh-Guldberg et al., 2014; Nurse et al., 2014; Pörtner et al., 2014; Wong et al., 2014). Endemic marine species are at higher risk of extinction due to limited possibilities to migrate northward (Kovats et al., 2014; Poloczanska et al., 2014; Balzan et al., 2020). Southern and Eastern Mediterranean coastal systems with narrow dune belts and often rapid urbanization are vulnerable to both warming and sea-level rise (Seneviratne et al., 2012; Wong et al., 2014; Balzan et al., 2020).

Most Mediterranean land ecosystems are impacted negatively by drier conditions, causing the ranges of many endemic species to shrink, and the health and growth rates of trees to decline (Kovats et al., 2014; Niang et al., 2014; Nurse et al., 2014; Settele et al., 2014). Climate change is expected to increase wildfire risk in the region (Kovats et al., 2014), although earlier estimates of burnt area have been reduced in the most recent assessments to approx. 40-100%, considering that prevention and mitigation actions have successfully reduced this risk so far (Balzan et al., 2020). Wetlands and mountain summits are hotspots for biodiversity loss and extinctions (*medium confidence*) (Jiménez Cisneros et al., 2014; Nurse et al., 2014; IPBES, 2018a; IPBES, 2018b; Balzan et al., 2020). Along with unsustainable land use practices, climate change is projected to increase soil erosion in semi-arid areas (Jiménez Cisneros et al., 2014).

The increasing water scarcity was found to be a significant threat to agriculture (Jiménez Cisneros et al., 2014; Kovats et al., 2014; Niang et al., 2014; Mrabet et al., 2020). Associated with increased extreme temperatures, the Mediterranean is expected to become less attractive for tourism (Kovats et al., 2014; Nurse et al., 2014; Wong et al., 2014; Dos Santos et al., 2020). Several critical risks for human health increase due to climate change, including heat waves and vector-borne diseases (Kovats et al., 2014; Nurse et al., 2014; Linares et al., 2020). Adaptation options have been identified for many risks (buildings, water management, coastal protection etc.) (Murray et al., 2012; Revi et al., 2014; Wong et al., 2014). There are synergies between adaptation and mitigation, e.g. renewable energies or nature-based solutions focused on the conservation and restoration of ecosystems (Nurse et al., 2014; Hoegh-Guldberg et al., 2018; Vafeidis et al., 2020).

CCP4.1.3 Observed and Projected Climate Change

The Mediterranean Basin is located in a transition zone between mid-latitude and subtropical atmospheric circulation regimes, with large topographic gradients. The analysis of observed climate changes and their impacts is strongly affected by the imbalance of observations between northern and southern countries, where available time series often have not allowed to reconstruct past climate evolution over a sufficiently long-time scale (Cramer et al., 2018).

Since the 1980s, Mediterranean atmospheric warming has exceeded global average rates (*high confidence*) (WGI AR6 Chapter 11; Lionello and Scarascia, 2018; Cherif et al., 2020). Future annual and summer warming rates are projected to be 20% and 50% larger than the global annual average, respectively. Summer warming is projected to be particularly strong in the north (Figure CCP4.2, WGI AR6 Chapter 11;Mariotti et al., 2015; Lionello and Scarascia, 2018). Temperature extremes and heat waves have increased in intensity, number, and length during recent decades, particularly in summer, and are projected to continue increasing (*high confidence*) (WGI AR6 Chapter 11Zittis et al., 2016; Hoegh-Guldberg et al., 2018; Cherif et al., 2020).

Sea surface temperatures have increased in recent decades (*high confidence*), with regional variation between +0.29 and +0.44°C per decade (Darmaraki et al., 2019a) and stronger trends in the eastern basin (Iona et al., 2018; Pastor et al., 2019), involving the whole upper mixed layer (Rivetti et al., 2017). Towards the end of the 21st century, ocean warming in the range 0.8-3.8°C is projected near the surface (*high confidence*), 0.8-3.0°C at intermediate depth and 0.15-0.18°C in deeper waters (Darmaraki et al., 2019b; Soto-Navarro et al., 2020). The duration and intensity of marine heat waves have increased (*high confidence*) (Darmaraki et al., 2019a) and both parameters are projected to continue increasing in the future (Galli et al., 2017). Under RCP8.5, at least one long-lasting marine heat wave is projected for every year by 2100, up to three months longer and about four times more intense than present day events (WGI AR6 Chapter 9) (Darmaraki et al., 2019b). Salinity is projected to increase, with anomalies from +0.48 to +0.89 psu at the end of the century (*medium confidence*) (WGI AR6 Chapter 9; Adloff et al., 2015).

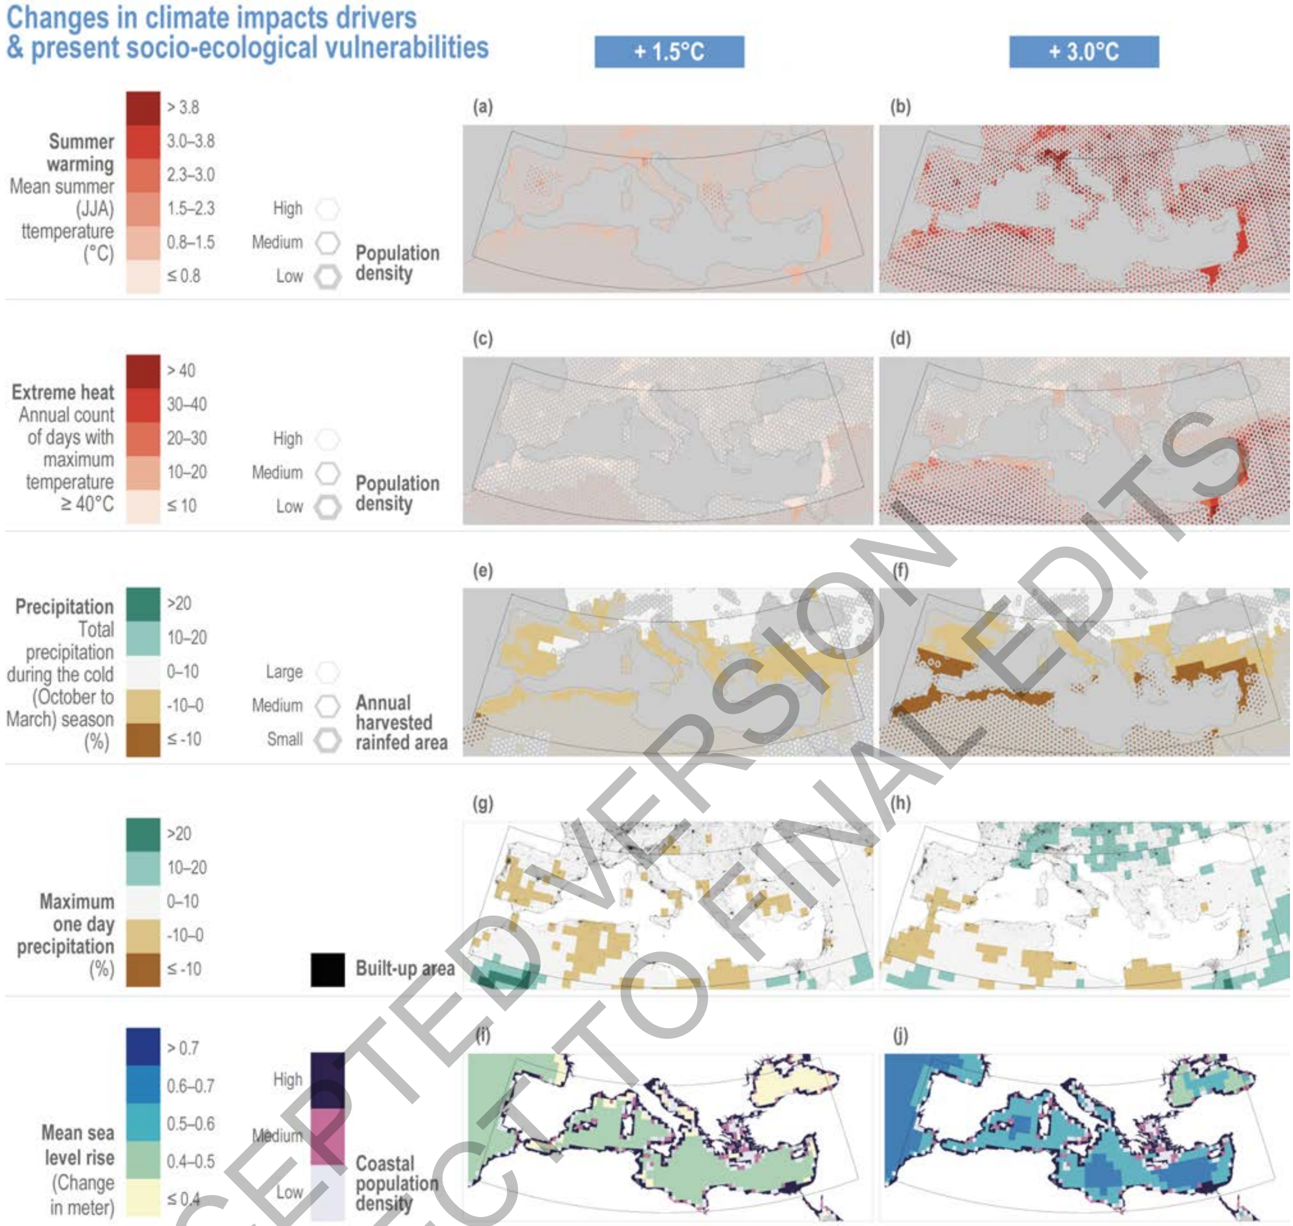

Figure CCP4.2: Changes in climate impact drivers with respect to the 1995-2014 period for 1.5°C (left column) and 3°C (right column) global warming: mean summer (June to August) temperature (°C, a, b), number of days with maximum temperature above 40°C (days, c, d), total precipitation during the cold (October to March) season (%, e, f)) and 1-day maximum precipitation (mm, g, h). Values based on CMIP6 global projections and SSP5 8.5 (source: Annex I: Atlas).

Observed trends in annual precipitation are significant only in some areas and some periods, and they are stationary on the long term throughout the region (*medium confidence*) (WGI AR6 Chapter 11, Figure CCP4.3; Harris et al., 2014; Lionello and Scarascia, 2018; Vicente-Serrano et al., 2020). Precipitation is projected to decrease (*high confidence* for global warming levels above 2°C) (Figure CCP4.2) by approximately 4% per 1°C global warming, for all seasons in the central and southern basin, and mostly in summer in the north (Mariotti et al., 2015; Hertig and Tramblay, 2017; Lionello and Scarascia, 2018). Precipitation extremes have increased in some northern areas (*medium confidence*), and are projected to increase in the north (*high confidence* for global warming levels above 2°C), potentially accompanied by an increase in of flash floods (Llasat et al., 2016), with no change in the south (*low confidence*) (WGI AR6 ATLAS, Figures CCP4.2 and CCP4.3; Tramblay and Somot, 2018; Lionello and Scarascia, 2020). These trends enhance the gradient between northern (already characterized by more intense events) and southern areas (where extreme precipitation events are comparatively milder) (Giorgi et al., 2014; Jacob et al., 2014; Vautard et al., 2014; Lionello and Scarascia, 2020).

Widespread increase of evaporative demand and some decrease of precipitation explain the drying of the Mediterranean region during recent decades (*high confidence*) (Chapter 11, Figure CCP4.3) (Spinoni et al., 2015; Gudmundsson and Seneviratne, 2016; Spinoni et al., 2017; Stagge et al., 2017; Caloiero et al., 2018). Droughts are projected to become more severe, more frequent and longer under moderate emission scenarios, and strongly enhanced under severe emission scenarios (*high confidence*) (WGI AR6 Chapter 11) (Hertig and Tramblay, 2017; Lehner et al., 2017; Ruosteenoja et al., 2018; Spinoni et al., 2018b; Grillakis, 2019; Lionello and Scarascia, 2020).

No trends in mid-latitude cyclones crossing the Mediterranean basin have been detected for recent decades (Lionello et al., 2016). For Mediterranean hurricanes ("medicanes"), no observed trends are known because of insufficient monitoring. In the future, mid-latitude cyclones and medicanes are projected to decrease in frequency, but medicane intensity will *likely* increase (Cavicchia et al., 2014; Nissen et al., 2014; Romera et al., 2017).

Mediterranean waters have acidified since the pre-industrial period, more rapidly than the global ocean, due to faster ventilation times (*high confidence*) (Palmiéri et al., 2015). Acidification is projected to continue (*virtually certain*) (WGI AR6 Chapter 11), with a pH decrease that might reach -0.46 in a high emission scenario (Goyet et al., 2016).

Mediterranean mean sea level has risen by 1.4±0.2 mm yr^{-1} during the 20th century (Wöppelmann and Marcos, 2012) and accelerated to 2.4±0.5 mm yr^{-1} for 1993 to 2012 (Bonaduce et al., 2016) and 3.4 mm yr^{-1} for 1990 to 2009 in the northwest (*medium confidence*) (Calvo et al., 2011). The accelerating trend is robust, although different methods and time horizons yield slightly different rates of change (Meyssignac et al., 2011; Cazenave et al., 2018; von Schuckmann et al., 2020). For 2150, sea level is *likely* to reach 0.52 m [0.32-0.81] for SSP1-1.9, to 1.22 [0.91-1.78] for SSP5-8.5 relative to 1996-2014 (*medium confidence*) (WGI AR6 Chapter 9; Figure FAQ-CCP4.2, SMCCP4.4), with uncertain variation between sub-basins (Slangen et al., 2017). Melting processes in Greenland and Antarctica could result in even higher levels (*low confidence*, WGI AR6 Chapter 9; Cross-Chapter Box SLR in Chapter 3).

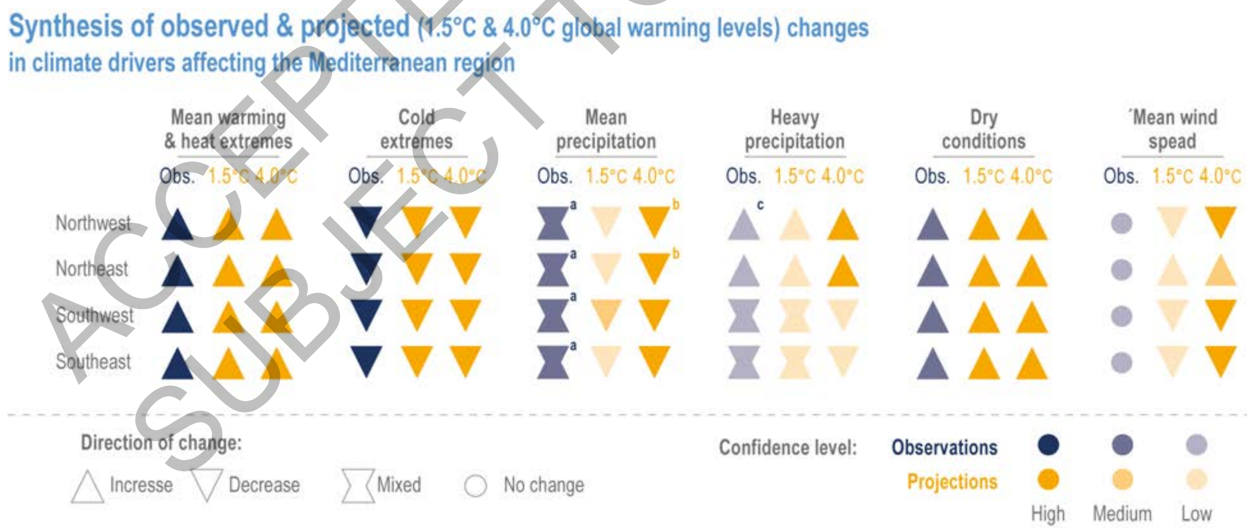

Figure CCP4.3: Observed and projected (at global warming levels of 1.5°C and 3°C) direction of change of climate drivers and confidence levels for Mediterranean land sub-regions. [a] The magnitude and sign of trends depend substantially on time period and study region. Although precipitation is highly variable, it is stationary on the long term for the whole region. [b] Marginal increase in winter at the northern boundary of the subregions. [c] There are subregional differences, with no change or even decrease over Iberia.

The Mediterranean Basin includes within small distances a large variety of climatic conditions that are *likely* to shift northward with global warming. Consequently, ecoregions will be exposed to potentially unsuitable conditions: more arid climate for Mediterranean forests of North-Africa, more subtropical climate and temperate climate for mountain forests of the Balkans and of the Alps, respectively, and Mediterranean climate for the temperate forests of North Anatolia (Figure CCP4.4; Lelieveld et al., 2012; Simpson et al., 2014).

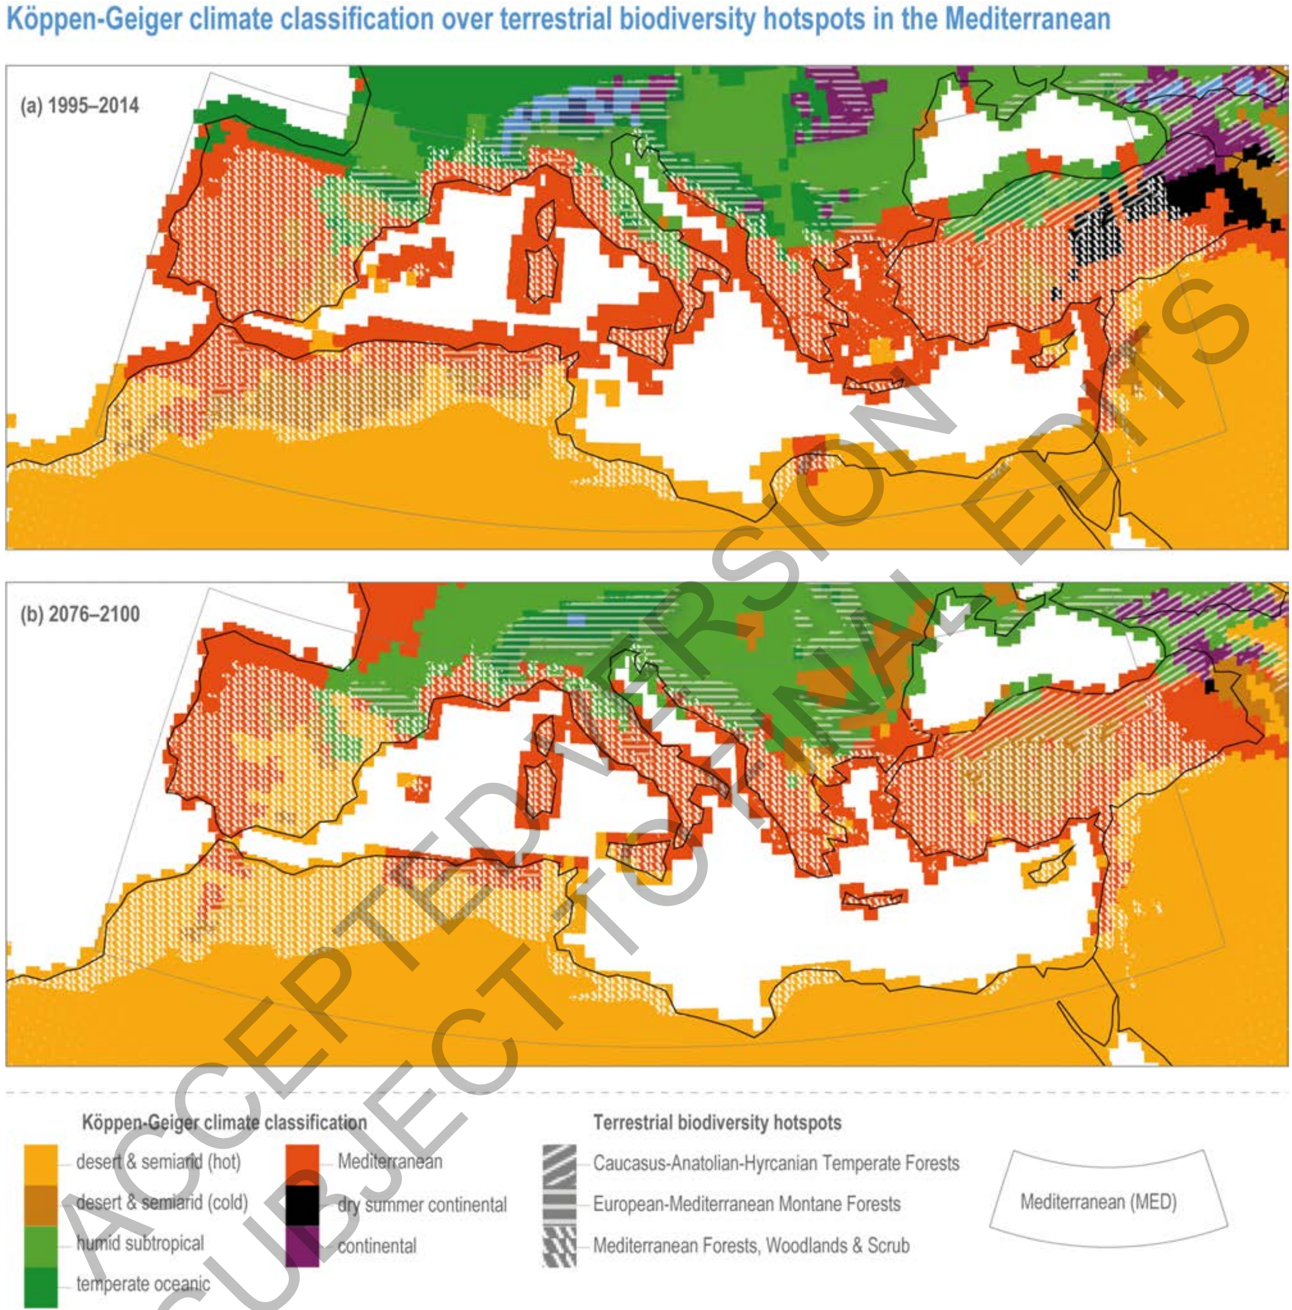

Figure CCP4.4: Climate and natural land ecosystems in the Mediterranean Basin, based on Köppen-Geiger climate types, for the AR6 baseline climate (panel a, 1985-2014) and future climate (panel b, 2076-2100, A1FI scenario, corresponding to global warming of approximately 4°C), based on (Rubel and Kottek, 2010) with the three biodiversity hot spots.

CCP4.1.4 Detection and Attribution of Climate Change Impacts

New evidence published since AR5 confirms that climate change is increasingly affecting many systems and sectors in the Mediterranean region (*high confidence*) (Figure CCP4.5; Chapter 9, 13 and 16). There is *high confidence* that climate change has worsened heat waves and droughts (CCP4.1.3;Lionello et al., 2014; Caloiero et al., 2018; Mathbout et al., 2018; Spinoni et al., 2019), and *medium to high confidence* that heat waves are impacting marine (Rivetti et al., 2014; Tsikliras and Stergiou, 2014; Stergiou et al., 2016; Corrales et al., 2017), freshwater and terrestrial ecosystems (Peñuelas et al., 2018; Bartsch et al., 2020; Carosi et al., 2021), as well as agriculture (El-Maayar and Lange, 2013; Ortas and Lal, 2013; Ponti et al., 2014; Garcia-Mozo et al., 2015; Moore and Lobell, 2015; Oteros et al., 2015; Di Lena et al., 2018) and fisheries (Fortibuoni et al., 2015; Givan et al., 2018; IPBES, 2018a). Heat waves have also increased thermal discomfort, especially in urban area (WGI AR6 Chapters 10 and 12; Zinzi and Carnielo, 2017). Despite increasing wildfire hazard, forest fires are generally decreasing in the European part of the basin, due to more efficient risk management (*medium confidence*) (Turco et al., 2016; Turco et al., 2017). Mixed trends of increasing and decreasing flash and river floods across the Mediterranean are reported, but there is *low confidence* in their attribution to climate change (Mediero et al., 2014; Baahmed et al., 2015; Gaume et al., 2016; Paprotny et al., 2018; Blöschl et al., 2019; Vicente-Serrano et al., 2019).

Flooding, erosion and salinization are significant observed impacts in coastal regions, especially where subsidence is significant, such as in the region of Thessaloniki in Greece or the eastern Nile Delta in Egypt (Raucoules et al., 2008; Frihy et al., 2010), with only *low confidence* in attribution to climate change so far (SMCCP4.1). Coastal urbanisation and engineering protection are expanding in the Mediterranean, resulting in substantial impacts on coastal biodiversity (Masria et al., 2015; Carranza et al., 2020).

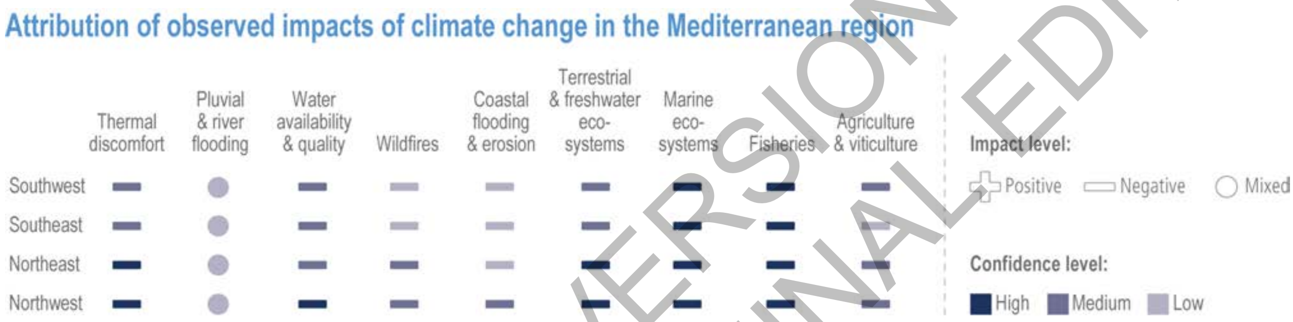

Figure CCP4.5: Attribution of observed impacts of climate change in the Mediterranean region (see SMCCP4.1 for supporting references).

The attribution of impacts displays little variability across sub-regions, but confidence in attribution to climate change is higher in the north, due to the larger number of observations and studies in Europe. While land use and fisheries are still major non-climatic drivers of changing hazards and biodiversity losses (Aguilera et al., 2015; Turco et al., 2016; IPBES, 2018a; IPBES, 2018b; Tramblay et al., 2019; Vicente-Serrano et al., 2019), impacts of climate change are now being observed in all parts of the Mediterranean region (*high confidence*).

CCP4.2 Vulnerability of Mediterranean Countries to Climate Change

CCP4.2.1 The Specific Vulnerability of Mediterranean countries

The Mediterranean region is predominantly vulnerable to the impacts of warming, notably prolonged and stronger heat waves, and increased drought in an already dry climate, and risk of coastal flooding (Section CCP4.1). Southern and Eastern countries are generally more vulnerable than countries in the north. Several countries (Tunisia, Algeria and Libya) are below the water scarcity threshold set by the Food and Agriculture Organization of the United Nations (FAO), others (Morocco) are close to the threshold for severe water stress. Uncertainties regarding the timing, duration, intensity and interval between extreme climatic events put some sectors such as agriculture and tourism at particular risk in the Mediterranean region (Section CCP4.3; Kallis, 2008; Kutiel, 2019).

CCP4.2.2 Economic Vulnerability

All Mediterranean countries are vulnerable to climate change across most socio-economic sectors. In low-income countries of the basin a 1.1-point reduction of Gross Domestic Product (GDP) could occur as a consequence of 1°C rise warming (Radhouane, 2013). In Morocco, GDP impacts of climate change could be

-3% to +0.4% by 2050 relative to 2003 (Ouraich and Tyner, 2018). In MENA countries, approx. 10-13 % of GDP loss in MENA are projected for an increase in global mean temperature of 4.8°C in 2100 (Kompas et al., 2018). In southern Europe, mean labour productivity loss would shrink by approx. 2% under 2°C warming, along with a GDP loss of 0.1% in 2030s, reaching 0.4% in the 2080s (Szewczyk et al., 2018).

Freshwater resources are vulnerable to climate change and growing demand, notably from agriculture (Section 4.1.3; Gudmundsson et al., 2017; Zabalza-Martínez et al., 2018; Masseroni et al., 2020). The share of GDP and population exposed to high or very high water stress in MENA countries are 71% and 61%, respectively, compared to 22% and 36% in the world (World Bank, 2018). Freshwater resources are also vulnerable to sea-level rise and associated salinization (Ali and El-Magd, 2016; Wassef and Schüttrumpf, 2016; Twining-Ward et al., 2018). Due to the impact of climate change on water supplies (-14% to -6%), MENA countries are projected to experience high losses in GDP by 2050 (World Bank, 2016).

The agricultural sector is important for most Mediterranean economies, both in terms of GDP and employment, with its share of the total GDP in the region at 6.7% in 2016 (Kutiel, 2019). Water stress in southern countries is largely driven by growing demand from agriculture, with a potential water deficit of 28-47% in 2030 (Sebri, 2017). In Spain, eleven out of fifteen river basin districts are under water stress due to demand from agriculture (Vargas and Paneque, 2019). In Greece, the largest agricultural region (Thessaly) where 70% of the irrigation water comes from groundwater, is under water stress (Gemitzi and Lakshmi, 2018). Water scarcity and high dependence on rain-fed agriculture make MENA countries vulnerable to warming and reduced rainfall, associated with high irrigation requirements (Dhehibi et al., 2015; Fader et al., 2016; World Bank, 2016; Asseng et al., 2018; World Bank, 2018), exacerbated by poverty and political instability (Price, 2017). For cropping systems in MENA countries, the Nile Valley and the western parts of North Africa on the Atlas Mountains are classified as the areas with highest vulnerability (ESCWA, 2017).

As MENA countries are net food importers, they are not only vulnerable to climate change on food production in the Mediterranean region, but also by the climate impacts on food production elsewhere, e.g. in China and Russia (Waha et al., 2017). The agri-food sector in the Mediterranean region is also important for global food security because several large producing countries in the region, such as France, Italy and Morocco, are net exporters of many essential micronutrients to low and lower-middle income countries. Changing quantity and quality of production would have direct (availability) and indirect (price signals) impacts on their trade partners.

The economic value of fisheries in the Mediterranean Sea is over 3.4 billion USD (Randone et al., 2017) with about 76250 fishing vessels in 2019 (FAO, 2020), most of them (about 62%) in the eastern and central Mediterranean (FAO, 2018). Total employment on-board fishing vessels is 202,000 and six countries, i.e. Tunisia, Algeria, Turkey, Italy, Greece and Egypt, account for approximately 82 percent of total employment (FAO, 2020). About 78% of the fish stocks in the Mediterranean are currently fished at unsustainable levels (Galli et al., 2015). The share of stocks in overexploitation has decreased from 88% in 2012 to 75% in 2018 (FAO, 2020). Nearly half of the catches consist of small pelagic species (anchovies, sardines, herrings), which are very vulnerable to increased seawater temperatures (FAOSTAT, 2019). Turkey is particularly sensitive to climate change in the fisheries sector (Turan et al., 2016; Hidalgo et al., 2018). Fisheries in northern countries are less vulnerable because they have a greater capacity to adapt (i.e. more assets, flexibility, learning potential, and social organization), while southern countries are more vulnerable (Ding et al., 2017). The reduction of fish availability directly impacts the income of employees, e.g. in the Italian fisheries industry (Tulone et al., 2019).

Mediterranean forests are diverse and play a major ecological and social role through significant ecosystem services, including wood, but also the recreational value and production of non-wood goods such as mushrooms (Ding et al., 2016; Peñuelas et al., 2017; Gauquelin et al., 2018; Herrero et al., 2019). Many forests grow at the dry margin of their distribution area, therefore projected drier conditions will affect their productivity and health (Doblas-Miranda et al., 2017; Dorado-Liñán et al., 2019; Sangüesa-Barreda et al., 2019). Vulnerability to wildfire is a significant matter of concern, particularly in the northern and south-western Mediterranean region (Ager et al., 2014; Gomes da Costa et al., 2020). In Córdoba (Spain), for example, fire suppression costs have increased by 66-87% in the last decade (Molina et al., 2019).

The Mediterranean region accounts for one third of global tourism with 330 million tourists in 2016 (Tovar-Sánchez et al., 2019). Before the COVID-19 crisis, international tourist arrivals were assumed to increase by 60% between 2015 and 2030 and reach 500 million then. In 2015, tourism supported 15% of the total employment in the region (Randone et al., 2017). France, Spain, Italy and Greece are the top tourist destinations (UNWTO, 2016), but the highest growth was in Turkey, Croatia and Albania during 1995-2015 (MGI, 2017). The tourism industry is vulnerable to climate change, particularly in low income countries (Dogru et al., 2016; Dogru et al., 2019). Coastal tourism in the region generates 300 billion USD annually followed by marine tourism (110 billion USD) (Radhouane, 2013; Randone et al., 2017).

By providing around 550,000 jobs in the Mediterranean region, the maritime transport and trade industry comprises approximately 20-40% of GDP. As a hub for trade, the Mediterranean, with approximately 600 ports of different sizes, accounts for 25% of all international seaborne trade, including 22% of its oil trade. In the region, the shift to green energy to combat climate change would significantly influence the structure of foreign trade in terms of commodities and maritime energy transport flows (Manoli, 2021).

CCP4.2.3 Social and Human Vulnerability

With population growth, food demand in the region increases and will continue to do so, while regional food production on land and from the sea is threatened by climate change, creating the need for additional import. In MENA countries, livestock production has increased by 25% in 1993-2013, causing animal feed imports to increase to about 32% of the total food import in 2014 (FAO, 2018), thereby increasing food-import dependence of southern countries (INRA, 2015; Saladini et al., 2018). Sharp increases in international food prices since 2007 have caused inflation, trade deficits, fiscal pressure, increased poverty as well as political instability, all affecting food supply, notably in the South and East of the region (Harrigan, 2011; Kamrava and Babar, 2012; Ferragina and Canitano, 2015; Paciello, 2015).

Heat waves and other climatic extremes affect densely populated urban centres and coastal regions, causing health risks for vulnerable groups, in particular those who live in poverty with substandard housing (Paz et al., 2016; Scortichini et al., 2018; Rohat et al., 2019). Nights with temperatures higher than 23°C have been increase health risks (Royé, 2017). Human health is also vulnerable to other risks altered by climate change, either directly through droughts, floods, fires etc., or indirectly through impacts on disease vectors, air pollution, water quality, and food security (Negev et al., 2015). Cases of dengue fever were recently reported from several countries, and there is an apparent threat of outbreaks transmitted by *Aedes* mosquitoes in the northern Mediterranean (Semenza et al., 2016; Semenza and Suk, 2017). The most vulnerable to climate impacts are the elderly, pregnant women, children, the chronically ill, the obese and people with cognitive impairment (Linares et al., 2015; Paravantis et al., 2017).

One third of the Mediterranean population (about 150 million people) currently lives close to the sea, often in growing urban regions and with infrastructure vulnerable to sea-level rise (Cross-Chapter Box SLR in Chapter 3; Briche et al., 2016; UN DESA, 2017). Future exposure to sea-level rise is related to demographic growth. All Shared Socio-Economic Pathways (SSP) project an increase of coastal population in the Mediterranean region to 2050. By 2100, coastal population could grow by up to 130%, mostly in the south, but it could also drop by 20% for SSP1 (Reimann et al., 2018b). Overall, countries in the South-Eastern Mediterranean are most vulnerable to coastal risks, but the exposure is also high in the Northern Mediterranean (Satta et al., 2017).

In terms of the number of people, Egypt, Libya, Morocco and Tunisia are the most exposed countries to sea-level rise (World Bank, 2014), and this difference is projected to increase under SSP2-4 (Reimann et al., 2018a). Among MENA countries, Egypt is particularly exposed with several coastal cities at risk of inundation (Frihy et al., 2010; Solyman and Abdel Monem, 2020; Elshinnawy and Almaliki, 2021). In the Nile Delta, between 1500 and 2600 km^2 of land are projected to be exposed to flooding by 2100 by a sea-level rise of 0.75 m (median sea-level rise scenario for SSP5-85) and additional subsidence up to 0.25 m, threatening around 6.3 million residents (Figure CCP4.6; Ali and El-Magd, 2016; Solyman and Abdel Monem, 2020). Basin-wide economic losses are estimated at US$5 billion assuming a rise of sea levels by 1.26 m in 2100 (Frihy et al., 2010; World Bank, 2014).

The Mediterranean area is characterized by high human mobility, mostly within countries but also between them (Cross-Chapter Box MIGRATE in Chapter 7; Charef and Doraï, 2016; Ben Youssef et al., 2017). In 2017, the value of remittances from migrants was about 16% of southern Mediterranean countries' exports to the EU (Alcidi et al., 2019). Impacts of recent climate change, notably drought and their effects on human livelihoods and vulnerability, may have contributed to migration decisions, although there is debate about the relative importance (Kelley et al., 2015; Fröhlich, 2016; Hamed et al., 2018; Ash and Obradovich, 2020). One study of five MENA countries estimated that extreme climate events account for about 10 to 20 % of migration, with an expected increase of the role of environmental factors in the future as climatic conditions deteriorate further (Wodon et al., 2014).

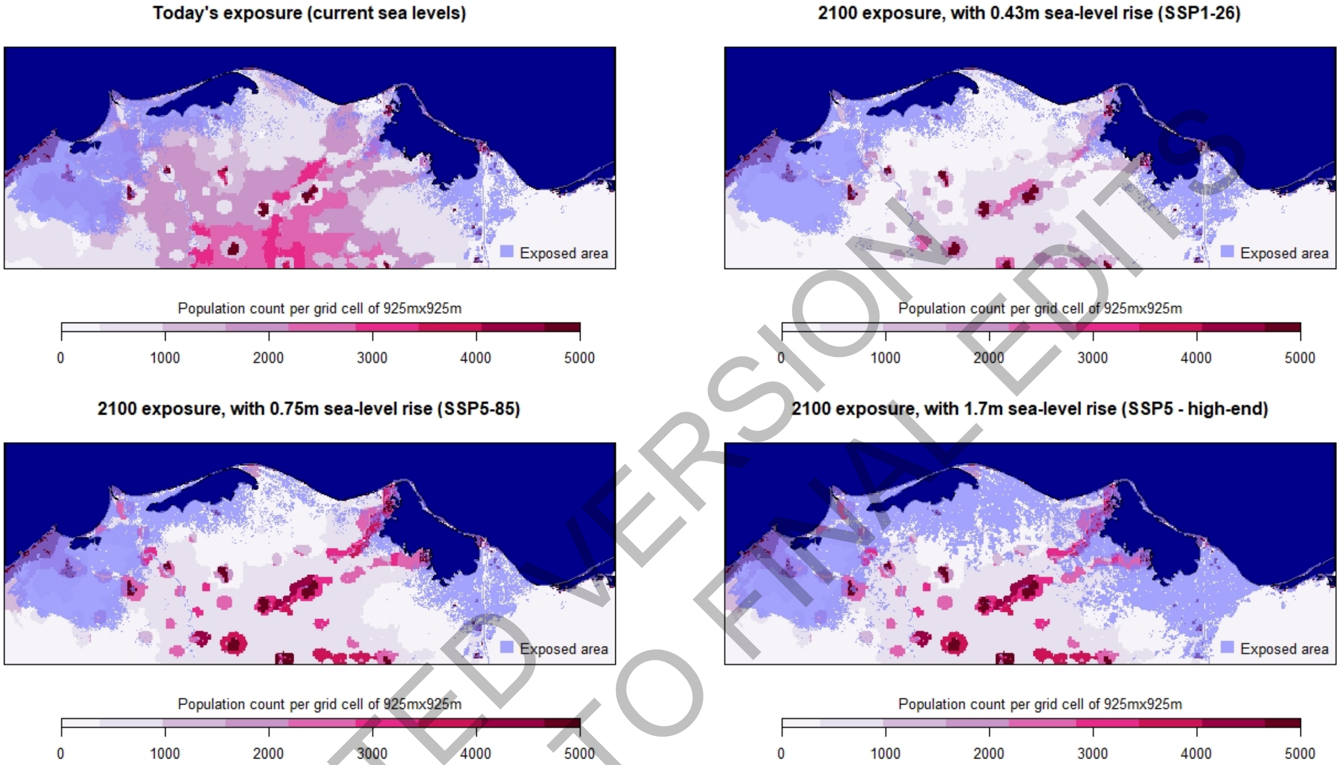

Figure CCP4.6: Present-day and projected exposure to sea-level rise in the Nile delta, due to sea-level change and land subsidence. A: Current exposure; B: Exposure for 2°C of global warming by 2100; C: Exposure for 3°C of global warming by 2100; D: Exposure for a high-end sea-level rise scenario involving additional mass losses from Antarctica ice-sheet (Frihy et al., 2010; Ali and El-Magd, 2016; Kulp and Strauss, 2019); sea-level scenarios from AR6-WG1-Ch9; see supplementary material for additional details.

Improved sharing and co-production of knowledge can support climate adaptation practices, ensure their implementation, and thereby reduce vulnerability (Nguyen et al., 2019), e.g. in the water sector (Iglesias and Garrote, 2015; Iglesias et al., 2018) and notably river management (Tàbara et al., 2018). The individual perception of climate risks is also a component of vulnerability (Nguyen et al., 2016). Understanding the gap between perceptions and scientific evidence, and increasing risk perception and awareness, will be crucial to promote adaptive responses both at the individual and the collective level throughout the Mediterranean Basin (Macias et al., 2015; Bodoque et al., 2016; Cramer et al., 2018).

CCP4.3 Projected Climate Risks in the Mediterranean Basin

CCP4.3.1 Ocean Systems

With warming, marine primary production is projected to decrease in the western and increase in the eastern Mediterranean Sea (Macias et al., 2015). The diversity of copepods (species which dominate the meso-zooplankton communities feeding Mediterranean fishes) is projected to decline over most of the Mediterranean, albeit with regional variation (Benedetti et al., 2018). Total marine biomass (and fishery potential) is projected to increase in the south-eastern Mediterranean, whereas significant decreases are most likely in the west (Moullec et al., 2019). The projected increase of marine heat waves in the Mediterranean Sea will add additional pressures on coastal and marine ecosystems. Warm-water fish species are expected to move northwards, while cold-water species will decline, and invasions of thermal-tolerant tropical species will increase (*high confidence*) (Lloret et al., 2015; Corrales et al., 2018). Fish species richness is predicted to increase in the eastern and decrease in the western Mediterranean by 2050, but by 2100 the cooler areas in the North will become a 'cul-de-sac' for many species (Albouy et al., 2013; Burrows et al., 2014). Out of 75 endemic fish species, 14 are projected to go extinct, almost all of them benthic and demersal species (Ben Rais Lasram et al., 2010). The abundance of small and medium-sized pelagic fish (e.g. European anchovy) is projected to decline by 15-33% by 2100 (Stergiou et al., 2016; Raybaud et al., 2017).

Heat waves will *likely* cause increasing mass mortality events of benthic species, mostly invertebrate organisms such as corals, sponges, bivalves, ascidians and bryozoans, increasing the risks of abrupt collapse of endemic species (Kersting et al., 2013; Rivetti et al., 2014; Rivetti et al., 2017; Garrabou et al., 2019; Garrabou et al., 2021). Deep water corals live near their upper thermal tolerance and further warming can thus reduce their biotic potential and long-term survival (Brooke et al., 2013; Nannini et al., 2015; Yasuhara and Danovaro, 2016; Marchini et al., 2019), although there are some exceptions (Naumann et al., 2013) and also knowledge gaps (Maier et al., 2019). Warming has been shown to severely reduce the metabolism of some Mediterranean coral species (Gori et al., 2016). In summary, the observed shift in marine ecosystems observed since 1980 is projected to continue and intensify, resulting in very high risks for marine ecosystems between 1.5°C to 2°C GWL (Figure CCP4.8; Chapter 3, 13 and CCP1; Manes et al., 2021).

CCP4.3.2 Coastal Systems

Sea-level rise is at the origin of multiple risks for low-lying areas in the Mediterranean Basin, such as the further increase in flooding at high-tide in some locations such as Venice (*high confidence*) (AR6 WGII Chapter 13;Cid et al., 2016; Pomaro et al., 2017). Currently, 37% of coastal areas are at moderate to high risk from coastal erosion and flooding (Satta et al., 2017). Due to rapid urban development, many coastal assets are directly exposed to projected sea-level rise and coastal hazards, with limited adaptation options and resilience of beaches (Section CCP4.2;Brown et al., 2016; Jiménez et al., 2017).

The Mediterranean is a micro-tidal sea, where storms may hit the coast during several hours or longer and and not only during high tides (Le Cozannet et al., 2015; Sánchez-Arcilla et al., 2016; Sierra et al., 2016; Sayol and Marcos, 2018). Projected changes of winds, storms and waves are small, and confidence in these changes is limited by the quality of climate models applied to the Mediterranean (Calafat et al., 2014; Androulidakis et al., 2015; Vousdoukas et al., 2017). Overall, sea-level rise is projected to increase the risk of coastal flooding despite the potential slight reductions of marine storms (*high confidence*) (Lionello et al., 2017; Vousdoukas et al., 2017). Risks of erosion and flooding will be amplified with climate change, particularly in river deltas (Figure CCP4.6;Ali and El-Magd, 2016), on low-lying floodplains, on sandy beaches around the basin and in many coastal cities (Satta et al., 2017). Impacts are projected to increase non-linearly during the 21st century with higher sea-level rise, because coastal flooding will progressively change from overtopping to overflow, high-tide flooding and ultimately permanent flooding and shoreline retreat (*high confidence*) (Le Cozannet et al., 2015; Sánchez-Arcilla et al., 2016; Sierra et al., 2016; Antonioli et al., 2017; Anzidei et al., 2017; Ciro Aucelli et al., 2017; Enríquez et al., 2017; Jiménez et al., 2017; Sayol and Marcos, 2018). These risks may be amplified further in areas with poor storm water management and sealed urban surfaces (Llasat et al., 2013; Gaume et al., 2016).

Combined with storm surges, sea-level rise may disrupt Mediterranean port operations (Sánchez-Arcilla et al., 2016; Sierra et al., 2016), with risks depending on adaptation, physical protection measures and basin depth. Risks for deep ports are more limited (Sierra et al., 2017), while low-depth small harbours, common in the Mediterranean, could be significantly affected (Sierra et al., 2016). Sea-level rise may enhance sandy beach erosion and thereby impact recreation and tourism (Bitan and Zviely, 2018; Rizzetto, 2020), magnifying coastal degradation and pollution (Enríquez et al., 2017; Gössling et al., 2018).

CCP4.3.3 Inland Ecosystems

Beyond 3°C GWL, 13-30% of the Mediterranean Natura 2000 protected area and 15 to 23% of Natura 2000 sites are projected to change towards more arid ecosystem types (Barredo et al., 2016). Biodiversity and ecosystem services would be exposed to degradation of wetland hydrology, which could affect 19-32% of localities under a 1.5 to 2°C GWL (48-73% under higher warming), particularly in Spain, Portugal, Morocco and Algeria (Lefebvre et al., 2019) and a substantial shrinking of terrestrial and freshwater ecosystem habitats, in particular in Mediterranean islands (Chapters 2 and 4; CCP1).

Increased aridity impacts forest ecosystems (Costa-Saura et al., 2017; García Sánchez et al., 2018). Increasing heat waves, combined with drought and land-use change, reduce fuel moisture, thereby increasing fire risk, extending the duration of fire seasons and increasing the likelihood of large, severe fires (*high confidence*) (EEA, 2017; Lozano et al., 2017; Peñuelas et al., 2017; Varela et al., 2019). Fires impact vegetation recovery after abandonment, thus transforming landscapes (González-De Vega et al., 2016). At warming levels of 1.5°C, 2°C and 3°C, burnt area in Mediterranean Europe could increase by 40-54%, 62-87% and 96-187%, respectively (Turco et al., 2018b), although changes are highly site-dependant and also affected by management (Caon et al., 2014; Wu et al., 2015; Parra and Moreno, 2018; Brotons and Duane, 2019; Hinojosa et al., 2019).

Desertification occurs in large parts of the region, generally due to unsustainable land use (Peñuelas et al., 2017). Increasing drought is projected to exacerbate desertification in North Africa and, under high warming, also southern Spain. In some areas, sclerophyllous vegetation could replace deciduous forests (Guiot and Cramer, 2016). Increasing temperatures and drought could trigger dieback for some forest species such as Mediterranean oak (Sánchez-Salguero et al., 2020), potentially also in combination with biotic factors such as pathogens (Matías et al., 2019).

CCP4.3.4 Water, Agriculture and Food Production

River runoff and low flows are expected to decrease (possibly by 12-15% or more) in most locations due to reduced precipitation (Giuntoli et al., 2015; Roudier et al., 2016; Andrew and Sauquet, 2017; Gosling et al., 2017; Marchane et al., 2017; Marcos-Garcia et al., 2017; Marx et al., 2018; Yeste et al., 2021). Groundwater recharge is projected to decrease due to reduced recharge (AR6 WG1 Chapter 11; Koutroulis et al., 2016; Guyennon et al., 2017; Braca et al., 2019; Calvache et al., 2020). Water levels in lakes and availability of reservoirs are expected to decline by up to 45% in 2100 (Koutroulis et al., 2016; Masia et al., 2018; Okkan and Kirdemir, 2018; Braca et al., 2019; Tramblay et al., 2020). The largest freshwater lake in the basin, Lake Beyşehir (Turkey), could dry out after 2070 (Bucak et al., 2017). In northern Africa, surface water availability is projected to be reduced by 5-40% in 2030-2065 and by 7-55% in 2066-2095 from 1976-2005 (Tramblay et al., 2018), with decreases of runoff by 10-63% by mid-century in Morocco and Tunisia (Marchane et al., 2017; Dakhlaoui et al., 2020). Reduced summer river flows and increasing water temperatures will constrain freshwater-cooled thermoelectric (including nuclear) power plants and hydropower plants, with possible reductions of production in the northern Mediterranean by 6-33% under 2°C and by 20-60% beyond 3°C warming (Lobanova et al., 2016; Solaun and Cerdá, 2017; Payet-Burin et al., 2018; Tobin et al., 2018).These findings confirm the AR6 WG1 Chapter 8 statement that drought duration and frequencies and water scarcity are projected to increase drastically between 1.5°C and 2°C of GWLs.

Climate change will *likely* reduce crop yields in many areas (Table CCP4.1), mainly due to higher temperatures affecting crop phenology and the shortening of the crop growing season (*high confidence*). Additional irrigation will be needed for most crops, although the shortening of the growing season could reduce irrigation needs in some cases (Saadi et al., 2015). Irrigation needs could increase by 25% in northern and two-fold in south-eastern Mediterranean (Fader et al., 2016), with arid southern areas at risk of insufficient water resources by 2100. The use of supplemental irrigation for winter wheat could become more common in northern Mediterranean (Saadi et al., 2015; Ruiz-Ramos et al., 2018).

Seawater intrusion is projected to cause additional risks in coastal aquifers, with severe impacts on agricultural productivity (Ali and El-Magd, 2016; Wassef and Schüttrumpf, 2016; Pulido-Velazquez et al., 2018; Twining-Ward et al., 2018; Omran and Negm, 2020). While elevated atmospheric CO_2 concentration could be positive for photosynthesis and cereal yields (Dixit et al., 2018; Ben-Asher et al., 2019; Kapur et al., 2019; Kheir et al., 2019), the net outcome for agricultural production is highly uncertain (Moriondo et al., 2016). The projected yield losses will *likely* reduce farm revenues, e.g., in Morocco (Ouraich and Tyner, 2018), in Egypt (Abd El-Azeem, 2020), Greece (Georgopoulou et al., 2017) and Israel (Zelingher et al., 2019). Given the growing water demand from agriculture and other users and the increasing competition over water resources, adaptation efforts for water supply need to be enhanced (Guyennon et al., 2017; Zabalza-Martínez et al., 2018).

Table CCP4.1: Projected risks for crop production in the Mediterranean Basin

Crop	Projected risk
Cereals and rice	Under 2°C warming and beyond, rain-fed wheat yield in most locations could decline by 2-59%, depending on agricultural practices (Chourghal et al., 2016; Dettori et al., 2017; Iocola et al., 2017; Brouziyne et al., 2018; Kheir et al., 2019). Under 1.5-3°C warming and reduced rainfall, yield decreases are also projected for maize (Georgopoulou et al., 2017; Iocola et al., 2017) and barley (Bouregaa, 2019; Cammarano et al., 2019), mainly due to the shortening of the crop growing season by up to 30 days due to higher temperatures (Saadi et al., 2015; Bird et al., 2016; Waha et al., 2017; Bouregaa, 2019). In Tunisia, cereal production may decrease by 0.79% with a 1% decrease in precipitation (Zouabi and Peridy, 2015). Reductions of rice yields in parts of the region are projected in the absence of adaptation, e.g. by 6-20% in southern France and Italy in 2070 under RCP8.5 (Bregaglio et al., 2017).
Olives	Higher temperatures and more frequent extreme heat events around flowering will *likely* affect phenology. While suitable areas for olive cultivation could extend northward and to higher elevations under the A1B scenario in 2036-2065 (Tanasijevic et al., 2014), negative consequences for several countries are expected, including southern Spain (Gabaldón-Leal et al., 2017; Arenas-Castro et al., 2020) and Tunisia (Ouessar, 2017) under 2°C warming. Under 1.5-2°C GWL, olive yields in northern Mediterranean locations could decrease by up to 21% (Brilli et al., 2019; Fraga et al., 2020). A 3°C warming could cause a 15-64% drop of production of rain-fed olives in Algeria (Bouregaa, 2019).
Vegetables	Yields could decline by up to 45% under current irrigation in some areas by 2050 under the A1B scenario (Zhao et al., 2015; Georgopoulou et al., 2017), while a lower availability of irrigation water would lead to further losses (Saadi et al., 2015) or even to non-viability of crops in some locations, e.g., in Tunisia beyond 2°C warming (Bird et al., 2016).
Fruit trees	Flowering of many fruit trees may be delayed, and chilling accumulation may be threatened. In Spain, under the A2 scenario, apples at maturity could be of inferior quality from mid-century, while after 2070 28-72% of the years could have winters not fulfilling chilling requirements (Funes et al., 2016; Rodríguez et al., 2019) Similar threats for other fruit trees were found beyond 3°C GWL (Funes et al., 2016; Rodríguez et al., 2019).
Grapevines and orchards	Climate change could advance bud break and flowering, shortening the growing season by 20-35 days after 2060 under RCP8.5 (Fraga et al., 2016; Ramos, 2017; Leolini et al., 2018; Ramos et al., 2018) and shifting maturation under high summer temperatures, thus affecting grape quality. Higher temperatures may increase evapotranspiration and therefore water deficit (Ramos et al., 2018). Some locations may suffer from high winter temperatures, causing a lack of chilling accumulation and finally a missed bud-break (Leolini et al., 2018). Early maturation may result in unbalanced wine quality through higher sugar and lower acids in the grape must after 2050 under RCP8.5 (Fraga et al., 2016; Koufos et al., 2018). Negative impacts of climate change on table quality vines and wine grape production in southern Europe after 2040 under RCP8.5 have been projected (Cardell et al., 2019).
Dates	Irrigation requirements for date palms in Tunisia under RCP8.5 could increase by 34% in 2050 from present to sustain date production (Haj-Amor et al., 2020), with adverse effects on groundwater resources.

Climate-driven change in pelagic production (Section CCP4.3.1), together with overfishing, will *likely* increase risks for fishery landings (Hidalgo et al., 2018). By 2060, more than 20% of exploited fishes and invertebrates currently found in eastern Mediterranean could become locally extinct (Jones and Cheung, 2015; Cheung et al., 2016; Balzan et al., 2020). Thermophilic and/or thermal-tolerant tropical species may increasingly dominate the catch composition (Moullec et al., 2019), creating possible opportunities depending on technology and consumer acceptance of new species (Hidalgo et al., 2018). Warming and acidification may weaken mussel shells, negatively impacting shellfish aquaculture (Martinez et al., 2018). High losses of clawed lobster production by the end of the century are projected under RCP4.5 (Boavida-Portugal et al., 2018). For much of the region, fisheries revenue may decrease by 15-30% by 2050 relative to 2000 under RCP8.5 (Lam et al., 2016).

Overall, reduced crop yields and fishery landings, combined with other factors such as rapid population growth and urbanization, increasing competition for water, and changing lifestyles, will *likely* impact food security, particularly in North Africa and the Middle East (Jobbins and Henley, 2015).

CCP4.3.5 Human Health and Cultural Heritage

Warming is projected to impact human health, mostly through increased intensity, frequency and duration of heat waves (*high confidence*) (Guerreiro et al., 2018; Jacob et al., 2018; Rohat et al., 2019; Smid et al., 2019). Under current socio-economic conditions, 53-93 million more people could be exposed to high or very high heat stress in northern Mediterranean by 2050 (Gasparrini et al., 2017; Rohat et al., 2019) and heat-related excess mortality could increase by more than 6-fold above 3°C GWL (Gasparrini et al., 2017; Rohat et al., 2019). In MENA countries, the mortality risk of the elderly in 2100 could be 8-20 times higher under RCP8.5 compared to 1951-2005, and still 3-7 times higher under RCP4.5 (Ahmadalipour and Moradkhani, 2018). Deaths attributable to high temperatures in the northern Mediterranean could increase by 18-20,000 in 2050 (50,000 in 2100) under RCP8.5 (1.4 and 2.6 times lower under RCP4.5) (Kendrovski et al., 2017).

Climate change and variability may also influence the emergence of vector-, food- and water-borne diseases (Negev et al., 2015). Under RCP8.5, the epidemic potential of dengue fever in southern Europe is projected to increase by 2100 (Liu-Helmersson et al., 2019), as well as the risk of infections by West Nile virus in 2050 under A1B (Semenza et al., 2016). Climate-induced diseases could reduce labour productivity in the region by 2060, particularly in MENA countries (Dellink et al., 2019). Overall, there is still uncertainty in projections of the future severity and distribution of diseases because of climate change due to the complex interactions between hosts, pathogens and vectors. Reductions in fruit and vegetable consumption as a result of climate change on food availability could lead to more than 20,000 deaths in 2050 under RCP8.5 from diseases caused by malnutrition (Springmann et al., 2016).

Extreme high temperatures, hot days and nights and consequently cooling degree days will likely increase (*high confidence*) (Spinoni et al., 2018a; Coppola et al., 2021), with specific cooling needs in cities possibly increasing by 50-278% under 2°C GWL and 134-375% beyond 3°C GWL (Cellura et al., 2018). Urban heat island effects will further increase cooling needs (Salvati et al., 2017; Zinzi and Carnielo, 2017). Higher temperatures will increase thermal and chemical stress on materials used in many ancient buildings and sculptures, such as marble, stone and masonry (Bonazza et al., 2009; Leissner et al., 2015).

Many studies project a decrease of climatic comfort for tourism in the Mediterranean by 2071 to 2100, particularly during summer (Grillakis et al., 2016; Jacob et al., 2018; Braki and Anagnostopoulou, 2019). There is adaptive potential in the extension of the period with favourable climatic conditions for urban tourism in Mediterranean cities (Scott et al., 2016). Water scarcity may create additional constraints for tourism (Köberl et al., 2016).

Cultural heritage sites in the region face risks from coastal flooding, with 37 out of 49 cultural World Heritage Sites today facing risk from a 100-year flood, and 42 of them from coastal erosion (Reimann et al., 2018b). Sea-level rise will increase these risks (*high confidence*) (Lionello, 2012; Rizzi et al., 2017; Reimann et al., 2018b; Ravanelli et al., 2019; Tagliapietra et al., 2019). By 2100, 47 of the 49 UNESCO sites are projected to be at risk from coastal flooding or erosion (Reimann et al., 2018b). Beyond 2100, sea levels are committed to rise further and represent an existential threat for the high number of coastal cultural heritage located in the Mediterranean (AR6 WGI Chapter 9; Chapter 13; Cross-Chapter Box SLR in Chapter 3; Marzeion and Levermann, 2014).

CCP4.3.6 Synthesis of Key Risks

For the Mediterranean Basin, all currently projected pathways of climate change will exacerbate climate-related risks in multiple systems and economic sectors, and for human health and well-being, amplifying current pressures on local ecosystems, economies and human well-being (Figures CCP4.7 and CCP4.8; Cramer et al., 2018; MedECC, 2020). While the majority of these risks apply across the entire region, many are specific for certain sub-regions or locations.

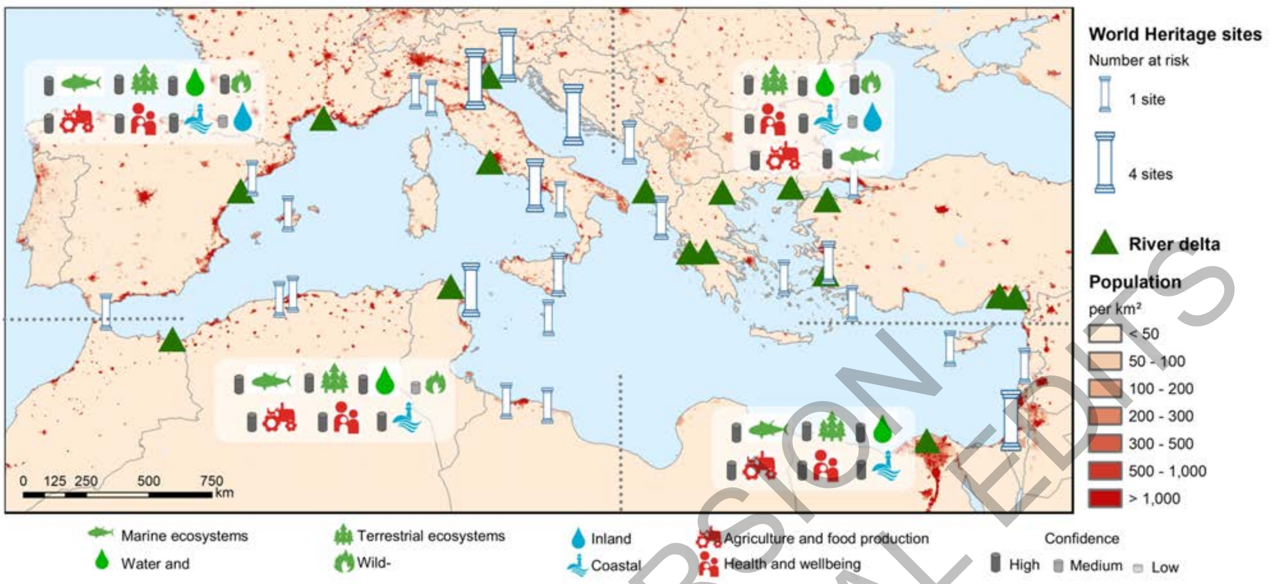

Figure CCP4.7: Key risks in the Mediterranean and their location for SSP5-RCP8.5 by 2100 across the Mediterranean region for SSP5-RCP8.5 by 2100 (Sections CCP4.3.2-6 and Table SMCCP4.2a & b for details). Risks to world cultural heritage sites from flooding or erosion due to sea-level rise in multiple locations (section CCP4.3.5) and Mediterranean river deltas are hotspots of vulnerability to climate change (Section CCP4.3.2). The population exposed to risks is mapped for an SSP5-8.5 pathway. Adaptation can reduce these risks (Section CCP4.4) (based on: Reimann et al., 2018a; Reimann et al., 2018b; Wolff et al., 2018).

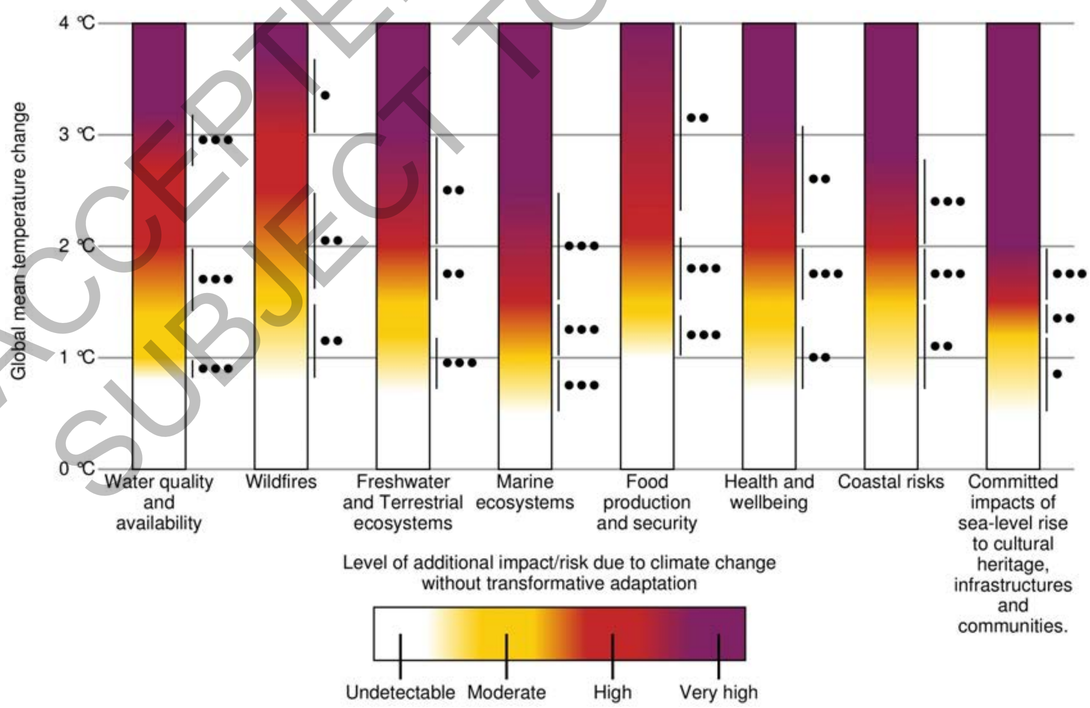

Figure CCP4.8: Summary of key risks for the Mediterranean (Sections CCP4.3.2-8 and Supplementary Tables SMCCP4.2a-h for details). Coastal risks include one burning ember displaying additional risks due to climate change as specific GWL are exceeded (Coastal risks), and one burning ember describing additional risks due to committed sea-level rise at timescales of centuries and millennia for long living infrastructure and cultural heritage (AR6 WGI Chapter 9; Marzeion et al., 2014; Marzeion and Levermann, 2014; Clark et al., 2016; see SMCCP4.2h).

CCP4.4 Adaptation and Sustainable Development in the Mediterranean Basin

CCP4.4.1 Ocean and Coastal Systems

Adaptation options for climate change impacts on marine ecosystems and fisheries include improving and enlarging the regional network of marine protected areas, transnational management of marine food resources, sustainable fishery practices, developing collaborative monitoring, research and managing knowledge platforms for fisheries (Bjørkan et al., 2020; Raicevich et al., 2020) and sustainable aquaculture (Ehlers, 2016; Lacroix, 2016).

Adaptation options to sea-level rise in the Mediterranean include nature-based solutions, such as beach and shore nourishment, dune restoration, or ecosystem-based adaptation and restoration in low-lying coasts, lagoons, estuaries and delta (Aragonés et al., 2015; Aspe et al., 2016; Loizidou et al., 2016; Danovaro et al., 2018). Engineering plays a major role for coastal adaptation too, through breakwaters, seawalls, dykes, surge barriers and submerged breakwaters (Sancho-García et al., 2013; Becchi et al., 2014; Balouin et al., 2015; Masria et al., 2015; Tsoukala et al., 2015; Bouvier et al., 2017). Many engineering-based coastal adaptation imply large residual impacts to coastal ecosystems (*high confidence*) (Micheli et al., 2013; Masria et al., 2015; Cooper et al., 2016; Bonnici et al., 2018). A sea surface height control dam at the Strait of Gibraltar has been proposed for mitigating sea-level rise in the Mediterranean, but this would *likely* involve major impacts on ecosystems and fisheries (Gower, 2015).

CCP4.4.2 Inland Ecosystems

In forests, adaptation to impacts of warming and drought may involve multiple forest management strategies such as thinning (Fernández-de-Uña et al., 2015; Giuggiola et al., 2016; Aldea et al., 2017; del Río et al., 2017; Gleason et al., 2017; Lechuga et al., 2017; Vilà-Cabrera et al., 2018), increasing the share of drought-tolerant species and provenances (Hlásny et al., 2014; Calvo et al., 2016), or promoting mixed-species stands (Ruiz-Benito et al., 2014; Guyot et al., 2016; Sánchez-Pinillos et al., 2016; del Río et al., 2017; Jactel et al., 2017; Ratcliffe et al., 2017).

Adaptation options to increased fire risks include improved planning of residential development such as to avoid inevitable wildfire (Schoennagel et al., 2017; Samara et al., 2018), improved fire suppression capacities and strategies (Brotons et al., 2013; Regos et al., 2014; Khabarov et al., 2016; Turco et al., 2018a; Turco et al., 2018b), managing and planning landscape matrix schemes to reduce fire risk (de Rigo et al., 2017; Erdős et al., 2018), thinning, slash management and prescribed burning techniques (Fernandes et al., 2016; Khabarov et al., 2016; Regos et al., 2016; Fernandes, 2018; Piqué and Domènech, 2018; Samara et al., 2018; Vilà-Cabrera et al., 2018; Duane et al., 2019), as well as understory grazing (Varga et al., 2016; Vilà-Cabrera et al., 2018).

Adaptation of forest management generally requires improved monitoring systems of forest condition and natural disturbances (Hlásny et al., 2014; Hengeveld et al., 2015; Maes et al., 2015), supported by participatory forest management and planning processes and local self-governance mechanisms (Bouriaud et al., 2013; Bouriaud et al., 2015).

For freshwater ecosystems, adaptation options include hydrological and land use planning at basin scale, which can be complemented with local conservation and restoration efforts, and the preservation of natural flow variability of rivers and streams (Aspe et al., 2016; Loizidou et al., 2016; Cid et al., 2017; Menció and Boix, 2018; Morant et al., 2020).

CCP4.4.3 Water Management, Agriculture and Food Security

Adaptation options to address water shortages at the national scale include transboundary resource management (Escriva-Bou et al., 2017; Pulido-Velazquez et al., 2018), promoting fair, equitable and sustainable water trade in international markets (Johansson et al., 2016; Lee et al., 2019), regional, national and basin-scale management plans for water resources (Wilhite et al., 2014; Paneque, 2015; Urquijo et al., 2015; Estrela and Sancho, 2016; Vargas and Paneque, 2019), improved groundwater monitoring and strategic management (Pulido-Velazquez et al., 2020) and economic instruments to manage water demand (prices policies, markets and subsidies).

Technical options include the reduction of losses in water distribution networks for drinking water and irrigation (Burak and Margat, 2016; Fader et al., 2016), desalinization, often combined with generation of electricity (Papanicolas et al., 2016; Bonanos et al., 2017; Jones et al., 2019), artificial recharge of groundwater and subterranean dams (Djuma et al., 2017; De Giglio et al., 2018; Missimer and Maliva, 2018; Baena-Ruiz et al., 2020), and waste water reuse (Kalavrouziotis et al., 2015; Barba-Suñol et al., 2018; Cherfouh et al., 2018). On the demand side, options include changing diet and water consumption patterns (Blas et al., 2016; Gul et al., 2017; Blas et al., 2018) and enhancing water use efficiency in the tourism and food sector (Hadjikakou et al., 2013; Moresi, 2014).

In the agriculture sector improved efficiency of irrigation practices can be achieved by changing surface water irrigation for other techniques and shifting to more sustainable practices (Mrabet et al., 2012; Benlhabib et al., 2014; Boari et al., 2015; Ćosić et al., 2015; Guilherme et al., 2015; Iglesias and Garrote, 2015; Cantore et al., 2016; Triberti et al., 2016; AbdAllah et al., 2018; Billen et al., 2018; Iglesias et al., 2018; Malek and Verburg, 2018; Vargas and Paneque, 2019). Overall, the region could save 35% of water resources by improved irrigation techniques (Fader et al., 2016). However, maladaptive drip irrigation subsidies and developments can also result in the unsustainable use of groundwater resources and excessive agriculture intensification, indicating the need for careful strategic planning, regulation and monitoring of these options (Venot et al., 2017). In the livestock sector, adaptation options for heat wave-induced mortality of animals include the choice of more resistant genetic provenances (Rojas-Downing et al., 2017).

Other adaptation options in the agricultural sector include agroecological techniques that increase the water retention capacity of soils (mulching, zero tillage, reduced tillage etc.) (Aguilera et al., 2013a; Aguilera et al., 2013b; Almagro et al., 2016; Sanz-Cobena et al., 2017; Tomaz et al., 2017; Bhakta et al., 2019; García-Tejero et al., 2020) and promoting crop diversification, adapting the crop calendar, and the use of new varieties adapted to evolving conditions. Many of these strategies for more sustainable production are also intended to address the food security risks and import dependence in the region. Other options are to manage nitrogen resources, food demand, change diets and reduce food waste (Billen et al., 2018; Schils et al., 2018; Billen et al., 2019; Garnier et al., 2019; Aguilera et al., 2020; Lassaletta et al., 2021).

CCP4.4.4 Human Health

In the Mediterranean region, adapting to increasing heat wave impacts involves local urban health adaptation plans, as well as increasing the capacity of the healthcare systems (Fernandez Milan and Creutzig, 2015; Larsen, 2015; Paz et al., 2016; Liotta et al., 2018; Reckien et al., 2018; Tsiros et al., 2018). Local urban adaptation strategies need to be integrative and address the housing and infrastructure, the increase and design of urban green areas, the education and awareness-raising of the most vulnerable communities, the implementation of early warning systems for extreme events and the surveillance of climate-change induced diseases, the strengthening of local emergency and healthcare services, and the general strengthening adaptive capacity of the community and of the local institutions.

CCP4.4.5 Limits to Adaptation, Equity and Climate Justice

There is low confidence that the Mediterranean region can adapt to rapid sea-level rise for the case of rapid Antarctic ice-sheets collapse, even in regions with high capabilities to adapt such as the northwest Mediterranean (Poumadère et al., 2008). Residual coastal risks are still largely unquantified. For moderate levels of sea-level rise, it is *unlikely* that these changes alone exceed the technical limits to coastal adaptation over the 21st century (Hinkel et al., 2018). Beyond 2100, continued sea-level rise may require managed retreat in low-lying Mediterranean areas, particularly in deltas area such as the Nile (Figure CCP4.6). There is little knowledge on the potential for adaptation at these timescales.

Regional adaptation initiatives occur in a highly asymmetric geographic context characterized by contrasting demographic, environmental and socioeconomic trends in the southern, eastern and northern parts of the Mediterranean Basin (Pausas and Fernández-Muñoz, 2012). Adaptation plans in Mediterranean countries are also limited by a lack of effective regional governance schemes (with the partial exception of European countries subjected to the European directives and strategies), hampering the effective implementation of regionally harmonized adaptation strategies, plans and quantitative targets (UNEP/MAP, 2016; Sachs et al., 2019). Adaptation to sea-level rise is essentially limited by social barriers along urban coasts in the northwest Mediterranean at present (Hinkel et al., 2018), while the adaptation dilemma involving economic and financial barriers are greater in peri-urban, rural and natural areas, as well as in the southern and eastern Mediterranean. In addition, limited regional monitoring of risks and adaptation options hampers adaptation in domains and sectors (Cramer et al., 2018).

In the Mediterranean region, vulnerability is strongly affected by equity: people most vulnerable to the effects of climate change are the elderly, especially women (Iñiguez et al., 2016; Achebak et al., 2018) and children, who are often strongly affected by climate change (Watts et al., 2019). An increase of heat waves poses a significant health risk especially for young children living in urban areas (UNICEF, 2014; Perera, 2017; Royé, 2017) and for elderly women, in particular those affected by other conditions such as respiratory diseases (Sellers, 2016; Achebak et al., 2018). Children and future generations in the eastern Mediterranean countries are those most at risk of food insecurity, in both quantity and quality (Prosperi et al., 2014). In the region many children are particularly vulnerable due to scarcity of drinking water and food, aggravated by droughts and flooding (Philipsborn and Chan, 2018). The potential for adaptation and preparation to vector-borne diseases and other health risks, expected to increase with climate change, differs among Mediterranean countries (Negev et al., 2015). Climate change in the Mediterranean region also impacts some groups disproportionately (e.g. poor farmers, urban migrants, seasonal workers) and livelihoods (Waha et al., 2017), favouring mobility and migration (Nori and Farinella, 2020).

To safeguard the rights of the most vulnerable people in the Mediterranean region, climate adaptation plans and measures must be designed by taking into account the cost of adaptation (Watts et al., 2019) and also that some adaptation options can have side and residual effects, by favouring some countries/groups over others. Climate-just adaptation options are those that promote fair solutions for all and take into account region-specific socio-economic and geopolitical variabilities and vulnerabilities, such as the lack of inclusive and participatory approaches (Iglesias and Garrote, 2015) and pre-existing vulnerabilities, as in the case of Palestine (Jarrar, 2015) and Syria (Gleick, 2014).

CCP4.4.6 Pathways for Sustainable Development

Climate-resilient sustainable development pathways are trajectories that combine adaptation and mitigation to realize the goal of sustainable development through iterative, continually evolving socioecological processes (Chapters 1, 18; Denton et al., 2014). Transformative adaptation can be promoted through social and political processes, identifying the enabling conditions and strategies that facilitate structural changes (UNEP/MAP, 2016; Ramieri et al., 2018; EC, 2020; UNEP/MAP and Plan Bleu, 2020). Among the main options is the ongoing structural change in the renewable energy system in this region, the production of renewable biological resources, measures towards increased water irrigation efficiency, for behavioural changes in multiple sectors, and improved regional governance (Table CCP4.2;Cramer et al., 2018).

Table CCP4.2: Transformative adaptation and mitigation options for climate resilient sustainable development in the Mediterranean Basin

Code	Sector	Transformative option	References
T1	Energy, transport and tourism	National plans and regulations to decarbonise fuel sources and electricity grids on the supply side, for reducing energy demand and increasing efficiency and converting transport systems from fossil fuels to electricity	UNEP/MAP (2016); Bastianin et al. (2017); EEA (2018a); EEA (2018b); OME (2018); CMI and EC (2019); EEA (2019); Sachs et al. (2019); EC, (2020); Simionescu et al. (2020)
T2	Energy	Deployment of large-scale Mediterranean transboundary renewable energy infrastructures and interconnections. Transboundary energy market integration schemes.	EIB and IRENA (2015); Tagliapietra (2018); CMI and EC (2019); Zappa et al. (2019); CMI and EC (2020)

T3	Energy	Definition of "Important Projects of Common European Interest" (IPCEI) pooling financial resources and funding large-scale innovation projects across borders in the Mediterranean. Green hydrogen projects in Mediterranean North Africa (especially Morocco) have already been suggested as strategic actions.	CMI and EC (2019); CMI and EC (2020)
T4	Energy-Finance	EU Renewable Energy Financing Mechanisms including calls for proposals to new renewable energy projects, including joint projects with third Mediterranean countries, joint support schemes, innovative technology projects or other projects that contribute to the enabling framework of the Renewable Directive 2018/2001. The mechanism can provide resources from payments by Member States, European Union funds (European Green Deal Investment Plan, the Sustainable Finance Strategy, the Just Transition Fund, Connecting Europe Facility) or private sector contributions.	CMI and EC (2019); CMI and EC (2020)
T5	Water	Improving efficiency of irrigation practices, including changing surface water irrigation for other techniques, use of remote sensing in intensive agriculture, optimization of irrigation practices and other approaches. The Mediterranean region could save 35% of water by implementing improved irrigation techniques	Iglesias et al. (2011); Boari et al. (2015); Ćosić et al. (2015); Dhehibi et al. (2015); Guilherme et al. (2015); Iglesias and Garrote (2015); Cantore et al. (2016); Fader et al. (2016); Iglesias et al. (2017); Kang et al. (2017); AbdAllah et al. (2018); Iglesias et al. (2018); Malek and Verburg (2018); Vargas and Paneque (2019)
T6	Water	Improvement of water resource availability and quality. Desalinization and co-generation of electricity and potable water in integrated Concentration Solar Power (CSP) plants. Reduce climate impacts on nitrate and other pollutant concentrations through improved agriculture and fertilizer management	Abufayed and El-Ghuel (2001); Elimelech and Phillip (2011); Aguilera et al. (2015); Papanicolas et al. (2016); Bonanos et al. (2017); Cramer et al. (2018); Jones et al. (2019); Lange (2019)
T7	Water	Reduce/control water demand and use through efficiency management and/or modernization in irrigation	Sanchis-Ibor et al. (2016); UNEP/MAP (2016)
T8	Water	Water demand management. Behavioural shifts in consumption and diet choice. Diet type influences the amount of water needed to produce and process food. Food waste implies the waste of the water used in the production cycle.	Blas et al. (2016); Gul et al. (2017); Blas et al. (2018)
T9	Water	Adaptation by increasing water trade in international markets (commodity markets)	Antonelli et al. (2012); Hoekstra and Mekonnen (2012); Johansson et al. (2016); Lee et al. (2019)
T10	Food and fisheries	Changing diets, managing food demand and reducing food waste. Reductions in the demand for livestock products	Bajželj et al. (2014); Havlík et al. (2014); Tilman and Clark (2014); Westhoek et al. (2014); Herrero et al. (2016); van Sluisveld et al. (2016)
T11	Food and fisheries	Shift to more sustainable fishery practices. Collaborative monitoring, research and managing knowledge platforms	Bjørkan et al. (2020); Raicevich et al. (2020)

T12	Human conflict, displacement, migration and security	Implementation of more effective Mediterranean regional policies and institutional frameworks for human rights protection, management of transboundary human migration, resolution of political and armed conflicts, increased internal displacements, and food security	UNEP/MAP (2016)
T13	Finance	Enhanced Mediterranean transnational governance and financial bilateral and multilateral capacity. Increased finance for regional cooperation and development (above current levels, 8300 million US$ yr^{-1}).	UNEP/MAP (2016); Midgley et al. (2018); Fosse et al. (2019)
T14	Coastal	Nature based solutions aiming at reducing future coastal risks by restoring a buffer zone in coastal areas (e.g., through managed realignment), leaving space for sediments and coastal ecosystems, thus reducing the hazard and exposure to coastal flooding and erosion.	Pranzini et al. (2015)

There also are risks for non-linear climate change impacts in key socioeconomic and environmental processes, which could promote reactive changes and forced transformations (Table CCP4.3).

Table CCP4.3: Non-linear processes that could force reactive changes and social transformations for climate resilient sustainable development in the Mediterranean Basin. Non-linearity implies the absence of straight-line relationship between the independent variable and the response variable. In other words, changes in the output do not change in direct proportion to changes in the independent variable and the form of the relationship is often described applying non-linear mathematical models. Gradual changes induced by climate warming in thermal exposure or rainfall availability can induce non-linear effects on social and ecological response variables.

Code	**Sector**	**Processes**	**References**
P1	Agriculture and migration	Adverse non-linear impacts of temperature on agricultural productivity can induce non-linear effect on human migration. The temperature–migration relationship is non-linear and resembles the nonlinear temperature–yield relationship. These relationships affect mostly agriculture-dependent countries and especially people in those countries whose livelihoods depend on agriculture	Reuveny (2007); Schlenker and Roberts (2009); Cai et al. (2016)
P3	All societal sectors	The increase in climatic impacts and catastrophic events is associated with non-linear changes in economic and social impacts	Burke et al. (2014); Burke et al. (2015); Carleton and Hsiang (2016); Hsiang et al. (2017); Prahl et al. (2018); Coronese et al. (2019)
P4	All economic sectors	Non-linear temperature effects on labour conditions	Burke et al. (2014); Graff Zivin and Neidell (2014); Burke et al. (2015); Somanathan et al. (2018)
P5	All economic sectors	Non-linear temperature effects on GDP. Higher temperature may reduce GDP in Mediterranean agricultural countries more than non-agricultural countries. Extreme heat over 30°C significantly reduce GDP of agricultural countries but not the non-agricultural ones. GDP is a main determinant of international migration. Nonlinear relationship between GDP and temperature in agricultural countries provide an indirect evidence for the agricultural linkage between temperature and migration.	Dell et al. (2012); Burke et al. (2014); Burke et al. (2015); Cai et al. (2016)

P6	All societal sectors	Non-linear effects of temperature on human conflict	Baylis (2015); Burke et al. (2018); Koubi (2018); Baylis (2020)
P7	Food, health and demography	In low-income areas of the Mediterranean Basin and sub-Saharan Africa regions higher poverty rates, malnutrition and elevated infant mortality are coupled with higher fertility, implying a higher rate of population growth that in turn can generate more poverty. These demographic cycles can in turn interact with climatic impacts and conflict-induced displacement and migration processes.	Vörösmarty et al. (2000); Barrios et al. (2006); Reuveny (2007); Hsiang et al. (2013); Ghimire et al. (2015); Brzoska and Fröhlich (2016); Cai et al. (2016); Cattaneo and Peri (2016); Grecequet et al. (2017); Waha et al. (2017); WFP (2017); Livi Bacci (2018); Raineri (2018); Scott et al. (2020)
P8	Energy	Non-linear effects of increased temperatures on energy demand and supply. High temperatures provoke demand surges while straining supply and transmission	Carleton and Hsiang (2016)
P9	Industry	Non-linear effects of temperature on industrial production	Hsiang and Meng (2015)

In the Mediterranean Basin, indicators for progress towards the Sustainable Development Goals (SDG) show multiple directions of transformative change (Sachs et al., 2019). In some sectors, such as energy, there are general positive trends in sustainability (UNEP/MAP, 2016), but there also are significant imbalances between northern and southern shores of the basin for most SDGs. Over the coming decades the Mediterranean Basin will *likely* experience sustained growth in renewable energy investments, accompanied by a shift in regional geographical patterns of energy demand (OME, 2018). But future developmental pathways, solution space and feasible system transformations could be constrained by multiple factors for several SDGs, such as social conflicts, lack of regional governance, limited action capacity and financial constraints (Figure CCP4.9, Table CCP4.3).

Figure CCP4.9: Differences in present day SDG indicator values between northern (blue) and southern (gold) Mediterranean countries. Yellow-shaded areas indicate better indicator values for the SDG descriptor. Red-shaded areas indicate poor performance on SDG values. Details on calculations and indicators in Table SMCCP4.3.

CCP4.4.7 Governance and Finance for Sustainable Development

Several multilateral institutions are managing international environmental governance in the Mediterranean Sea, including, i) the Barcelona Convention or Convention for the Protection of the Marine Environment and the Coastal Region of the Mediterranean (established under the United Nations Environment Programme; UNEP), ii) the General Fisheries Commission for the Mediterranean (GFCM, a subsidiary of the FAO), and iii) the ACCOBAMS (Agreement on the Conservation of Cetaceans in the Black Sea, Mediterranean Sea, also under the UNEP). These institutions act cooperatively pursuing synergies and greater effectiveness (Lacroix, 2016). The Mediterranean Action Plan (MAP) under the Barcelona Convention System involves 21 Mediterranean countries and the European Union and promotes the Mediterranean Strategy for Sustainable Development (MSSD), coordinated by the Mediterranean Commission on Sustainable Development (MCSD) (UNEP/MAP, 2016). MAP is primarily financed by national governments and the EU. Its financial capacity for regional environmental governance remains limited, with available annual funds in the range of 5-10 million Euro (Humphrey and Lucas, 2015).

Bilateral public climate finance in the Mediterranean area includes loans by multilateral development banks, bilateral official development aid, and international climate funds projects (Midgley et al., 2018; Tagliapietra, 2018). Bilateral public and private financial resources invested in international climate finance in southern Mediterranean countries are two orders of magnitude greater than the existing multilateral regional governance programmes for the environment (EC, 2018; Midgley et al., 2018; Fosse et al., 2019). The Mediterranean Strategy for Sustainable Development (MSSD) is a tool for enhancing the governance of environmental issues, proposing the biannual reporting by the national parties of a set of quantitative indicators, including the commitments and obligations under the UNFCCC climate agreement, and other climate change mitigation and adaptation policy actions.

Existing legal and institutional structures can facilitate coordination and collaboration across scales (DeCaro et al., 2017). Legislative mechanisms, such as the rules governing water uses in time of drought, already exist in some Mediterranean countries, but they might not be suitable to cope with irreversible changes (e.g. the depletion of groundwater aquifers) or be flexible enough to respond to the needs of water users under a changing climate (Nanni, 2012). Although legislation can be recognized as a tool in support of adaptive water management, there is a need of better coordination among the various legal provisions that define institutional roles and set out the mechanisms for the management of water resources across different scales (regional/national/sub-national) and sectors (agriculture, industry, urban, energy).

[START FAQ CCP4.1 HERE]

FAQ CCP4.1: Is the Mediterranean Basin a "climate change hotspot"?

Is the Mediterranean "a geographical area characterized by high vulnerability and exposure to climate change"? Climate change projections for the Mediterranean Basin indicate with very high consistency that the region will experience higher temperatures, less rainfall during the coming decades and continued sea-level rise. Given that summers are already comparatively dry, these factors together will likely cause substantially drier and hotter conditions as well as coastal flooding, impacting people directly but also harming ecosystems on land and in the ocean.

For the Mediterranean Basin, climate models consistently project regional warming at rates about 20% above global means and reduced rainfall (-12% for global warming of 3°C). While it is not the region with the highest rate of expected warming on Earth, the Mediterranean Basin is considered particular in comparison to most other regions due to the high exposure and vulnerability of human societies and ecosystems to these changes: a "climate change hotspot".

Rising temperatures trigger large evaporation of water from all wet surfaces, notably the sea, lakes, rivers but also from soils. Along with decreasing rainfall, this evaporation leads to shrinking water resources on land, drier soils, reduced river flow and significantly longer and more intensive drought spells. Since the Mediterranean climate is already relatively dry and warm in the summer, any additional drought (and also heat) will affect plants, animals and people significantly, and ultimately entire societies and economies.

In general, increasing temperatures and more intensive heatwaves in the basin threaten human well-being, economic activities and also many ecosystems on land and in the ocean. Extreme rainfall events, which despite the lower total rainfall are expected to increase in intensity and frequency in some regions, generate significant risks for infrastructure and people through flash floods. Warming also affects the ocean and its ecosystems, jointly with acidification caused by atmospheric carbon dioxide. Finally, sea-level rise, currently accelerating as a consequence of global ice loss, threatens coastal ecosystems, historical sites and a growing human population.

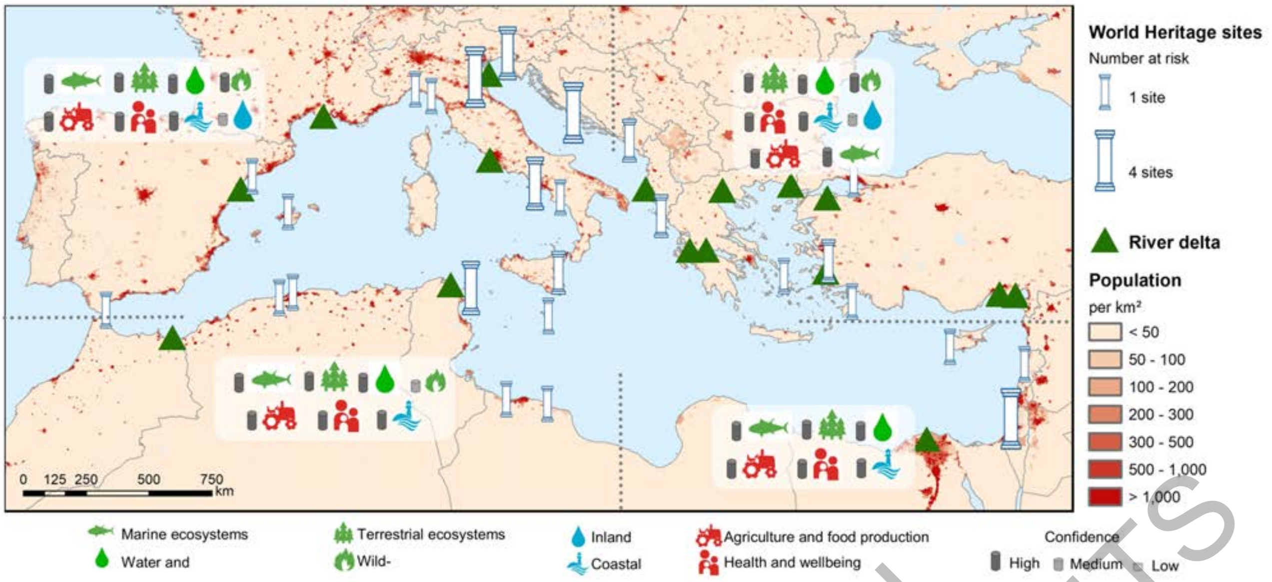

Figure FAQ CCP4.1.1: Key risks across the Mediterranean region by 2100. The symbols above the map highlight risks enhanced by climate change which apply to the entire region with *high confidence*. Other risks are localized in the map (for details, see CCP4).

Risks associated with projected climate change are particularly high for people and ecosystems in the Mediterranean Basin due to the unique combination of many factors, including:

i) a large and growing urban population exposed to heat waves, with limited access to air conditioning,
ii) a large and growing number of people living in settlements impacted by rising sea level,
iii) important and increasing water shortages, experienced by 180 million people today already,
iv) growing demand for water by agriculture for on irrigation,
v) high economic dependency on tourism, which is likely to suffer from increasing heat but also from the consequences of international emission reduction policies on aviation and cruise-ship travel,
vi) loss of ecosystems in the ocean, wetlands, rivers and also uplands, many of which are already endangered by unsustainable practices (e.g. overfishing, land use change).

[END FAQ CCP4.1 HERE]

[START FAQ CCP4.2 HERE]

FAQ CCP4.2: Can Mediterranean countries adapt to sea-level rise?

The rates of observed and projected sea-level rise in the Mediterranean are similar to the Northeast Atlantic, potentially reaching 1.1 m at the end of the present century. Erosion, flooding and the impacts of salinization are projected to be particularly severe due to the special conditions of the coastal zones in the region. Beyond a few tens of centimeters, adaptation to sea-level rise will require very large investments and may be impossible in some regions.

Sea level in the Mediterranean has been rising by only 1.4 mm yr^{-1} during the 20th century, more recently by 2.4±0.5mm yr^{-1} from 1993 to 2012, and it is bound to continue rising in the future. Future rates are projected to be similar to the global mean (within an uncertainty of 10-20 cm), potentially reaching 1.1 m or more around 2100 in the event of 3°C of global warming (Figure FAQ-CCP4.2; SMCCP4.4). Due to the ongoing ice loss in Greenland and Antarctica, this trend is expected to continue in coming centuries. Sea-level rise already impacts extreme coastal waters around the Mediterranean and it is projected to increase coastal flooding, erosion and salinization risks. These impacts would affect agriculture, fisheries and aquaculture, urban development, port operations, tourism, cultural sites, and many coastal ecosystems.

Most of the Mediterranean Sea is a micro-tidal environment, which means that the difference between regular high and mean water levels (astronomical tides) is very small. Storm surges and waves can produce coastal floods that persist for several hours, causing particularly large impacts on sandy coasts and eventually also on coastal infrastructure. Mediterranean coasts are also characterized by narrow sandy beaches that are highly valuable for coastal ecosystems and tourism. These beaches are projected to be increasingly affected by erosion and eventually disappear where sedimentary stocks are small.

Overall, Mediterranean low-lying areas of significant width occur along 37% of the coastline and currently host 42 million inhabitants. The coastal population growth projected until 2050 mostly occurs in southern Mediterranean countries, with Egypt, Libya, Morocco and Tunisia being the most exposed countries to future sea-level rise. The area at risk also hosts 49 cultural World Heritage Sites, including the city of Venice and the early Christian monuments of Ravenna. The Mediterranean also includes areas subjected to sinking of the land (subsidence), including the eastern Nile delta (Egypt) and the Thessaloniki flood plain (Greece), where local relative sea-level rise can exceed 1 cm yr^{-1} today.

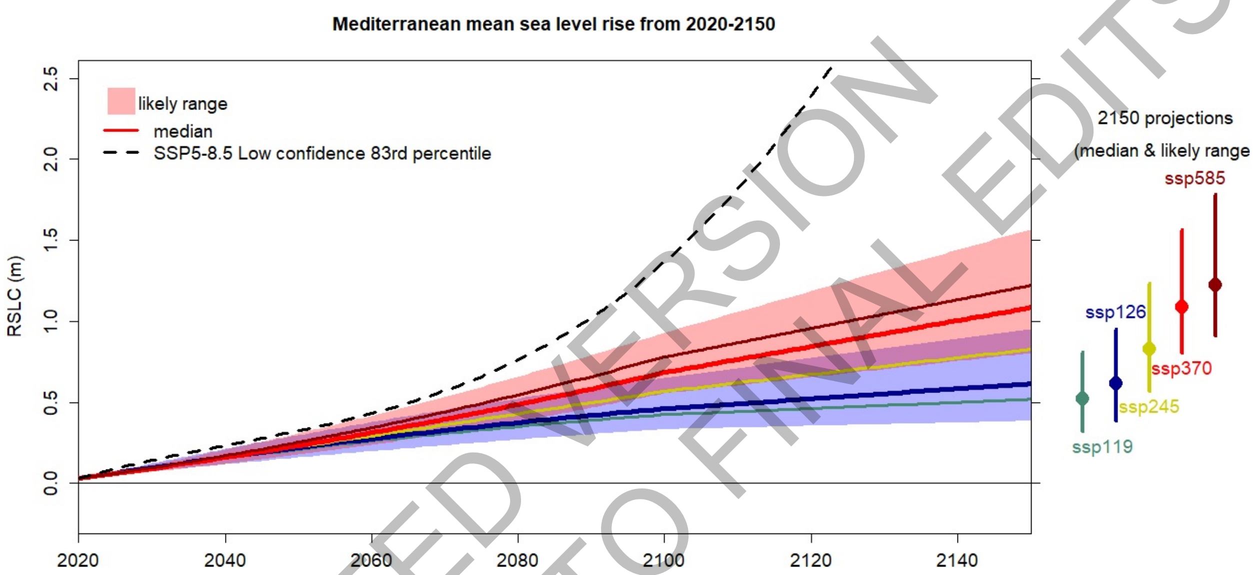

Figure FAQ CCP4.2.1: Mediterranean sea level projections. These projections translate the global estimates in WGI AR6 Chapter 9 to the Mediterranean basin. They assume that sea-level change in the Mediterranean continues to be forced by Atlantic sea-level change seen at the Gibraltar Strait (Section CCP4.1) and thus follow the global mean beyond 2100. Vertical ground motions induced by glacial isostatic adjustments are also included, but not those due to other natural or anthropogenic processes such as tectonics or groundwater extractions. Intra-basin sea-level changes are not included. Data available as supplementary material.

Adaptation to sea-level rise in the Mediterranean includes engineering or soft/ecosystem-based protection, accommodation and retreat or managed realignment. Despite various limitations, adaptation already happens today to some extent, as for example the coastal flood and erosion protections along the subsiding Nile delta coast. Only massive coastal protection and other sustainable development policies could reduce the growing number of people exposed to sea-level rise by 20%, it appears therefore likely that the number of people exposed could increase by up to 130% by 2100.

Without drastic mitigation of climate change, sea-level rise is projected to accelerate and will require additional coastal engineering protection projects (e.g. dikes or groins). Despite their efficiency for the few next decades, these engineering options have also adverse impacts for coastal ecosystems and may not ensure that the recreative value of Mediterranean coasts can be sustained (see Chapter 13 Box on Venice on the movable barriers protecting the Venice Lagoon). Among nature-based solutions, there are immediate benefits of restoring dunes and coastal wetlands to restore a buffer zone between coastal infrastructure and the sea and therefore reduce coastal risks (Cross-Chapter Box SLR in Chapter 3). Yet, this kind of protection is not feasible everywhere, facing its limits particularly in urbanized areas. The limits for adaptation in the Mediterranean to further acceleration of sea-level rise have stimulated ideas of large-scale geoengineering projects such as surface height control dams at Gibraltar. However, such projects come with unknown risks for humans and ecosystems.

[START FAQ CCP4.3 HERE]

FAQ CCP4.3: What is the link between climate change and human migration in the Mediterranean Basin?

Climate change already influences conflict and migrations occurring within countries or regions. However, climate is only one of the multiple factors affecting conflict and migration decisions across countries and regions. It is currently not possible to attribute particular conflicts or migrations to climate change and also in the future migration will most likely depend on economic, social and governance context.

The Mediterranean Sea is the world's most dangerous place for migrants, with more than 20,000 deaths reported since 2014. Although empirical evidence indicates that migration related to climate impacts is mostly internal to national borders, climate change is likely to contribute to migration in the Mediterranean Basin as one out of several factors. Climate impacts contribute to migration flows particularly by affecting the economic and political drivers of migration.

Many migrants attempting to cross the Mediterranean to Europe originate from sub-Saharan Africa, a region heavily affected by climate change. In West Africa for example, migration decisions are heavily influenced by perceptions of climate change and of its economic impact on resources and income. However, projections are uncertain, because climate impacts in Africa might both increase human suffering and thus enhance mobility, but they could also limit mobility of people through lack of financial resources.

The impacts of climate change on conflicts and security are increasingly documented, especially in Africa. Climate impacts may not in itself have caused social and political unrest but can contribute to them. The conflict in Syria has occurred after the drought that marred the country in the years before, but there is no evidence for direct causal linkage. There is however significant agreement that food insecurity and land degradation, which can be induced by climate change, are major drivers of political upheavals and instability in northern and sub-Saharan Africa.

Table of Contents

Executive Summary

Mountains are highly significant regions in the context of climate change and sustainable development, at the intersection of accelerated warming and a large population depending directly or indirectly on them. They are regions of high biological and cultural diversity and provide vital goods and services to people living in and around mountain regions and in downstream areas. Building on the IPCC's Fifth Assessment Report (AR5), Chapter 2 "High Mountain Areas" of the Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC), and the IPCC Working Group I contribution to AR6, this Cross-Chapter Paper (CCP) assesses new evidence on observed and projected climate change impacts in mountain regions, their associated key risks and adaptation measures.

Observed changes, their impacts, and adaptation responses in mountains

Climate change impacts in mountains and their attribution to human influence have increased in recent decades with observable and serious consequences for people and ecosystems in many mountain regions (*high confidence*[1]). Observed changes include increasing temperatures, changing seasonal weather patterns, reductions in snow cover extent and duration at low elevation, loss of glacier mass, increased permafrost thaw, and an increase in the number and size of glacier lakes (*high confidence*). {CCP5.2.7, Figure CCP5.4, SROCC Chapter 2, WGI Section 9.5}

The spatial distributions of many plant species have shifted to higher elevations in recent decades, consistent with rising temperatures across most mountain regions (*high confidence*). Around two-thirds of treeline ecotones have also shifted upwards in recent decades, though these shifts are not ubiquitous and slower than expected based on rising temperatures (*high confidence*). Impacts on biological communities and animal species are also increasingly being reported, with species of lower elevations increasing in mountain regions, creating more homogeneous vegetation and increasing risks to mountain top species (*medium confidence*). {CCP5.2.1; Chapter 2.4}

Climate and cryosphere change have negatively affected the water cycle in mountains, including variable timing of glacier- and snow-melt stream discharge (*high confidence*). These changes have variable impacts on water availability for people and economies, contributing to increasing tensions or conflicts over water resources, especially in seasonally dry regions (*medium confidence*). Mountains are an essential source of freshwater for large, and growing populations; the number of people largely or fully dependent on water from mountains has increased worldwide from ~0.6 billion in the 1960s to ~2 billion in the past decade and globally two-thirds of irrigated agriculture depends on essential runoff contributions from the mountains. {CCP5.2.2; Figure CCP5.2; SROCC Chapter 2; 4.2.2.3; 4.4.4.1}

Climate change-driven changes in precipitation, river flow regimes and landslides affect the production and use of energy in mountain regions, in particular hydropower (*high confidence*). Billions of USD in investment and assets of energy production are exposed to changing mountain hazards. Combined effects of climate change, hydropower development and other human interventions have exacerbated water security problems and social injustice (*medium confidence*). {CCP5.2.2, SROCC Chapter 2}

Observed climate-driven impacts on mountain ecosystem services, agriculture and pastoralism are largely negative in most mountain regions (*medium confidence*). Agriculture has been negatively affected through increased exposure to hazards such as droughts and floods, changes in the onset of seasons, the timing and availability of water, increasing pests and decreasing pollinator diversity, which in turn have negatively influenced overall production, dietary diversity and nutritional value (*medium confidence*). Negative climate impacts on pastoralism, such as drought induced degradation of rangelands and pastures, have affected livestock productivity and livelihood of pastoralists, while other non-climatic factors such as

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

land-use change and management also play a role (*medium confidence*). {CCP5.2.3; CCP5.2.5; Table CCP5.2; SROCC Section 2.3.1.3.2; SROCC Section 2.3.7}

While contributing to poverty reduction in some mountain regions, there is *limited evidence* of adaptations effectively contributing to remediating the underlying social determinants of vulnerability such as gender and ethnicity (*medium confidence*). Exposure and vulnerability exacerbate the negative effects of climate impacts on livelihoods, and intertwines with power imbalances, gender and other inequalities (*medium confidence*). {CCP5.2.7; CCP5.3.2.2}

Observed changes in seasonality (timing and extent) are negatively affecting mountain winter tourism and recreation (*high confidence*), and variably affect tourism and recreation activities in other seasons (*medium confidence*). For winter activities such as skiing, diminishing snow at lower elevations has challenged their operating conditions (*medium confidence*), increasing the demand for and dependence on snow management measures such as snow-making (*high confidence*). Climate-induced hazards are negatively affecting some climbing, mountaineering, and hiking routes (*medium confidence*). In some regions, options to change routes or shift seasons to reduce hazard exposure have been employed as adaptation strategies, with variable outcomes (*medium confidence).* In some cases, higher temperatures and extreme heatwave conditions at lower elevations have made some mountain destinations more appealing, increasing the potential for summer visitation demand (*medium confidence*). {CCP5.2.5; Table CCP5.2; SROCC Ch2.3.5}

Climate-related hazards, such as flash floods and landslides, have contributed to an increase in disasters affecting a growing number of people in mountain regions and further downstream (*high confidence*). The resulting number of disasters has increased, however there is *limited evidence* that this is due to changes in the underlying hazard processes, pointing mainly to increasing levels of exposure (*medium confidence*). {CCP5.2.6; CCP5.2.7; CCP5.3.2.1}.

Adaptation responses to climate-driven impacts in mountain regions vary significantly in terms of goals and priorities, scope, depth and speed of implementation, governance and modes of decision-making, and the extent of financial and other resources to implement them (*high confidence*). Observed adaptation responses in mountains are largely incremental and mainly focus on early warning systems and the diversification of livelihood strategies in smallholder agriculture, pastoralism, and tourism. However, there is *limited evidence* of the feasibility and long-term effectiveness of these measures to address climate-related impacts and related losses and damages, including in cities and settlements experiencing changing demographics. {CCP5.2.4; CCP5.2.7.2}

Projected impacts, key risks and limits to adaptation in mountains

Increasing temperatures will continue to induce changes in mountain regions throughout the 21st century, with expected negative consequences for mountain cryosphere, biodiversity, ecosystem services and human wellbeing (*very high confidence*). Many low elevation and small glaciers around the world will lose most of their total mass at 1.5°C GWL (*high confidence*). A large majority of endemic mountain species will be at risk of extinction; regions heavily relying on glacier- and snow-melt for irrigation will face erratic water supply and increased food insecurity, whereas agriculture in some regions might see positive changes. Damages and losses from water related hazards such as floods and landslides are projected to increase considerably between 1.5 and 3° GWL. {CCP5.3.1}

Projected changes in hazards, such as floods and landslides, as well as changes in the water cycle, will lead to severe risk consequences for people, infrastructure and the economy in many mountain regions (*high confidence*). These risks will be more pervasive and also increase more rapidly in South and Central Asia and Northwestern South America. However, nearly all mountain regions will face at least moderate and some regions even high risks at around 2°C GWL (*medium confidence*). {CCP5.3.2.1, CCP5.3.2.2; 16.B.4}

There is an increasing risk of local and global species extinctions where they are not able to move to higher elevations or other cooler locations (*high confidence*), with risks from extreme events such as wildfire potentially exacerbating those risks (*medium confidence*). The topographic variation in mountains may mean that some species can survive in cooler microclimates with aspect as well as elevation.

Mountain regions may act as refugia for some species from lower elevations, if they can move into them. This may enable some species to persist in a region, although it can present a threat to cold-adapted species, including endemics, which may be outcompeted (*high confidence*); invasive non-native species may become an increasing problem in some places. {CCP5.3.2.3, Box CCP5.1; CCP1.2.2.1; 2.6.6; 16.6.3.1}

Climate change is projected to lead to profound changes and irreversible losses in mountain regions with negative consequences for ways of life and cultural identity (*medium confidence*). Intangible losses and loss of cultural values will become increasingly more widespread in mountain regions mainly driven by a decline in snow and ice and an increase in intangible harm to people from hazards (*medium confidence*). However, there is *limited evidence* on the magnitude of the consequences. {CCP5.3.2.4; 16.5.2.1; 16.5.2.3.7}

Options for future adaptation and climate resilient sustainable development in mountains

The current pace, depth and scope of adaptation is insufficient to address future risks in mountain regions, particularly at higher warming levels (*high confidence*). While the incremental nature of most implemented adaptations will not be sufficient to reduce severe risk consequences, options exist which offer practical and timely prospects to address risks before limits to adaptation are reached or exceeded. Reducing climate risks will depend on addressing the root causes of vulnerability, which include poverty, marginalization, and inequitable gender dynamics *(high confidence*). {CCP5.4.1, Figure CCP5.7; CCP5.4.2, Cross-Chapter Box DEEP in Chapter 17; Cross-Chapter Box LOSS in Chapter 17; 17.3, 17.6}

Adaptation decision-making processes that engage with and incorporate people's concerns and values and address multiple risks are more robust than those with a narrow focus on single risks (*medium confidence*). Risk management strategies that better integrate the adaptation needs of all affected sectors, account for different risk perceptions and build on multiple and diverse knowledge systems, including Indigenous knowledge and local knowledge, are important enabling conditions to reduce risk severity (*medium confidence*). {CCP5.2.6, CCP5.4.2; 17.3; 17.4; Cross-Chapter Box PROGRESS in Chapter 17; Cross-Chapter Box DEEP in Chapter 17}

Regional cooperation and transboundary governance in mountain regions, supported by multi-scale knowledge networks and monitoring programmes, enable long-term adaptation actions where risks transcend boundaries and jurisdictions (*medium confidence*). Collectively, they show potential to form an important component of the adaptation solution space in mountains. There are increasing calls for more ambitious climate action in mountains, providing impetus for stronger cooperation within and across mountain regions, and downstream areas (*medium confidence*). {CCP5.4.2; CCP5.4.3}

With warming above 1.5°C, the need for adaptation to address key risks in mountains becomes increasingly urgent (*high confidence*). Pathways and system transitions that strengthen climate-resilient sustainable mountain development are starting to receive attention, but current levels of resourcing are substantially insufficient to support timely action. {CCP5.4.2; CCP5.4.3; CCP5.5; 18.1; 18.2}

CCP5.1 Point of Departure

Mountains are an extensive and significant *typological region* (Section 1.3.3 and AR6 Glossary) in the context of climate change and sustainable development, with a large population directly or indirectly depending on mountains. These are areas of high biological and cultural diversity that provide vital goods and services – such as water, food, energy, minerals, medicinal plants, tourism and recreation, and aesthetic and spiritual values – to people living in and around these mountain regions and in downstream areas. Mountain regions are hotspots of climate related losses in, for example, ecosystems, landscapes, culture, and habitability, and while mountain people are adaptive, resourceful, and independent, they live in highly fragile environments and in some regions under challenging socioeconomic circumstances that enhance their vulnerability to climate change (Alfthan et al., 2018).

Chapter 2 "High Mountain Areas" (Hock et al., 2019) of the IPCC Special Report on the Ocean and the Cryosphere in a Changing Climate (SROCC), presented an assessment of observed changes in the high mountain cryosphere, their resulting impacts in-situ and further downstream, and the state of adaptation responses to these impacts. Before SROCC, the last time climate change in mountain regions were systematically assessed in IPCC reports was in Chapter 5 of the Second Assessment Report (SAR) (Beniston et al., 1996). Projections made at the time for climate-related changes in mountain regions were expected towards the middle and the second half of the twenty-first century, rather than as early as the past decades (Haeberli and Beniston, 2021), underscoring the striking pace of change already observed in mountain regions.

Whereas SROCC focused on impacts from a changing climate on high mountain cryosphere, this Cross-Chapter Paper (CCP) on "Mountains" synthesizes key relevant content from across the AR6 WGII report with a broader scope on the impacts and adaptation to climate change in mountain regions as defined for this assessment (Figure CCP5.1, SMCCP5.1). It provides a wider assessment of the solutions space and consequences for sustainable development due to climate change in mountain regions and downstream areas.

To define the geographical scope of the assessment in this CCP and to quantify the human population residing within these regions, the mountain characterization given by Kapos et al. (2000) (Figure CCP5.1a and SMCCP5.1), minus Antarctica, Svalbard and Greenland (which fall under the assessment scope of CCP6 Polar Regions), was employed. This characterization is consistent with the mountain region extents used in the AR6 WGI report (see AR6 WGI Atlas) and yields a global mountainous area of 31.74 million km^2, which corresponds to approximately 23.5% of the global land surface. In 2015, a total of 1.28 billion people resided in mountain regions as delineated for this CCP (SMCCP5.1).

The scope of the assessment presented in this CCP covers observed and projected climate change impacts in mountains, present, emerging and future key risks and observed adaptation responses, leading to an exploration of the adaptation solution space and climate-resilient development (pathways) in mountains. Section 5.2 presents observed impacts and adaptation responses by synthesizing information on mountains in the sectorial and regional chapters of WGII AR6, additional supporting evidence found in the literature, a Detection and Attribution assessment (SMCCP5.2) and a reanalysis of the mountain literature collected and synthesised in the Global Adaptation Mapping Initiative (GAMI) (SMCCP5.3). Section 5.3 presents an assessment of future key risks in mountains drawing from the regional and sectorial chapters and a key risks assessment for this CCP (SMCCP5.4). Section 5.4 explores the solution space for future adaptation opportunities and constraints as well as climate resilient development in mountains. This CCP concludes with key assessment limitations and knowledge gaps and prospects to address these gaps in Section 5.5.

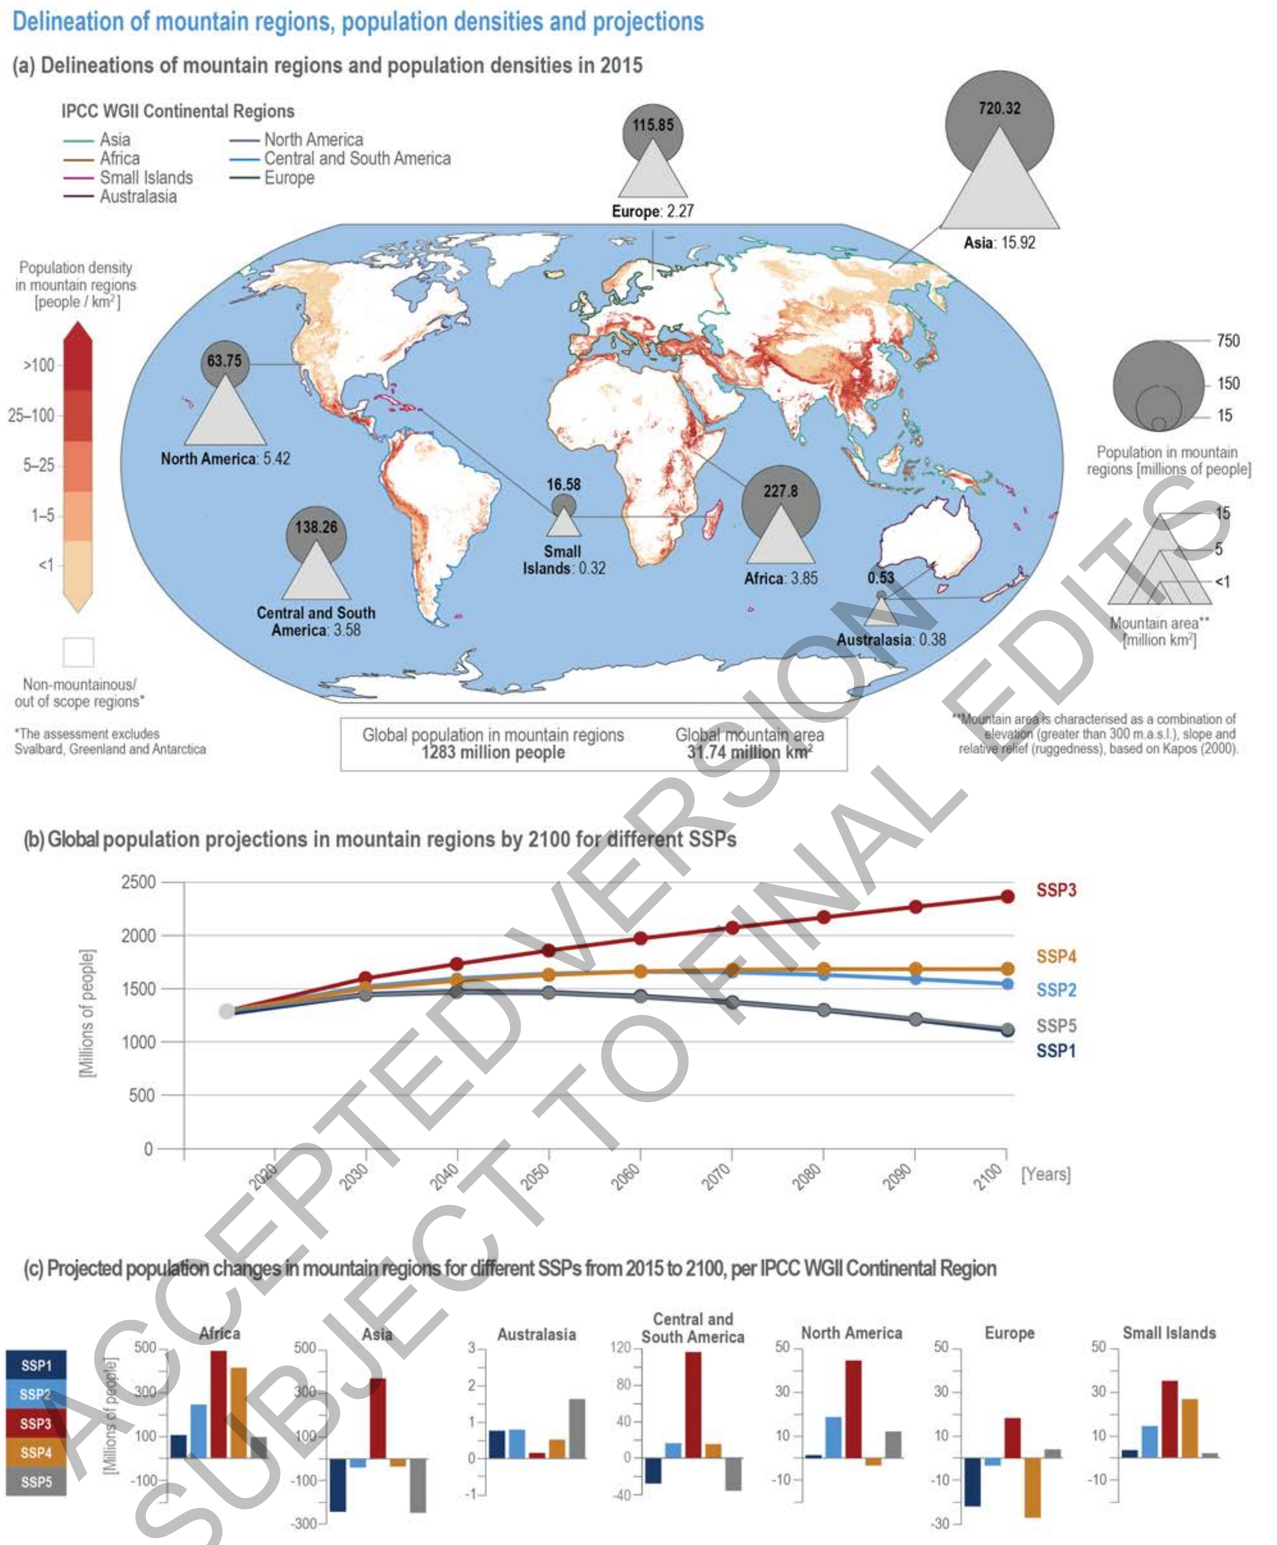

Figure CCP5.1: Delineation of mountain regions in CCP Mountains, population numbers and densities in 2015, and their projections to 2100. a) Population in mountain regions in 2015 aggregated per IPCC WGII Continental Regions, considering population densities, mountain areas and total population in mountain regions. b) Population projections in mountain regions by 2100 for different Shared Socioeconomic Pathways (SSP) scenarios. c) Projected changes in population in mountain regions from 2015 to 2100 across five different SSP scenarios, per IPCC WGII Continental Region (see SMCCP5.1 and Tables SMCCP5.1-5.4).

CCP5.2 Observed Impacts and Adaptation in Mountain Social-Ecological Systems

CCP5.2.1 Ecosystems and Ecosystem Services

Changes in climate over short distances in mountains are reflected in large ecological gradients. AR5 reported new evidence that plant species of mid and low elevations were starting to colonise high elevations in mountains. Since AR5, new studies have been published (e.g. Steinbauer et al., 2018; Payne et al., 2020), including in some previously less well studied areas such as the Andes (e.g. Morueta-Holme et al., 2015; Báez et al., 2016) and parts of Asia (e.g. Telwala et al., 2013; Artemov, 2018). There is now *high confidence* that many plant species distributions have shifted to higher elevations in recent decades, consistent with climatic warming (Sections 2.4.2; 10.4.2.1.1; 13.3.1.1). In recent years publications have also started to show similar trends in some animal species include those on birds (Freeman et al., 2018; Bani et al., 2019; Lehikoinen et al., 2019) and snails (Baur and Baur, 2013). Other climatic variables besides temperature can also affect elevational limits of species (Section 2.4.2) and sometimes in contrasting ways to temperature, for example increasing precipitation can allow some species to occur at lower elevations in dry climates (Crimmins et al., 2011; Coals et al., 2018). Tsai et al. (2015) reported large changes in the montane bird community in Taiwan which they link to changes in weather patterns including more severe typhoons. Changes in the amplitude and frequency of bank vole population waves in the Ilmen Nature Reserve, Middle Urals can be linked to a longer frost-free periods (Kiseleva, 2020).

There are interactions with land use, for example a decrease in forest cover can exacerbate the effects of rising temperatures (Guo et al., 2018). In contrast, Bhatta et al. (2018) showed a downward shift of species assemblages in Langtang National Park, Nepal, most likely related to interactions with land use, especially reduced grazing. Where glaciers are retreating, new areas become available for pioneer species to colonise and new communities to form (Cuesta et al., 2019; Hock et al., 2019; Muhlfeld et al., 2020). The risk of extreme events such as wildfire, drought, floods and landslips is increasing in a wide range of places as a result of climate change and the evidence of the disturbance they cause to ecosystems has grown in recent decades (Section 2.3.1, Box CCP5.1). The impacts of such extreme events may be larger than those of incremental changes.

For species at lower elevations, mountains may represent refugia to which they can retreat. In this respect, Elsen et al. (2018) have highlighted the importance of protecting areas along elevational gradients. This applies in freshwater as well as terrestrial habitats with mountain streams acting as potential refugia (Isaak et al., 2016). In contrast, species restricted to the highest elevations are increasingly at risk, including from competition with colonising species (Britton et al., 2016; Winkler et al., 2016). Mountain top species are often separated from potential new habitat by large areas with unsuitable climates and tropical mountain species often have particularly narrow thermal tolerance and limited dispersal capacity (Polato et al., 2018).

The risks posed by non-native species may increase with climate change (Carboni et al., 2018; Shrestha et al., 2018; Thapa et al., 2018). Koide et al. (2017) found that non-native plant species on Hawaii were moving to higher elevations, whereas native species distributions were retracting at their lower elevational limit. Dainese et al. (2017) found that non- native plant species spread to higher elevations approximately twice as fast as native species. Following recent climate warming, invasive bamboo *Phyllostachys edulis* and *Phyllostachys bambusoides* (Poaceae) in Japan has shifted northward and upslope in the last three decades (Takano et al., 2017). New evidence has shown that variations in microclimate, with topography and cold groundwater seeps, can provide micro-refugia small areas of locally suitable conditions where cold adapted species can survive (Bramer et al., 2018; Muhlfeld et al., 2020) (Section 2.6.2). Some alpine species have thrived in recent years, and the range of microclimates may partly explain this (Rumpf et al., 2018).

Treeline elevation is linked to temperature (Paulsen and Körner, 2014) but may also be affected by water supply (Sigdel et al., 2018; Lu et al., 2021) and land management. A recent summary of treeline shifts worldwide found that 67% of studied alpine treelines had shifted upwards while 33% remained stable (based on 142 published studies); 88.8% of the 143 undisturbed alpine treelines across the northern Hemisphere had shifted upwards (Hansson et al., 2021; Lu et al., 2021). Since AR5, new evidence of shifting treeline ecotones has emerged for a wide variety of species in different locations including in Siberia (Pospelova et al., 2017), various parts of the Ural Mountains (Shiyatov and Mazepa, 2015; Zolotareva and Zolotarev, 2017; Sannikov et al., 2018), in Canadian Rocky Mountains (Trant et al., 2020) and Himalaya (Tiwari and Joshi, 2015; Chakraborty et al., 2016; Gaire, 2016; Yadava et al., 2017). Recent studies of treelines that have not or hardly shifted include the Himalaya (Singh et al., 2015; Sigdel et al., 2018), eastern Tibetan Plateau (Wang et al., 2020), and the Andes (Lutz et al., 2014). Migration rates are not proceeding as fast as warming climate, implying other processes also limit treeline ecotone response (e.g. Sigdel et al., 2020; Lu et al., 2021).

Whether treeline shifts occur, and if so at what rate, depends on a range of factors including: land use (especially livestock grazing and fire), species interactions, wildfires, and climatic stress factors (wind, frost, drought, excess or shortage of snow) interacting with tree population processes (viable seed production, dispersal, seedling establishment, clonal propagation, growth, dieback, mortality). Differences in treeline shifts between North- and South-facing slopes have been demonstrated in the Rocky Mountains (Elliott and Cowell, 2015). Grigorieva and Moiseev (2018) showed that significant factors limiting the number of seedlings and shoots are the snow depth, the topsoil temperature dependent on it, and the degree of competition from the parental tree stand and grass–shrub vegetation. There is also an influence of land use and management in many mountains around the world. Suwal et al. (2016) found that elevational shifts in Himalayan silver fir in Nepal were larger when areas were protected from management. Similarly, Lutz et al. (2014) found faster treeline shifts in the Peruvian Andes in protected areas than that in other areas, where cattle grazing and fires are more frequent. Treeline ecotones can also change independent of climate change if land use changes (Vitali et al., 2019; Körner, 2020).

Changes in community composition are also happening within ecosystem types. Duque et al. (2015) showed a change in the composition of north Andean forests, and Feeley et al. (2013) in that of forests up to 2800 m in Costa Rica. In both cases the proportion of species adapted to warmer conditions increased, driven primarily by patterns of mortality, indicating that the changes in composition are mostly via range retractions, rather than range shifts or expansions. An analysis of 200 forest inventory plots in the Andes likewise indicated a widespread, though not ubiquitous, thermophilization of the tree species' composition (Fadrique et al., 2018). Within a period of eight years (2003–2010), significant shifts in communities of vascular plants, butterflies and birds were found in Switzerland (Roth et al., 2014). At lower elevations, communities of all species groups changed towards warm-dwelling species, corresponding to an average uphill shift of 8 m, 38 m and 42 m in plant, butterfly and bird communities, respectively. However, rates of community changes decreased with elevation in plants and butterflies, while bird communities shifted towards warm-dwelling species at all elevations (Roth et al., 2014).

Changes in mountain biodiversity and ecosystems have a wide range of impacts on ecosystem services and effects on people. Some mountain ecosystems, particularly those with peatlands or forests are important carbon stores and climate change presents a risk to these in some locations (Dwire et al., 2018) (Sections 2.4.3.8; 2.4.4.4; 2.4.4.5). Palomo (2017) identified a wide range of threats to the lives, livelihoods and culture of mountain people as a consequence of the impacts of climate change on ecosystems. However, impacts are very heterogeneous between locations, even within the same region and ecosystem type (for example mountain forests in Europe; Mina et al. (2017) and are not necessarily all negative. As well as changes in services, other impacts on humans from a changing climate may be mediated through species and ecosystems, for example changes in vector distribution shifting disease incidence into higher elevation areas (Escobar et al., 2016).

[START BOX CCP5.1 HERE]

Box CCP5.1: Wildfires and Mountain Ecosystems

Mountain ecosystems have long been known to be highly sensitive to the direct impacts of climatic warming and drying (Beniston et al., 1994; Nogués-Bravo, 2009; Gottfried et al., 2012; Guisan et al., 2019). Furthermore, wildfires in these ecosystems, as with many others (Sections 2.4.4.2 and 2.5.3.2), are also expected to increase (Abatzoglou et al., 2019). This is because the occurrence and severity of fire is governed by four fundamental processes that are intricately linked to climate: 1) fuel biomass growth; 2) fuel moisture and type; 3) ignition source; and 4) favourable weather conditions for fire spread (Bradstock, 2010).

In temperate and tropical mountain ecosystems, increases in fire activity are potentially linked to changing climate on most continents, including Europe (Dupire et al., 2017), North America (Westerling, 2016; Halofsky et al., 2020; Burke et al., 2021), South America (Román-Cuesta et al., 2014), Africa (Hemp, 2005), Asia (Tian et al., 2014) and Australia (Bradstock et al., 2014; Abram et al., 2021). In these ecosystems, fire frequency, severity and extent (i.e. the fire regime) are increasing because of climate-induced impacts on fuel moisture (Gergel et al., 2017; Littell et al., 2018), vegetation composition (i.e. fuel types) (Camac et al., 2017; Prichard et al., 2017; Zylstra, 2018), fire-conducive weather patterns and the length of fire seasons (Westerling, 2016; Fill et al., 2019; Di Virgilio et al., 2020).

Fire in mountain ecosystems alters many ecological processes and ecosystem services across all elevational zones, from foothill montane forests to the high elevation alpine (treeless) zones (Turner et al., 2003; Williams et al., 2008; Oliveras et al., 2014; Rocca et al., 2014; Oliveras et al., 2018). However, the magnitude of short-term and long-term fire impacts depends on the degree of novelty of future fire regimes and the capacity of species to adapt to change (Camac et al., 2017; Archibald et al., 2018; Camac et al., 2021).

Montane and subalpine ecosystems have variable ecological responses to fire that are ultimately influenced by long-term, historical fire regimes and the evolutionary forces that have governed post-fire regeneration strategies of the biota. Two contrasting strategies in temperate forests are illustrated here. SE Australian mountain ash (*Eucalyptus regnans*) forests are adapted to a high severity fire regime, consisting of infrequent (>100 years), large stand-replacing wildfires (Bowman et al., 2016). Mountain ash is a long-lived obligate seeder but is slow to reach reproductive maturity (>20 years; Bowman et al., 2016). As such, natural post-fire regeneration takes decades to centuries to recover to pre-fire conditions, and if fire recurs before reproductive maturity is reached, the species can be eliminated. By contrast, ponderosa pine (*Pinus ponderosa*) forests of the SW United States have evolved with a low- or mixed-severity fire regime, where fire is frequent (5-25 year), low intensity, less likely to kill the dominant stand, and thus, allow faster post-fire recovery (Prichard et al., 2017). However, post-fire recovery times in this ecosystem are also becoming longer due to a century of effective fire suppression shifting the fire regime to one which is more infrequent, high-intensity, extensive and stand replacing (Prichard et al., 2017).

Above the treeline, fire is less common than in foothill forests. Post-fire recovery times also tend to be shorter (Williams et al., 2008; Camac et al., 2013; Verrall and Pickering, 2019) because of the dual influences of the low flammability traits coupled with most alpine plant species exhibiting strong resprouting strategies that have evolved in response to harsh climate conditions (Körner, 2003). However, fires in alpine treeless landscapes can still have long-term and catastrophic impacts on fire-sensitive vegetation types such as ground-water dependent wetlands dominated by hygrophilous plants and peat soils (De Roos et al., 2018). Similar impacts can be severe on long-lived, slow growing vegetation such as coniferous heathlands (Bowman et al., 2019), and highly restricted and threatened fauna (e.g. Mountain pygmy possum) that depend on these plant communities (Gibson et al., 2018). Such fires have even been found to have significantly impact subalpine treeline mortality rates (Fairman et al., 2017), and in some cases have resulted in treelines shifting to lower elevations (e.g. Hemp, 2005).

The long-term implications of a warmer global climate, coupled with more frequent and/or severe fires in mountain ecosystems, are expected to be transformative for mountain biota. Fire sensitive montane forests, such as Australia's alpine ash (*Eucalyptus delegatensis*) are expected to become highly susceptible to population collapse and local extinction as intervals between fire events contract and become too short for species to reach reproductive maturity (Bowman et al., 2014; Enright et al., 2015) – an impact that will *likely* be further exacerbated by recruitment failure caused by post-fire drought and moisture deficiencies (Davies et al., 2019; Halofsky et al., 2020; Rodman et al., 2020). Fire and climate change are also *likely* to act synergistically in mountainous ecosystems, via positive feedbacks that increase fire frequency by changing vegetation composition to more flammable fuel types, and thus increasing landscape susceptibility to future fire (Camac et al., 2017; Tepley et al., 2018; Zylstra, 2018; Lucas and Harris, 2021). More frequent fires in these ecosystems will also exacerbate native and exotic species invasions (Catford et al., 2009; McDougall et al., 2011; Gottfried et al., 2012; Kueffer et al., 2013), faunal population declines (Ward et al., 2020), poor air quality (de la Barrera et al., 2018; Burke et al., 2021), soil erosion and landslide risk (de la Barrera et al., 2018), and reduce freshwater catchment volumes and quality (Rust et al., 2018; Niemeyer et al., 2020), all of which will impact negatively on human health and wellbeing (Ebi et al., 2021).

Taking this evidence together, there is a significant risk of wildfire exacerbating other impacts of climate change on already vulnerable ecosystems in many mountain regions (*medium confidence*).

[END BOX CCP5.1 HERE]

CCP5.2.2 Water and Energy

CCP5.2.2.1 Water

Water is a fundamental source of life in mountain regions; it is also a central element and 'connector' in coupled natural-human systems and bears diverse meanings in different socio-cultural contexts, including in indigenous ontologies (Boelens, 2014). Water is also a key component connecting upstream mountains and downstream lowlands (Salzmann et al., 2016; Di Baldassarre et al., 2018; Encalada et al., 2019). Mountains are of paramount importance as water towers for people in the mountains and for around 2 billion people living in connected lowland areas (Immerzeel et al., 2020; Viviroli et al., 2020).

Mountain river systems are especially sensitive to, and affected by, climate change and continuing anthropogenic disturbance, including water pollution, hydropower development, water withdrawals for agriculture and human consumption, and biodiversity loss and ecosystem changes (Honda and Durigan, 2016; Encalada et al., 2019; Bissenbayeva et al., 2021; Chen et al., 2021) (*high confidence*). The effect of climate and cryosphere change in mountains on downstream water and river systems has been studied and quantified for many regions worldwide (Barnett et al., 2005; Huss, 2011; Lutz et al., 2014; O'Neel et al., 2015; Huss and Hock, 2018). Comprehensive approaches focusing on both water demand and supply aspects provide regionally or locally specified information on water availability, scarcity and security (Buytaert et al., 2014; Drenkhan et al., 2015; Brunner et al., 2019) (Chapter 4). Present and potential future hotspot regions of water scarcity that rely heavily on mountainous water sources include Central Asia, South Asia, tropical and subtropical western South America, and southwestern North America (*robust evidence, medium agreement*) (Kummu et al., 2016; Biemans et al., 2019; Immerzeel et al., 2020; Viviroli et al., 2020).

Figure CCP5.2 represents different levels of dependences of lowland areas on mountain water. At a global scale, 68% of irrigated agricultural areas in lowlands depend on essential runoff contributions from the mountains. The dependence of lowland populations on essential mountain runoff contributions increased by a factor of more than three from the 1960s to the 2000s, with increases of up to ten-fold in some major river catchments (Viviroli et al., 2020).

Many mountain regions have one or more cryosphere components (glaciers, permafrost and perennial or seasonal snow), and the mountain cryosphere is among the natural systems most sensitive to climate change worldwide (*high confidence*). The SROCC assessed a decline in all cryosphere components due to climate change over the past decades, i.e. for low-elevation snow cover (*high confidence*), permafrost (*high confidence*), and glaciers (*very high confidence*) (Hock et al., 2019). More recent studies using globally more complete data sets show a considerably higher glacier mass loss (267 ±16 Gt yr^{-1}) for 2000-2019 as compared to a (*very likely*[2]) range of 123 ±24 Gt yr^{-1} for 2006-2015 in SROCC, with a mass loss acceleration of 48 ±16 Gt per year and decade over 2000-2019 (Hugonnet et al., 2021). Assessment conclusions in SROCC found with *high confidence* that glacier shrinkage and snow cover changes over the past two decades has led to changes in the amount and timing of runoff in many mountain regions (Hock et al., 2019).

The effects of climate and environmental changes in upstream areas on downstream water quantity and quality, including nutrient, pollutant, heavy metals and sediment flux, have only been assessed in a limited number of catchments (Rakhmatullaev et al., 2009; Dong et al., 2015; Milner et al., 2017; Ilyashuk et al., 2018; Lane et al., 2019; Li et al., 2020; Chen et al., 2021). Groundwater contributions to streamflow are highly variable in mountains, but can be substantial (up to 70 to 80% or more) during low-flow periods (Frisbee et al., 2011; Baraer et al., 2015; Gordon et al., 2015; Käser and Hunkeler, 2016; Somers et al.,

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

2019). Groundwater may provide some resilience to loss of melt water from glacier and snow decline but in the longer term groundwater recharge and contribution to streamflow is expected to decrease with ongoing climate change (*medium confidence*) (Somers and McKenzie, 2020). In some mountain regions springs are a particularly important source of water, e.g. in the Himalayan region where large populations depend on them. Observations indicate reduction of water provision from springs in recent years in the Himalaya, caused by multiple causal factors (human interventions, climatic) (section 10.4.4.).

Both small-scale interventions (e.g. livestock grazing in sensitive high-elevation wetlands) as well as high-investment interventions (e.g. hydropower dams and plants) in upstream regions can strongly affect water availability, river connectivity, biodiversity and catchment management (Anderson et al., 2018; Ramsar Convention on Wetlands, 2018; Encalada et al., 2019), and are often contested and have led to conflict (*medium evidence, high agreement*) (Drenkhan et al., 2015; French et al., 2015). Climate change often exacerbates tensions or conflicts between different users over water at local, national and transboundary or regional scales; many tensions and social or political conflicts are documented, especially in seasonally dry regions; where large power inequalities among users exists; where clear and established regulations are lacking; and especially also in transboundary settings (e.g. Central Asia, Hindu-Kush-Himalaya, Andes) (Carey et al., 2014; Bocchiola et al., 2017; Yapiyev et al., 2017; Hock et al., 2019; Mukherji et al., 2019).

Water plays a fundamental role in climate change adaptation in mountains. A majority of documented adaptation efforts in mountain regions address water-related aspects (precipitation variability and extremes, including drought, water availability, floods) (McDowell et al., 2019; McDowell et al., 2020) (*high confidence*). This is a robust finding across different mountain regions and adaptation project and program types, and also in line with findings for cryosphere change related adaptation as reported in SROCC (Hock et al., 2019). Water also plays a role for adaptation in other sectors such as agriculture, disaster management and tourism and recreation (McDowell et al., 2019). There is *high confidence* that water conservation efforts, also including restoration and protection of particularly vulnerable areas (e.g., wetlands), and increase of efficiency in water use, are robust, low-regret adaptation measures.

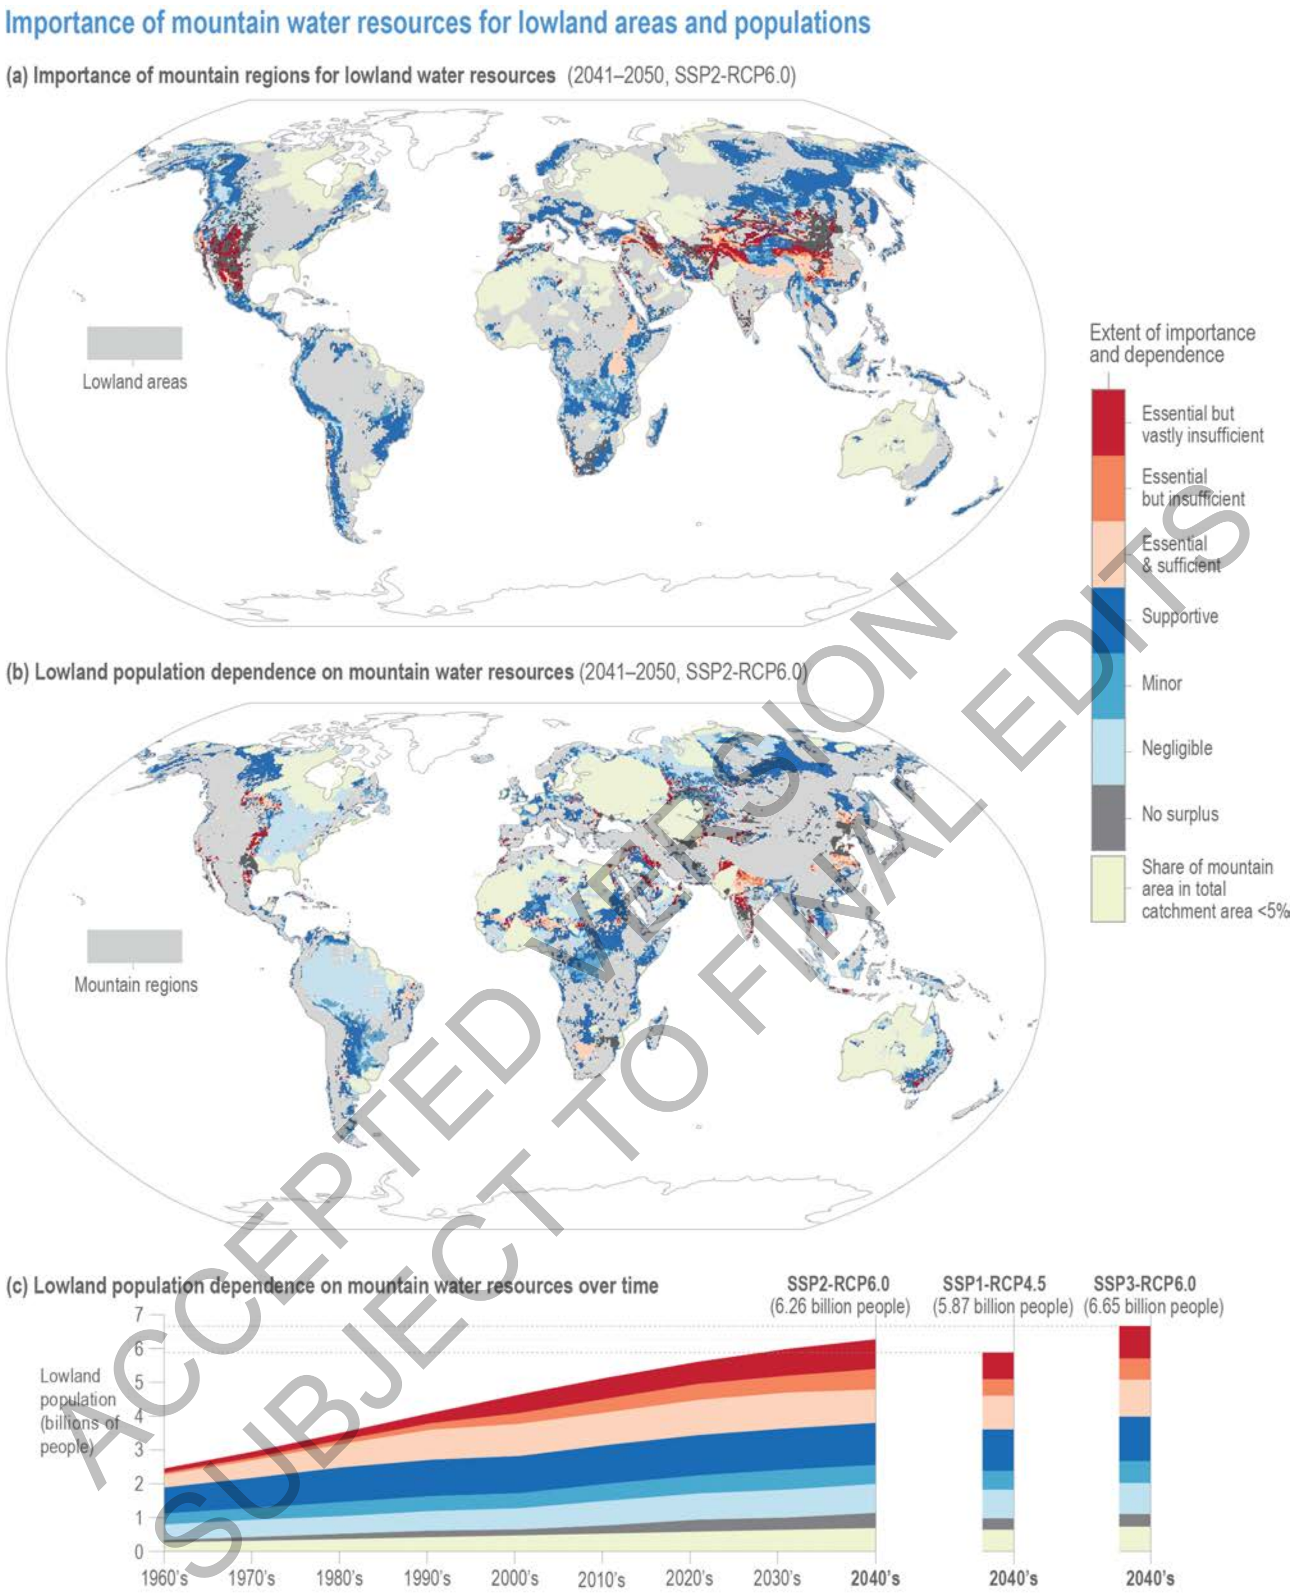

Figure CCP5.2: Dependence of land surface areas and population on mountain water resources 1961–2050. Results are shown as decadal averages for lowland population in each category of dependence on mountain water from no surplus and negligible to essential; a) map of global mountain regions and their differentiated importance for lowland water resources; b) map of lowland population and their differentiated dependence on mountain water resources, both for the scenario combination SSP2-RCP6.0 and for the time period 2041-2050; c) number of lowland population and their differentiated dependence on mountain water resources from the 1960's to the 2040's for three different scenario combinations (based on Viviroli et al., 2020).

CCP5.2.2.2 Energy

Increasing temperatures and variability in precipitation and river flow affect energy availability and use in mountain regions. Mountain peoples, more so than national or global populations, are dependent on local sources of energy, accentuating climate adaptation cost and barriers (*medium evidence, high agreement*) while also offering opportunities for mountain-specific solutions (*medium evidence, high agreement*). In mountain regions, inadequate infrastructure (Tiwari et al., 2018), remoteness, and reliance on traditional forms of energy that may be difficult to diversify (Dhakal et al., 2019), exacerbating impacts of climate change on energy use and demand.

A review of the renewable energy transition in the context of adaptation across global mountain regions, including hydropower, wind, solar and biomass, shows that observed climate change impacts on these energy sources include altered seasonality, timing as related to snow and glacial melt runoff (30.9% of analysed cases), variable or declining precipitation and runoff (26.4%), increased flooding (15.5%), altered wind patterns (8.2%), and other/not specified effects (19.1%) (Scott et al., 2019). Combined effects of climate change, hydropower development and further anthropogenic effects in upstream mountain basins, have increased and are expected to further negatively affect several aspects of ecosystem functions and water security (e.g. negative effects on river geometry, water chemistry, sediment transport, fish composition and migration) (Anderson et al., 2018; Encalada et al., 2019; Lepcha et al., 2021) (*high confidence*).

With respect to hydropower, mountains have a unique role for the production of renewable energy for large downstream populations, but it also comes with important trade-offs affecting mountain ecosystems and populations (*high confidence*) (Farinotti et al., 2019; Viviroli et al., 2020; Vaidya et al., 2021). Climate change requires adaptation in the hydropower sector; for instance, some advocate for increased water storage in dams and the importance of mountains for pumped hydropower storage systems (Gurung et al., 2016; Hunt et al., 2020), while others emphasize adaptive water management (Gaudard et al., 2014; Caruso et al., 2017b). An example is multi-purpose use of water strategies where water management storage is designed to accommodate different uses, including hydropower, agriculture, and flood risk reduction (Haeberli et al., 2016a; Drenkhan et al., 2019) (Section 12.6.3). Hydropower is also particularly exposed to glacier and snow decline (Schaefli et al., 2019), and is subject to risks from extreme events (Rangecroft et al., 2013; Schwanghart et al., 2016; Mishra et al., 2020; Shugar et al., 2021), social and political opposition (Ahlers et al., 2015; Díaz et al., 2017) and the resulting financial uncertainty for hydropower investors. There is still *limited evidence* on how climate change impacts wind, solar and biomass energy production, and use.

Overall, synergies between adaptation to climate change and renewable energy transition can be successfully generated where benefit-sharing improves local involvement and support, adaptive capacity is enhanced, local health and livelihoods supported, Sustainable Development Goals (SDGs) met, and environmental justice considered and sustainable mountain development pursued (*high agreement, medium evidence*).

CCP5.2.3 Food, Fibre, and Other Mountain Ecosystem Products

There is *high confidence* that climate change is largely negatively impacting on food, fibre and other ecosystem products, including agriculture (Porter et al., 2014; Ingxay et al., 2015; Upgupta et al., 2015; Chirwa et al., 2017; Rojas-Downing et al., 2017; Chitale et al., 2018; Pretzsch et al., 2018; Barberán et al., 2019; Sultan et al., 2019; Huang and Hao, 2020; Godde et al., 2021), and ecosystem services (Grêt-Regamey and Weibel, 2020) across many different mountainous region e.g. Africa (Bondé et al., 2019; Musakwa et al., 2020), Asia (Guo et al., 2018; Sunderland and Vasquez, 2020), Europe (Nair, 2019), North America (Hupp et al., 2015; Prevéy et al., 2020), South America (Herman-Mercer et al., 2020) (Section 5.4, 5.4.1, 5.5.1, 5.6.2, 5.7, 5.11.1.1).

Ecosystem products are vital to support the livelihoods and economic prospects for communities living in and around mountains (Figure CCP5.3). For instance, collection and trade of caterpillar fungus contributed to 53.3 - 64.5% annual household cash income in Nepal (Shrestha and Bawa, 2014; Shrestha et al., 2019); 40-80% in Bhutan (Thapa et al., 2018); 60-78% in Uttarakhand, India (Laha et al., 2018; Yadav et al., 2019) (Section 5.7.1). Livelihood support from ecosystem products in Southern Malawi region (Pullanikkatil et al., 2020), south-western Ethiopian mountains (Nischalke et al., 2017) and Southern China (Min et al., 2017), Himalayan mountains (Nepal et al., 2018), South Africa (Ngwenya et al., 2019) is reported. Additionally, the sacredness of mountains in different religions and cultures is widely acknowledged (Ceruti, 2019; Benedetti et al., 2021).

Climate change and associated impacts on multiple ecosystem services and related products (timber production, carbon sequestration, biodiversity and protection against natural hazards) have been observed across European mountains, e.g. in central Iberian Mountains (Spain), Western and Eastern Alps (France, Austria) and Dinaric Mountains (Slovenia) (Mina et al., 2017). Dumont et al. (2015) demonstrated that climate change negatively affects the forage nitrogen (N) content by 8% but increase the total non-structural carbohydrate content by 25% in European mountains. Positive impacts have been reported on mushroom productivity in the mountains of Spain (Karavani et al., 2018) (Section 5.7.3.3), yet negative impacts on the *Ophiocordyceps* in the Himalayan region (Hopping et al., 2018), likewise on apple production in Himachal Pradesh, India, which declined by 9.4 tonnes per hectare in the past two decades (Das, 2021). Shifts in crop wild relatives richness from south to north, and increase in the numbers of threatened taxa with an increase of 1.5 and 3^0C temperature rise, have been observed in European mountains (Phillips et al., 2017).

Medicinal and aromatic plants and their secondary metabolites are also observed to be affected by climate change (Das et al., 2016; Zhang et al., 2019a) *(medium confidence)*. Phenological changes like early flowering and reduced vegetative phase are negatively affecting the productivity of such plants (Harish et al., 2012; Gaira et al., 2014; Maikhuri et al., 2018). While increasing atmospheric temperature and CO_2 are reported to improve the biomass of *Gynostemmapentaphyllum* (Chang et al., 2016) (Section 5.7.3.3), they adversely affect its antioxidant compounds/activity, health-promoting properties and phytochemical content (Gairola et al., 2010; Das et al., 2016; Kumar et al., 2020). Experimental trials have shown that when medicinal plants are stressed by drought there is an increase in phytochemical content, either by decreasing biomass or by increasing actual production of the metabolites (Selmar and Kleinwächter, 2013; Al-Gabbiesh et al., 2015) *(medium confidence)*. Strong effects of climatic and non-climatic factors have been observed to affect the distribution of selected medicinal plants species in northern Thailand (Tangjitman et al., 2015), as well as in Egypt, Sub-Saharan Africa, Spain, Central Himalaya, China, Nepal, with some species at risk of being lost (Munt et al., 2016; Yan et al., 2017; Brunette et al., 2018; Chitale et al., 2018; Zhao et al., 2018; Applequist et al., 2020). Negative climate-related impacts on the distribution range of forty one medicinal plant species have been predicted for Spanish and Asian mountains (Munt et al., 2016) (Section5.7.3.3), and decreasing size of fruits of *Myrica esculenta* in Himalaya (Shah and Tewari, 2016).

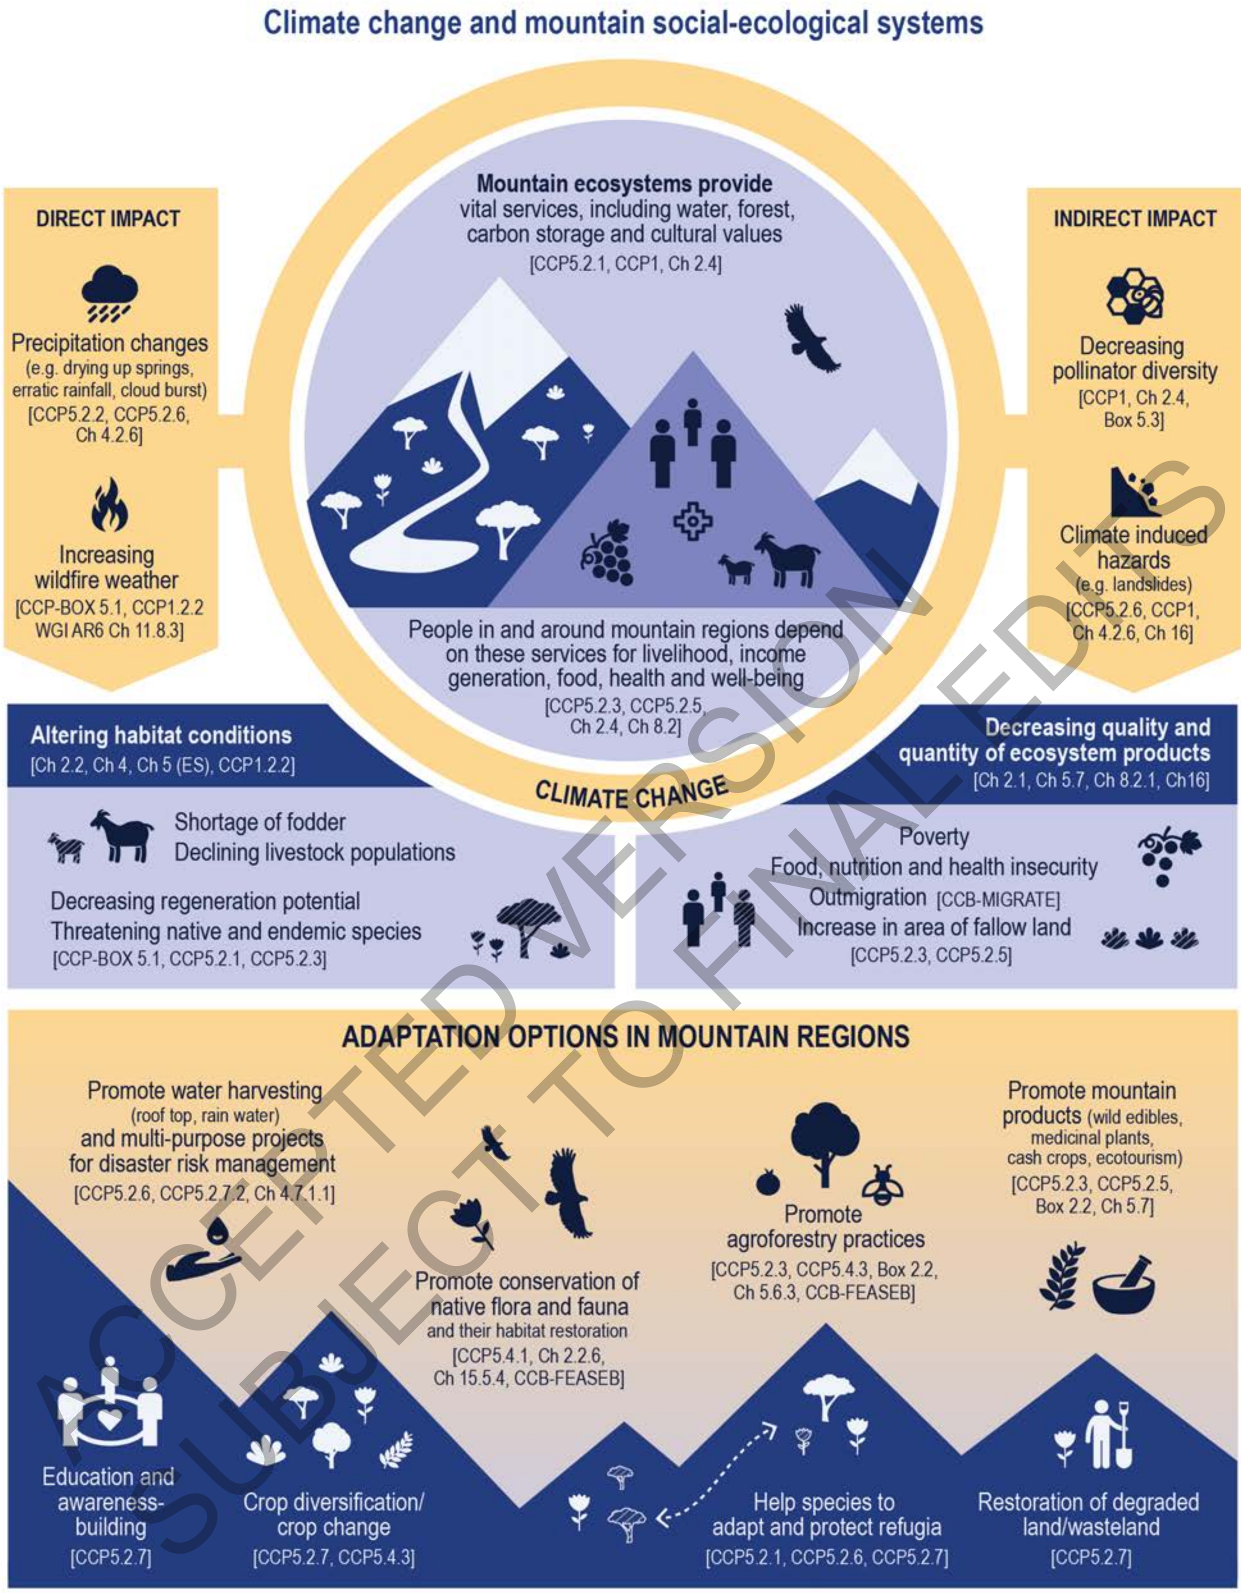

Figure CCP5.3: Impact of climate change on mountain social-ecological systems, including ecosystem services and products, livelihoods of mountain people and examples of adaptation options to address direct and indirect impacts.

CCP5.2.4 Cities, Settlements and Key Infrastructure

Mountain settlements and people are globally distributed and represent a significant proportion of the total global population that is exposed to the effects of climate change (Section CCP5.1, SMCCP5.1). Cities with one or several million inhabitants located in mountainous environments or at high elevations are predominantly found in Latin America e.g., in El Alto and La Paz (Bolivia), Quito (Ecuador), Mexico City (Mexico) and Bogotá (Colombia); Asia e.g., Kabul (Afghanistan), Kathmandu (Nepal), Srinagar (India), Peshawar (Pakistan), Quetta (Pakistan), Xining and Kunming (China), and Dehradun (India); and in Africa e.g., Harare (Zimbabwe) and Addis Ababa (Ethiopia) (Wang and Lu, 2018; Balderas Torres et al., 2021; Ehrlich et al., 2021). Mountain regions also host many settlements with fewer than 500,000 inhabitants (Alfthan et al., 2016). In many cases, particularly in developing countries, portions of the population also reside in informal and low-income settlements (French et al., 2021), where rates of poverty and inequality exacerbate their vulnerability and exposure to climate-related hazards such as landslides (Alfthan et al. 2018) (Section CCP5.2.5.1), environmental pollution or even pandemic diseases (Marazziti et al., 2021).

In many mountain regions, particularly in developing countries, the increasing urban population has put considerable pressure on water services and basic amenities for urban dwellers (Singh et al., 2021), for example in cities such as La Paz (Kinouchi et al., 2019), which are regions already under pressure due to the negative effects of climate change coupled with poor water availability and governance (Chapter 4; Section CCP5.2.2.1; FAQ CCP5.1; Hock et al. (2019). In many areas of the Hindu Kush Himalaya (HKH) region, water demand far exceeds municipal supply and people often cope with water insecurity in myriad ways (Bharti et al., 2020; Sharma et al., 2020; Singh et al., 2020), such as turning to inter-basin water transfers and deep pumping to supply their water needs (Ojha et al., 2020). Additionally, the influx of migrants, tourists and retirees, combined with the growth of the incumbent population, places considerable stress on urban infrastructure to supply adequate clean water and sewage disposal (Prakash and Molden, 2020), which is also observable in other regions (Chapter 4; Section 6.4.7; Case Study 6.1 in Chapter 6). Energy provision in and around mountain settlements, is another key sector affected by climate-related impacts (Hock et al., 2019) (CCP5.2.2.2), and which bear relevance for the adaptation prospects for urban mountain settlements (*medium confidence*).

CCP5.2.5 Mountain Communities, Livelihoods, Health and Wellbeing

People living in and around mountain regions strongly depend on the ecosystem functions, services and resources available in these areas for their livelihoods, health and wellbeing. Overall, subsistence agriculture and livestock remain key sources of livelihood in many mountain regions (FAO, 2019), with non-agricultural income sources such as remittances, small businesses, medicinal plants, wage labour and tourism also contributing to these economies (Montanari and Koutsoyiannis, 2014; Palomo, 2017; Minta et al., 2018). This section provides an illustrative overview of key reported observed impacts and adaptation responses to climate change on mountain communities (Table CCP5.1), and livelihood activities and economic sectors such as agriculture and pastoralism, and tourism and recreation (Table CCP5.2), reported since AR5.

Table CCP5.1: Overview of key observed impacts and adaptation on mountain communities – livelihoods and poverty; migration, habitability, and displacement; health and wellbeing.

Overview of key observed impacts and adaptation on mountain communities		References and relevant AR6 WGII Sections
Mountain livelihoods and poverty		
Impacts	• In some mountain regions, the incidence of poverty can be higher compared to other areas, with observed impacts of climate change intensifying the deterioration of socio-economic conditions that support livelihoods, thereby exacerbating already existing conditions of non-climate related vulnerabilities and livelihood insecurity (*medium confidence*).	Gioli et al. (2019); Tiwari and Joshi (2012); Rasul and Hussain (2015); Hussain et al. (2019); McDowell and Hess (2012); FAO (2015); FAO (2019); Shrestha et al. (2015); Motschmann et al. (2020a); Section 8.3
Responses and adaptation	• Diversification of livelihoods through the integration of drought-resilient livestock and crops and changes in farming practices (i.e. water management or migration of crops from low to high land) with some shifting to non-agricultural livelihood options, reported for cases such as in the HKH, the Andes, Rwenzori mountains of Uganda and Simien Mountains of Ethiopia.	Ashraf et al. (2014); Hussain et al. (2016a); Skarbø and VanderMolen (2016); Nkuba et al. (2020); Yohannes et al. (2020); CCP5.4.1

	Overview of key observed impacts and adaptation on mountain communities	**References and relevant AR6 WGII Sections**
Migration, habitability and displacement		
Impacts	• There is growing evidence of links between climate change impacts and migration and mobility through a complex web of causal links (*medium confidence*). In mountain contexts, migration and mobility are indirectly impacted by climate change through adverse effects on mountain livelihoods that are dependent on mountain ecosystem services.	Wrathall et al. (2014); Hunter et al. (2015); Brandt et al. (2016); Mastrorillo et al. (2016); Gautam (2017); Sagynbekova (2017); Cattaneo et al. (2019); Maharjan et al. (2020)
	• Extreme events are resulting in temporary and in some cases permanent displacement of populations in mountains (*medium confidence*), with hazards such as floods and mass movement (avalanche, flood, landslide) leading to population displacements e.g., in Afghanistan, Pakistan, Peru, Thailand, and Uganda.	Iribarren Anacona et al. (2015); Stäubli et al. (2018); IDMC (2020); Wang et al. (2020)
	• Cases of entire settlements either abandoned or relocated due to prolonged slow onset events such as water shortage, drought, and heat stress have been reported.	Mueller et al. (2014); Nawrotzki and DeWaard (2016); Prasain (2018)
	• In contrast, place attachment is increasingly cited as one of the reasons for the immobility choices for some people. However, in some cases, vulnerability to climatic events contribute to the in-migration decisions of vulnerable populations exposed to hazards from downstream to upland areas.	Adams (2016); Dandy et al. (2019); Khanian et al. (2019); Islam et al. (2020)
Responses and adaptations	• Migration, in turn, is often cited as a risk management strategy, where migration can lead to the diversification of livelihood options, improves access to information and resources, and expands social networks, all of which can support households in their capacity to adapt to climate change impacts • Migration is often gendered, with men migrating and leaving women to manage households at origin. Women's capacities are often constrained due to institutional barriers and social norms, resulting in low adaptive capacity and increased vulnerability to hazards. Capacity-building interventions strengthens adaptation capacity as well as links to access institutional support (*medium confidence*).	Banerjee et al. (2018); Banerjee et al. (2019); Siddiqui et al. (2019); Maharjan et al. (2020); Maharjan et al. (2021)
Health and wellbeing		
Impacts	• Direct links between climate change and health in mountain regions are reported in terms of physical injury or fatality due to exposure to climate-related hazards such as floods or landslides, or exposure to vector-borne diseases such as malaria or dengue fever reported at higher elevations with warming temperatures (*medium confidence*), such as in Mexico, Nepal, Ethiopia, and Colombia.	Dantés et al. (2014); Siraj et al. (2014); Dhimal et al. (2015); Wu et al. (2016); Equihua et al. (2017); Alfthan et al. (2018); Gilgel et al. (2019); Chapter 7
	• Indirect impacts to health by climate change are linked to water-borne diseases and pathogens associated with floods and droughts.	Table 7.6
	• Whilst reports on the ongoing challenges associated with the COVID-19 pandemic are emerging in relation to their compounding impacts on adaptive capacities, there is *limited evidence* to assess those effects with respect to other climate-related impacts on health.	Baiker et al. (2020); Cross-Chapter Box COVID in Chapter 7
	• Mental health issues associated with climate-related impacts are reported with respect to climate anxiety and ecological grief and their effects on the wellbeing of individuals. For example, the grief and loss associated with changes in glaciated landscapes, such as the 'death' of the Okjökull glacier in Iceland. However, there is *limited evidence* on mountain-specific cases and experiences that would allow for an assessment of the broader and longer-term impacts to mental health associated with a changing climate in the mountains.	Trombley et al. (2017); Cunsolo and Ellis (2018); Clayton (2020); Sideris (2020)
	• Other heightened vulnerability to climate-related impacts on health and wellbeing are also experienced by specific groups, for example	Furberg et al. (2011); Section 7.1.7.2

Overview of key observed impacts and adaptation on mountain communities		References and relevant AR6 WGII Sections
	Sami pastoralists facing changes in mountain snow cover that negatively affect their reindeer herding, a key activity for their identity and spiritual health.	
Responses and adaptations	• Approximately a fifth of observed adaptations reported in the GAMI mountain re-analysis address health and wellbeing as an aspect of vulnerability. This includes raising communities' awareness of and coping strategies climate change-induced health issues.	Furu and Van (2013); Section CCP5.4.1

Table CCP5.2: Overview of key observed impacts and adaptation on select livelihood activities and economic sectors – mountain agriculture and pastoralism; and tourism and recreation.

Overview of key observed impacts and adaptation on select livelihood activities and economic sectors		References and relevant AR6 WGII Sections
Mountain Agriculture and Pastoralism		
Impacts	• Changes in temperature and seasonal precipitation patterns are affecting the timing and availability of water for agricultural activities (*high confidence*), e.g. in the Bolivian Andes, Andean-Amazon foothills of Colombia, Ecuador, and Peru, High Atlas of Morocco, the Hindu Kush Himalaya (HKH), and Golestan province of Iran.	Rangecroft et al. (2013); Kaboosi and Kordjazi (2017); Hussain et al. (2018); Kalbali et al. (2019); Zkhiri et al. (2019); Beltrán-Tolosa et al. (2020); Torres-Batlló and Martí-Cardona (2020)
	• Changes in temperature and seasonal precipitation patterns are reported to affect nutrient depletion of soils and increased incidence of pest attacks in crops, e.g. in cases in the HKH and in Peru, however there is generally *limited evidence* on directs links to climate-related changes in mountain regions, specifically.	Oliver-Smith (2014); Hussain et al. (2016b)
	• Climate-induced hazards such as erratic precipitation (rain, snow and hail), floods, droughts and landslides have negatively affected the stable supply and transport of agricultural products in and out of remote mountain areas, such as in the Peruvian Altiplano and HKH.	Hussain et al. (2016b); Gonzales-Valero (2018); Thapa and Hussain (2020)
	• Warming temperatures and changes in timing of seasons and frost conditions needed for seeding of certain tree crops, are impacting lower elevation mountain areas, such as in Oman.	Buerkert et al. (2020)
	• Drought conditions are negatively affecting mountain grasslands (*medium confidence*), as reported in cases in Tyrol (Austria), Nepal, Afghanistan, Pakistan and China, which can contribute to a decline in agrobiodiversity.	Ashraf et al. (2014); Zomer et al. (2014b); Grüneis et al. (2018); Adhikari et al. (2019); Chaudhary et al. (2020); Hussain and Qamar (2020)
	• In some cases, climate-related hazards are leading to outmigration in mountain areas, with indirect negative impacts on labour deficits to support agricultural practices and productivity in mountain areas (*medium confidence*), e.g. in Ghana, Tanzania, Thailand and HKH.	Warner and Afifi (2014); Wester et al. (2019)
	• Positive impacts (favourable growing conditions) are reported for the production of some fruits and vegetables in Gilgit-Baltistan province of Pakistan, and for the production of traditional crops (e.g. local beans) in the Karnali region of Nepal.	Hussain et al. (2016b); Thapa and Hussain (2020)
	• Impacts on pastoralism include changes in growing conditions associated with warming temperatures and declining precipitation, which in turn leads to negative impacts on livestock productivity, food security and livelihoods of pastoralist communities, including drought-induced degradation of rangelands (*medium confidence*) e.g. in mountainous areas of Mongolia, Tanzania, Nepal, and Ethiopia, which exacerbate impoverished conditions for pastoral communities.	Batima et al. (2013); Rasul et al. (2014); Gentle and Thwaites (2016); Kimaro et al. (2018); Mekuyie et al. (2018); Tiwari et al. (2020)

Overview of key observed impacts and adaptation on select livelihood activities and economic sectors		References and relevant AR6 WGII Sections
Responses and adaptations	• Recharging groundwater and adopting rainwater harvesting (including appropriate tillage methods to improve soil moisture), restoration and rehabilitation of land, diversification of agricultural crops (including introduction of stress resistant crop varieties), promotion of in situ (protected areas, conservation areas) and ex situ (nurseries, gene banks, home gardens) conservation strategies, afforestation and agro-forestry.	Sections 4.7.1.1; 5.6.3; Cross-Chapter Box FEASIB in Chapter 18
	• Local knowledge is being used to help maintain the productive and cultural value of mountain agriculture and pastoralism, such as in the French and Italian Alps, Western Himalaya in India, and mountains in northern Morocco.	Fassio et al. (2014); Kmoch et al. (2018); Das (2021)
	• Ecosystem-based and community-based adaptation are contributing to supporting the diversity and complementarily of management options, permaculture, and local capacities to adapt and support ecosystem functions vital for agrobiodiversity (*medium confidence*).	Reid (2016); Grêt-Regamey and Weibel (2020); Cross-Chapter Box NATURAL in Chapter 2
Tourism and Recreation		
Impacts	• Since SROCC, the literature on climate change impacts on ski winter tourism has remained dominated by studies focused on future climate change impacts and projected risks due to decreasing seasonal snow reliability (see CCP5.3.1), most relevant when considering snow management and in particular snowmaking.	Hock et al. (2019); Sauri and Llurdés (2020); AR6 WG1 Sections 9.5.3 and 12.4.10.4
	• Climate-induced hazards in mountains, such as rockfalls, are negatively affecting access to some climbing, mountaineering, and hiking routes in summer (*medium confidence*), with cases mainly reported in the European Alps.	Hock et al. (2019); Mourey et al. (2019); Mourey et al. (2020)
	• Higher temperatures and extreme heatwave conditions at lower elevations have made some mountain destinations more appealing for human comfort, increasing the potential summer visitation demand and opportunities for tourism and recreation in mountains, such as in the European Alps and the Catalan Pyrenees (*medium confidence*). However, there is *limited evidence* reported for similar trends in mountain regions outside of Europe.	Serquet and Rebetez (2011); March et al. (2014); Pröbstl-Haider et al. (2015); Steiger et al. (2016); Juschten et al. (2019a); Juschten et al. (2019b)
Responses and adaptation	• Diversification of tourism activities to non-snow activities is reported as an adaptation approach to maintain economic viability in some winter ski areas, partly due to the high cost of running snowmaking infrastructure in winter e.g. in the Pyrenees (Europe) and Australian Alps.	Morrison and Pickering (2013); Sauri and Llurdés (2020)
	• In some cases, managing the availability and demand for water resources used for snowmaking is reported, with destination and large-scale governance highlighted as critical aspects for managing trade-offs, including overcoming conflicts arising from competing demands for environmental resources and land use, e.g. in the French Alps and in Scandinavia.	Demiroglu et al. (2019); Gerbaux et al. (2020)
	• For snow management, there are examples of dedicated climate services designed to enable better-informed decision making on appropriate long-term adaptation e.g. through a dedicated Copernicus Climate Change Service, or real-time early warning systems.	Köberl et al. (2021); Morin et al. (2021)
	• Barriers to adaptation strategies such as snowmaking, for instance in Switzerland, have been linked to perceived economic constrains to their implementation, as well as the social acceptability of these measures.	Matasci et al. (2014); Moser and Baulcomb (2020)
	• Adaptation options to limit exposure to hazards in hiking, climbing or mountaineering activities, include shifting the seasonal timing for practicing these activities, or changing routes entirely.	Hock et al. (2019); Mourey et al. (2019); Mourey et al. (2020)

Overview of key observed impacts and adaptation on select livelihood activities and economic sectors	References and relevant AR6 WGII Sections
• In some cases, such as in Bolivia, Peru, and New Zealand, and more recently reported in the French Alps, 'last chance' tourism has increased the appeal of some mountain destinations, resulting in visitation demand to witness the effects of climate change on iconic mountain landscape features such as glaciers.	Hock et al. (2019); Salim and Ravanel (2020)

Other sections in this CCP provide detailed assessments that synthesise impacts and adaptation on the detection and attribute of impacts to anthropogenic climate change (CCP5.2.7), projected impacts and key risks (CCP5.3), and adaptation responses to reduce those key risks (CCP5.4.1).

CCP5.2.6 Natural Hazards and Disasters

Climate and weather-related disasters in mountain regions have increased over the last three decades (*medium confidence*). Disaster frequency shows increasing trends in the Hindu Kush Himalaya, the Andes and mountain regions in Africa, whereas no clear trends for the European Alps and Central Asia are observed (*medium confidence*) (Froude and Petley, 2018; Stäubli et al., 2018).

Floods, debris flows, landslides and avalanches are the most frequent hazards affecting the highest number of people in mountain regions (*medium confidence*) (Stäubli et al., 2018). Landslides count amongst the deadliest hazards globally with over 150,000 reported fatalities for the period 1995-2014 (Haque et al., 2019). There is *high confidence* that the number of fatalities from landslides has increased globally over the past twenty years (Froude and Petley, 2018; Haque et al., 2019), but there is *limited evidence* that this is due to changes in landslide event frequency and/or magnitude. Infrastructure expansion on unstable terrain can increase disaster risk (Zimmermann and Keiler, 2015; Huggel et al., 2019; Kirschbaum et al., 2019; Schauwecker et al., 2019; Terzi et al., 2019; Motschmann et al., 2020a; Shugar et al., 2021). A study from western Nepal concludes that the exposure of people and infrastructure has been the main cause of disasters (Muñoz-Torrero Manchado et al., 2021). Decreasing numbers of fatalities from disasters resulting from decreasing vulnerabilities have been reported in Europe and North America (see Section 13.2.2.1*)* (Gariano and Guzzetti, 2016; Strouth and McDougall, 2021). Evidence from Africa suggests that disasters from climate induced natural hazards in mountain areas are often due to droughts, pests and changes to rainfall and associated impacts on smallholder farmers' agricultural livelihoods (Shikuku et al., 2017).

Characteristics of natural hazards in mountain areas have been largely explored and evidence suggests that conditions favouring cascading impacts are a common feature (*high confidence*) (Section 8.2.1.1) (Zimmermann and Keiler, 2015; Huggel et al., 2019; Kirschbaum et al., 2019; Schauwecker et al., 2019; Terzi et al., 2019; Motschmann et al., 2020a; Shugar et al., 2021). Compound and cascading impacts have affected people, ecosystems and infrastructure and generate significant spillovers across numerous sectors, resulting in destructive impacts (Nones and Pescaroli, 2016; Kirschbaum et al., 2019; Schauwecker et al., 2019).

Most adaptation responses to natural hazards in mountain regions are reactive and autonomous to specific climate stimuli or post-disaster recovery (*robust evidence, medium agreement*) (McDowell et al., 2019; Rasul et al., 2020). Hard structural measures such as dikes, dam reservoirs and embankments have largely been employed to contain the hazards alongside early warning systems, zonation and land management (Sections 4.4.1.3, 10.3, 12.5.3, 13.2.2). Awareness raising, preparedness and disaster response plans are increasingly used in the context of more unpredictable hazard trends (see Cross-Chapter Box DEEP in Chapter 17) (Allen et al., 2016; Allen et al., 2018; Hovelsrud et al., 2018). Ecosystem based adaptations (EbA) are widely implemented to mitigate risks from shallow landslides (e.g. afforestation and. reforestation and improved forest management), floods (e.g. river restoration and renaturation) (Renaud et al., 2016; Klein et al., 2019b) and droughts (e.g. adapting watershed) (Renaud et al., 2016; Klein et al., 2019b; Palomo et al., 2021).

Evidence from different mountain regions show that adaptation and risk reduction efforts are less successful if they focus on hazards or risks, without considering diverse risk and value perceptions of affected people (*medium confidence*) (French et al., 2015; Allen et al., 2018; Hovelsrud et al., 2018; Kadetz and Mock, 2018; Klein et al., 2019b). Previous experience and local social contexts of exposure to climate-related disasters affect the perception of people and influence the patterns associated with disaster risk management and associated coping strategies (*high confidence*) (see SROCC Chapter 2) (Kaul and Thornton, 2014; Shijin and Dahe, 2015; Landeros-Mugica et al., 2016; Wirz et al., 2016; Carey et al., 2017; Adler et al., 2019).

Important synergies exist between disaster risk reduction, climate change adaptation and sustainable development in mountain regions (*medium confidence*) (Zimmermann and Keiler, 2015), where the multiple and diverse perceptions of risk and risk tolerance to natural hazards are relevant considerations (Schneiderbauer et al., 2021). Global agreements for integrated disaster risk management and climate change adaptation (Alcántara-Ayala et al., 2017), including the Sendai Framework for Disaster Risk Reduction 2015–2030 (UNISDR, 2015), the SDGs (UN, 2015), the Paris Agreement (UNFCCC, 2015) and the New Urban Agenda-Habitat III (UN, 2016) create opportunities for synergies to address disaster risks (see also Section 6.3). Although these agreements are well established in the international agendas, there is *limited evidence* of their implementation to address disaster risk reduction and adaptation in mountains (Alcántara-Ayala et al., 2017).

CCP5.2.7 Synthesis of Observed Impacts and Attribution and Observed Adaptation

CCP5.2.7.1 Observed Impacts and Attribution to Anthropogenic Climate Change

The assessment of observed impacts identified a large number of impacts across all major mountain regions of the world and for a large variety of systems, based on more than 300 references (see SMCCP5.2). The literature was assessed, and results classified on a per regions and systems basis. Confidence statements on detection and attribution are based on expert judgement following IPCC guidelines (see Section 1.3.4), building on evidence from multiple sources in the literature (Mach et al., 2017) (see SMCCP5.2). Figure CCP5.4 provides an overview of the assessment results.

Climate change impacts have been documented in mountains of all continents. A wide range of human and natural systems have been affected by climate change to date, including the cryosphere, water resources, terrestrial and aquatic ecosystems, agriculture, tourism, energy production, infrastructure, health and life, migration, disasters and community and cultural values. The confidence levels for detection of impacts are generally in the range of medium to high. The contribution of climate change to the detected impact varies depending on the affected system, and climatic and non-climatic drivers. The highest levels of confidence for attribution of detected impacts to anthropogenic climate change is assigned to the cryosphere. More generally, those impacts are more strongly driven by increasing temperatures and show higher confidence for attribution than those impacts mainly driven by precipitation changes. The level of contribution of climate change to observed impacts is predominantly medium or high, indicating the high sensitivity of natural and human systems in mountains to climate change. Furthermore, the vast majority of detected impacts imply negative impacts on natural and human systems (*high confidence*).

Local knowledge plays an important role in documenting impacts of climate change in mountain regions. Since IPCC AR5 the evidence of meaningful climate change impacts being reported using local knowledge sources has increased substantially (*high confidence*). Similarly, important regional gaps present in the IPCC AR5 have been addressed here (e.g. Africa), resulting in a much more comprehensive and regionally balanced assessment and perspective.

Furthermore, the science of attributing negative impacts of climate change to anthropogenic emissions or even individual polluters is becoming increasingly important for climate litigation (Marjanac et al., 2017; McCormick et al., 2017; Otto et al., 2017; Setzer and Vanhala, 2019) and there is emerging evidence that mountains are becoming sites of litigation cases, with cases for instance in Peru, Colombia, and India (UNEP, 2017). Recent studies put litigation cases such as the Lliuya vs RWE case on risk of glacier lake floods in Peru in a broader context of differentiated responsibilities and justice (Huggel et al., 2020b).

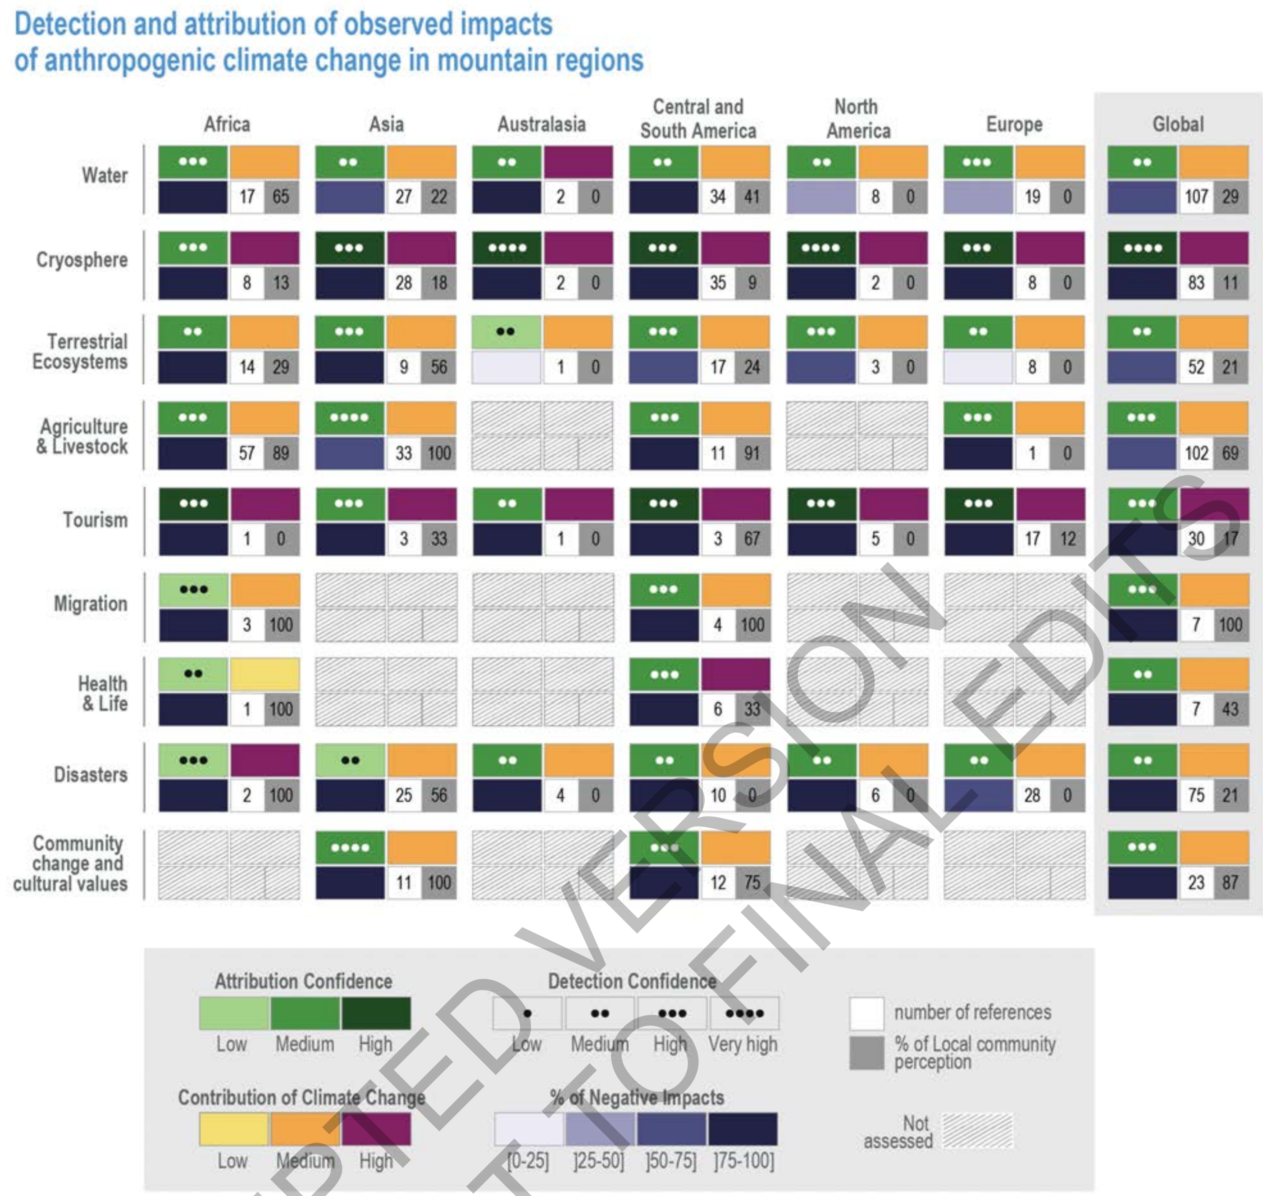

Figure CCP5.4: Synthesis of detection and attribution of impacts of anthropogenic climate change on different natural and human systems in mountain regions. For each system and region assessed, the level of confidence for detection and for attribution to anthropogenic climate change is indicated. Also indicated is how strong the contribution of climate change is to the observed changes, considering climatic and non-climatic causal factors. Observed impacts were analysed in terms of negative impacts (e.g. economic or non-economic damages, losses, contribution to increasing risks for society), where the numbers refer to the percentage of references indicating negative impacts for a given impact. The percentage of local community perception indicates the percentage of all literature references for a given system and region that account for local knowledge. The number of references refers to the total number of literature references considered for an impact to a specific system and region. "Not assessed" refers to *limited evidence* in the literature (see SMCCP5.2 and Table SMCCP5.5-5.14).

CCP5.2.7.2 Synthesis of Observed Adaptation

Extending from recent assessments of observed adaptation in high mountain areas (Hock et al., 2019; McDowell et al., 2019) new evidence for the geographically larger space for mountains assessed in this CCP is available from a mountain specific re-analysis of the GAMI dataset, which contains 423 articles reporting adaptation in mountains (Berrang-Ford et al., 2021; McDowell et al., 2021b) (SMCCP5.3), some of which also include those reported in section CCP5.2. In these articles, adaptation measures in mountains are reported from all regions worldwide, with predominance from Asia and Africa. Of all reported adaptations, 91% involve individuals or households, frequently engaged in smallholder agriculture and/or pastoralism; local governments are also often involved (31%) and sub-national or local civil society actors (29%) while private sector involvement remains scarce (below 10%). Food, fibre and other ecosystem products (76%) and poverty, livelihoods and sustainable development (55%) are by far most often involved in reported adaptation in mountains, followed by water and sanitation (28%) and health, well-being and communities (26%) (McDowell et al., 2021b) (SMCCP5.3.2).

Adaptation measures most commonly found include farming-related changes (e.g. resilient or drought-tolerant crop varieties, irrigation techniques, crop storage, and livestock insurance schemes), infrastructure development, Indigenous knowledge, community-based capacity building, and ecosystem-based adaptation (McDowell et al., 2021b) (SMCCP5.3.2) (*high confidence*). Nature-based solutions (NbS) are an adaptation component in NDC's of many mountain countries around the world (UNEP, 2021). Furthermore, Indigenous knowledge and local knowledge are often reported as informing adaptation efforts, and Indigenous Peoples, marginalized people and gender issues are recognized in several national adaptation strategies but autonomous responses are often insufficiently understood (Mishra et al., 2019).

The GAMI based re-analysis for mountains indicates that food security (75%), poverty (47%), consumption and production (36%), terrestrial and freshwater ecosystem services (19%) and clean water and sanitation (18%) are important aspects of vulnerability that adaptations address, with an emphasis on responses to climate-related shocks and stressors (McDowell et al., 2021b) (SMCCP5.2). The re-analysis also shows that more than 80% of adaptations in mountains are behavioural/cultural in nature, and more than 50% ecosystem-based, or technological or infrastructural.

About a third of the assessed adaptation activities are in the planning and early implementation stage, and around one-fifth in a stage of advanced implementation (McDowell et al., 2021b) (SMCCP5.3.2). Several lines of evidence converge, indicating that most observed adaptation in mountains is incremental in nature and not transformative (*high confidence*) (Mishra et al., 2019 ; McDowell et al., 2021b) (SMCCP5.3.2). Nevertheless, some adaptation measures such as NbS were found to bear important transformative potential in mountains if different knowledge types are combined, and community engagement and ecosystem management processes are in place (Palomo et al., 2021).

Overall, and consistent with findings in SROCC, there are still limited systematic monitoring and evaluation processes implemented to track adaptation progress, and there is *limited evidence* and prevailing uncertainties on the extent to which observed adaptation efforts reduce risks (Hock et al., 2019; McDowell et al., 2021b; UNEP, 2021) (SMCCP5.3.2).

Limits to adaptation are found in a majority (>80%) of the assessed adaptation studies; around half of the studies reported soft limits and less than a third identified both hard and soft limits to adaptation (McDowell et al., 2021b) (SMCCP5.3.2) (*high confidence*). Soft limits are frequently related to governance, economics, and social/cultural constraints, and can be overcome in principle through targeted efforts to address social conditions that impede adaptation planning and action. Hard limits are more frequently described as biophysical, such as precipitous declines in water supply. Examples of adaptation limits include lack of access to credit and markets, fixed livelihoods, insufficient awareness of climate risk, poor access to technology, and the erosion of existing skills and knowledge, social inequities, lack of trust and social cohesion, inequitable gender norms, and perceptions of conflict or scarcity. Furthermore, land tenure insecurity, poor integration of adaptation programmes across governing scales, and lack of decision-making power among vulnerable groups, along with inadequate funding for government-implemented adaptation programmes are reported to limit adaptation (Mishra et al., 2019; McDowell et al., 2021b) (SMCCP5.3.2). Hard limits imply that further adaptation action is unfeasible, ineffective, or unacceptable, resulting in inevitable losses and damages in mountain areas (Huggel et al., 2019) (*medium evidence, medium agreement*).

Overall, adaptation in mountain regions is taking place in various ways, in different sectors, scales, levels, quality, and effectiveness (*high confidence*). Most responses are incremental, with asymmetries of power among state, institutions and individuals, costs or capital requirements of adaptation, lack of coordinated planning, resistance to institutional change, household risk aversion, and lack of access to information inhibiting more transformational responses (SMCCP5.3.2). Aside from poverty reduction, there is *limited evidence* of adaptations effectively remediating the underlying social determinants of vulnerability (e.g. gender, ethnic identity).

CCP5.3 Projected Impacts and Risks in Mountains

CCP5.3.1 Synthesis of Projected Impacts

Declines and extinctions have been projected in a range of montane plants and animal species, including rare endemic species and subspecies due to climate change (*medium evidence, high agreement*) (Li et al., 2017; Ashrafzadeh et al., 2019; Brunetti et al., 2019; Zhang et al., 2019b; Manes et al., 2021). Up to 84% of endemic mountain species are found to be at risk of extinction (Manes et al., 2021). By using a simple model, Helmer et al. (2019) predict a large-scale contraction in the next 25 years of alpine ecosystems above tropical mountains cloud forest in the Andes due to tree invasion. Topographic complexity can smoothen and delay transition of montane forests in terms of size and composition for warming up to 3°C GWL (Albrich et al., 2020).

Hydrological changes will determine how some ecosystems change, more than changes in temperature. For example, (Dwire et al., 2018) found that changes in riparian areas, wetlands and forests were likely under climate change in the Blue Mountains, Oregon, USA, as a result of altered snowpack, hydrologic regimes, drought and wildfire. In the Bolivian Cordillera Real, wetland cover variations were associated with increases in precipitation extreme events and glacier melting over the 1984-2011 period but might be reversed with predicted future decrease in both total precipitations and glacier run-off (Dangles et al., 2017). About 30% of the wetland area in the Great Xing'an Mountains, northeastern China has been projected to disappear by 2050, with this value doubling by 2100 under CGCM3-B1 scenario (Liu et al., 2011).

Climate change impacts on food, fibre and ecosystem products will be highly variable across mountain regions (*medium confidence*) (Briner et al., 2013; Rasul and Hussain, 2015; Mina et al., 2017; Palomo, 2017; Said et al., 2019; Xenarios et al., 2019) (Sections 10.4; 12.3; 13.5; 14.4). In some regions, tree crops that are cultivated at certain elevations may reach the limit of their agroclimatic plasticity, for instance for crop types that require winter chills and where projected growing conditions would be too warm (Buerkert et al., 2020). In the European Alps, agricultural production in some areas may benefit from temperature rises, as total productivity in grasslands is projected to increase (Mitter et al., 2015; Grüneis et al., 2018), whereas some areas in Asia and South America heavily depended on glacier- and snow fed irrigation will be at risk of food insecurity (Rasul and Molden, 2019). In a study in the Eastern Pamir, (Mętrak et al., 2017) found that summer droughts and water changes lead to functional transformations of the wetland ecosystems which can affect food security of the local population. Climate change affects the phenology of plants (Harish et al., 2012; Gaira et al., 2014; Maikhuri et al., 2018), secondary metabolites (Chang et al., 2016; Kumar et al., 2020), and pharmacological properties of medicinal plants (Gairola et al., 2010; Das et al., 2016).

Water resources in mountains and dependent lowlands will continue to be strongly impacted by climate change throughout the 21st century (*high confidence*). The difference in impacts will be particularly strong for regions that highly depend on glacier and snow melt, and in pronounced dry seasons (*high confidence*), regions including Central Asia, South Asia, tropical and subtropical western South America, and southwestern North America (Huss and Hock, 2018; Hock et al., 2019; Immerzeel et al., 2020). Glaciers are expected to continue to lose mass throughout the 21st century, with higher mass loss under high emission scenarios (AR6 WGI Chapter 9). Many low elevation and small glaciers around the world will lose most of their total mass at 1.5°C GWL (*high confidence*) (Marzeion et al., 2018; Vuille et al., 2018; Hock et al., 2019; Zekollari et al., 2020) (WGI 9.5). For tropical and mid-latitude mountains, around half of the current ice mass can be preserved under low-emission scenarios, while two-thirds up to more than 90% will be lost under high emission scenarios compared to the 2000's (*medium confidence*) (Schauwecker et al., 2017; Vuille et al., 2018; Hock et al., 2019) (WGI 9.5). Strong differences in impacts between the emission scenarios are also assessed for decline in snow depth or mass at lower elevation [10 to 40% for RCP2.6 and 50 to 90% for RCP 8.5 by the end of the century (Hock et al., 2019)]. However, limitations in long-term climate, glaciological and hydrological monitoring data adds uncertainty to current understanding and adaptation support, e.g. when peak water is reached in different mountain catchments (Salzmann et al., 2014; Hock et al., 2019). Furthermore, context specific socio-cultural and economic factors can magnify, or moderate impacts related to hydrological change (McDowell et al., 2021a).

The dependence of lowland populations on mountain water resources will grow by mid-century across several climate and socio-economic scenarios, and several seasonally dry or semi-arid mountain regions (e.g. parts of South Asia, North America) are projected to be highly dependent (*medium confidence*) (Viviroli et al., 2020) (Figure CCP5.2). Changing sediment, nutrient and pollutant flows due to climatic and non-climatic drivers will impact populations and economic sectors (*medium evidence, high agreement*). Hydropower in all mountain regions will experience higher flux of water and sediment in some seasons, but lower water flow with demands from other water uses (e.g., irrigation) (Chevallier et al., 2011) in other seasons (Beniston and Stoffel, 2014; Gaudard et al., 2014; Majone et al., 2016; Caruso et al., 2017a; Caruso et al., 2017b; Patro et al., 2018). Recharge from groundwater and its buffer function is expected to decrease on the longer term (Somers and McKenzie, 2020). Glacier and snow depth or mass decline will impact current hydropower facilities and production in various complex ways, requiring changes in hydropower management, with further potential for evidence informed solutions (Gaudard et al., 2014; Schaefli, 2015; Schaefli et al., 2019). On the other hand, deglaciation in mountain regions opens topographic space and thus potential for additional long-term hydropower development and production (Haeberli et al., 2016a), with an estimated additional production of up to several hundred terawatt-hour per year, a potentially important contribution to national energy supplies, in particular in the High Mountain Asia region (Farinotti et al., 2019). However, water supply from glacier melt will decrease once source glaciers pass peak discharge (Huss and Hock, 2018), and the areas with available sediment will grow as glaciers shrink, posing potential risks to downstream populations and assets (Lane et al., 2019) (*high confidence*).

Since SROCC (Hock et al., 2019), several new studies have addressed projected impacts of future climate change on snow reliability in ski resorts, complementing previous findings or bridging existing knowledge gaps for winter tourism. This includes, in particular, new studies for China (An et al., 2019; Fang et al., 2019), showing that average ski seasons are projected to shorten (-4 to -61% for RCP4.5; -6 to -79% RCP8.5 in the 2050s) along with increases in snowmaking water demand (27 to 51% for RCP4.5; 46 to 80% for RCP8.5 in the 2050s), with large differences across the country. Changes in future snow reliability are projected across Europe at the national or pan-European scale (Demiroglu et al., 2019; Steiger and Scott, 2020; Morin et al., 2021), highlighting strong contrasts at the local (across ski resorts size and/or elevation range, or local social or environmental context) and continental scales. Higher latitude and high elevation locations generally exhibit delayed declines in snow reliability compared to lower latitude and lower-elevation locations (*high confidence*), consistent with assessment conclusions reached in SROCC (Hock et al., 2019). In general, climate change impacts and risks to ski tourism are found to be spatially heterogeneous, within and across local and international markets, with potential for significant disruptions to related socio-economic sectors due to a growing mismatch between ski area supply and skier demand in the coming decades (Fang et al., 2019; Hock et al., 2019; Steiger et al., 2020a) (*high confidence*). These disruptions are plausible, even though a fraction of current ski resorts could technically be able to operate under comparatively favourable locations (elevation, latitude) and operating models (business models, socio-cultural assets and conditions, governance) (Steiger et al., 2020b).

Severe damage and disruptions to people and infrastructure from floods are projected to increase in Northwestern South America (NWS), South Asia (SAS), Tibetan Plateau (TIB) and Central Asia (WCA) between 1.5°C to 3°C GWL mainly driven by river floods and an increase in the number of glacial lakes with high potential for outburst (*high confidence*) (Drenkhan et al., 2019; Motschmann et al., 2020b; Furian et al., 2021; Zheng et al., 2021). For example, the formation of new lakes at the foot of steep icy peaks largely extends the hazard zones with respect to the earlier situation without lakes (Haeberli et al., 2016b). Projected changes in ice and snow-melt, as well as seasonal increases in extreme rainfall and permafrost thaw, will favour chain reactions and cascading processes which can have devastating downstream effects well beyond the site of the original event (Cui and Jia, 2015; Beniston et al., 2018; Terzi et al., 2019; Vaidya et al., 2019; Shugar et al., 2021) (*high confidence*). The incidence of disasters is projected to increase in the future due to some hazards becoming more pervasive, with an increase in the exposure of people and infrastructure with future environmental and socio-economic changes either contributing to reduce or enhance these disaster risks (Klein et al., 2019b) (*medium confidence*).

CCP5.3.2 Key Risks Across Sectors and Regions

Key risks are derived from the detection and attribution assessment (CCP5.2.7) and from the projected impact and risks (CCP5.3.1). The assessment is informed by evidence in the regional and sectoral chapters and supports the key risk assessment in Chapter 16. Four key risks (KR1 to KR4) have been identified in this CCP and are presented in Sections CCP5.3.2.1-CCP5.3.2.4 (see SMCCP5.4 for methodology and references).

CCP5.3.2.1 KR1: People and Infrastructures at Risks from Landslides and Floods

The amount of people and infrastructure at risk of landslides will increase in regions where the frequency and intensity of rainfall events is projected to rise (Gariano and Guzzetti, 2016; Haque et al., 2019). Extreme precipitation in major mountain regions is projected to increase leading to consequences such as floods and landslides (AR6 WGI TS, *medium confidence*). Rain-on-snow events which can accelerate all flood stages and result in widespread consequence for societies are projected to increase between 2-4°C GWL (but decrease afterwards) (SROCC Chapter 2; WG I Chapter 12). There is *high confidence* that glacial retreat, slope instabilities and heavy precipitation will affect landslides and flood activities although for landslides there are considerable uncertainties in the direction of change (Patton et al., 2019) (AR6 WGI Chapter 12).

Future risk consequences which are considered severe include for example an increase of 10-20% compared to present of the population exposed to landslides activities in certain regions (e.g. High Mountain Asia) (Kirschbaum et al., 2020). This does not consider the expected increase in landslide activity relating to glacier and permafrost changes (Picarelli et al., 2021) (see SROCC Chapter 2) and therefore it is expected to be a conservative estimate. Other severe consequences are on average a projected twofold increase in the number of people exposed to inland flooding between 2°C and 4°C with highest increases in South Asia, Southeast Asia and South America (*high confidence* in the direction of change and *medium confidence* in the absolute values because based on global studies) (Hirabayashi et al., 2013; Allen et al., 2016; Arnell and Gosling, 2016; Zheng et al., 2021). Therefore, high to very high risks are expected between 2°C and 4°C GWL in several mountain regions (Figure CCP5.5 red and violet shaded bars). Many regions are projected to experience high risks due to the timing (potentially for severe consequences to happen sooner rather than later), the magnitude in terms of number of people and infrastructure affected) and the persistence of hazard conditions (Figure CCP5.5, AR6 WGI Chapter 12). Comparatively, more severe risks consequences are expected under SSP3 and/or SSP4 given the high population projections in certain regions compared to SSP1 (Kirschbaum et al., 2020) (see Figure CCP5.1) (*medium confidence*).

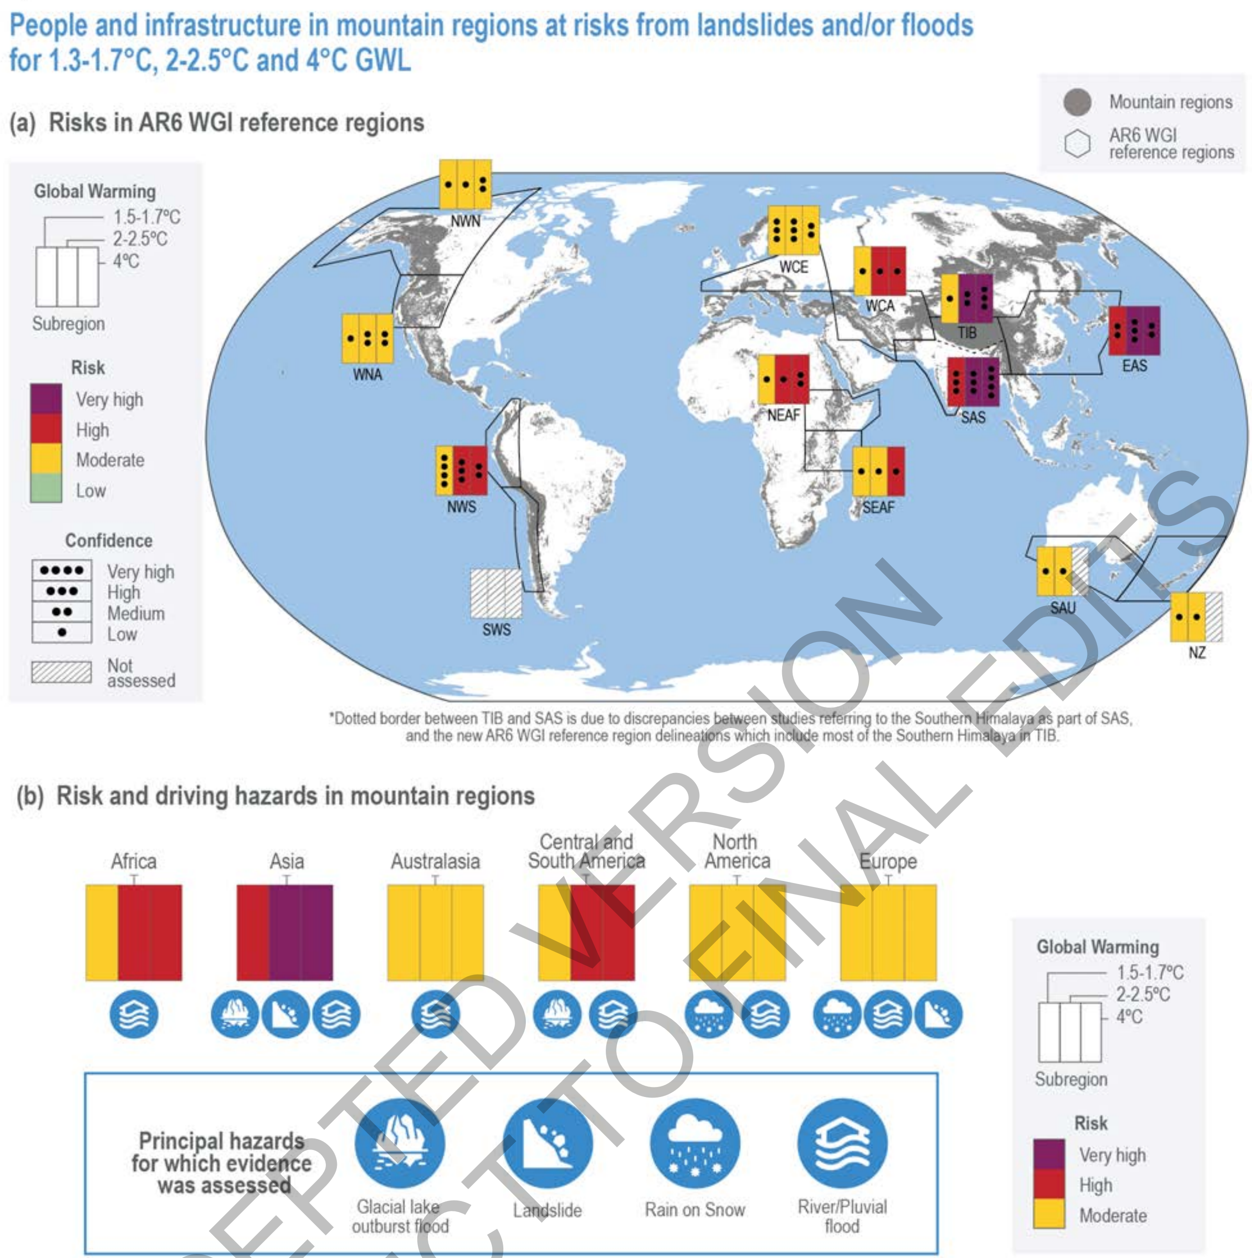

Figure CCP5.5: People and infrastructure in mountain regions at risk from landslides and/or floods for various Global Warming Levels (GWLs). Panel a) shows the level of risk assessed per AR6 WGI reference regions (see AR6 WGI Atlas). For some mountain regions, there is limited evidence to adequately assess the level of risks against GWLs, therefore this is labelled as "not assessed". Panel b) shows the level of risk aggregated at the continent scale and the principal hazards for which evidence was available and assessed. Methodological details and traceability are provided in SMCCP5.4, Figure SMCCP5.1, Table SMCCP5.15 and SMCCP5.17.

CCP5.3.2.2 KR2: Risks to Livelihoods and the Economy from Changing Water Resources

KR2 encompasses the relative and absolute dependency on water resources for economic activities and livelihood sustainment in mountain regions and in the lowlands. Particularly affected by changes in water resources will be regions with (seasonally) high dependence on snow and glacier melt, i.e. arid and semi-arid zones in the Andes, Central Asia and the Upper Indus Basin (Huss et al., 2017; Huss and Hock, 2018; Viviroli et al., 2020) (Section CCP5.3.1).

Consequences that are considered severe refer to the magnitude (number of people and economic activities affected), the timing (increase of water stress as early as mid-century in several regions) and the likelihood (severe risk consequences are more *likely* where high population density is projected) (see Figure CCP5.1,

Figure CCP5.6, Section 4.2.2.3) (Fuhrer et al., 2014; Wijngaard et al., 2018; Biemans et al., 2019; Immerzeel et al., 2020; Viviroli et al., 2020) (*high confidence*). Severe consequences are that by mid-century more than a half of agriculture regions equipped for irrigation are projected to be dependent on mountain runoff and could therefore be unsustainably using blue water (e.g. water from river, lakes and aquifers) (Viviroli et al., 2020) or that the number of people being water stressed will increase by 50% to 100% in areas already water stressed today (Munia et al., 2020). Hotspot regions are those with large lowland populations depending on essential mountain water resource contributions and include river catchments such as Ganges, Brahmaputra, Meghna, Yangtze, Nile, Niger, Indus, Euphrates-Tigris or Pearl (Viviroli et al., 2020) (*high confidence*) (see Figure CCP5.6). Limited governance and integrated management of water resources, power and gender inequalities and level of disruption of local community practices also contribute to make risks more severe (*medium confidence*) (Lynch, 2012; Boelens, 2014; Wijngaard et al., 2018; Scott et al., 2019; Immerzeel et al., 2020). Consequences for hydropower are comparatively less severe than for agriculture and domestic/municipal use although this depends on region and timing (see also Section 5.2.2.2). For example, a study shows low risk to hydropower production in High Mountain Asia until the end of the century and even for warming levels beyond 3°C (Mishra et al., 2020) *(robust evidence, moderate agreement).*

Large scale and transformative interventions can reduce the high-end impacts of changing water resources and in particular the risks of water scarcity (see Section CCP5.4.1). These interventions have long lead times, are costly and may face institutional constraints (see Section 4.5.3), resulting in adaptation shortfall. Therefore, high to very high-risk levels cannot be excluded in regions where other key risks characteristics such as magnitude, timing and likelihood are assessed as high due to potential losses (e.g. in many Asian regions, see Figure CC5.6, SMCCP5.4 and Table SMCCP5.16).

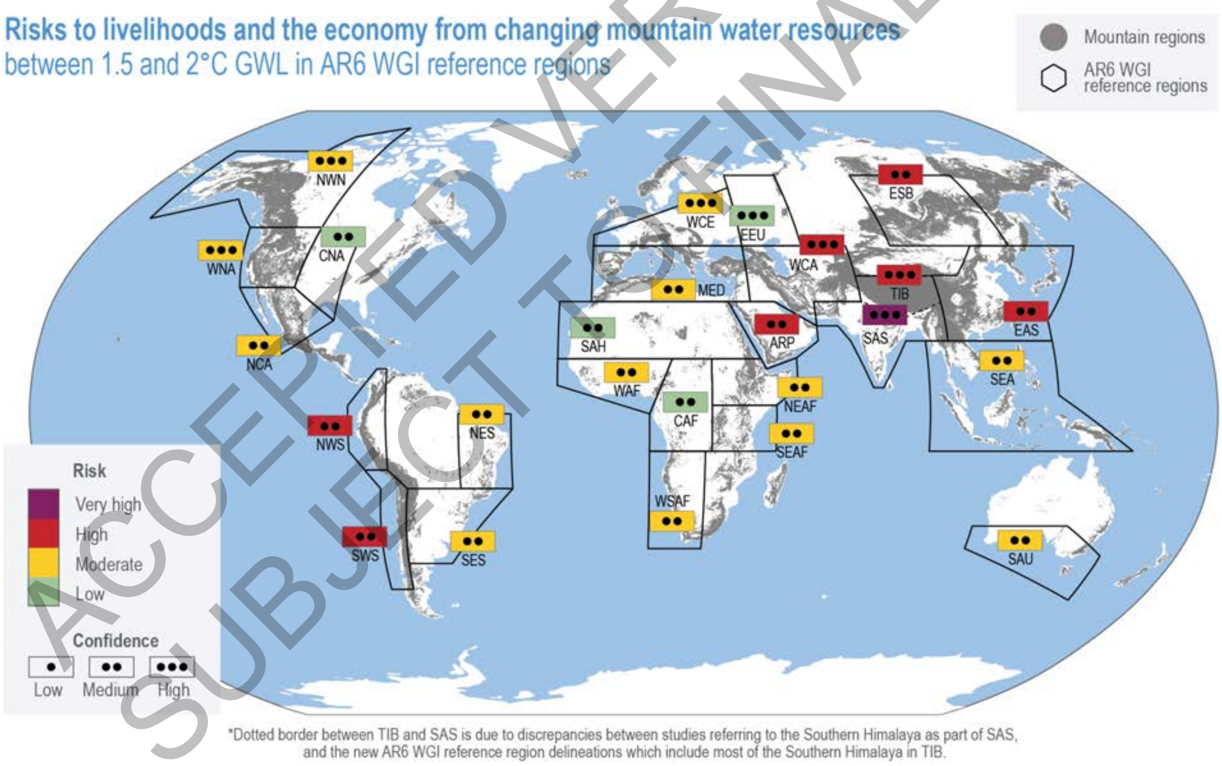

Figure CCP5.6: Risk levels assessed per AR6 WGI reference regions (see AR6 WGI Atlas). The majority of studies assessed focus on impacts up to mid-century (2030-2060) and for RCP-2.6, RCP-4.5 and RCP-6.0, which was converted into the corresponding warming level range 1.5-2.0°C GWL (see Cross-Chapter Box CLIMATE in Chapter 1). Methodological details are provided in Section SMCCP5.4, Figure SMCCP5.1, Table SMCCP5.16 and SMCCP5.18. Due to the *limited evidence* available to determine risks against high Global Warming Levels (GLWs), and the relatively high uncertainties associated with future irrigation trends for the second half of the century (see e.g. Viviroli et al., 2020), assessment of risks associated with GLWs greater than 2.0°C GWL was not conducted.

CCP5.3.2.3 KR3: Risks of Ecosystem Change and Species Extinction

Risks to mountain ecosystems and the services they provide to people are varied in magnitude, timing, likelihood and potential to adapt and place specific (see Table SMCCP5.19). However, many mountain ecosystems are already showing impacts of climate change (CCP5.3.1), reflecting the strong influence climate has in many situations and indicative that risks are large, immediate and will *likely* increase in the near as well as long-term. There is *robust evidence (high agreement*) of vegetation zones and individual species shifting to higher elevations (Section 5.2.1; Chapter 2.4) and projections indicate that current will continue and accelerate at higher rates of warming (*medium evidence, high agreement*) (Section 2.5).

Many mountain species are at risk of range contraction and ultimately extinction if dispersal at the upper range limit is slower than losses due to mortality at the lower range limit (observed for trees in the Neotropics; (Feeley et al., 2013; Duque et al., 2015), or if mountains are not high enough to allow species to move to higher elevations. Ramirez-Villegas et al. (2014) modelled 11,012 species of birds and vascular plants in the Andes, finding large decreases by 2050 (SRES-A2 scenario); in absence of dispersal 10% of species could become extinct. Even assuming unlimited dispersal, most of the Andean endemics would become severely threatened. Other modelling studies have also projected declines in a range of communities and species, including rare endemics (Zomer et al., 2014a; Rashid et al., 2015; Bitencourt et al., 2016; Li et al., 2017; Rehnus et al., 2018; Ashrafzadeh et al., 2019; Zhang et al., 2019b; Cuesta et al., 2020; Hoffmann et al., 2020).

Many treelines will continue to shift to higher elevations with increasing temperatures (Chhetri and Cairns, 2018), although very few are changing as fast as climate change (Liang et al., 2016; Hansson et al., 2021) and some are not moving or even shifting to lower elevations (CCP5.2.1). If treelines fail to shift uphill, this presents a risk for species of the upper-montane forest that experience range contraction at their lower range limit but lack a suitable habitat to expand into beyond their upper range limit (Rehm and Feeley, 2015). Changes in phenology can also present risks to species and ecosystems (Chapter 2), including a potential desynchronization of mutualistic relationship such as pollination and increased freezing damage due to premature emergence from winter dormancy. In European broadleaved trees, for example, the upper elevational limits of different species involve a trade-off between maximizing growing season length and limiting the risk of spring freezing damage (Vitasse et al., 2012; Körner and Spehn, 2016).

A wide range of mechanisms can cause changes within ecological communities, some of which are hard to predict but there are an increasing number of studies illustrating some of the risks which are expected to be most common. If treelines shift upwards, this presents a risk for alpine species, which cannot compete with trees. This may lead to extinction of alpine species on mountains where there is insufficient room for the alpine zone to shift uphill. Shifts in species distributions, and in particular shifts in ecosystem types, can cause changes in ecosystem function, which may in turn have cascading impacts on people, for example leading to increased exposure to diseases such as malaria at high elevation (Section 2.4.2.7.2) as vector distribution changes and wider impacts on ecosystem services (Section 2.5.3) such as water supply, flood alleviation and food.

CCP5.3.2.4 KR4: Risk of Intangible Losses and the Loss of Cultural Values

The risk of intangible losses and loss of cultural values is associated with the decline of ice and snow cover and temperature increase, as well as the increase in intangible harm from hazards such as floods and droughts (*high agreement, medium evidence*) (Diemberger et al., 2015; Jurt et al., 2015; Vuille et al., 2018; Tschakert et al., 2019; Vander Naald, 2020). Losses are intangible because they characterise aspects which are difficult to quantify, i.e. loss of identity, loss of self-reliance, loss of rituals and traditions and place attachment (Allison, 2015; Baul and McDonald, 2015; Motschmann et al., 2020a; Schneiderbauer et al., 2021). A global systematic analysis of case studies shows that this risk is more prevalent in the Andes, the Himalaya and the Alps (Tschakert et al., 2019). Often mentioned across studies is the loss of intrinsic memories and culture related to changes in world heritage landscapes and iconic sites (Jurt et al., 2015; Sherry et al., 2018; Bosson et al., 2019). Changes in the hazard landscapes are also reported to contribute to the loss of peace of mind and loss of well-being (Diemberger et al., 2015). Overall, there is *limited evidence but medium agreement* that the risk of intangible losses and the loss of cultural identity will rapidly increase and that consequences will go from reversible damage to irreversible losses (Tschakert et al., 2019).

CCP5.4 Options for Adaptation and Climate Resilient Development Pathways

CCP5.4.1 Synthesis of Adaptation Responses to Reducing (Key) Risks

More than half of the studies having a focus on mountains (423 articles) extracted from the GAMI dataset report that adaptation responses are contributing to reducing climate risks (Berrang-Ford et al., 2021; McDowell et al., 2021b) (see SMCCP5.3.2). However, the extent of adaptation in terms of time (i.e. speed), the scale of change (i.e. scope) and its depth (i.e. degree to which a change is substantial) is low in mountain regions, with the level of agreement across studies varying from one region to the other (*medium confidence*) (Figure CCP5.7, SMCCP5.3.2). In regions where risk levels remain moderate, a low adaptation extent might be sufficient to constrain risks (see Figure CCP5.5 and Figure 5.6; Section 16.3.2.5).

Adaptation responses in mountains are mainly incremental changes from existing practices (*high confidence*) (McDowell et al., 2019; Rasul et al., 2020; McDowell et al., 2021b), signalling that the potential of current and planned adaptation responses to reduce risks in the future will not be adequate to mitigate high to very high risks. For example, measures to contain floods or landslides (KR1) are designed with specific magnitudes and types in mind often assuming stationarity of return periods (Montanari and Koutsoyiannis, 2014; Gariano and Guzzetti, 2016). In the case of events showing decreasing return periods, risk mitigation standards need to be elevated to provide for more protection in the future (Felder et al., 2018; François et al., 2019). The portfolio of adaptation options to mitigate risks from changing water resources (KR2) is large but challenging and includes integrated catchment management, implementation of multiple use of water strategies, improved water governance (including community based and participatory water governance), overcoming power inequalities among users and sectors, and balancing economic pressure and sustainable development (*high confidence*) (Bekchanov and Lamers, 2016; Yapiyev et al., 2017; Jalilov et al., 2018; Drenkhan et al., 2019; Allen et al., 2020; Aggarwal et al., 2021; Huang et al., 2021) (SMCCP5.3.2). There is *limited evidence* on the effectiveness of adaptation responses to reduce the severity of ecosystem change (KR3) (also see Section 16.3.1). Prevention rather than control and eradication efforts can contribute to curbing biological invasions of alien species in the short turn, whereas colonisation by native trees following land use abandonment can be more effective in the long run (Carboni et al., 2018). Reducing intensified grazing, agricultural expansion, and conservation management in buffer zones of protected areas can limit the altitudinal range shift of endemic species (Kidane et al., 2019).

EbA has been effective in mountain regions to reduce risks from floods (e.g. restoration of buffer zones and floodplains) and landslides (e.g. protective forests) (Muccione and Daley, 2016; Klein et al., 2019b; Lavorel et al., 2019). Ecosystem based measures have been implemented for water management purposes to supply clean water and improve water quality (see Section 4.5.2.1). Furthermore, they provide scope for conservation and improvement of habitats, e.g. forest ecosystems (Nagel et al., 2017; Lamborn and Smith, 2019) (*high agreement, medium evidence*). However, repeated, and recurrent disturbances that increase recovery times can reduce the effectiveness of EbA (Sebald et al., 2019; Scheidl et al., 2020) (*medium confidence*).

Adaptation in mountain areas is currently constrained predominantly by soft limits related to existing social, economic, and political conditions (*high confidence*) (Gioli et al., 2014; Sansilvestri et al., 2016). Progress in overcoming soft limits is currently minimal due to insufficient engagement with socio-economic and political issues in existing adaptation (*medium confidence*) (McDowell et al., 2019; McDowell et al., 2021b) (Sections 8.4.5.3, Cross-Chapter Box LOSS in Chapter 17). This is expected to lead to an expansion of residual risks as risk severity increases (McDowell et al., 2021b).

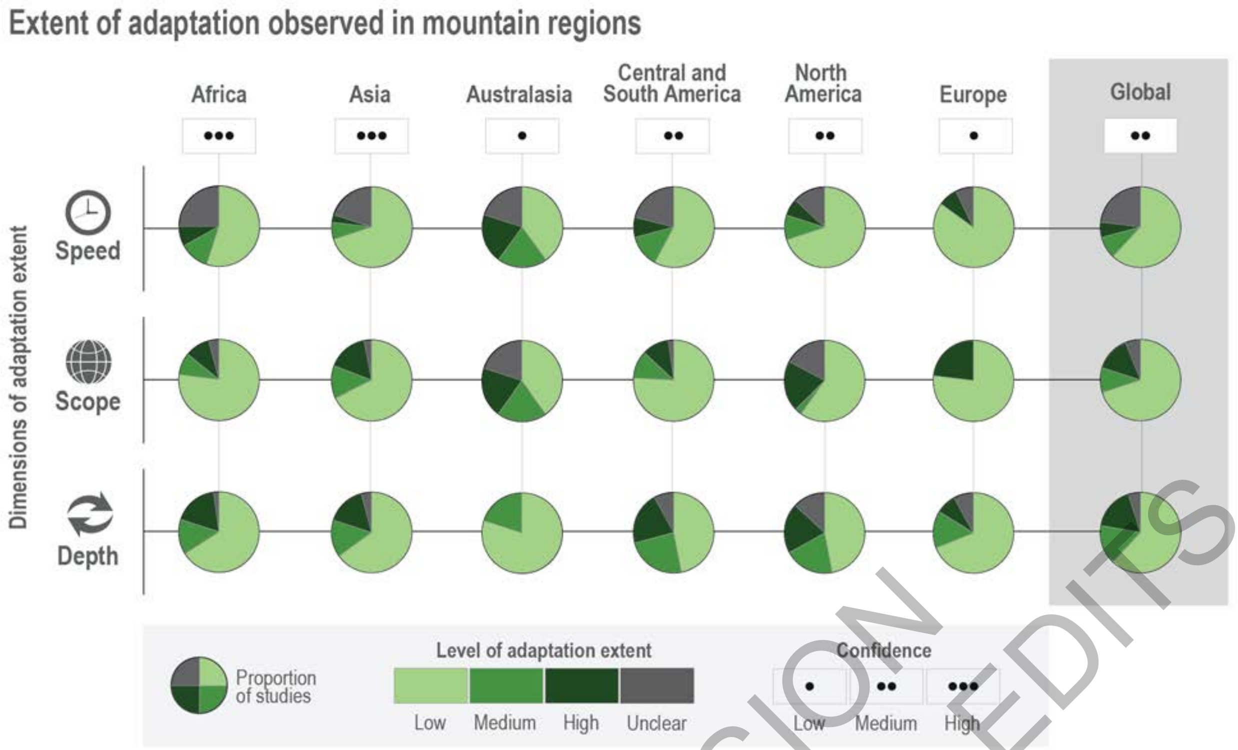

Figure CCP5.7: Extent of planned and implemented adaptation actions observed in mountain regions shown in terms of three dimensions: i) speed (timeframe within which adaptations are being implemented), ii) scope (the scale of changes observed from the adaptation action), and iii) its depth (i.e., degree to which a change reflects something new) (see Section 16.3.2.5). The data are obtained from the Global Adaptation Mapping Initiative (GAMI) re-analysis for mountains (see SMCCP5.3.2 and Berrang-Ford et al., 2021; McDowell et al., 2021b).

CCP5.4.2 Challenges, Opportunities and the Solution Space for Adaptation in Mountains

The effects of climate change on mountain environments pose significant challenges for people, ecosystems, and sustainable development, with issues such as difficult access, environmental sensitivity, and socio-economic marginalization making adaptation particularly complex. Furthermore, varied and dynamic biophysical characteristics as well as high socio-cultural diversity preclude one-size-fits-all responses; adaptation planning and action in mountains rooted in context-specific socio-ecological and climatic realities are more effective (Hock et al., 2019; Lavorel et al., 2019; McDowell et al., 2020) (*high confidence*). Despite these challenges, there is growing evidence of opportunities for advancing effective responses to climate risks in mountain areas (McDowell et al., 2020) (Section 16.3; Cross-Chapter Box NATURAL in Chapter 2).

The solution space for adaptation represents a realm of possibility for addressing climate risks; it is shaped by both socio-economic and climatic factors that influence who adapts, when they adapt, and how they adapt to climate change (Haasnoot et al., 2020) (Sections 1.5.1 and 17.4). The space includes both planned and autonomous responses (Hock et al., 2019; McDowell et al., 2019). Autonomous response can be appropriate when local resilience is high (Mishra et al., 2019; Ford et al., 2020); however, many mountain communities continue to face socio-economic challenges that constrain their adaptive capacity (*high confidence*). Planned adaptations are a critical component of the solution space, although external interventions can also reinforce, redistribute, or create new vulnerabilities when they proceed without sincere engagement with local communities (Eriksen et al., 2021). The solution space also evolves as social and climatic conditions change and can be capped by social and biophysical limits to adaptation that render further responses to climate change inaccessible, unfeasible, or ineffectual. Such limits are already observed and are *likely* to become more widespread as climatic stressors move beyond historical experience (IPCC, 2018; Hock et al., 2019; McDowell et al., 2020) (Section 17.3; Cross-Chapter Box DEEP in Chapter 17) (*high confidence*).

Evidence shows the significant potential of adaptation actions such as Nature-based Solutions or multiple use of water approaches but with a need to carefully evaluate environmental, economic and social co-benefits, trade-offs (Yang et al., 2016; Drenkhan et al., 2019; Lavorel et al., 2019; McDowell et al., 2019; Palomo et al., 2021) (*high agreement, medium confidence*). The potential for adaptation to contribute to sustainable development and transformative change in mountains is also becoming increasingly evident (Palomo et al., 2021) (*medium confidence*), yet there is currently *limited evidence* with respect to the long-term effectiveness of adaptations in achieving such outcomes (Balsiger et al., 2020). To better achieve the adaptation potential in mountains, adaptation finance and private sector inclusion and contribution are key enablers (Mishra et al., 2019; UNEP, 2021) (*high confidence*).

There is increasing recognition that inclusive and comprehensive adaptation approaches can be more successful (Allen et al., 2018; Hock et al., 2019; Huggel et al., 2020a; Huggel et al., 2020b) (*medium evidence, high agreement*). Stakeholders such as local communities and government entities often prioritize different dimensions of climate related risks (López et al., 2017; McDowell et al., 2020). Adaptation initiatives that identify locally-relevant climate stressors and risks through knowledge co-production have the potential to be more acceptable and effective (*medium evidence, high agreement*) (Huggel et al., 2015; Muccione et al., 2016; Allen et al., 2018; Quincey et al., 2018; Balsiger et al., 2020; McDowell et al., 2020; McDowell et al., 2021b) (Cross Chapter Box DEEP in Chapter 17). However, tenable co-production requires recognition of the validity and integrity of diverse knowledges systems, including those held by Indigenous Peoples and local communities, as well as the provision of sufficient time and resources for meaningful engagement between stakeholder groups (Howarth and Monasterolo, 2016; Bremer and Meisch, 2017; Schoolmeester and Verbist, 2018; McDowell et al., 2019; Ford et al., 2020). Power imbalances and knowledge politics continue to impede the inclusion of historically underrepresented voices in adaptation planning and action(Ojha et al., 2016; Mills-Novoa et al., 2017). Citizen science plays an additional role in facilitating the inclusion of multiple knowledges (Buytaert et al., 2014; Dickerson-Lange et al., 2016; Tellman et al., 2016; Njue et al., 2019).

Progress in addressing climate risks requires targeting the root causes of vulnerability, which are often socio-economic in origin and can include poverty, marginalization, and inequitable gender dynamics (Ribot, 2014; Carey et al., 2017; Shukla et al., 2018; McDowell et al., 2019) (*high confidence*). Promoting resilience in many mountain regions requires responses that address the social determinants of susceptibility to harm. Context-specific manifestations of such determinants (and leverage points for positive action) can be identified through participatory processes with affected populations, with action on social determinants of climate change vulnerability having important co-benefits for equity, justice, and sustainability. Addressing the root causes of vulnerability can also resolve soft limits to adaptation, thereby increasing the solution space (McDowell et al., 2020).

There is growing evidence of the potential for coordination and monitoring networks to overcome existing data deficiencies, to fill knowledge gaps, and to streamline implementation, all of which currently impede adaptation in mountains (Salzmann et al., 2014; Muccione et al., 2016; Ryan and Bustos, 2019; McDowell et al., 2020; Shahgedanova et al., 2021; Thornton et al., 2021; Price et al., Accepted/In press). Furthermore, there is increasing evidence that key conventions related to mountains, such as the Alpine Climate Board (SROCC 2.4), provide opportunities for accelerating adaptation efforts through mainstreaming responses into other policies aimed at addressing climate-related risks (Balsiger et al., 2020) (*medium confidence*). Regional cooperation among countries and transboundary landscape and river basin governance initiatives are an important mechanism for advancing adaptation in mountains (Molden et al., 2017; Mishra et al., 2019; Balsiger et al., 2020) (*high agreement, medium evidence*), particularly as many mountain ranges and mountain ecosystem services are transboundary in nature.

Access to major adaptation support programs such as through the UNFCCC, national governments, multi- and bi-lateral aid arrangements, the private sector, and non-governmental organizations (NGOs) has been relatively limited to support adaptation action in mountain regions, indicating significant unutilized support options for increasing the solution space in mountains (McDowell et al., 2020). Enhanced uptake of available support and funding could help to ease the adaptation burden for mountain communities. This will require addressing soft limits to adaptation, which currently constrain the ability of actors to identify, access, and mobilize resources for planned adaptations (McDowell et al., 2020).

More inclusive adaptation approaches, engagement with the root causes of vulnerability, improved coordination and monitoring activities, and upscaling of support for adaptation are key enablers and are indicative of a substantial solution space for adaptation in mountains regions (*high confidence*). However, trajectories of climate change and the prospect of hard limits to adaptation, which are often biophysical in origin, portend climate futures that could overwhelm adaptation efforts. Success therefore hinges on increasing the quality and quantity of adaptation efforts, including through transformative action, as well as enhanced mitigation efforts, consistent with the recommendations of IPCC SR 1.5C (IPCC 2018) (Cross-Chapter Box PROGRESS in Chapter 17).

CCP5.4.3 Climate Resilient and Sustainable Development in Mountains

With accelerating warming and compounding risks increasing above 1.5ºC warming, the need for climate resilient development in mountains is evident, and intricately linked to achieving the SDGs and equity (*high confidence*). In this context, Chapter 18 draws attention to climate resilient development pathways (CRDP), as processes that strengthen sustainable development and efforts to eradicate poverty and reduce inequalities while promoting fair and cross-scalar adaptation and mitigation. Pathways that strengthen climate-resilient sustainable mountain development are starting to receive attention (Chelleri et al., 2016; Trabacchi and Stadelmann, 2016; AlpineConvention, 2021). This section treats four domains of emerging evidence related to climate resilient development in mountains: 1) climate actions that support both adaptation and mitigation; 2) Indigenous knowledge and local knowledge in support of climate resilient development; 3) climate resilient development in climate policy and planning; and 4) mainstreaming of climate action into development pathways.

Nature-based Solutions (NbS) can be pursued in mountains that will mitigate climate change and its impacts while at the same time contributing to improving livelihoods, social and economic well-being, and sustainable environmental management *(high confidence).* A global review of 93 Nature-based Solutions in mountains, such as afforestation, protection of existing forests, agroforestry and climate smart agriculture, confirm the potential of NbS for change towards sustainable trajectories (Palomo et al., 2021). Agroforestry is widely cited for delivering on food security as well as increasing resilience and mitigating climate change (Mbow et al., 2014; Amadu et al., 2020; Gidey et al., 2020). Also, the prudent use of biomass for wood-based bioenergy in mountains can mitigate the impacts of climate change, reduce vulnerability to disturbance events such as fires, and enhance rural socioeconomic development (Beeton and Galvin, 2017). Yet, there can be trade-offs contingent upon place-based and context-specific social and environmental factors, such as between the use of bio-energy, agricultural production and conservation concerns (Beeton and Galvin, 2017). Evidence from the world's mountains highlights the importance of cross-scale partnerships and interdisciplinary, bottom-up approaches that facilitate stakeholders in envisioning locally tailored, climate-resilient and sustainable development pathways (Chelleri et al., 2016; Capitani et al., 2019; Klein et al., 2019b; Pandey et al., 2021).

Mountains are the home of many cultures and diverse Indigenous knowledge and local knowledge (systems), which can and do provide strong support for place-based integrated adaptation and mitigation strategies (Merino et al., 2019). Indigenous knowledge and local knowledge reinforce community adaptive capacity, yet governance structures and processes, including the deliberate design and implementation of climate policy, can constrain that capacity from being realised (Hill, 2013; McDowell et al., 2014; Wyborn et al., 2015; Klepp and Chavez-Rodriguez, 2018; Lavorel et al., 2019) (*high confidence)*. Communities, particularly poor and remote mountain communities, are vulnerable to climate change and there is a need for capacity building in research, policy development and implementation for pursuing climate resilient development (Manton and Stevenson, 2014). Climatic stressors and socio-economic changes are changing traditional genderscapes in mountain communities (Goodrich et al., 2019). There is increasing evidence on the roles that gendered diversity in knowledge, institutions, and everyday practices can play in addressing barriers and creating opportunities for achieving resilience, adaptive capacity and sustainability in societies (Gioli et al., 2014; Ravera et al., 2016; Su et al., 2017; Udas et al., 2018; Goodrich et al., 2019; Sujakhu et al., 2019).

Concerning climate policy and planning for climate resilient development in mountains, a review of mountain specific priorities in the National Adaptation Programmes of Action (NAPA) submitted to the UNFCCC shows that countries have prioritized improving agricultural outputs by introducing climate smart crops and upgrading and building climate resilient irrigation infrastructure (UNFCCC, 2020c). Countries that have submitted their NAPs to the UNFCCC have prioritized improving ecosystem resilience through conserving agro-biodiversity in mountains. Countries have also focused on achieving food security in mountain regions and laying the foundations for food availability, stability, access and safety amidst increasing climate risks (UNFCCC, 2020a).

In the Nationally Determined Contributions (NDCs) where mountain regions are specifically mentioned, countries have prioritized climate resilient solutions, including, developing a low carbon green economy through implementing low carbon transport systems and encouraging sustainable waste management practices, as well as developing infrastructure for climate resilient agriculture, the sustainable management of forests and the conservation of biodiversity. Several countries have specifically pledged to build climate resilient mountain infrastructure taking into account future climate uncertainties. Countries have also identified the need for capacity building of national stakeholders and have pledged to provide relevant climate information (UNFCCC, 2020b).

Similar pledges are announced in formal institutional arrangements such as the Alpine Convention and the Carpathian Convention. The Alpine Convention's climate action plan prioritises reaching climate-neutral and climate resilient Alps by 2050. For this, implementation pathways on specific sectors have been identified ensuring coherence to global and regional goals such as the Paris agreement, SDGs, EU legislations and climate laws (AlpineConvention, 2021). Likewise, the Carpathian Convention's working group on climate change has presented a long-term vision towards combating climate change thorough amending the article of the convention to focus specifically on climate change adaptation and mitigation (CarpathianConvention, 2020).

Sustainable and climate resilient mountain development is predicated on effective and timely climate action building on cross-scalar partnerships among researchers, stakeholders, and decision makers to jointly identify desired futures and pathways and assess trade-offs and synergies between climate action and the SDGs (Klein et al., 2019a; Pandey et al., 2021) (*high agreement, medium evidence*). Understanding of the complexity of mountain ecosystems as well as path-dependency from earlier and current decisions is of critical importance for the sustainable future of mountain regions (Satyal et al., 2017; Chanapathi and Thatikonda, 2020; Berkey et al., 2021). Framing pathways through questions such as "to whom or to what is climate action positive" and "which trade-off should be accepted, and why" can serve as a tool for addressing sustainable development goals, while avoiding lock-ins or unsustainable path dependencies (Chelleri et al., 2016). Increasingly, climate action is mainstreamed into sustainable development, which signifies a shift from climate policy as an end-point to a continuing process for managing change and facilitating long-term sustainable development. The Ethiopian government's Climate Resilient Green Economy (CRGE) strategy is an example of such a shift (Simane and Bird, 2017) as are emerging initiatives to build-back-greener in response to COVID-19 impacts (Schipper et al., 2020).

CCP5.5 Key Assessment Limitations and Relevant Knowledge Gaps

The assessment presented in this CCP has several limitations, principally in terms of the amount, often fragmented and biased geographic coverage, or lack of relevant thematic scope covered in the literature published since AR5 and SROCC. Key assessment limitations and relevant knowledge gaps identified in this CCP fall within the following broad categories: 1) detection and attribution of observed impacts to climate change; 2) limitations and uncertainties associated with predictive models of projected impacts and risks; 3) integrated and systems-oriented research on mountain ecosystem services and their limits under climate change; and 4) measurable tracking of adaptation action implemented in mountain regions and their suitability for addressing climate risks. These are summarised in Table CCP5.3. While these limitations and assessment-relevant gaps in knowledge offer important caveats for the interpretation of this assessment, they also highlight prospects to address and improve the evidence basis in future assessments.

Table CCP5.3: Summary of key assessment-relevant knowledge gaps and limitations identified in CCP5.

Key assessment-relevant knowledge gaps and limitations	Relevant WGII report sections
Detection and attribution of observed impacts to climate change	

Key assessment-relevant knowledge gaps and limitations		Relevant WGII report sections
Limited amount and scope of literature available on impacts for assessment of detection and attribution to climate change.	• While there is *high confidence* on the links between future impacts and risks associated with climate change, there is *medium evidence* available on robust detection and attribution of past changes in mountain regions. • Considerable assessment gaps exist given the limited scope (temporal, spatial, or thematic coverage) and number of published studies reporting data and information that capture how mountains social-ecological systems function, and their trends over the past decades, that may be applicable for detection and attribution of changes to climatic change. • Additionally, there are limitations in current methodologies to include and account for other knowledges with respect to detection and attribution of impacts to climate change in mountain regions (e.g. Chakraborty and Sherpa, 2021).	CCP5.2.7; Figure CCP5.4; SMCCP5.2.
Consequences of shifting treelines and their interactions with other ecosystem functions	• The net effects of ongoing climate change with treeline advance and vegetation change on ecosystem carbon exchange, or possible effects on mountain hydrology, remain unresolved in the literature. • Uncertainties remain regarding effects to ecosystem-level carbon storage, given that above-ground biomass is higher in forests than in alpine vegetation and (new) trees may change soil carbon fluxes, for instance by introducing new soil organisms, thereby increasing soil carbon flux (e.g. Tonjer et al., 2021). • Short- and long-term effects of combined warming and changed species cover on mountain soils are complex and insufficiently quantified (Hagedorn et al., 2019).	CCP5.2.1; CCP1-Biodiversity Hotspots
Limitations and uncertainties associated with predictive models of projected impacts and risks		
Shared socioeconomic pathways (SSPs)	• There are relevant knowledge gaps in the understanding of future vulnerabilities in mountain social-ecological systems in relation to highly variable and dynamic trends in projected demographic change, socio-economic development pathways, and demands for resources.	CCP5.3.1; SMCCP5.1
Species distribution models (SDM)	• Species distribution models (SDMs), which rely on statistical correlations between occurrence records and environmental variables to make spatially explicit predictions, are commonly used to project climate change impacts on mountain ecosystems (Guisan et al., 2017). • However, they are associated with some limitations that can limit their utility to derive reliable predictions of future mountain vegetation distributions, and therefore ability to provide a sound basis for mountain nature conservation and climate change adaptation. • In particular, they only indicate the potential future species distributions based on the static relationships between species and predictors in the calibration data; in reality, vegetation dynamics will be heavily modulated by phenomena that are commonly overlooked by such models like changing species interactions and competition due to variance in response rates amongst different species, dispersal limitations, and demographic processes (Scherrer et al., 2020). • In addition, SDMs are often limited by data availability and therefore tend to omit several environmental factors known to be important for plants such as soil formation processes, disturbances (e.g. rockfalls, avalanches), and microclimatic conditions (Scherrer et al., 2011; Enright, 2014; Mod et al., 2015; Bråthen et al., 2018). • More complex dynamic and process-based models are available, but still rarely represent all potentially influential vegetation co-variates; applying both model types in conjunction demonstrates potential (Horvath et al., 2021).	CCP5.2.1
Quantifiable estimates of monetary costs and potential material losses	• There is *limited evidence* on climate-related risks to economic sectors that are vital for mountain regions, specifically on quantifiable estimates of monetary costs and potential material losses for economic sectors and communities in mountains, adjacent lowlands, and other regions dependent on these economic activities.	CCP5.3.1

Key assessment-relevant knowledge gaps and limitations		Relevant WGII report sections
Other model limitations	• Ecological models which could allow to better forecast the effectiveness of EbA as NbS, under different climate scenarios, are not fully developed (Seddon et al., 2020).	CCP5.4
Integrated and systems-oriented research on mountain ecosystem services and their limits under climate change		
Water	• Few assessment-relevant integrative studies are available in the published literature that address relevant aspects of water security, beyond water availability from glacier-fed meltwater, or snow, groundwater, other water stores, such as wetlands, sediments, etc. Likewise, few studies address seasonality with respect to a more systems-oriented approach to supply (e.g. water availability) and demand (irrigated agriculture, and other multiple uses and user groups).	CCP5.2.2 Chapter 4
Measurable tracking of adaptation action implemented in mountain regions and their suitability for addressing climate risks		
Conditions under which adaptation interventions work against stated goals	• Few studies report on how adaptation measures and programmes function in mountainous contexts that yield the outcomes reported (McDowell et al., 2020). • Despite transformative processes, to date there is *limited evidence* of how knowledge co-production activities support the planning and implementation of successful adaptations in mountain areas.	CCP5.4.2
Metrics and heuristics for tracking effectiveness	• Adaptation responses to intangible losses and loss of cultural values are reported and take different forms as demonstrated in studies from different world regions (de la Riva et al., 2013; Wang and Qin, 2015; Vander Naald, 2020). However, there is *limited evidence* on their adequacy for addressing increasing losses, which remains largely unexplored in the available literature.	CCP5.3.2.4; Section 4.4.3.3
Methods and frameworks for monitoring and evaluation	• Regarding adaptation efforts and effectiveness, there are considerable gaps in adequate monitoring and appropriate evaluation of successful implementation of diverse adaptation measures. • Across mountain areas, integrated monitoring of key environmental and socio-economic variables, including international efforts for the acquisition and sharing of data, offers prospects for supporting the tracking of impacts and adaptation responses, including community-based monitoring initiatives (Shahgedanova et al., 2021; Thornton et al., 2021).	Section 17.5; CCP5.4.2
Feasibility and suitability of adaptation options for managing climate risks	• The feasibility of adaptation options for managing risks, for example those that could facilitate systems transitions with respect to energy, remains largely unexplored in the literature, with *limited evidence* on how projected climate change could impact prospects to develop wind, solar or biomass energy production and use in mountain contexts. • Given assessments on observed adaptation (Section CCP5.2) and adaptation responses (Section CCP5.4), few studies report a 'systems approach' to the study and evaluation of adaptations that combine all relevant aspects of the risk framework (i.e. hazards, exposure, and vulnerabilities), including how synergies and trade-offs are considered in context for managing risks. • There is *limited evidence* of the feasibility and long-term effectiveness of adaptation measures to address climate-related impacts and related losses and damages in cities and settlements experiencing changing demographics.	CCP5.2.2.2; CCP5.4.2; CCP5.4.3

[START FAQ CCP5.1 HERE]

FAQ CCP5.1: How is freshwater from mountain regions affected by climate change, and what are the consequences for people and ecosystems?

Sources of freshwater from mountains such as rainfall, snow and glacier melt, and groundwater are all strongly affected by climate change, leading to important changes in water supply in terms of quantity, and *partly quality, and timing (e.g. shifts and changes in seasonality). In many cases, the effects on ecosystems and people are negative, e.g. creating or exacerbating ecosystem degradation, water scarcity, or competition or conflict over water.*

River flow is a main source of freshwater both in mountain regions and downstream areas. Various sources contribute to it, including rainfall, snow and glacier melt, and groundwater. Climate change affects these different sources in different ways. Climate change affects rainfall patterns such as long-term increase or decrease, seasonal shifts or changes in rainfall intensity. Rising temperatures strongly influence snow and glacier melt generated river discharge; the snowmelt season starts earlier, less snow mass is available for melt, and snowmelt contribution to river flow thus decreases over the year. Whether rising temperatures produce meltwater from glaciers depends on the state and characteristics of the glaciers and the catchment basin. The concept of 'peak water' implies that first, as glaciers shrink in response to a warmer climate, more meltwater is released until a turning point (peak water) after which glaciers melt and thus its contribution to river flow decreases. In many mountain regions worldwide, glaciers and their basins have already passed peak water, and the runoff contribution of glaciers is on the decline. Glacier shrinkage not only influences river discharge but also water quality. In the Andes of Peru, for instance, it has been observed that retreating glaciers expose bedrock, resulting in more acid water because of minerals that dissolve from the rock. Mountain ecosystems are also affected by changing freshwater availability. For instance, high-elevation wetlands in the tropical Andes critically depend on glacier meltwater during the dry season and the disappearance of this freshwater source results in ecosystem degradation.

The effect of climate change on groundwater in mountains is insufficiently understood. Infiltrating water from glaciers and snowmelt plays an important role in groundwater recharge. Groundwater recharge is expected to decrease with continued climate change in several mountain regions. In the Himalaya many springs have already been observed to decline.

The availability of freshwater is a function of water supply and water demand, with the latter being determined by sectors such as agriculture, energy, industry, or domestic use, as well as by competition between these sectors. Formal and informal water extraction and use prevail, and competition includes issues of inequalities, and power relations and asymmetry. Consequently, the effects of climate change on water resources, people and ecosystems are strongly modulated and often exacerbated by socio-economic development and related water resource management. For example, increasing frequency and intensity of droughts in the European Alps, combined with decline and seasonal shifts of river runoff from snow and glacier melt, is expected to result in growing competition between different sectors, such as hydropower, agriculture, and tourism. Similar developments are projected or have already been observed in many other mountain regions. This situation calls for strengthening and improving negotiation formats for water management that are transparent, equal, and socially and environmentally just. Management of water demand and strategies that entail multiple uses of water will become increasingly important in this context.

[START FAQ CCP5.2 HERE]

FAQ CCP5.2: Are people in mountain regions, and further downstream, facing more severe risks to water-related disasters due to climate change, and how are they coping?

Mountain regions have always been affected by either too much or too little water. Because of climate change, hazards are changing rapidly and becoming even more unpredictable. Whether or not these changes will result in more disasters locally and further downstream depends on several factors, not least the fact that more people are settling in exposed locations. People in mountains have a history of developing skills to live in a dangerous and dynamic environment, which will be invaluable in the future when combined with inclusive and long-term disaster risk reduction measures.

Water-related hazards in mountains include rainfall (pluvial) and river (fluvial) floods, extreme rainfall-induced landslides, debris flows, ice and snow avalanches and droughts. When people are exposed and vulnerable to these hazards, there is potential for them to result in disasters. Floods and landslides in mountains contribute to, and count amongst the most devastating disasters globally, often resulting in significant losses such as high numbers of fatalities and damages. Climate change may change rainfall frequency/intensity distributions, potentially leading to floods and droughts. Climate change may also lead to shifts in precipitation type, with more precipitation falling as rain than snow in the future., which further impacts both short- and long-term water storage, and therefore impacts downstream ecosystems and cities.

Although climate change directly affects water-related hazards, studies indicate that above and beyond natural hazards, disaster risk and disasters are influenced to a major extent by vulnerability and exposure. This is of relevance in mountains, where disaster risk is influenced by population growth, induced displacements, land-use changes and inefficient water distribution systems. For example, current trends suggest that more people are settling in exposed locations, with more infrastructure being built and activities such as tourism and recreation being promoted, exacerbating this exposure.

Experiences in dealing with water-related disasters provide a basis from which to build adequate responses to increasing risks in the future. For example, upgrading infrastructure such as dams and embankments can help address water shortages, but diversification of income-generating activities, such as subsistence farming moving away from certain drought-sensitive crops, can also help.

The risk perceptions of people also shape their behaviours in coping with disaster risks. For example, based on their longstanding observations and local knowledge, communities in the southern part of the Peruvian Andes identified the shrinking of glaciers, more frequent and intense extreme weather events, more extreme temperatures, and shortened rainy seasons as key challenges. The recognition of local knowledge is key to address these challenges, as well as provide a basis for the transformation of current systems. A lack of community involvement and participation in decision making on how to addresses disaster risk can contribute to a mismatch between perceptions and behaviours towards those risks, and the actions needed to reduce losses. Therefore, measures which are flexible, address the objectives and needs of all those affected by disasters and bring long term benefits have more chances of being successful in dealing with future disaster risks.

[END FAQ CCP5.2 HERE]

[START FAQ CCP5.3 HERE]

FAQ CCP5.3: Is climate change a risk to mountain species and ecosystems, and will this affect people?

Treeline position, bioclimatic zones and species ranges move up in elevation as the climate warms, increasing the risk of extinction for species isolated on mountaintops as a result of exceeding their physiological limits, loss of habitat or competition from colonising species. Additionally, climate change may alter the quality and quantity of food and natural products on which the livelihood of many mountain communities depends.

Mountain regions cover about a quarter of the Earth's land surface, scattered around the globe and may support a wide range of climates within short horizontal distances. Mountains have experienced above-average warming, and this trend is expected to continue. Mountains provide a variety of goods for people, are home to many Indigenous Peoples and are attractive for tourism and recreational activities. Mountain regions support many different ecosystems and some are very species rich. Mountain regions can be vast and diverse, and climate change and impacts on ecosystems vary greatly depending on location.

With increasing average global temperature, the climatic conditions under which plants and animals can thrive are shifting to higher elevations. Movement of some plant taxa toward mountaintops, has been observed in the past decades. However, for species restricted to the highest elevations, there is nowhere to move to, meaning they are increasingly at risk of extinction. Climatic conditions may exceed the physiological limits for species and the habitat may become unsuitable for others. There is also a risk from competition with colonizing native species and invading non-native species, spreading to higher elevations and some species cannot move quickly enough to keep pace with the change in climate. The most vulnerable species are those that reproduce and disperse slowly and those that are isolated on the mountaintops, including endemic species, which may face global extinction. In other cases species will be lost from some parts of their current range. Mountains can however allow other species to survive in areas where they would not otherwise do so, because of small scale variations in climate with elevation or different aspects of slopes.

Changes in snow cover and snow duration are related to changes in temperature and precipitation and are also critical for plants and animals. In particular, glacier retreat and changing snow patterns affect both streamflow dynamics (including extremes) and soil moisture conditions and can cause moisture shortages during the growing season. Change of snow patterns can critically affect animal movements in mountains. Other processes creating stresses on mountain ecosystems are direct human impacts, such as the influence of grazing, tourism, air pollution and nitrogen deposition on alpine vegetation. In some cases, these impacts can be so large on the goods and services provided by alpine ecosystems, that they can overshadow the effects of climate change or exacerbate its effects.

In many mountain regions, multiple sources of evidence point to tree expansions into treeless area above (and in some cases below) the forest belt. This may increase forest productivity at the upper treeline. Treelines have moved up in the last 30-100 years in many mountain regions, including e.g. Andes, Urals and Altai. At the same time, since the 1990s, treelines responses in different parts of the Himalaya have been highly variable, in some places advancing upslope, in others demonstrating little change, and in others moving downward. This can be explained by site-specific complex interactions of the positive effect of warming on tree growth, drought stress, change in snow precipitation, land-use change, especially grazing, and other factors. Treelines are affected by land use and management around the globe and changing land-use practices can supersede climate change effects in some mountain regions. An upward shift in elevation of bioclimatic zones, decreases in area of the highest elevation zones, and an expansion of the lower zones can be expected by mid-century, for examples in regions such as the Himalaya.

In some regions, the livelihoods of many local mountain communities depend on access to firewood, pastures, edible plants and mushrooms, medicinal and aromatic plants. Climate change can alter the quality and quantity of these ecosystem services; however, the degree and direction of change are context specific. The appeal and feasibility of mountains for tourism and recreation activities are also affected by climate change.

[END FAQ CCP5.3 HERE]

[START FAQ CCP5.4 HERE]

FAQ CCP5.4: What type of adaptation options are feasible to address the impacts of climate change in mountain regions under different levels of warming, and what are their limits?

The feasibility of adaptation to address risks in mountain regions is influenced by numerous factors, many of which are unique to mountain people and their environment. Adaptation efforts in mountains are mainly made of small steps and largely autonomous. Robust and flexible adaptation measures have a better chance to address risks, but eventually large systemic transformation will be needed for higher levels of warming. Empirical evidence on "what works and what does not work" is largely absent, but urgently needed.

The term feasibility refers to climate goals and adaptation options that are possible and desirable. Feasibility is influenced by factors such as economic viability, availability of technical resources, institutional support, social capital, ecological and adaptive capacity, and biophysical conditions. Establishing the feasibility of options under changing climatic and socio-economic conditions is not an easy task – mostly because even present feasibility is difficult to assess in mountains, due to a lack of systematic information on opportunities and challenges of adaptation in practice.

Underlying environmental conditions such as limited space, shallow soils, exposure to numerous hazards, climate-sensitive ecosystems and isolation make it particularly difficult to implement adaptation at scales relevant for implementation. Common adaptation options are often implemented at the individual, household or community scale. These options are incremental and have generated observable results and outcomes. Adaptation actions that involve partial changes that do not dramatically alter established practices and behaviours seem to have better chances of being implemented than systemic or structural changes. Formal or planned adaptation efforts which are more institutionally driven are only a small proportion of observed adaptation in mountains regions. Where adaptation options are implemented, they are often not only targeting climate change, but an array of other issues, priorities, and pressures experienced by and in those communities (e.g. livelihood diversification in farming practices).

Whether or not adaptation options are feasible does not say much about their effectiveness, i.e. the degree to which adaptation has been or will be successful in reducing the risks of negative impacts. Adaptation is difficult to disentangle from other factors that contribute to both increasing and decreasing risks. Since adaptation in mountains is often autonomous and unplanned, measuring its effectiveness is complex and missed by more conventional, formal, or structured monitoring and evaluation frameworks.

Evidence suggests that promising measures being taken in mountains are those that are robust under uncertain futures, allow for adaptive planning and management, and respond to multiple interests and purposes. For example, multi-purpose water reservoirs can alleviate multiple stressors and address several risks such as those from natural hazards and water shortages. Capacity building and awareness-raising can go a long way to ensure that these measures are also socially acceptable if combined with more structural and systemic changes. Indeed, transformations are happening slowly in mountains and it is unlikely that small steps and incremental measures will be able to cope with more severe and pervasive risks.

Overall, empirical evidence on the effectiveness of adaptation to reducing risk is largely missing but is urgently needed to better understand what works and what does not work under certain circumstances.

[END FAQ CCP5.4 HERE]

[START FAQ CCP5.5 HERE]

FAQ CCP5.5: Why regional cooperation and transboundary governance is needed for sustainable mountain development?

Regional cooperation and transboundary governance are key to managing our vast mountain resources because they do not necessarily share political boundaries. Mountain countries need to come together, share data and information, form joint management committees, bring in policies and take decisions that benefit all countries equitably. Lack of cooperation may lead to missing important opportunities to address climate risks and adequately manage mountain resources, which can cause potential social unrest and spark conflict within and between countries.

Mountains are climate change hotspots that are highly susceptible to climate change. Due to rapidly changing climatic conditions, climate change is one of the major issues that would benefit from regional cooperation. The transboundary management of mountains means shared legal and institutional frameworks for sharing the benefits and costs of managing the mountain ranges across boundaries, be it local or district jurisdictions within countries or indeed across national boundaries.

The IPCC's Special Report on Oceans and Cryosphere refers to governance as an "effort to establish, reaffirm or change formal and informal institutions at all scales to negotiate relationships, resolve social conflicts and realise mutual gains". Governance is an act of governments, NGOs, private sectors, and civil society in establishing rules and norms for restricting the use of common goods. "Institutions can guide, constrain, and shape human interaction through direct control, incentives, and processes of socialisation". How do we apply the definitions of governance and institutions in the context of mountains? Since governance not only refers to government, which is a formal arm of the state, it also talks about other agencies such as community organizations, non-profit or businesses that play a vital role in society and influences individual or collective decisions and help in preventing the overexploitation of its resources.

To comprehend the processes of governance in mountain areas, we need to recognize how each of these agencies add to the enduring task of enabling and managing change at the system level but also to preserving social structure and reconciling disputes. For the sustainable and resilient development of mountain regions, governance mechanisms may be different than those applied for managing other resources such as coastal zones or rivers. This is also because mountains are mostly transboundary and do not necessarily follow political boundaries. Mountain governance, therefore, is about managing the resources across political boundaries for the benefit of all countries. This includes downstream countries that also rely on these resources such as water, silt, and other resources from these mountain regions. These include high rangelands, biodiversity hotspots, forests, glaciers etc.

There are several examples of regional cooperation around the governance of shared resources in mountains. Some examples come from the Arctic (bottom-up and science-based evolution of Arctic cooperation), South-East Europe (regionalisation of environmental benefits) and the Hindu Kush Himalaya region (inter-governmental scientific institution for research and data sharing). Mountains share resources and therefore, their management will benefit from cooperation between countries. Transboundary cooperation is not only needed to address transboundary climate risks and regional adaptation to climate change in mountains, but also to work across countries to reduce greenhouse gas emissions.

Executive Summary

Observed impacts and future risks

Climate change impacts and cascading impacts in polar regions, particularly the Arctic, are already occurring at a magnitude and pace unprecedented in recent history (*very high confidence*), and much faster than projected for other world regions (*high confidence*[1]).

The polar regions, notably the Arctic and maritime Antarctic, are experiencing impacts from climate change at magnitudes and rates that are among the highest in the world, and will become profoundly different in the near-term future (by 2050) under all warming scenarios (*high confidence*). In the Arctic, accelerated sea-ice loss (particularly during summer), increased permafrost thaw and extreme high temperatures have substantially impacted marine, freshwater and terrestrial sociological-ecological systems (*very high confidence*). Multiple physical, ecological and societal elements of polar regions are approaching a level of change potentially irreversible for hundreds of years, if not millennia (*high confidence*). Evidence of borealization of terrestrial and marine systems is emerging (*high confidence*), and cascading impacts are on-going and widespread yet challenging to quantify fully due to complexity and lags in ecological expression of change. Loss of multi-year sea-ice and the occurrence of a seasonally ice-free Arctic Ocean by the middle of this century will result in substantial range contraction, if not the disappearance of several Arctic fish, crab, bird and marine mammal species, including possible extinction of seals and polar bears in certain regions (*high confidence*). In the Arctic, permafrost thaw and snowfall decrease lead to profound hydrological changes, an overall greening of the tundra and regional browning of tundra and boreal forests (*high confidence*). (CCP6.1; Table CCP6.1; Table CCP6.2; CCP6.2.1; CCP6.2.2; Table CCP6.5)

Contractions of the polar climate zones lead to distribution shifts and changes in food webs, induce declines in many species (*medium confidence*) with impacts on subsistence harvests and commercial fisheries, and threaten global dependence on polar regions for substantial marine food production (*high confidence*). Climate change has induced food web changes resulting in population declines in polar seabirds, including penguins, and marine and terrestrial mammals (*high confidence*). Globally and regionally important harvested fish and invertebrate species are also contracting ranges and declining productivity, including Pacific cod, salmon, snow and king crab in the Arctic and krill in the Antarctic (*medium confidence*), with implications for global food systems (*high confidence*). (Table CCP6.2; CCP6.2.1; CCP6.2.3; Table CCP6.3; Table CCP6.4)

Loss of sea-ice is rapidly expanding opportunities, but also increasing risks for shipping and other economic industries in polar regions (*very high confidence*). Reduced sea-ice enables greater access to high-latitudinal seas for industries, such as fisheries, shipping, tourism (*very high confidence*) and Arctic maritime trade and resource extraction (*medium confidence*). Navigational risks have grown due to increasingly mobile multi-year ice, poor hydrographic charting in newly open areas, and limited weather, water, ice, and climate data and services (*high confidence*). Cascading risks from polar shipping growth include increased air emissions, underwater noise pollution, disruption to subsistence hunting and cultural activities in the Arctic (*high confidence*) and potential for invasive marine species and geopolitical tensions (*medium confidence*). (Table CCP6.3; CCP6.2.4; Box CCP6.1; Table CCP6.5; Table CCP6.6)

Increased permafrost thaw and flooding will disrupt economically important transportation and supply-chain infrastructure to remote Arctic settlements (*high confidence*), increasing risks to economies, Arctic tourism and tourism to cultural heritage sites (*medium confidence*). Arctic permafrost thaw is projected to impact most infrastructure by the middle of this century, impacting millions of people and their economies, and costing billions in damages (*high confidence*). (CCP6.2.3; CCP6.2.4; Box CCP6.1; CCP6.2.5; CCP6.3.1; Table CCP6.5; Table CCP6.6)

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

Climate change increasingly threatens many facets of Arctic livelihoods, culture, identity, health and security, particularly for Indigenous Peoples (*very high confidence*). It has negatively impacted mental health and increased risks of injury, food insecurity and foodborne and waterborne disease, with risks amplified for those reliant on the environment for subsistence, livelihoods and identity (*high confidence*). Permafrost thaw, sea-level rise and reduced sea-ice protection have already damaged or destroyed many cultural heritage sites in some Arctic regions (*very high confidence*) and are projected to continue across all Arctic regions (*very high confidence*). (CCP6.2.3; Table CCP6.3; CCP6.2.4; CCP6.2.5; CCP6.2.6; Figure CCP6.3; Box CCP6.2; CCP6.3.1; Table CCP6.5; Table CCP6.6)

Adaptation

Adaptations to manage climate change impacts and risks in polar regions are urgently needed (*very high confidence*), but implementation is uneven (*high confidence*), limits to adaptation are high and maladaptation is probable (*high confidence*).

Polar zones will continue to contract and diminish in extent under climate change, and local adaptations will be insufficient to achieve long-term resilience of polar systems (*medium confidence*). The pace and extent of change in polar regions is challenging the ability of social and natural systems to adapt (*medium confidence*). Management of different sectors with specific measures to reduce the potential for compounding risks and the development of climate-sensitive strategies would support the resilience of polar systems. Resilience of natural systems can be enhanced through strategies that maintain ecological connectivity over large spatial scales and reduce the particular impact of local extreme events on biodiversity (*medium confidence*). (CCP6.2; Box CCP6.1; CCP6.3; Table CCP6.5; Table CCP6.6; Figure CCP6.6; CCP6.4)

Timing, direction and scale of polar climate change impacts differ sub-regionally and will require adaptation strategies that are flexible, equitable, inclusive and integrated across sectors and governance arrangements to effectively reduce risks (*high confidence*). Governance around climate change planning, preparation and response has been limited in scope, and has often not considered interacting effects of climate change with other risks (*high confidence*). Reactive management strategies will not succeed in reducing risks in polar regions given the rapid change and increasing potential for extreme events (*high confidence*). Greater inclusivity of stakeholders and communities, along with using diverse sources of information, including Indigenous knowledge and local knowledge, can benefit robust planning and decision-making, and uptake of adaptations (*high confidence*). Effectiveness in preparing for and adapting to climate risks can benefit from improved climate, weather and ice forecasting services, tools for integrating climate change data and different types of knowledge into management processes and enhanced polar search, rescue, and emergency response capabilities (*high confidence*). (CCP6.2.3.1; CCP6.3; Table CCP6.6; CCP6.4; Box CCP6.2; Box CCP6.3; Figure CCP6.8)

Climate resilient development

Climate resilience for Arctic Indigenous Peoples and local communities is dependent on Indigenous self-determination in climate-adaptation action (*very high confidence*), inclusive, coordinated, and transboundary governance (*high confidence*) and ecosystem-based policies (*high confidence*) to effectively address climate change impacts and risks across scales and sectors, and to achieve a resilient, secure and equitable future.

Development of robust pathways for climate resilience in the Arctic can be accelerated by adaptation strategies and governance that reflect local conditions, cultures and adaptive capacities of communities and sectors (*high confidence*). Effectiveness of adaptation strategies will be enhanced by accounting for the geographic, climatic, ecological and cultural uniqueness of the polar regions (*medium confidence*). Colonialism can inhibit the development of robust climate adaptation strategies, and exacerbate climate risks (*very high confidence*). Inclusive decision-making in establishing climate adaptations can foster resilience, reflect the unique environmental, cultural, and economic imperatives of the region and support both market-based and sharing economies (*high confidence*). (Box CCP6.2; Table CCP6.6; CCP6.3.2; CCP6.4)

Indigenous self-determination in managing climate change impacts, adaptations, and solutions can accelerate effective robust climate-resilient development pathways in the Arctic (*very high confidence*). Arctic Indigenous self-determination in decision-making can establish robust climate resilience, especially in Indigenous communities, incorporating locally-derived definitions of social and economic success, culturally legitimate institutions of government, strategic visioning and thinking and public-spirited, nation-building leadership (*very high confidence*). (Box CCP6.2; CCP6.3; CCP6.4)

CCP6.1 The Global Importance of Climate Change in Polar Regions

Polar regions (Figure CCP6.1) are considered flagship areas for climate change, since some of the most extreme climate change impacts that are projected to occur by 2050 elsewhere in the world have already been observed in the Arctic and Antarctic and have resulted in transformative and unprecedented change. Polar regions are not only home to cultural keystone species such as polar bears (Arctic) and penguins (Antarctic), they also play fundamental roles in regulating the global climate system and in the provision of ecosystem services for the global community and for Arctic Indigenous Peoples and local communities in the region.

These changes are causing a suite of direct and cascading risks for all polar ecosystems with larger effects to date in the Arctic than the Antarctic (*high confidence*), due to larger and regionally more consistent physical changes (Figure CCP6.2, Table CCP6.1; Chapter 3) (Meredith et al., 2019; Ranasinghe et al., 2021). In the Arctic, these changes affect every sector of society, impacting its 4,000,000 inhabitants, including 400,000 Indigenous People. The Antarctic has no permanent human settlements; however, many nations conduct field research, operate seasonal and permanent stations and have an interest in the management of the region (Hughes et al., 2018; Grant et al., 2021). During summer, when Antarctic science, tourism and fishery activities are greatest, 4,400 people live there, whereas only 1,100 people live there over winter (Meredith et al., 2019). Although adaptation is occurring in polar regions, it is uneven and sporadic and does not meet the risks posed by future climate change. Indigenous knowledge-based solutions, inclusive ecosystem-based policies and integrated technologies demonstrate the potential to effectively address climate change impacts across scales and sectors; yet implementation barriers remain (CCP6.4.1).

This Cross Chapter Paper (CCP) assesses the impacts, risks and adaptation implications resulting from the physical and chemical changes in the polar regions that were detailed in the WGI contribution to the AR6 (IPCC, 2021). Several key WGI AR6 findings have important implications for natural and human systems in polar regions. Warming and wetting have persisted as key climatic impact drivers in polar regions (*very high confidence*) and will *very likely*[2] continue to 2100 (Fox-Kemper et al., 2021; Gulev et al., 2021) with cascading climate effects regarding heatwaves, fire, weather, floods and heavy precipitation, river runoff, snowfall, glaciers and ice sheets, permafrost, lake, river and sea-ice, relative sea level and coastal flooding and erosion (Gutiérrez et al., 2021; Ranasinghe et al., 2021) (Table CCP6.1). They represent major climate hazards in all key risks for polar regions (Table CCP6.5). Key points of departure for this CCP also include AR5 (IPCC, 2014) and the Polar Regions chapter in the Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC) (Meredith et al., 2019). SROCC assessed physical, biological and social systems concerning the Arctic and Antarctic Oceans and cryosphere, and how they are affected by current and future climate change. This CCP assesses the rapidly increasing evidence that has been published since AR5 and SROCC, and advances previous IPCC assessments. First, results from the Coupled Model Intercomparison Projects (CMIP6) are an important advance since SROCC, which improve the certainty and resolution of projections of the main climate impact drivers and the risks they have for polar systems (Fox-Kemper et al., 2021; Ranasinghe et al., 2021). Second, building from the framework outlined in SROCC (Crate et al., 2019), scientific, Indigenous knowledge (IK) and local knowledge (LK) systems are included in this assessment. Importantly, Indigenous authors led the assessment of the impacts, adaptation and governance of climate change for Indigenous Peoples, which is an important advance since AR5 and represents an important step towards Indigenous self-determination in international assessment processes (Ford et al., 2012; Ford et al., 2016; Hill et al., 2020).

Herein, observed impacts and future risks (CCP6.2), key risks and adaptation (CCP6.3) and climate resilient development pathways (CCP6.4) in the polar regions are assessed. The CCP describes how the implications of climate change impacts in the Arctic and Antarctic extend beyond their boundaries, in terms of transregional coupled ecological systems (CCP6.2.1, CCP6.2.2), global nutritional security (CCP6.2.3), global trade and shipping (CCP6.2.4) and cultural value (CCP6.2.5, CCP6.2.6). Given the synthetic and

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

policy-facing mandate of CCPs and with SROCC as a key point of departure, this CCP is not intended to cover the full breadth of issues for polar regions but rather it highlights select key policy-relevant topics by synthesizing and adding value to the relevant material from AR6 sectoral and regional chapters.

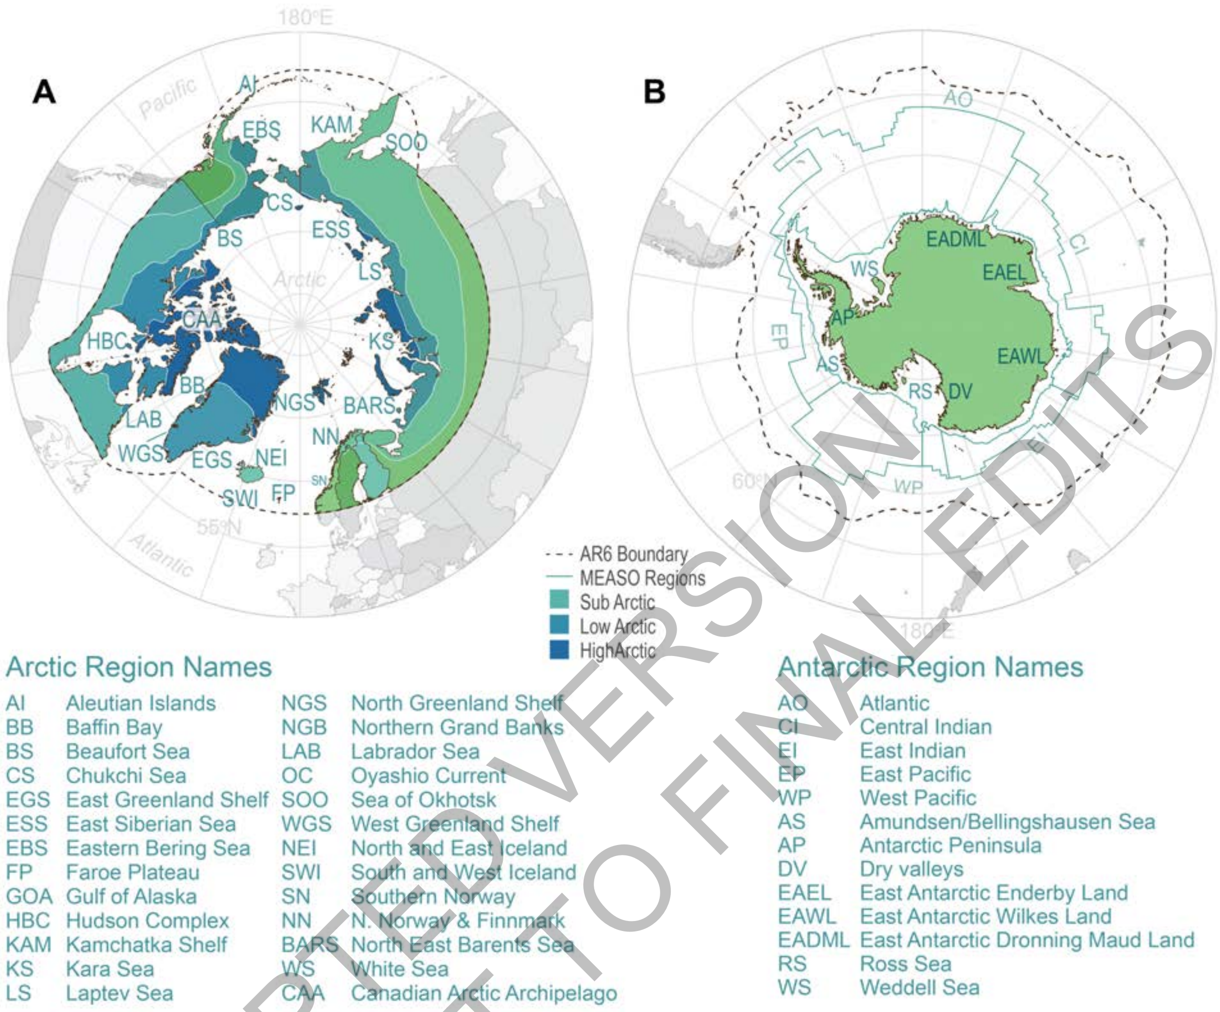

Figure CCP6.1: Polar regions include the Arctic, Antarctica, Iceland, Greenland, Faroe Islands, and some sub-Arctic areas (e.g., Bering Sea and Aleutian Islands as well as the Fennoscandian and Siberian boreal areas), and all sub-Antarctic areas. This CCP augments the geographical boundaries for the Arctic (Meredith et al., 2019) to also include the subarctic boundary (as defined by the Arctic Biodiversity Assessment), northern boreal areas, parts of the Siberian taiga and southern Labrador. The Antarctic region is delineated along the sub-Antarctic Front (Orsi et al., 1995). Geographic boundaries of the polar regions and important sub-regional locations are displayed including five marine sectors as defined in the Marine Ecosystem Assessment for the Southern Ocean (MEASO), e.g., Grant et al., (2021).

Table CCP6.1: Climatic impact drivers in the Arctic and Antarctic derived from WGI-AR6 chapters (indicated as WG1-9 (Fox-Kemper et al., 2021) and WG1-12 (Ranasinghe et al., 2021)) and Meredith et al (2019) (indicated as SROCC-3). Supplementary Material (SMCCP6.1) contains supplemental data for these drivers of projected changes (2021-2040, 2041-2060, 2081-2100) derived from the WGI-AR6 Interactive Atlas (indicated as Atlas)(Gutiérrez et al., 2021)(https://interactive-atlas.ipcc.ch).

Driver	Region	Observed Changes	Projected Changes
Marine and sea-ice			
Sea level (relative)	Arctic	No consistent trend (increase in NW America, decrease in NE America, stable in Greenland and Arctic Russia) (WG1-12)	Rise in all polar regions (except areas of substantial land uplift in NE Canada, the west coast of Greenland) (*high confidence*);

			Increase of extreme sea levels in Russian Arctic and NW America (*high confidence*) Greenland/Iceland and NE America (given glacial isostatic adjustment) (*medium confidence,* WG1-12)
	Antarctic		Rise in all polar regions (except areas of substantial land uplift in W Antarctica) (*high confidence*, WG1-12)
Sea-surface temperature	Arctic	Increase of ~0.5°C per decade during 1982-2017 in ice-free regions in summer (*high confidence*, SROCC-3)	Further increases (*high confidence*, WG1-12)
	Antarctic	Warmed in northern areas of Southern Ocean but cooled in its southernmost regions since the 1980s (*high confidence*, SROCC-3)	Circumpolar increases (*high confidence*, WG1-12)
Sea-ice cover	Arctic	Loss (particularly of multi-year sea-ice) accelerated since 2001 (*very likely*, WG1-9)	Will become sea-ice free (< 1 x 10^6 km^2) during summer before 2050, irrespective of global warming level (*likely*, WG1-9)
	Antarctic	No significant circumpolar trend from 1979–2018 (*very high confidence*), but decrease off the Antarctic Peninsula (*high confidence*) and increases and decreases in other regions (*medium confidence*, WG1-9)	Circumpolar decrease (*low confidence* due to limited understanding of driving processes, WG1-9)
Ocean surface pH	Both Poles	Decrease since 1980 at rates of 0.003–0.026 pH units per decade in open polar zones (*very likely*, WG1-12)	Further acidification by 0.1–0.6 pH by 2100 (Atlas), characterized by year-around conditions corrosive for aragonite minerals by 2100 (*very likely*, SROCC-3)
Terrestrial, freshwater and ice			
Atmospheric Temperature	Arctic	Increase of means higher than twice global mean, most pronounced in cold season (*high confidence*, WG1-12)	Further increase (Table SMCCP6.1)
	Antarctic	Warmed from 1957–2016 at 0.2–0.3°C per decade in W. Antarctica (*very likely*); No consistent change in E. Antarctica (*limited evidence*, WG1-12)	Region: Future warming across continent (*high confidence*, WG1-12)
Extreme Heat Events	Arctic	Increase since 1979 (WG1-12)	Polar amplification will drive further increases (*high confidence*, WG1-12)
	Antarctic	Heatwave across Antarctica (2020) (WG1-12, (Robinson et al., 2020).	Further increase, with > 50 additional days above freezing by 2100 (under RCP8.5, vs. 2014) over the Antarctic Peninsula but smaller changes over mainland Antarctica (*medium confidence,* WG1-12)
Fire Weather (FW)	Arctic	Over 4 decades, fire season lengthened and number of fires increased in N America (WG1-12)	FW index increases and more frequent fires in tundra regions (*high confidence*, WG1-12)
Precipitation	Arctic	Increase, highest during the cold season (*likely*, Atlas)	

	Antarctic	Increasing trend over the 20th century, while large interannual variability masks any existing trend since the end of 1970 (*medium confidence*, Atlas)	
Floods	Arctic	Increasing river runoff, increasing heavy precipitation (*high confidence*, WG1-12)	Further increases in all variables (*high confidence*, WG1-12)
Snowfall	Arctic	Recent overall declines in snow extent and seasonal duration (*high confidence*, WG1-12)	Higher % of precipitation as rain (fall and spring) (*high confidence*, WG1-12)
	Antarctic	Increases in the 20th century (*medium confidence*, WG1-12)	Further increases (over land) (*likely*, WG1-12)
Glaciers and Ice Sheets (IS)	Arctic	Losses in glacier mass since 2000 (*high confidence*, WG1-12); Losses in Greenland IS mass since 1980 at increasing rates (*high confidence*, WG1-9)	Further mass loss until 2100 under all warming scenarios (*virtually certain*, WG1-9 and -12)
	Antarctic	Losses in glacier mass since 2000 (*high confidence*, WG1-12); Losses in Antarctic IS mass since 1992 (in W Antarctica but also parts of E Antarctica since 2000) (*high confidence*, WG1-9)	Further mass loss until 2100 under all warming scenarios (*likely*, WG1-9 and -12)
Permafrost	Arctic	Rising permafrost temperatures over past 3-4 decades (*high confidence*, WG1-9); Decreases in permafrost active layer thickness (*very high confidence*) (Biskaborn et al., 2019). Submarine permafrost warming (*medium confidence*, WG1-9)	Increases in temperature and active layer thickness (WG1-9); Near-surface terrestrial permafrost extent will reduce under all scenarios by 2100 (*virtually certain*, WG1-9)
	Antarctic	Rising permafrost temperatures over past 3-4 decades (high confidence, WG1-9).	
Lake, River Ice	Arctic	Declines in seasonal lake ice cover thickness and duration over most Arctic lakes; Declines in cold-season river ice extent (*high confidence,* WG1-12)	Many lakes will lose > 1 month lake ice cover by 2050 (*medium confidence*), Reductions in average Northern Hemisphere seasonal river ice duration of 6.10 days per 1°C GWL (WG1-12)
Coastal floods / erosion	Arctic	Increase (*medium confidence*, WG1-12)	Further increase (*high agreement-limited evidence,* WG1-12)
	Antarctic	(Lack of studies, WG1-12)	

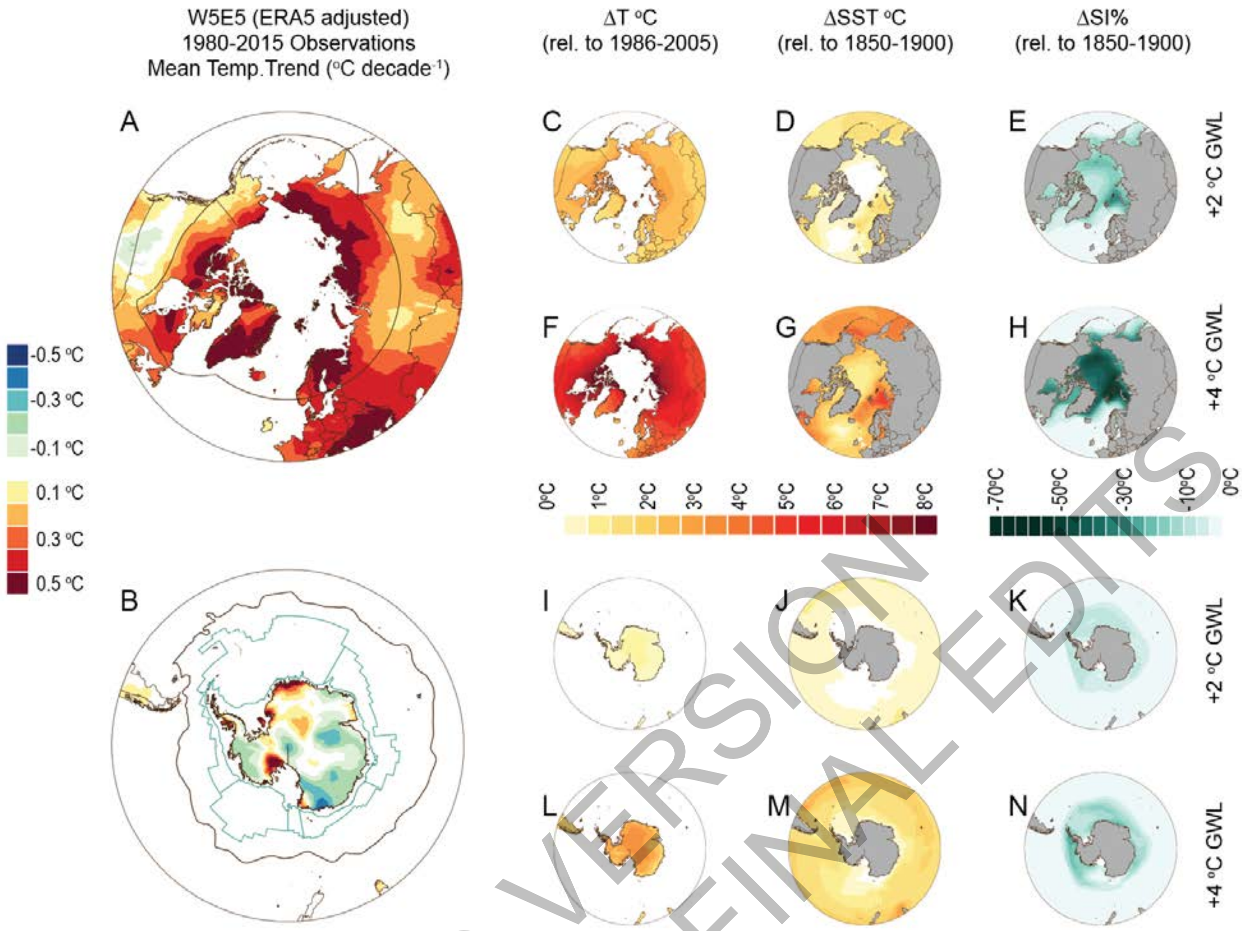

Figure CCP6.2: Observed and projected climate changes across the Arctic (A, C-H) and Antarctic (B, I-N). Boundary lines in each plot are based on the polar regions defined in Figure CCP6.1. All data shown here are extracted from the IPCC WGI Interactive Atlas (Gutiérrez et al., 2021; Iturbide et al., 2021); data set details can be found in the Atlas (https://interactive-atlas.ipcc.ch/). Arctic (A) and Antarctic (B) are observed temperature trends (°C/decade) over land for the period 1980-2015, derived from ERA5 adjusted dataset. Projected changes from an ensemble of CMIP6 projections: annual mean temperature over land is depicted for 2°C (C, I) and 4°C (F, L). Global Warming Levels (GWL) in the Arctic and Antarctic, respectively; annual mean sea surface temperature is depicted for 2°C (D, J) and 4°C (G, M) GWL in the Arctic and Antarctic respectively; annual sea-ice (%) is depicted for 2°C (E, K) and 4°C (H, N) GWL in the Arctic and Antarctic, respectively.

CCP6.2 Observed Impacts and Future Risks

Table CCP6.2: Summary of observed impacts (and projected risks of climate change for polar marine, terrestrial and freshwater ecosystems identified in Section 3.2.3 and Box 3.4 in Chapter 3 of the IPCC SROCC (Meredith et al., 2019).

Affected system	Hazard *Cascading Effect	Observed impacts, future risks and natural adaptations identified in SROCC (Confidence Level)
Arctic marine ecosystems		
Primary Producers (PP-1)	Sea-ice loss * Freshening * Stratification	Impact: Timing (earlier and later blooms), distribution and magnitude (>30% increase in annual net primary production since 1998) (*high confidence*)
	Acidification	Adaptation: phytoplankton may compensate for decrease pH

Zooplankton	* PP-1	Impact: Changing production and community composition (*medium confidence*)
Benthos	* PP-1	Impact: Changing production and biodiversity (*medium confidence*)
	Acidification	Risk: Effects on zooplankton and pteropods depends on climate scenario and species' sensitivity/adaptive capacity
Fish	Warming * Prey changes	Impact: Northward expanding ranges of sub-Arctic/boreal species (e.g., Atlantic cod) in Bering Sea (Detection - *high confidence*, Attribution - *medium confidence*) negatively affecting Arctic polar cod (*medium confidence*)
	* Prey declines	Risk: Decreasing production of walleye pollock, Pacific cod and arrowtooth flounder, due to declines in large copepods (*medium confidence*)
Birds and Marine Mammals	Sea-ice loss	Impact: Phenological, behavioural, physiological, and distributional changes; Endemic marine mammals have little scope to move northwards in response to warming (*high confidence*)
Polar Bears	Sea-ice timing, distribution, thickness	Impact: Phenological shifts, and changes in distribution, denning, foraging behaviour and survival rates (*high confidence*)
Antarctic marine ecosystems		
Primary Productivity	Sea-ice loss * Freshening * Stratification	Impact: Little overall change in biomass at circumpolar scale from 1998–2006, but sub-regional differences (*medium confidence*); Changes difficult to detect and attribute to climate change.
Microbes	Acidification	Impact: Detrimental effect on primary production and changes to the structure and function of microbial communities (*medium confidence*)
Antarctic Krill	Warming	Impact: Declines in abundance in the South Atlantic sector (*medium confidence*); May not represent a long-term, climate-driven trend but a decline following a period of anomalous peak abundance (*low confidence*)
		Risk: Southward range shift due to changes in the location of the optimum conditions for growth and recruitment, with decreases most apparent in the areas with the most rapid warming, such as the southwest Atlantic/Weddell Sea region (*medium confidence*)
Zooplankton	Acidification	Risk: Vulnerability of pteropods through effects on eggs (*medium confidence*)
Benthos	Sea-ice loss	Risk: Increase of biomass on the Antarctic continental shelf as productivity from longer phytoplankton blooms outweigh ice-scour mortality (*low confidence*)
	Sea-ice loss	Risk: Shallow-water communities may become dominated by macroalgae due to increases in the amount of light (possible loss of endemic species by 12% due to warming temperatures) (*low confidence*)
Fish	Warming	Risk: Icefish may be displaced from shallow regions around sub-Antarctic islands (*low confidence*)

Birds and Marine Mammals	Sea-ice cover	Impact: Predictability of foraging grounds and sea-ice cover associated with climate are main drivers of population changes: Increases for gentoo penguins (decreases for Adélie, chinstrap, king and Emperor penguins) (*high confidence*)
Arctic terrestrial and freshwater ecosystems		
Vegetation	Warming	Impact: Greening (*high confidence*)
		Risk: Decrease tundra areal extent >50% by 2050; wood shrubs expected to increase (*medium confidence*)
Vertebrates	Warming	Impact: Expanding range into Arctic
Freshwater Primary Productivity	* Increased runoff * Increased permafrost thaw	Impact: Increased productivity in rivers, lakes and coastal areas
		Risk: Expected to mobilise stores of pollutants
Pathogens	Warming	Impact: Expanding range into Arctic
		Risk: Mobilisation may increase in high latitudes, including anthrax from frozen carcasses possibly released from permafrost
Fish	* Freshwater winter habitat * Increased discharge	Risk: Disruption of the life history of Arctic freshwater fish
	* Warming freshwater	Risk: May make some surface waters inhospitably warm for cold water fish species
Biodiversity	Warming	Impact: Subarctic biodiversity expanding into Arctic
Reindeer/ Caribou	Climate factors	Impact: Reindeer/caribou declined overall without adaptation (*high confidence*), with climate affecting many aspects of their life history (*medium confidence*)
		Risk: Domesticated reindeer/caribou can be affected by fire, which reduces pasture, as well as by increased ice-on-snow, which can cause starvation
Antarctic terrestrial and freshwater ecosystems		
Terrestrial Biota	* Increased coastal ice melt	Impact: Increasing coastal ice-free areas available for colonisation (*high confidence*)
Alien Species	Warming	Risk: Barriers to alien species reduce, affecting terrestrial biodiversity (*medium confidence*)

CCP6.2.1 Marine and Coastal Ecosystems

CCP6.2.1.1 Warming and sea-ice retreat cause shifts in distribution ranges of species

In Arctic seas, warming and other climate impact drivers, primarily sea-ice retreat, have led to range contractions of Arctic marine and ice-associated species and poleward expansions of boreal species (*very high confidence*) (Table CCP6.2) (Bouchard and Fortier, 2020; Huntington et al., 2020; Mueter et al., 2020) even though light and energetics at seasonal extremes may limit some range shifts (*limited evidence*) (Ljungström et al., 2021). Altered conditions allow more microorganisms to move poleward and provide opportunities for invasive species (Cavicchioli et al., 2019; Nielsen et al., 2020; Mustonen, 2021).

Phytoplankton communities harbour increasing numbers of taxa, including harmful species (Lovejoy et al., 2017) and the coccolithophore *Emiliania huxleyi*, which meanwhile forms regular blooms in the Barents Sea (Neukermans et al., 2018; Silkin et al., 2020). Northward shifts of pelagic, benthic and demersal species and subsequent changes in Arctic community composition have been observed in the Bering, Greenland and Barents Seas (Grebmeier et al., 2018; Mueter et al., 2020), as have higher numbers of economically important boreal species such as haddock and Pacific and Atlantic cod (CCP6.2.3). Cold-adapted Arctic fish species such as polar cod (*Boreogadus saida*) are expected to decline further and lose spawning habitats at global warming levels >1.5 °C, mainly due to a lack of phenotypic plasticity, as well as increasing interspecific competition with and predation from invading boreal species (Dahlke et al., 2018; Marsh and Mueter, 2020). Numerous mammals and seabirds respond to changes in the distribution of their preferred habitats and prey by shifting their range, altering the timing or pathways for migration or switching prey (*very high confidence*) (Hamilton et al., 2017; Loseto et al., 2018; Meredith et al., 2019). Ice-breeding seals (e.g., harp seals - *Pagophilus groenlandicus*) often have little scope to shift distribution, leading to increases in strandings and pup mortality in years with little ice cover (*medium confidence*) (Table CCP6.2) (Boveng et al., 2020). Recent studies confirm that polar bears (*Ursus maritimus*) are negatively affected by changing ice and snow conditions with decreases in denning, foraging, reproduction, genetic diversity and survival rates (*very high confidence*) (Table CCP6.2) (Boonstra et al., 2020; Johnson and Derocher, 2020; Maduna et al., 2021).

In the Southern Ocean, southward range shifts are expected to result from increased warming coupled with the narrow thermal tolerance of cold-adapted Antarctic species (Convey and Peck, 2019; Morley et al., 2019; Gutt et al., 2021). Such shifts have so far only been detected for Antarctic krill (*Euphausia superba*), with a poleward contraction of the highest densities of krill in the Atlantic sector (*medium confidence*) (Table CCP6.2); (Atkinson et al., 2019). Ocean warming is expected to put pressure on Antarctic phytoplankton (Pinkerton et al., 2021) and fish species unable to move further south in shelf areas, including waters off sub-Antarctic islands (*low confidence*) (Table CCP6.2) (Caccavo et al., 2021). Off the Antarctic Peninsula and sub-Antarctic islands, invasive benthic invertebrates and macroalgae have already been detected (*medium confidence*) (Fraser et al., 2018; Avila et al., 2020; Brasier et al., 2021), and projected changes will further favour the spread of invasive species (Fraser et al., 2020; Macaya et al., 2020). On a local to regional scale, the benthic recolonization of the newly exposed seabed after the disintegration of ice shelves shows typical succession patterns, with mass occurrences of few pioneer species followed by gradual shifts to a more diverse typical shelf community, driven by increasing pelagic primary production upon ice-shelf collapse and strengthening of the pelagic-benthic coupling (*high confidence*) (Brasier et al., 2021; Gutt et al., 2021). Range changes of Antarctic birds and marine mammals have been observed, which vary among sub-regions and are mostly attributable to changes in sea-ice extent and food availability (*high confidence*) (Table CCP6.2) (Gutt et al., 2018; Convey and Peck, 2019; Bestley et al., 2020). With projected sea-ice retreat and associated change in prey distribution (Henley et al., 2020), foraging areas of sub-Antarctic seabirds and marine mammals will shift southwards, leading to elevated pressure on populations due to higher foraging costs during the breeding season (*medium confidence*) (Ropert-Coudert et al., 2018; Bestley et al., 2020; Hindell et al., 2020; Hückstädt et al., 2020; Wege et al., 2021). These changes are particularly impacting emperor penguins (*Aptenodytes forsteri*) (Table CCP6.2), with the projected population declining close to extinction by 2100 under business-as-usual climate scenarios (*medium confidence*) (Jenouvrier et al., 2020; Trathan et al., 2020; Jenouvrier et al., 2021), whereas population decline is halted by 2060 under the 1.5°C climate scenario (*low confidence*) (Jenouvrier et al., 2020).

CCP6.2.1.2 Ocean warming and sea-ice changes affect marine primary productivity

In the central Arctic Ocean, primary productivity remains low (*medium confidence*), mostly due to persisting nutrient and light limitations (Randelhoff and Guthrie, 2016; Ardyna and Arrigo, 2020). In inflowing (Barents and Chukchi Sea) and interior shelf regions (Laptev, Kara, and Siberian Sea), changes in sea-ice extent, thickness and seasonal timing have altered light and mixing regimes, causing increasing overall productivity in open-water and under-ice habitats, and in leads (*high confidence*) (Table CCP6.2) (Ardyna and Arrigo, 2020; Lannuzel et al., 2020). Productivity changes are associated with the earlier onset phytoplankton spring blooms and the increasing occurrence of autumn blooms, particularly at lower latitudes of the Arctic (*high confidence*) (Table CCP6.2) (Tedesco et al., 2019; Ardyna et al., 2020). Ice algal communities are expected to change in productivity and species composition in response to the transition from a predominantly multi-year to a seasonal sea-ice pack (*high confidence*) (Meredith et al., 2019; Tedesco et al., 2019; Lannuzel et al., 2020). Thinner sea-ice increases the likelihood of surface flooding, resulting in the occurrence of snow-infiltration algal communities, which have been described in the Atlantic sector of the Arctic Ocean (Fernández-Méndez et al., 2018) and observed by Indigenous Peoples off northern Greenland (Box CCP6.2). The observed transition from marine-terminating to land-terminating glaciers has a negative impact on coastal ecosystems in Greenland (*medium confidence*) (Meire et al., 2017; Hopwood et al., 2018) and Svalbard (Halbach et al., 2019), as land-terminating glacial meltwater input increases stratification, which hinders vertical mixing and lowers local productivity, whereas marine-terminating glaciers can trigger upwelling, which supplies nutrients and enables higher productivity in the summer (Hopwood et al., 2020). Macroalgae and seagrass are generally expanding in the Arctic (*medium confidence*), though there are negative trends in some regions, partly due to increased runoff and turbidity from melting glaciers (Hopwood et al., 2020; Krause-Jensen et al., 2020). In the future Arctic Ocean, higher light availability in response to further sea-ice decline and reduced deep mixing is projected to generally increase primary productivity (*medium confidence*), leading to an increase in phytoplankton biomass from 2000-2100 by ~20% for SSP1-2.6 and ~30-40% for SSP5-8.5 (Chapter 3) (Kwiatkowski et al., 2020). However, productivity may increase less than predicted and eventually even decrease once nutrient limitation outweighs the benefits of higher light availability (*low confidence*) (Randelhoff et al., 2020; Seifert et al., 2020).

Despite large-scale environmental changes in the Southern Ocean, such as the deepening of the summer mixed layer (*medium confidence*) (Panassa et al., 2018; Sallée et al., 2021), and the expected impacts via altered nutrient entrainment, light availability and grazer encounter rates (Chapter 3) (Behrenfeld and Boss, 2014; Llort et al., 2019), assessments indicated no consistent changes in primary production at the circumpolar scale, as sectors and regions show different trends (*medium confidence*). Although a global assessment found no overall changes in circumpolar primary production from 1998-2015 (Table CCP6.2) (Gregg and Rousseaux, 2019), another study showed an overall increase in phytoplankton biomass in the mixed layer over the period 1997-2019 (Pinkerton et al., 2021). Primary productivity has increased in the Pacific sector and decreased in the Atlantic sector and the Ross Sea (*low confidence*) (Kahru et al., 2017; Henley et al., 2020; Pinkerton et al., 2021). Higher productivity has also been observed in regions where rapid environmental changes occurred, such as in the vicinity of retreating ice sheets and declining sea-ice cover off the Antarctic Peninsula (*medium confidence*) (Henley et al., 2020; Rogers et al., 2020), although diversity of phytoplankton may decrease with warming temperatures and less sea-ice (*limited evidence*) (Lin et al., 2021). In the future Southern Ocean, stronger upwelling due to strengthened westerly winds is projected to increase primary productivity at the circumpolar scale in the Antarctic Zone and to the north of the sub-Antarctic Front, but not in the sub-Antarctic Zone (*low to medium confidence*) (Chapter 3) (Henley et al., 2020; Kwiatkowski et al., 2020; Pinkerton et al., 2021). The largest changes are projected to occur after 2100 at 2-6°C warming of the surface ocean (Moore et al., 2018). Such an increase in Southern Ocean productivity will lead to a decline in global ocean productivity (*medium confidence*), due to nutrient trapping (Moore et al., 2018) and altered ocean carbon uptake through ecosystem feedbacks (Hauck et al., 2018).

CCP6.2.1.3 Impacts of ocean acidification vary spatially and among biotas

In Arctic seas, areas with acidification levels corrosive to organisms forming $CaCO_3$ shells or skeletons expanded between the 1990s and 2010 (*high confidence*), with instances of extreme aragonite under-saturation (Ding et al., 2017; Zhang et al., 2020). Key species of diatom and picoeukaryote phytoplankton species yet appear relatively resilient to decreasing pH levels over a range of temperature and light conditions (*medium confidence*) (Table CCP6.2) (Thoisen et al., 2015; Wolf et al., 2018; White et al., 2020). In contrast, there is evidence for species- and stage-specific sensitivities of zooplankton, pteropods and fishes (*high confidence*) (Table CCP6.2) (Bailey et al., 2016; Dahlke et al., 2018; Thor et al., 2018). Warming, rising river-sediment discharge and coastal erosion in Arctic shelf regions are expected to increase the input of labile, often permafrost-derived organic carbon, the remineralisation of which further increases acidification rates (*medium confidence*) (Semiletov et al., 2016; AMAP, 2018b; Bröder et al., 2018). Interactions with other physical changes, such as warming or freshening, are expected to aggravate the impacts of ocean acidification (Chapter 3) (Falkenberg et al., 2018).

In the Southern Ocean, calcifying organisms are also most vulnerable to ocean acidification (*high confidence*) (Table CCP6.2), as evidenced by rates of calcification declining by 3.9% between 1998-2014 (Freeman and Lovenduski, 2015). Calcifying species with low-magnesium calcite or mechanisms to protect their skeletons are less vulnerable to the corrosive effects of acidification than those using aragonite or high-magnesium calcite (*high confidence*) (Figuerola et al., 2021). In diatom-dominated communities, silicification diminishes with reduced pH levels, albeit with rates differing among taxa (*low confidence*) (Petrou et al., 2019). Species-specific responses exist regarding growth and primary production, which are further strongly modulated by iron and light availability (*high confidence*) (Hoppe et al., 2013; Trimborn et al., 2013; Hoppe et al., 2015; Henley et al., 2020; Seifert et al., 2020). A meta-analysis yielded different CO_2 thresholds for Antarctic organismal groups, e.g., negative impacts emerged at >1,000 µatm CO_2 in phytoplankton and at >1,500 µatm CO_2 in invertebrates, whereas bacterial abundance was positively affected by ocean acidification (Hancock et al., 2020). Species sensitivity can also differ strongly between life-cycle stages (Chapter 3.3.2). For instance, eggs and embryos of Antarctic krill are negatively impacted at >1,250 µatm CO_2 whereas adults can thrive even at 1,000-2,000 µatm CO_2 over one year (Kawaguchi et al., 2013; Ericson et al., 2018).

CCP6.2.1.4 Climate change alters food web dynamics

Climate change has transformed Arctic marine ecosystems from sea-ice-associated to open-water production regimes, with profound impacts on trophic energy transfer efficiencies and pathways (*high confidence*) (Behrenfeld et al., 2017; Meredith et al., 2019; Huntington et al., 2020) as well as benthic-pelagic coupling (*medium confidence*) (Birchenough et al., 2015; Degen et al., 2016; Solan et al., 2020). Shifts in bloom phenology favour small phytoplankton and smaller zooplankton over large lipid-rich macro-zooplankton, leading to longer, less efficient food chains (*medium confidence*) (Aarflot et al., 2018; Feng et al., 2018; Kimmel et al., 2018; Weydmann et al., 2018; Møller and Nielsen, 2020). In the Beaufort Sea and Svalbard waters, earlier spring phytoplankton blooms have resulted in a mismatch in dynamics between microalgae and herbivorous copepods (Renaud et al., 2018; Dezutter et al., 2019). In the Bering Sea, zooplankton declines following the particularly pronounced sea-ice retreats in 2017 and 2018 were associated with reduced forage fish production (Duffy-Anderson et al., 2019), as well as multitrophic mortality of ctenophore, fish, bird, and mammal species, coupled with severe emaciation, reproductive failure, disease, and high mortality rates of seabird predators (Section 14.4.4.2) (Jones et al., 2019; Maekakuchi et al., 2020; Piatt et al., 2020; Romano et al., 2020). Species range shifts have restructured higher trophic levels in Arctic food webs (*high confidence*) (Table CCP6.2; CCP6.2.3.3 Chapter 3) (Huntington et al., 2020). In the northern Barents Sea, increased predation mortality for key species and incursions of boreal fish have induced entire ecosystem reorganization (Degen et al., 2016; Pecuchet et al., 2020a; Pecuchet et al., 2020b). Regional taxonomic and functional diversity increased with immigration of boreal species, although the ongoing decline in Arctic species suggests high species turnover (Table CCP6.2) (Frainer et al., 2017). Recent marine heatwaves induced rapid and profound food web changes unprecedented over the last four decades (Siddon et al., 2020).

Climate impacts on Arctic marine food webs will be profound and intensify with global warming levels (*high confidence*), regardless of mitigation scenarios due to multidecadal lags in sea-ice extent and atmospheric carbon (WGI) (Jones et al., 2020). However, the exact nature of these impacts remains unclear due to attenuating and amplifying dynamics of both top-down and bottom-up processes in polar food webs and the management of fisheries (*high confidence*) (Chapter 3) (Cavicchioli et al., 2019; Meredith et al., 2019). Projected sea-ice loss is associated with a >50% decline in the density of large zooplankton species by 2100 (relative to early 21st century levels) in the southern Bering Sea and a net increase in large zooplankton in the northern Bering Sea in scenarios without carbon mitigation (RCP8.5), whereas these declines are roughly half the magnitude under moderate mitigation scenarios (RCP4.5) (Hermann et al., 2019; Kearney et al., 2020). Warming is expected to reduce the quantity and quality of lipid-rich copepod prey (*high confidence*) (Aarflot et al., 2018; Kimmel et al., 2018; Bouchard and Fortier, 2020; Møller and Nielsen, 2020; Mueter et al., 2020), leading to declines in survival and growth of multiple upper-trophic level fish species; these impacts are amplified over time under low mitigation scenarios (RCP8.5) (*high confidence*) (CCP6.2.1.1) (Dahlke et al., 2018; Holsman et al., 2020; Mueter et al., 2020; Oke et al., 2020; Reum et al., 2020; Thorson et al., 2020; Whitehouse et al., 2021). Marine mammals and seabirds will continue to attenuate climate change impacts by shifting their diets and behaviour (*medium confidence*) (Table CCP6.2) (Hamilton et al., 2017; Lowther et al., 2017; Lydersen et al., 2017; Vihtakari et al., 2018; Boveng et al., 2020). However, seabirds generally have low temperature-mediated plasticity of reproductive timing, making them vulnerable to mismatches with their prey and limiting long-term adaptation (*medium* *confidence*) (Keogan et al., 2018; Kharouba and Wolkovich, 2020; Piatt et al., 2020; Samplonius et al., 2021).

Many factors have contributed to changes in Antarctic food webs, including historical exploitation of fish and marine mammals as well as changes driven by the ozone hole and climate factors (Meredith et al., 2019; Morley et al., 2020; Grant et al., 2021). Most documented changes resulting from warming and sea-ice losses relate to shifts in ranges and dynamics of species, with most impacts occurring around the Antarctic Peninsula (CCP6.2.1.1; Table CCP6.2).

The projected general rise in primary production in Antarctic seas by 2100 (CCP6.2.1.2) suggests a concomitant increase in the abundance of higher trophic species, but changes in the structure and function of food webs will vary (McCormack et al., 2021; McCormack, accepted) depending on regional differences in changing drivers (Morley et al., 2020; Cavanagh et al., 2021; Grant et al., 2021). Primary production in open water habitats is expected to be supported by smaller phytoplankton species in the future (Henley et al., 2020), which could increase the relative importance of the copepod-mesopelagic fish pathway (McCormack, accepted), because krill prefer larger diatoms as food (Siegel, 2016). The optimum habitat for Antarctic krill is expected to decline with a shortening of suitable season for krill growth and reproduction, particularly in the northern Scotia and Bellingshausen Seas (*medium confidence*) (Veytia et al., 2020), although changes may be difficult to distinguish from natural variability until later in the century (Sylvester et al., 2021). More subtle and unpredictable changes may occur in the structure and relative importance of energy pathways in the food webs (Trebilco et al., 2020). Small mesopelagic fish are increasingly recognized for their importance as mid-trophic level species in the Southern Ocean, particularly in the sub-Antarctic zone (Caccavo et al., 2021) and Central Indian Sector (Subramaniam et al., 2020; McCormack et al., 2021). Although salps have long been considered to be competitors of Antarctic krill (Suprenand and Ainsworth, 2017; Rogers et al., 2020), they provide a third energy pathway in pelagic food webs, and, given the changing ocean conditions and their preference for smaller phytoplankton, may increase in importance for copepods (*low confidence*) (Plum et al., 2020; Trebilco et al., 2020; McCormack et al., 2021; Pauli et al., 2021; McCormack, accepted). Declining ice shelves, such as those off the Antarctic Peninsula, will open up new pelagic and benthic habitats (CCP6.2.1.1) with expected increases in productivity of benthic assemblages in the new areas (Barnes, 2017; Morley et al., 2020; Brasier et al., 2021; Gutt et al., 2021).

CCP6.2.2 Terrestrial and Freshwater Ecosystems

Since the publication of AR5 (IPCC, 2014) and SROCC (IPCC, 2019) and their findings (Table CCP6.2), more studies confirm rapid changes in Arctic terrestrial and freshwater systems including increased permafrost thaw, changes to tundra hydrology and vegetation (overall greening of the tundra, regional browning of tundra and boreal forests), coastal and riverbank erosion (*high confidence*) (Canadell et al., 2021; Mustonen and Shadrin, 2021), reduced duration of snow cover and river and lake ice, increased rain-on-snow events, and reduced land-ice extent and thickness (Bieniek et al., 2018; Brown et al., 2018). Climate change continues to alter vegetation and attendant biodiversity, with divergent regional trends across the Arctic due to disparities in local conditions and changes in growing seasons (Zhu et al., 2016; Taylor et al., 2020). Warming facilitates woody vegetation growth in northeastern Siberia, western Alaska, and northern Quebec (Song et al., 2018; García Criado et al., 2020), as well as a northward expansion of shrub vegetation and sub-Arctic and boreal species (Davidson et al., 2020).

Further evidence shows that warming and changes to the Arctic hydrologic cycle increase the risk of wildfire (*medium confidence*) (Mustonen and Shadrin, 2021). Both the frequency of and the area burned by wildfires during recent years are unprecedented compared to the last 10,000 years (*high confidence*) (Meredith et al., 2019; Irannezhad et al., 2020). Fire risk levels are projected to increase across most tundra and boreal regions, and interactions between climate and shifting vegetation (Song et al., 2018) will influence future fire intensity and frequency (*medium confidence*) (Curtis et al., 2018).

For all warming scenarios, declines in snow cover in the Arctic by 2050 (Table CCP6.1) may accelerate vascular plant, moss, and lichen extinction rates (32% for Arctic–alpine and 12% for boreal species), especially after the tipping point of 20−30% decrease in snow cover duration is passed (Niittynen et al., 2018). Even though the overall regional water cycle will intensify, including increased precipitation, evapotranspiration and river discharge to the Arctic Ocean (Table CCP6.1), snow and permafrost decline may lead to further soil drying (*medium confidence*) (Meredith et al., 2019). Glacial ice melt poses a risk to ecosystems and people through remobilization of sequestered hazardous waste and transported pollutants (Table CCP6.3) (Wang et al., 2019).

In the Antarctic, there is further *high agreement* since the publication of SROCC that melt and ice-free areas are causing increases in the rates of colonisation and utilization of coastal environments by terrestrial biota and land-based colonies of seals and birds (Gutt et al., 2021), although colonisation rates remain variable (Ruiz-Fernandez et al., 2017; Bokhorst et al., 2021). Soil temperatures along the Antarctic Peninsula are now sufficient for germination of non-native plants; invasions by non-endemic species are expected to increase with rising temperatures (*high confidence*) (Bokhorst et al., 2021), posing a risk to endemic polar species (*medium confidence*) (Chown and Brooks, 2019; Gutt et al., 2021).

Vegetation responses to warming are contingent on water availability and local temperature (*medium confidence*) (Guglielmin et al., 2014; Royles and Griffiths, 2015; Amesbury et al., 2017; Cannone et al., 2017; Charman et al., 2018; Robinson et al., 2018; Stelling et al., 2018), which vary greatly around Antarctica (Figure CCP6.1) (Turner et al., 2020a). Antarctic terrestrial ecosystem responses to changes in water availability are not homogeneous (Ball and Levy, 2015; Sadowsky et al., 2016; Fuentes-Lillo et al., 2017; Gooseff et al., 2017; Schroeter et al., 2017; Lee et al., 2018). West Antarctica is showing evidence of greening in the dominant cryptogrammic vegetation, with greater growth in mosses (*high confidence*) (Casanova-Katny et al., 2016; Amesbury et al., 2017; Shortlidge et al., 2017; Charman et al., 2018; Prather et al., 2019). Peatland ecosystems may increase on the west Antarctic Peninsula with future warming (*low confidence*) (Yu et al., 2016; Loisel et al., 2017). In contrast, some parts of East Antarctica and the subantarctic islands to the north have been experiencing a drying climate, with declining health of mosses and other vegetation (*high confidence*) (Bergstrom et al., 2015; Bramley-Alves et al., 2015; Robinson et al., 2018; Bergstrom et al., 2021).

Antarctica encountered its first reported heatwave in 2020 (Table CCP6.1). Such abrupt heating can cause wide-ranging effects on biota, from flash-flooding damage and dislodgement of plants to excess melt waters supplying moisture to arid Antarctic ecosystems. This suggests that increased melt may reverse the drying trend if plant communities remain connected to melt streams and there is sufficient precipitation (*high agreement, limited evidence*) (Bergstrom et al., 2021).

Warming of the Antarctic Peninsula has resulted in increased soil microbial abundance and biomass. However this trend is not as great in southern colder locations (*medium confidence*) (e.g., Kim et al., 2018; Newsham et al., 2019), as the microbial community structure is affected by vegetation cover and water availability (*high confidence*) (Dennis et al., 2019; Newsham et al., 2019).

Antarctic terrestrial invertebrate communities on the West Antarctic Peninsula may be controlled more by vegetation and water availability than by air temperature (*medium confidence*) (Bokhorst and Convey, 2016; Knox et al., 2016; Andriuzzi et al., 2018; Prather et al., 2019; Newsham et al., 2020). Evidence from laboratory studies, field programs and sedimentary records indicate that Antarctic freshwater ecosystems may become more productive under climate warming scenarios (*medium confidence*) (e.g., Schiaffino et al., 2011; Borghini et al., 2016; Píšková et al., 2019; Čejka et al., 2020).

CCP6.2.3 Food, Fiber, and other Ecosystem Products

Food and fiber production underpins regional identities, cultures, and communities of practice and place in polar regions, are vital to local and distant economies (Table CCP6.4) and they represent for fisheries a critical source of global nutrition and food security (Hicks et al., 2019). Since SROCC, there is further evidence that climate change alterations of polar ecosystems increasingly challenge production of, and access to, sufficient, healthy, and nutritious food, posing risks to future food and nutritional security within and beyond polar regions (*high confidence*).

CCP6.2.3.1 Arctic subsistence resources

Subsistence harvest of fish, seabirds, and marine mammals is the basis for economic, cultural and spiritual connections with Arctic marine systems (Box CCP6.2)(Fall et al., 2013; Haynie and Huntington, 2016; Raymond-Yakoubian et al., 2017; Slats et al., 2019) and nature-based livelihoods (e.g., caribou and reindeer (*Rangifer tarandus*) herding, fishing, hunting, trapping, small-scale forestry) are fundamental to Indigenous Peoples across the Arctic as they have been for millennia (Koivurova et al., 2015; Betts, 2016; Gavin et al., 2018; Raheem, 2018; Mustonen and Shadrin, 2021). Climate change has impacted Indigenous subsistence resources across the Arctic (*very high confidence*) (SMCCP6.2), and future food systems and ecological connections are at risk from future climate change hazards interacting with non-climate pressures, some of which are mediated or amplified by novel conditions and opportunities in Arctic regions (*high confidence*) (Moerlein and Carothers, 2012; Fall et al., 2013; Raymond-Yakoubian et al., 2017; Meredith et al., 2019; Slats et al., 2019; Huntington et al., 2020; Huntington et al., 2021). Increasing heatwaves, wildfires, extreme precipitation, permafrost loss and rapid seasonal snow and ice thaw events will further threaten terrestrial subsistence food resources across the Arctic (*high confidence*) (Table CCP6.3). Although climate impacts and non-climate factors systematically undermine access to and productivity of subsistence resources, resilience is inherently high for Indigenous Peoples, illustrating critical elements underpinning successful adaptation to climate change (Box CCP6.2) (Huntington et al., 2021).

Table CCP6.3: Illustrative examples of climate change impacts on subsistence resources in the Arctic.

Changing Drivers	Observed impacts and projected risks	References
Snow, ice, river environments	Climate change is disrupting subsistence harvests for Indigenous Peoples in Arctic communities that depend on snow, ice and river environments for travel and access to subsistence resources.	(Wildcat, 2013; Meredith et al., 2019; Slats et al., 2019)
Multiple	Across the Canadian Arctic, multiple populations of reindeer and caribou are in decline with 95% of assessed herds listed as rare, decreasing or "threatened"; Reindeer and caribou abundances in the Alaska-Canada region have declined 56% over the past 20 years.	(Russell et al., 2018)
Multiple	Reindeer herding is an important economic and Indigenous cultural activity in the Eurasian Arctic and is being affected by non-climate and climate events, including changes to thaw cycles, drought and unpredictable summer weather, which threaten pasture areas in Siberia. Although changes in vegetation and the freeze thaw cycle are impacting Sami reindeer herding, adaptive measures by herders have been effective at offsetting multiple climate and non- climate impacts.	(Furberg et al., 2011; Uboni et al., 2020; Mustonen and Shadrin, 2021)
Sea-ice; winds; visibility	Loss of multiyear "mother ice", declines in seasonal sea-ice thickness and stability, as well as changes in winds and visibility have impacted the availability of, and access to, subsistence resources (*high confidence*) and have increased interactions between coastal communities and shipping, tourism and commercial fisheries, which directly impact human safety and well-being in Arctic communities (*high confidence*).	(Stephenson and Smith, 2015; Brinkman et al., 2016; Melia et al., 2016; Raymond-Yakoubian et al., 2017; Ford et al., 2019; Slats et al., 2019; Huntington et al., 2020; Huntington et al., 2021)
Multiple	MHW-induced ecosystem changes contributed to widespread mortality events and declines in Northern Bering Sea seabirds and disrupted subsistence harvests in western Alaska.	(Jones et al., 2019; Piatt et al., 2020; Siddon et al., 2020)
Storminess; sea-ice; whale migration timing; shipping	Although some communities have seen reduced whale harvests due to climate impacts on survival and productivity, changes in storminess and whale migration timing have lengthened the July harvest season for Inuvialuit from Inuvik, Aklavik and Tuktoyaktuk. Changes in Beluga migration routes have increased accessibility to communities of Ulukhaktok and Paulatuk. In Western Greenland, loss of sea-ice has both reduced access to sealing and increased subsistence and commercial harvest of Atlantic cod, halibut, and other fish species. Increased impacts of noise and ship strikes associated with shipping are expected to	(George et al., 2017; Hauser et al., 2018; Loseto et al., 2018; Mustonen et al., 2018a)

	impact subsistence species, especially seals and whales in Lancaster sound as well as the Pacific Arctic.	
Sea-ice	Changes in sea-ice will continue to undermine subsistence resources and disrupt access by smaller scale commercial and subsistence-based ice-edge fishing.	(Jacobsen et al., 2018; Ford et al., 2019)
Shifting distributions; Food web changes	Shifting species distributions and climate change mediated food web reorganization pose a risk to near-shore subsistence harvests that are essential to sustaining Indigenous Peoples in Western Greenland and the Northern Bering, Beaufort, and Chukchi Seas; , e.g., cod biomass in the Inuvialuit region is projected to decrease 17% by 2100 (RCP8.5). Climate-related declines in harvester access drive projected declines in subsistence availability in Alaska.	(Moerlein and Carothers, 2012; Fall et al., 2013; Brinkman et al., 2016; Loseto et al., 2018; Steiner et al., 2019; Marsh and Mueter, 2020; Ribeiro et al., 2021)

CCP6.2.3.2 Agriculture, forestry, livestock, and aquaculture

In addition to reindeer herding, Arctic agriculture primarily consists of local production of cool season crops, forage, small grains, and livestock (sheep and goats) (Westergaard-Nielsen et al., 2015; Natcher et al., 2019). Short growing seasons, cold conditions, permafrost, and moisture stress, especially along coasts, have historically limited production, but agriculture is generally increasing across the region (Westergaard-Nielsen et al., 2015). Although only ~ 0.2% of Alaska is farmland, area farmed and income from agriculture have increased 2% and 80% (respectively) since 2012 (United States Department of Agriculture, 2017). It is *likely* that growing seasons have extended by 1-3 days per decade in interior Alaska, although some coastal areas exhibit declines in growing season (Lader et al., 2018).

Arctic temperatures rarely exceed thermal tolerances for crops (e.g., 35-38°C across corn, rice and grain) and warming will provide new opportunities for food and forage production in areas such as SW Greenland and interior Alaska (Westergaard-Nielsen et al., 2015; Tripathi et al., 2016; Lader et al., 2018). Higher atmospheric CO_2 favours plant growth if soil quality and condition are sufficient, but benefits can be offset by increased heat and water stress associated with climate change (Tripathi et al., 2016; Unc et al., 2021). Growing seasons in Alaska will lengthen by 48-87 days per year relative to historical growing season length (1981-2010) and the start of growing season is expected to shift 1-4 weeks earlier (Lader et al., 2018). Feasible growing areas across the Arctic are expected to shift northward and increase within the 55°-69°N region (King et al., 2018). Permafrost thaw (Table CCP6.1) increases drainage, which is a potential benefit, but can also increase erosion, subsidence and irregular surfaces, inhibiting agriculture (Lader et al., 2018). Conversion of Arctic soils to croplands may also release carbon stored in vegetation and soils (Unc et al., 2021).

Arctic aquaculture contributes approximately 2% to global farm production (primarily Norwegian salmon (*Salmo salar*), as well as finfish in Iceland and Sweden and shellfish in Alaska), and will face increasing challenges from climate change (Troell et al., 2017) including increased frequency of storms (impacting sea farms), extreme temperatures, and warmer conditions that favour pathogens, parasites and harmful algal blooms. Aquaculture feeds often depend on small pelagic fish or krill and supply may be affected by climate impacts on fisheries (Table CCP6.6) (Troell et al., 2017; Chen and Tung, 2018; Mørkøre et al., 2020). Integrated policies and coordination across multiple food production sectors in Arctic regions are needed to address climate opportunities and challenges (Altdorff et al., 2021; Unc et al., 2021).

CCP6.2.3.3 Commonalities in impacts and risks across polar fisheries

Fisheries play an increasingly important role in addressing global food and nutritional deficits (Section 3.6.3)(Béné et al., 2016; Ding et al., 2017; Hicks et al., 2019; Costello et al., 2020), especially as climate change has already reduced global yields from key crops (Myers et al., 2017; Ray et al., 2019; Thiault et al., 2019). Antarctic and Arctic systems support some of the world's largest fisheries, including those for Antarctic krill and Arctic walleye pollock (*Gadus chalcogrammus*), which constitute a critical source of protein and macronutrients to a growing population of seafood consumers, as well as various aquaculture and livestock feeds (Cross-Chapter Box MOVING PLATE in Chapter 5) (Table CCP6.4) (Huntington et al., 2013; Raheem, 2018; Hicks et al., 2019; Steiner et al., 2019; FAO, 2020; Cavanagh et al., 2021; Grant et al., 2021; Murphy et al., 2021). Marine sources of protein and nutrition are important in transformational future scenarios where dietary shifts and provisioning policies provide multiple co-benefits to equity, food security and carbon mitigation (Springmann et al., 2016; Poore and Nemecek, 2018; Thiault et al., 2019; Kim et al., 2020). Shifting spatial distributions of fish stocks have led to transboundary management challenges in the Atlantic, Bering Sea, and Arctic areas previously inaccessible due to sea-ice (Table CCP6.6) (Gullestad et al., 2020).

Cascading and interacting effects of climate change impacts in polar regions (Table CCP6.1) will reduce access to, and productivity of future fisheries, and pose significant risks to regional and global food and nutritional security that increase with atmospheric carbon levels and declines in sea-ice (*high confidence*) (Table CCP6.6). Although it is expected that fisheries will continue to contract poleward under future warming (Cross-Chapter Box MOVING PLATE in Chapter 5) (Table CCP6.4) (Alabia et al., 2018; Morley et al., 2018; Stevenson and Lauth, 2019; Caccavo et al., 2021; Grant et al., 2021), global and regional models differ in their projections of fisheries catch potential for the polar regions under climate change. For example, some global-scale models project increases in potential fishery yields in Arctic Canada (Cheung, 2018; Bindoff et al., 2019; Tai et al., 2019), whereas many observational studies and high resolution regional projections suggest overall declines in biomass, productivity, and yield associated with warming and loss of sea-ice in multiple regions such as the Bering Sea (*medium confidence*) (Free et al., 2019; Hollowed et al., 2020; Holsman et al., 2020; Mueter et al., 2020; Reum et al., 2020). Reduced production of macronutrients and protein by polar marine sources will disproportionately impact people already experiencing food and nutritional scarcity (Myers et al., 2017), marine-dependent communities within and beyond polar regions, and women and children who require higher quantities of macronutrients (*high confidence*).

Large-scale commercial fisheries are expected to continue to operate in polar regions (*high confidence*) (Barange et al., 2018; Cavanagh et al., 2021; Grant et al., 2021), and will shift poleward (*high confidence*) toward geopolitical and management boundaries (*high confidence*) (CCP6.3.2.3; Table CCP6.6). Warming and climate impacts will continue to impact transboundary stocks and increase the potential for conflict in fisheries management (Pinsky et al., 2018; Mendenhall et al., 2020; Palacios-Abrantes et al., 2020; Sumaila et al., 2020). Increased distances from ports to redistributed fishing grounds, as well as increased frequency of storms and other extreme events are expected to increase risks and costs for fishery operations (*medium confidence*) and impact shore-based infrastructure and emergency response services (CCP6.2.4). Observed and expected increases in mobile ice combined with abrupt wind can create major hazards for fish operators in Antarctica and the Arctic, with consequences to human safety and total revenue (Dawson and et al., 2017; Barber et al., 2018; Grant et al., 2021). There will be increased demand for new port infrastructure across the Arctic (*high confidence*); new ports have already been proposed for the northern Bering Sea, and small craft harbour investments are being considered across Arctic Canada and Greenland. Ecosystem-based management, increasing diversity and flexibility in harvest portfolios, access to high-resolution ecological forecasts and projections, and climate-informed advice will promote adaptation and climate resilience in fisheries (Dawson and et al., 2017; Brooks et al., 2018; Karp et al., 2019; Hollowed et al., 2020). Coupling adaptation measures with global carbon mitigation strategies substantially decreases climate change risks to polar fisheries (*very high confidence*) (CCP6.3).

[START FAQ CCP6.1 HERE]

FAQ CCP6.1: How do changes in ecosystems and human systems in the polar regions impact everyone around the globe? How will changes in polar fisheries impact food security and nutrition around the world?

Polar regions are commonly known to be experiencing particularly fast and profound climate change, which strongly affects areas and people all around the world in several ways. Physical processes taking place in these regions are critically important for the global climate and sea level. Less known is that regional climate-driven changes of ecosystems and human communities will also have far-reaching impacts on a number of sectors of human societies at lower latitudes.

Climate change has triggered rapid, unprecedented, and cascading changes in polar regions that have profound implications for ecosystems and people globally. Although physically remote from the largest population centers, polar systems are inextricably linked to the rest of the world through interconnected ocean currents, atmospheric interactions and weather (IPCC, 2021), ecological and social systems, commerce, and trade. The nutrient-rich waters of the polar regions fuel some of the most productive marine ecosystems on earth, which in turn support fisheries for species packed with vital macronutrients that are essential for human health and wellbeing. The largest most sustainable fisheries in the world are located in polar waters, where a mix of ice, seasonal light, and cold nutrient-rich waters fuel schools of millions of fish that swell and retract in numbers across the years, reflecting interlaced cycles of icy cold waters, lipid-rich prey, and abundant predators. Polar systems thus exist in a productive balance that has supported vibrant ecocultural connections between Indigenous Peoples and the Arctic for millennia and has supported global food production and trade for centuries. Climate change increasingly destabilizes this balance with uncertain outcomes for Indigenous Peoples and local residents in the Arctic as well as for the rest of the world. Triggered by warming oceans and air temperatures, accelerated melting of sea-ice, glaciers and ice sheets in polar regions in turn impacts ocean salinity, sea levels, and circulation throughout the global ocean. Warming waters have also pushed cold-adapted species poleward, eroded the cold barrier between boreal and Arctic species, and induced rapid reorganization of polar ecosystems. Studies increasingly indicate that the complex web of physical and biological connections that have fuelled these productive regions will falter without the strong regulating influence of cryospheric change. At the same time the global demand for food is increasing, particularly the demand for highly nutritious marine protein, placing increasing importance on stabilizing polar ecological systems and minimizing climate change impacts and risks.

[END FAQ CCP6.1 HERE]

Table CCP6.4: Climate change impacts on Arctic and Antarctic fisheries and fishing communities. Additional detail in Table SMCCP6.3.

Driver	Observed impacts and projected risks	References
Current and past climate change impacts		
Warming	Fisheries productivity declined in multiple stocks across the Arctic including the EBS while Atlantic cod and other fisheries have increased.	(Free et al., 2019; Cheung and Frölicher, 2020)
Extreme heat	Commercially important fish species declined rapidly during recent MHWs (2016-2019), in the EBS due to reduced recruitment, increased metabolic demand, and increased predation mortality and it is probable that climate impacts have contributed to the closure of Pribilof islands blue king crab (*Paralithodes platypus*) fisheries.	(Zheng and Ianelli, 2018; Duffy-Anderson et al., 2019; Stabeno et al., 2019; Basyuk and Zuenko, 2020; Reum et al., 2020; Thorson et al., 2020)
Temperature; shifting species distributions	In the Barents Sea, northward redistribution of stocks led fisheries into previously unfished habitats, exposing benthic ecosystems to novel trawling impacts. Large-scale redistributions of Pacific cod (>1000 km decade^{-1}) and other groundfish species have challenged fisheries management in the EBS; ~50% of the biomass is now located in the NBS, outside of historical survey areas and in a region where bottom trawling is prohibited (although pelagic gear is permitted).	(Christiansen et al., 2014; Jørgensen et al., 2019; Spies et al., 2019; Stevenson and Lauth, 2019)
OA, warming, winds	Shellfish species such as snow crab are undergoing range contractions poleward in the Barents and Northern Bering Seas, with increased catches in the north and declines in the south.	(Jørgensen et al., 2019; Fedewa et al., 2020) (Cross-Chapter Box MOVING PLATE in Chapter 5)
Warming; poleward expansion	Poleward expansion of Pacific salmon into Arctic watersheds and Greenland fjords presents both new opportunities and novel threats to key subsistence and commercial species such as Arctic char and Atlantic salmon.	(Bilous and Dunmall, 2020; Nielsen et al., 2020)
Warming; HABs	Altered seasonal freshwater habitats are impacting salmon productivity and phenology of important salmon resources in	(Brattland and Mustonen, 2018; Cline et al., 2019; Mustonen and

	Alaska and in the Fennoscandian North, with subsequent community-specific impacts on commercial and subsistence resources.	Feodoroff, 2020; Mustonen and Shadrin, 2021)
Multiple; sea-ice	Losses of winter sea-ice to the north and west of the Antarctic Peninsula have enabled krill fishing vessels to fish all year round in that area.	(Meredith et al., 2019)
Future climate change impacts and risks		
Multiple	Climate change impacts on the ecology and physiology of polar cod species contribute to expected increases in biomass and catch potential under high to moderate mitigation (RCP2.6 and RCP4.5) and reductions in groundfish recruitment and yield under low mitigation (RCP8.5) scenarios (CCP6.2.2) across range of multispecies models.	(Laurel et al., 2016; Spencer et al., 2016; Lotze et al., 2018; Spencer et al., 2019; Dahlke et al., 2020; Grüss et al., 2020; Hollowed et al., 2020; Reum et al., 2020; Thorson et al., 2020)
Climate x management interaction	Assuming no climate adaptation in current Ecosystem Based Management (EBM), 50% declines (relative to projections under persistent current climate conditions) in Eastern Bering Sea pollock and cod yield is *likely* under moderate carbon mitigation scenarios (RCP4.5), and *very likely* under low mitigation scenarios (RCP8.5).	(Holsman et al., 2020; Reum et al., 2020; Whitehouse et al., 2021)
Warming; OA	Warming, Ocean Acidification, fish predators, and thermal tolerance differentiate impacts across crab species in the Arctic; increased productivity and redistribution offshore is expected for tanner crab; red king crab and snow crab are projected to continue to shift north and decrease in productivity. OA is expected to impact demographies, altering harvest recommendations and biological reference points for some species of some shellfish and flatfish (e.g., red king crab, Northern rock sole) in projection simulations.	(Punt et al., 2014; Sawatzky et al., 2020; Punt et al., 2021)
Climate x management interaction	Multiple rights-based fisheries operate in the Arctic, increasing investment in long-term sustainability but reducing harvest portfolio diversity and increasing vulnerability to climate shocks.	(Kasperski and Holland, 2013; Ojea et al., 2017)
Multiple; sea-ice	Physical and biological changes in Antarctic waters are expected to result in net declines in krill habitat and growth potential, although one study indicates a potential increase. Reduction in the Antarctic ice pack is as *likely as not* to increase total season length in areas near to land-based predators.	(Melbourne-Thomas et al., 2016; Piñones and Fedorov, 2016; Klein et al., 2018; Rogers et al., 2020; Veytia et al., 2020)
Phytoplankton and temperature	Projected changes in primary production and temperature are expected to cause declines in krill growth and availability to predators; impacts may be countered by reducing fisheries, signifying a potential conflict between fisheries and top predators.	(Piñones and Fedorov, 2016; Klein et al., 2018)

CCP6.2.4 Economic Activities

Climate change presents significant risks to economic activities in the polar regions (*very high confidence*) and simultaneously enables development possibilities for fisheries (CCP6.2.3.3), agriculture (CCP6.2.3.2), the sharing and subsistence economy (CCP6.2.3.1) (SMCCP6.2) (*high confidence*), maritime trade (Box CCP6.1), natural resource development (CCP6.2.4.1) (*medium confidence*), tourism (CCP6.2.4.2), and transportation (including shipping) (CCP6.2.4.3; FAQ CCP6.2). Hundreds of billions of dollars are expected to be invested in the polar regions in the next several decades (Lloyd's, 2012; Barnhart et al., 2016; Pendakur, 2017; Tsukerman et al., 2019) and, as this unfolds, there are opportunities to simultaneously implement adaptation strategies that support climate resilient development pathways in line with self-determination for Indigenous Peoples and local communities and locally derived visions of successful adaptation and development (CCP6.3.2, CCP6.4.3) (Jorgenson, 2007; Ritsema et al., 2015; Ready and Power, 2017; Larsen and Petrov, 2020).

CCP6.2.4.1 Changing access to natural resources with consequences for safety, economic development and climate mitigation

Climate change is improving access to natural resources in the Arctic with consequences for human safety (*high confidence*), economic development (*very high confidence*) and global mitigation efforts (*medium confidence*). Reductions in sea-ice combined with improved extraction and transportation technologies have increased accessibility to natural resources across the Arctic (Eliasson et al., 2017; Dawson et al., 2018b; Stephen, 2018); a situation that could support continued global dependence on relatively cheap and abundant fossil fuels resources and contribute to further warming. By 2040 (RCP4.5) it is expected that sea-ice will have receded enough to make gas production technologically feasible in the European off-shore Arctic (Petrick et al., 2017). However, increased sea-ice mobility, iceberg abundance, storm surge, and surface wave action (Ng et al., 2018; Howell and Brady, 2019; Casas-Prat and Wang, 2020) will also increase risks to ships servicing mines in a region that already exhibits disproportionately high accident rates (Council of Canadian Academies, 2016) (CCP6.3.1, Table CCP6.1). Season lengths for ship-based support to mines and extraction sites will increase with sea-ice change, while access via ice roads will decrease with warming (Perrin et al., 2015; Council of Canadian Academies, 2016; Trofimenko et al., 2017; Southcott and Natcher, 2018). By 2050, climate change impacts to the Tibbitt to Contwoyto Winter Road servicing mines in the northeastern region of the Northwest Territories, Canada could cost between $55 million to $213 million CAD to maintain for a shorter period of time than at present (Perrin et al., 2015). Changes in submarine permafrost, critical to mining infrastructure, such as pipelines and offshore infrastructure (Bashaw et al., 2016; Paulin and Caines, 2016), are expected to increase production costs and impact safety for workers (Riedel et al., 2017). By mid-century, regardless of emissions scenario, it is expected that risks from permafrost thaw will be disproportionately high for industrial infrastructure along major pipeline systems in Alaska and natural gas extraction areas in the Yamal-Nenets region in northwestern Siberia, Russia (Hjort et al., 2018).

CCP6.2.4.2 Changing demand, opportunities and risks for polar tourism

Climate change has increased risks to, and demand for, polar tourism experiences related to increased maritime accessibility (*high confidence*), lengthening of warm weather season lengths (*very high confidence*) and development of a 'last chance tourism market' (*medium confidence*). Reductions in sea-ice extent have facilitated increased access for polar cruising (Dawson et al., 2018b; Stewart et al., 2020). Demand for Arctic cruises has increased by 20.5% over the past five years and resulted in 27.2 million passengers in 2018 (Shijin et al., 2020). In the Antarctic, tourist numbers increased by 27% from 1992-2018 and attracted 75,000 visitors in 2019-2020 (IAATO, 2020; Shijin et al., 2020), making it the largest economic sector in the entire region (Stewart et al., 2020). The recent increase in polar tourism is due in part to the development of a niche market called 'last chance tourism', which involves explicitly marketing vulnerable or vanishing destinations or features (i.e., glaciers, polar bears, landscapes) and encouraging tourists to see them 'before they are gone' (Dawson et al., 2018a; Groulx et al., 2019). However, tourism development opportunities will also contend with ongoing risks related to the COVID19 pandemic, which halted tourism globally in 2020-2021 (Frame and Hemmings, 2020; Lorenzo et al., 2020), as well as those related to increased climatic risks limiting participation and reducing safety and security. By 2100 under RCP8.5, snow cover season length suitable for winter recreational activities is projected to decrease by 21−49% in West Greenland (Schrot et al., 2019). Reduced sea-ice and snow cover creates hazards for and could limit dog sledding, cross country skiing, snowmobiling and floe edge tours, with limited adaptation strategies available for low elevation areas (Stephen, 2018; Palma et al., 2019).

CCP6.2.4.3 Risks and opportunities in transportation systems

Climate hazards create risks to transportation sectors with consequences for human safety (*very high confidence*), security (*low confidence*), and economic development (*high confidence*). Remote polar regions are highly reliant on transportation systems (air, road, sea) to support and service communities (Arctic) and scientific stations (Antarctic and Arctic). Changes in permafrost, snow, ice, and precipitation patterns have increased the risk of rail infrastructure and of using permanent roads and semi-permanent trails that service Antarctic research stations, connect Arctic communities, and support Indigenous food harvesting activities

(Calmels et al., 2015; Council of Canadian Academies, 2016; Ford et al., 2019; Stewart et al., 2020). Warming temperatures have particularly decreased the reliability, safety level, and season length of winter ice roads (Perrin et al., 2015; Council of Canadian Academies, 2016; Gädeke et al., 2021) in the northern Baltic (Finland) (Kiani et al., 2018), James Bay (Canada) (Hori et al., 2018a; Hori et al., 2018b), and Yakutia (Russia) (Mustonen and Shadrin, 2021). Dog sled travel in northwest Greenland has experienced shorter season lengths (Nuttall, 2020), Alaskan whale hunters have had difficulty finding suitable ice for safe harvest activities (Huntington et al., 2016; Nyland et al., 2017), and unpredictability in break-up and freeze-up of sea-ice has compromised safe travel to and from culturally significant hunting and camping areas in Canada (Dawson et al., 2020; Simonee et al., 2021), and northeast Siberia (Ksenofontov et al., 2017; Mustonen and Shadrin, 2021). Fog (*low confidence*) and an increase in precipitation falling as ice pellets or hail (*high confidence*) (Kochtubajda et al., 2017) is expected to continue to cause operational delays and create safety issues for aviation in the Polar regions (Debortoli et al., 2019).

[START FAQ CCP6.2 HERE]

FAQ CCP6.2: Is sea-ice reduction in the polar regions driving an increase in shipping traffic?

The polar seas have captured the imagination of global nations for centuries for its natural resource, tourism, scientific, and maritime trade potential. As the polar regions are warming at two to three times the rate of the global average leading to rapid reductions in sea-ice extent and thickness, international attention has been reinvigorated and investments are being made by Arctic and non-Arctic nations alike with a view to utilize newly accessible seaways. Between 2013 and 2019 ship traffic entering the Arctic grew by 25% and the total distance travelled increased by 75%. Similar shipping growth trends are evident in the Antarctic albeit to a lesser extent. Expected growth in Arctic shipping will influence a suite of cascading environmental and cultural risks with implications for Indigenous Peoples.

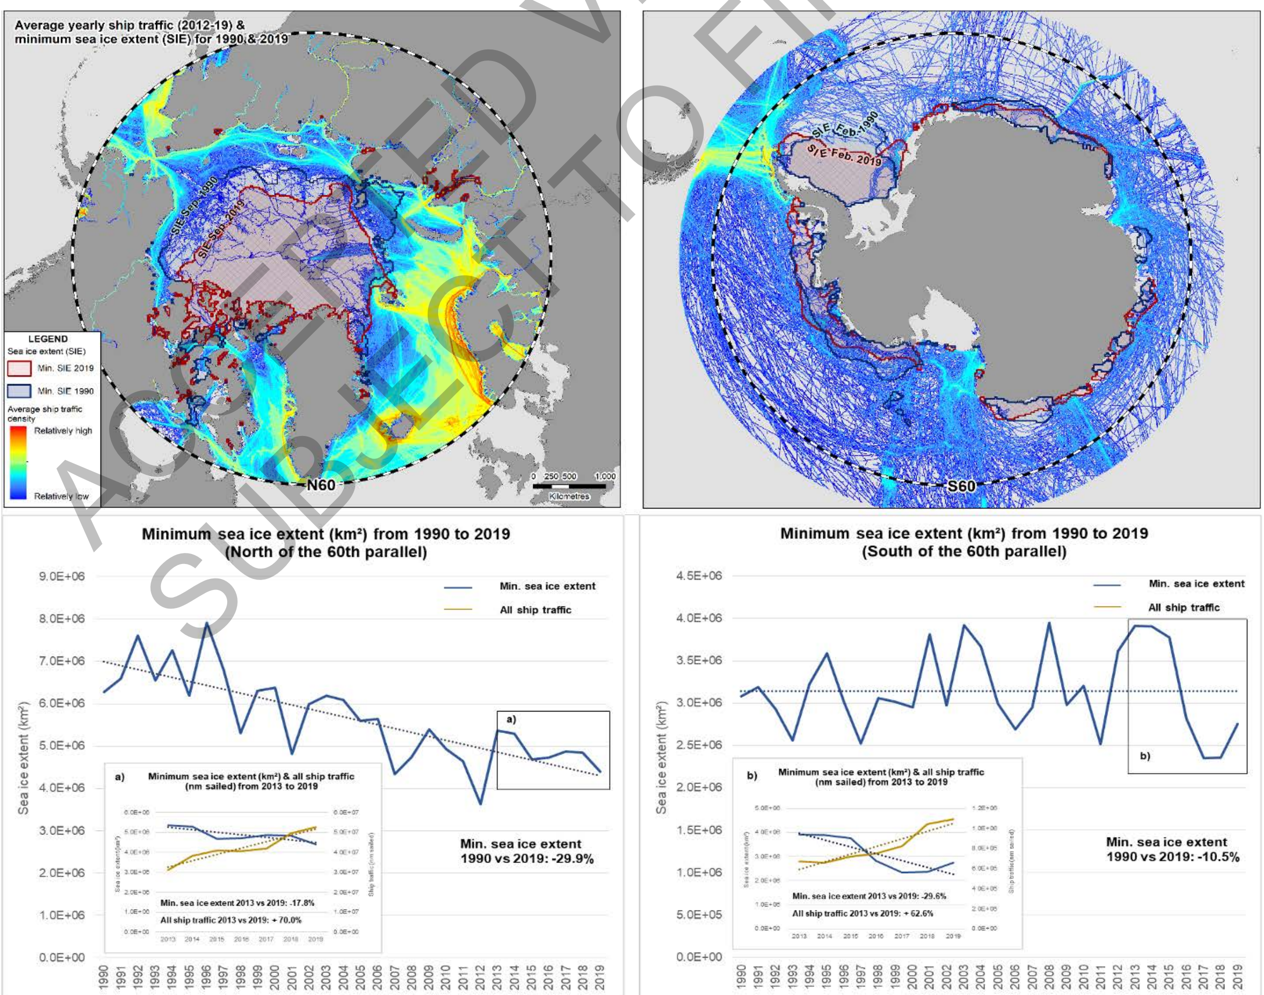

Figure FAQ CCP6.2.1: Projected operational accessibility along Arctic maritime trade routes (Northwest Passage, Transpolar Route, and Northern Sea Route) under future warming (left) and observed increases in commercial ship traffic along the routes from 2012-2019

There has been debate among shipping stakeholders, rightsholders, and experts about the extent to which climate change and sea-ice change is directly influencing increases in shipping activity in the polar regions relative to other social, technological, political, and economic factors such as commodity prices, tourism demand, global economic trends, infrastructure support, and service availability. Understanding the connection between climate change and polar shipping activity will allow for more reliable projections of possible future traffic trends and will aid in identifying appropriate adaptation and infrastructure needs required to support future management of the industry. Recent studies have observed increasing statistical correlations between sea-ice change and shipping trends in the polar regions and many have concluded that although economic factors remain the main driver of shipping activities, followed by infrastructure availability, climate change does indeed play a varying but important role in influencing operator intentions. The 'opening of polar seaways' due to sea-ice reduction is indeed 'enabling' opportunities for polar shipping among all types of vessels due to increasingly accessible areas that were previously covered by multiyear ice, but the extent to which climate change will specifically 'drive' an increase in shipping demand remains highly dependent on the vessel type and the reasons for operation. There are certain vessel types, such as those supporting international trade, mining operations or community re-supply, where analysis shows no correlation or weak correlations with sea-ice change suggesting that climate change is enabling these types of ships via increased open water areas and season lengths but that it is not necessarily driving demand. Conversely, there are certain vessel types, such as yachts and cruise ships, where correlations between sea-ice change and traffic increases are stronger, and where there is evidence to suggest that these vessels are indeed driven to visit the polar regions because they perceive waterways as exotic and exciting due to being newly accessible or they want to have a Polar experience before it disappears or is irreversibly changed as is the case with last chance tourists. As sea-ice recedes and polar shipping opportunities grow there will be an increased need to better identify and implement Indigenous self-determined and equitable shipping governance frameworks that facilitate benefits and minimize risks.

[END FAQ CCP6.2 HERE]

[START BOX CCP6.1 HERE]

Box CCP6.1: Climate Change and the Emergence of Future Arctic Maritime Trade Routes

Discovering a viable maritime trade route linking the Atlantic and Pacific oceans through the Arctic has captured the collective global imagination for centuries (Bockstoce, 2018). Geographically shorter than southern trade routes via the Panama and Suez Canals, the Arctic presents the possibility for more economical and timely commercial trade, but has historically been limited by thick multi-year ice and other navigational challenges. Amplified warming in the Arctic has caused September sea-ice extent to decline at a rate of -13% per decade (Serreze and Meier, 2019) and reduced sea-ice thickness by 66% (2 m) between 1958-1976 and 2011-2018 (Kwok, 2018). Regardless of mitigation efforts, it is expected that before mid-century the Arctic will be seasonally ice free for the first time in 2,600,000 years (defined as < 1,000,000 km2) (Knies et al., 2014; SIMIP Community, 2020; Fox-Kemper et al., 2021; Lee et al., 2021) and will make Arctic maritime trade a reality (Eguíluz et al., 2016; Melia et al., 2016; Pizzolato et al., 2016; Bennett et al., 2020; Wei et al., 2020).

There are three identified trade routes in the Arctic: Northern Sea Route (NSR), Northwest Passages (NWP), and the Transpolar Sea Route (TSR). Over the last decade economic trends and reductions in sea-ice have facilitated significant increases in ship traffic in the NSR (Aksenov et al., 2017; Li et al., 2020), including a 79% increase in total transit tonnage from 2010 to 2017 (Babin et al., 2020) related mostly to domestic resource development. Relative to an early 21st century baseline, it is expected that the NSR will become 18% more accessible by mid-century (Stephenson et al., 2013) and could navigable even for non-ice strengthened vessels for 101-118 days annually by 2050 and 125-192 days by 2100 (Khon et al., 2017). The NWP has experienced a tripling of km travelled by ships since 1990, attributed mostly to resource extraction and increases in tourism opportunities (Johnston et al., 2017; Dawson et al., 2018a). The NWP could become 30% more accessible by 2050 compared to current conditions (Stephenson et al., 2013). Before 4°C global warming above pre-industrial, re-supply vessels (Polar Class 7) in the western NWP could gain an additional month of operating time, whereas the eastern NWP could gain just two weeks (Mudryk et al., 2021) due to the dynamic import of mobile and hazardous ice from the Arctic Ocean (Haas and Howell, 2015; Howell and Brady, 2019). Comparatively, the TSR has historically only been viable for nuclear icebreakers, submarines, and occasional military and scientific activity due to thick multiyear ice regimes (Bennett et al., 2020). However, this most sought-after route offers the greatest reduction in sailing times compared to southern routes (19-24 days) of all Arctic Sea routes and could be 56% more accessible by mid-century compared to current conditions (Stephenson et al., 2013; Melia et al., 2016).

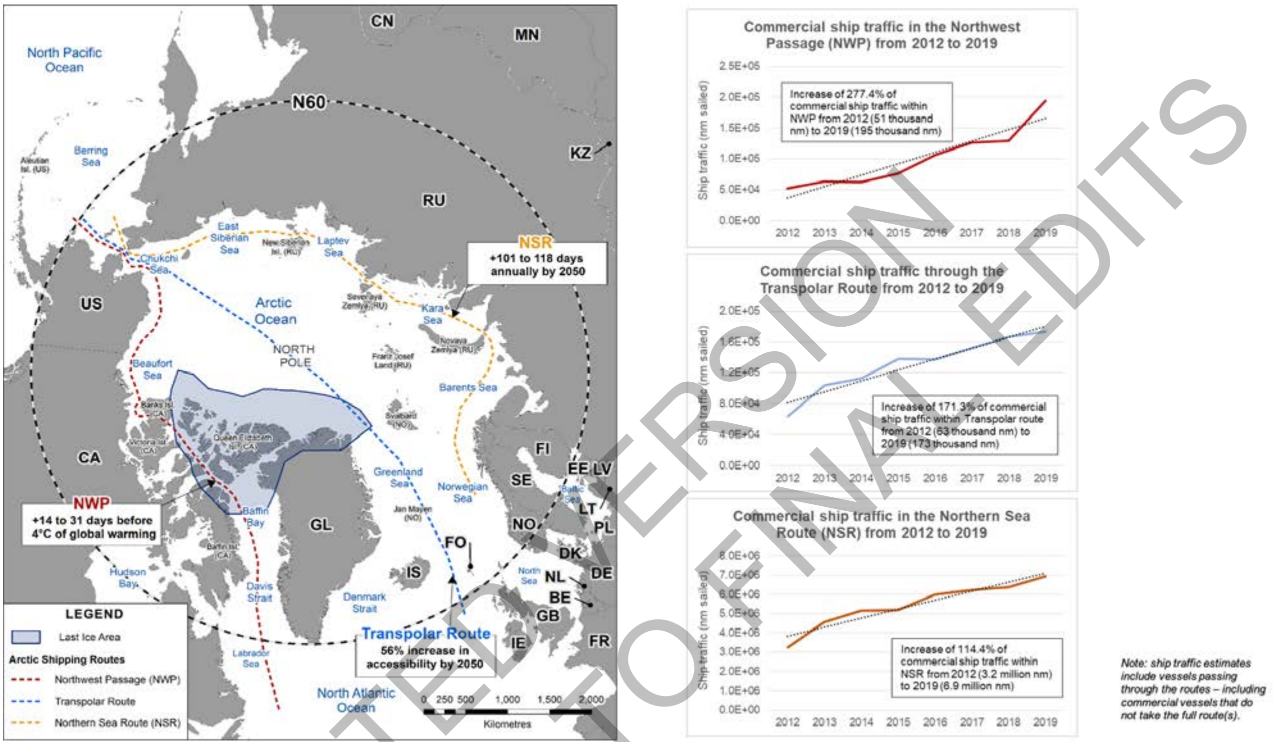

Figure Box CCP6.1.1: Arctic trade routes and projected operations related to sea-ice loss.

Growth in Arctic maritime trade will result in increased emission of black carbon (Stephenson et al., 2018; Zhang et al., 2019; Wang et al., 2021), increases in ship-source underwater noise impacts on marine mammals (Halliday et al., 2017), higher rates of accidents and incidents among vessels from increasing mobile sea-ice and newly accessible ice-free waters that lack charting (Haas and Howell, 2015; Howell and Brady, 2019), impacts to cultural sustainability for Indigenous Peoples (Olsen et al., 2019; Dawson et al., 2020) (*high confidence*), the potential for the introduction and propagation of invasive species (Chan et al., 2019; Rosenhaim et al., 2019), and sovereignty tensions with implications for global geopolitics (Drewniak et al., 2018) (*medium confidence*). Globalization and the almost universal adherence to economic growth models among nations will continue to fuel maritime trade (Box 14.5). As sea-ice decreases facilitates growth in Arctic maritime trade and transportation specifically, adaptation strategies designed to facilitate mitigation co-benefits and that target the cascading implications and double exposure of climate change and Arctic shipping impacts will be essential in reducing risks (Ng et al., 2018; Pirotta et al., 2019; Bennett et al., 2020; Zeng et al., 2020). Electric and solar powered vessels, new engine and emission reduction technologies, investment in wind, water, ice, and climate forecasting technologies and services (Haavisto et al., 2020; Stewart et al., 2020; Simonee et al., 2021), and efforts by the International Maritime Organization to reduce sulphur and the use of heavy fuel oils (PAME, 2020; van Luijk et al., 2020) could play a key role in limiting emissions and reducing risks related to the environmental and cultural impacts of fuel spills in ice-infested Arctic waters. The development of low impact shipping corridors (Chénier et al., 2017; Dawson et al., 2020) and multilateral agreements such as those implemented by the Arctic Council and Indigenous Peoples' organizations on joint search and rescue (Arctic Council, 2011) and shared spill responsibilities

(Arctic Council, 2013) represent important co-governance efforts that will be increasingly important in the future due to projected climate related risks.

[END BOX CCP6.1 HERE]

CCP6.2.5 Arctic Settlements and Communities

Polar settlements range from large well-serviced cities such as Tromsø, Murmansk and Reykjavik, to remote fly-in Indigenous communities, to scientific outposts and research stations. Polar settlements are at significant risk from climate change through shoreline erosion, permafrost thaw, and flooding (*high confidence*) (CCP6.2.2). Opportunities for community development in small communities are underestimated as they are emergent and unknown (*highly likely*) (CCP6.2.5).

Degradation of ice-rich permafrost can threaten the structural stability and functional capacities of community-based infrastructure (i.e. airports and roads; CCP6.2.5), and can have implications for local economies with coupled impacts for local livelihoods, health and wellbeing (CCP6.2.5, CCP6.2.6) (*high confidence*). For instance, in Canada, infrastructure damage from permafrost instability caused temporary closures of schools in Yukon, permafrost degradation contributed to runway damage at Iqaluit International Airport in Nunavut, and flooding from heavy rains resulted in thermal erosion of river banks that interrupted water and sewage service in Nunavut (Oldenborger and LeBlanc, 2015; Council of Canadian Academies, 2016; Lemmen et al., 2016). In northeast Siberia, the floods of Alazaeya river attributed to thawing permafrost have severely affected Andreyushkino in Yakutia (Mustonen and Shadrin, 2021).

By 2050, 69% of fundamental human infrastructure in the Arctic are projected to be at risk under an RCP4.5 scenario, including more than 1,200 settlements and 36,000 buildings, leaving 4,000,000 people living in areas with high potential for thaw (Hjort et al., 2018). Widespread permafrost thaw could increase the cost of infrastructure lifecycle replacement by 27% by mid-century under RCP8.5 (Suter et al., 2019). Northern Canada and Western Siberia are at particularly high risk, which are projected to cost additional annual spending of over 1% of annual gross regional product to maintain existing infrastructure (Suter et al., 2019). For instance, under an RCP8.5 scenario, climate change could affect over 19% of structures and infrastructure assets in Russia, which would cost an estimated $84.4 billion USD to mitigate damages (Streletskiy et al., 2019). 54% of residential buildings are projected to be affected by significant permafrost degradation by the mid-century, costing an additional estimated $52.6 billion USD (Streletskiy et al., 2019). SLR and reduced sea-ice protection is projected to compound permafrost thaw damages, including low lying coasts (e.g., along southern Beaufort Sea), low-lying barrier islands (e.g., along Chukchi Sea), and deltas (e.g., Mackenzie, Lena) (Fritz et al., 2017; Lantz et al., 2020). In Alaska, proactive adaptation was substantially cost-saving (reducing costs by $2.9 billion USD for RCP8.5 and $2.3 billion USD for RCP4.5), highlighting the financial benefit of investing in adaptation now (Melvin et al., 2017). Permafrost damage and SLR may result in tipping points, leaving some communities no longer habitable. In Alaska, US, many communities at-risk of flooding and storm surges are already engaged in community-led relocation planning processes (e.g., Shishmaref) (Melvin et al., 2017; Farbotko et al., 2020; Rosales et al., 2021).

Climate change has important intangible loss and damage implications in the Arctic, with negative impacts ranging from livelihoods to spirituality to solastalgia (i.e. distress caused by environmental change) (Cunsolo and Ellis, 2018; Middleton et al., 2020b; Sawatzky et al., 2020; Mustonen and Shadrin, 2021). Permafrost thaw, SLR, and reduced sea-ice protection also presents risk to socio-cultural assets, including heritage sites in all Arctic regions (*very high confidence*) (Friesen, 2015; Hollesen et al., 2016; Radosavljevic et al., 2016; O'Rourke, 2017; Hillerdal et al., 2019; Fenger-Nielsen et al., 2020; Jensen, 2020). A large number of archaeological sites are at risk from climate change in southwest Greenland; Yukon's Beaufort coast, Canada; and Auyuittuq National Park Reserve, Nunavut, Canada (Westley et al., 2011; Hollesen et al., 2018; Irrgang et al., 2019; Fenger-Nielsen et al., 2020). Siberian nomadic reindeer herding and fishing livelihoods are vulnerable to permafrost thaw, which alters northern landscapes and lakes, as well as rain-on-snow events, and rapidly changes landscapes and terrestrial and aquatic habitats (Mustonen and Mustonen, 2016; Brattland and Mustonen, 2018; Mustonen and Huusari, 2020) (CCP6.2.2). The intangible loss and damage to nomadic cultures could cascade to losses of identity and social challenges (CCP6.2.6; Chapter 13).

[START FAQ CCP6.3 HERE]

FAQ CCP6.3: How have Arctic communities adapted to environmental change in the past and will these experiences help them respond now and in the future?

For thousands of years Arctic Indigenous Peoples and local communities have survived several major changes to the ecosystems in which they rely; however, the present changes in climate are more challenging than pre- and early historic changes in the Arctic and new unprecedented risks will now face polar communities.

The challenges for responding to present change are due to the multiple imposed and simultaneous drivers combined with elimination and/or removal of endemic capacity to respond in culturally and locally appropriate ways. Adapting in the past may therefore inform and produce novel solutions for the present and convey baselines of important contextual information on significance of change. Arctic communities, especially Indigenous Peoples, have been marginalized in terms of their autonomous responses spaces and self-assessment that could be made without external pressures. Therefore, in order to increase the possibility of community-led adaptation, colonialism and the resultant lack of upheld rights, resources and equity need to be solved simultaneously with the present climate change impacts. New research, governance, policy, and collaborations are needed in order to effectively adapt to risks that are projected to emerge in the polar regions as a result of rapid climate change.

[END FAQ CCP6.3 HERE]

CCP6.2.6 Human Health and Wellness in the Arctic

Climate change continues to have wide-ranging physical human health risks in the Arctic, particularly for Indigenous Peoples (*high confidence*); however, future projections of physical risks are nascent. Climate change has already challenged food and nutritional security (CCP6.2.5). Climate change also creates safety concerns for those who access the land, ice, and water for food, cultural, and recreational purposes, with changing environmental conditions linked to injury and death (Durkalec et al., 2014; Clark et al., 2016a; Clark et al., 2016b; Driscoll et al., 2016; Brattland and Mustonen, 2018). Foodborne disease risks are expected to increase in the Arctic, with warming temperatures linked to increased risk of microbial contamination of locally harvested foods (Grjibovski et al., 2013; Harper et al., 2015), chemical contamination of locally harvest foods (Hansen et al., 2015; Long et al., 2015; Alava et al., 2017), compromised structural integrity and utility of ice cellars used to store locally harvested meat (Nyland et al., 2017; Markon et al., 2018), and new challenges to traditional food preparation techniques (Shadrin, 2021). Waterborne disease risks have increased, with decreased drinking water quality and quantity, water treatment infrastructure failures, and new waterborne pathogens emerging in the Arctic (Berner et al., 2016; Thivierge et al., 2016; Markon et al., 2018; Yoder, 2018; Masina et al., 2019; Sachal et al., 2019; Harper et al., 2020; Mustonen and Shadrin, 2021). Emerging environmental exposures to pathogens is also a concern. In 2016 a Nenets boy and over 200,000 reindeer died from anthrax linked to warming environments (Ezhova et al., 2021) - a risk which is projected to increase with climate change (Liskova et al., 2021). Thawing permafrost increases smallpox risk in former nomadic campsites and graveyards (Mustonen and Shadrin, 2021; Shadrin, 2021). Arctic health systems - which are often already stressed - will be further challenged by climate change (Harper et al., 2015; Clark and Ford, 2017), especially in conjunction with other system shocks (e.g., COVID-19) (Cross-Chapter Box COVID in Chapter 7) (Zavaleta-Cortijo et al., 2020). While physical health impacts have been observed, research examining future health projections or evaluating the efficacy of health adaptations are rare (Dobson et al., 2015; Harper et al., 2020; Harper et al., 2021).

Climate change has negative, widespread and cumulative impacts on mental health in the Arctic, particularly for Indigenous Peoples (*very high confidence*) (Figure CCP6.3). Climate-sensitive mental health outcomes are complex, overlapping, and interrelated, and have multiple direct and indirect pathways stemming from: acute (e.g., major storms, flooding, wildfires) and chronic (e.g., temperature increases, sea-ice loss, permafrost thaw) environmental conditions, and resulting disruptions to livelihoods, culture, food systems, social connections, health systems, and economies (Cunsolo Willox et al., 2013a; Cunsolo Willox et al., 2013b; Cunsolo Willox et al., 2014; Beaumier et al., 2015; Durkalec et al., 2015; Hamilton et al., 2016; Clayton et al., 2017; Dodd et al., 2018; Jaakkola et al., 2018; Markon et al., 2018; ITK, 2019; Minor et al., 2019; Middleton et al., 2020a; Middleton et al., 2020b; Feodoroff, 2021).

Negative mental health outcomes from climate change include: emotional reactions (e.g., sadness, fear, anger, distress, and anxiety); psychosocial outcomes (e.g., depression, post-traumatic stress disorder, and generalized anxiety); experiences with grief and loss (i.e. ecological grief); increased drug and alcohol usage, family stress, and domestic violence; increased suicide ideation and suicides; loss of cultural knowledge and continuity, disruptions to intergenerational knowledge transfer; and deterioration and loss of place-based identities and connections (i.e. solastalgia) (Cunsolo Willox et al., 2013a; Cunsolo Willox et al., 2013b; Cunsolo Willox et al., 2014; Durkalec et al., 2015; Harper et al., 2015; Cunsolo and Ellis, 2018; Hayes et al., 2018; Jaakkola et al., 2018; Markon et al., 2018; Minor et al., 2019; Middleton et al., 2020a; Feodoroff, 2021).

The negative mental health impacts from climate change are amplified among those most reliant on the environment for subsistence and livelihoods, those who already face chronic physical or mental health issues, and those facing socio-economic inequities and marginalization, particularly for Indigenous Peoples (*high confidence*). These climate change related mental health impacts are unequally distributed (Cunsolo Willox et al., 2014; Minor et al., 2019), and may vary by gender (Beaumier et al., 2015; Harper et al., 2015; Feodoroff, 2021) and age (Petrasek MacDonald et al., 2013; Ostapchuk et al., 2015; Petrasek MacDonald et al., 2015; Kowalczewski and Klein, 2018).

Climate change will increase mental health risks in the Arctic in the future (*medium confidence*). Future risks include exposures to severe weather events and changing precipitation patterns, sea-ice loss, wildfires, and changing place attachment, as well as disruptions to underlying determinants of mental health and social support networks (Cunsolo Willox et al., 2014; Cunsolo and Ellis, 2018; Markon et al., 2018; Council of Canadian Academies, 2019; ITK, 2019; Middleton et al., 2020a; Middleton et al., 2020b).

There is *limited evidence* assessing adaptation options that effectively reduce climate-related mental health risks, but developing or enhancing access to mental health resources and infrastructure are critical, such as land-based healing programs, enhanced access to culturally-appropriate mental health resources, and climate-specific counselling services to support individual and community psychosocial resilience, particularly among Arctic Indigenous Peoples (Cunsolo and Ellis, 2018; Middleton et al., 2020a). Incorporating a climate-sensitive mental health lens into mitigation and adaptation planning holds potential for increasing mental health and resilience in the Arctic, as well as supporting other social, economic, and cultural co-benefits.

Figure CCP6.3: The pathways through which climate change impacts mental and emotional health in the Arctic.

[START BOX CCP6.2 HERE]

Box CCP6.2: Arctic Indigenous Self-determination in Climate Change Assessment and Decision-making

Similar to Indigenous Peoples globally (Cross-Chapter Box INDIG in Chapter 18), climate change vulnerability for Arctic Indigenous Peoples is often rooted in colonialism, which has led to land dispossession and displacement, carbon-intensive economies, discrimination, racism, marginalization, and social, cultural, and health inequities (Whyte, 2016; Whyte, 2017; Whyte et al., 2019; Chakraborty and Sherpa, 2021). Therefore, effective responses to climate change risks for Indigenous Peoples are self-determined and underpinned by Indigenous knowledge (*very high confidence*).

Indigenous knowledge systems are diverse among and within Arctic Indigenous Peoples, and reflect deep and rich knowledge that situates and contextualizes values, traditions, governance, and practical ways of adapting to the ecosystem over millennia (Raymond-Yakoubian et al., 2017; Brattland and Mustonen, 2018). Indigenous knowledge is a valuable source of knowledge; a method to detect change, evaluate risk, and inform adaptation approaches; and a cultural ecological service (Brattland and Mustonen, 2018; Crate et al., 2019; Meredith et al., 2019) that is critical for decision-making (Mustonen and Mustonen, 2016; Huntington et al., 2017). For instance, Kalaallit knowledge in Greenland has been used to detect and attribute long-term (over 50 years) marine change that reaches beyond scientific instrumental data (Mustonen et al., 2018b).

This Box was written by Indigenous authors, recognizing that Indigenous knowledge and local knowledge are intellectual property (Cross-Chapter Box INDIG in Chapter 18), alleviating the risk of this knowledge being misinterpreted (David-Chavez and Gavin, 2018; Hughes, 2018; Raymond-Yakoubian and Daniel, 2018), and acknowledging that meaningful inclusion of Indigenous Peoples strengthens and supports Indigenous self-determination (ITK, 2019). Self-determination signifies and values the capacity and decisions made by these peoples in their own right and from their own autonomous cultural positioning. Following the format used in SROCC, this Box prioritizes Indigenous voices by presenting climate change assessments premised on Indigenous knowledge and written by Indigenous Peoples.

Climate change, nomadic lifestyles, and preservation of traditions

Perspectives from the Yukaghir Council of Elders and Russian Association of Indigenous Peoples, Russia

Climate change threatens reindeer herding, hunting, fishing, and gathering, which form the basis of Siberian Indigenous societies. Nomadic herding lifestyle is premised on Indigenous knowledge which has accumulated over millennia. IK, including the ability to predict weather, has played a substantial role in the adaptation to the extreme conditions. According to Shadrin (2021) present, rapid changes are changing Indigenous concepts of reality - they are increasingly finding themselves in situations where their experience and knowledge cannot help them. An Elder in Northeast Siberia explained that "nature does not trust us anymore" (Mustonen and Shadrin, 2021).

A major problem for nomadic reindeer herding is the degradation of reindeer pastures (Mustonen and Shadrin, 2021). The expansion of willows and shrubs into the tundra has resulted in losses of pastures. In other nomadic communities, these changes have led to the expansion of moose into tundra area and effects of reindeer populations, as well as changes in wild reindeer migration routes leading to the destruction of domestic reindeer pastures (Mustonen and Shadrin, 2021).

Due to the steady changes in precipitation in recent years, a deeper than usual snow cover has formed in Northeast Siberia (Mustonen and Shadrin, 2021). This alters the capacity of reindeer to access lichen, their primary food source. Late onset of cold weather has led to difficulties in the herds moving to their winter pastures. In the summer, increased rainfall has led to waterlogging of low-lying pastures. The most important challenge is the instability of the weather (Mustonen and Shadrin, 2021). These include frequent, never-before-seen warming, combined with rains in the late winter and early spring. Sharp temperature drops of over 30 degrees occurring within a few hours leads to formation of an ice crust on the ground which becomes a challenge for reindeer, especially in autumn, and are becoming more frequent. Furthermore, the number of summer storms and rapid cooling accompanied with snowfall during July has increased. Using Indigenous knowledge to predict weather is the basis of effective survival. It has become extremely difficult due to the unprecedented fast changing conditions (Mustonen and Shadrin, 2021) (Shadrin, 2021). All of these events lead to increased risks in the lives of Indigenous Peoples (Mustonen and Shadrin, 2021).

Climate change impacts Indigenous Peoples' health. Degradation of the quality of surface waters has increased, resulting from new floods and the thawing of permafrost, which increases risk of gastrointestinal diseases (CCP6.2.8). The 2007 flood on Alazaya river was of special importance and was locally identified to have produced the first regional "climate refugees" (Mustonen and Shadrin, 2021). Warming has expanded the distribution of new disease-carrying insects and ticks into new territories (Mustonen and Shadrin, 2021). Ancient cemeteries and campsites, as well as the burial sites of reindeer, become dangerous as permafrost thaws and coastal erosion proceeds.

Traditional food security is under threat. Permafrost-based storage facilities have deteriorated (CCP6.2.6) (Mustonen and Shadrin, 2021). There is an increase in the number of people who are forced to abandon the consumption of raw fish. As a result, the likelihood of losing cultural traditions is growing. These combined climate change impacts result in loss of Indigenous knowledge and nomadic lifestyles, thus, losing important aspects of their identity as distinct Indigenous Peoples (Mustonen and Shadrin, 2021).

Climate change impacts on Sámi women

Perspectives from Sámi in Finland

Feodoroff (2021) stresses that many Sámi women are central to Indigenous-led adaptation. Indigenous women use their bodies as gauges of change. For example, the restoration work in Näätämöjoki River in Finland (Ogar et al., 2020; Feodoroff, 2021) is based on the knowledge of traditional fishers and reindeer herders. Indigenous knowledge and Western science offer possibilities to reflect on changes that the waters in Indigenous bodies have known of events of the past (Feodoroff, 2021). Changes in temperature, pain and the gradual passing of pain, waves, and intrusions within Indigenous bodies are knowledges that are difficult to communicate according to Feodoroff (2021). Women are sensitive to receiving messages from their home environments. Feodoroff (2021) stresses that Indigenous conservation work is a bodily commitment. This realisation is linked with difficult questions of what or who controls Indigenous bodies. Feodoroff (2021) links present change with lingering impacts of global environmental damage that has not been dealt with or addressed. It may lead to real pain in Indigenous bodies and minds, causing feelings of being nauseated and ultimately causing fade out, wilt, wither and extinguishment of Indigenous Peoples.

Adaptation successes underpinned by Inuit knowledge

Perspectives from Inuit Circumpolar Council

Inuit have survived and thrived in Inuit Nunaat, their homelands, for millennia. In an environment that presents unique challenges, they have cultivated resourceful and innovative approaches tailored to their surroundings. Their values and knowledge guide their relationships with all that is within the Arctic and this has informed their decisions and management practices that continue to be in place today (Inuit Circumpolar Council Alaska, 2020). They are experts in adaptation. Now more than ever, in the time of anthropogenic climate change, living in the fastest warming region on the planet requires this expertise and capacity.

The extraordinary developments in the field of Indigenous Knowledge have crystallized the main tenant of interaction with the natural world that is "integral to a cultural complex that also encompasses language, systems of classification, resource use practices, social interactions, ritual and spirituality" (UNESCO, 2017). Inuit have used their knowledge of the land and coastal seas to design technology, monitoring systems (Atlas of Community-Based Monitoring in a Changing Arctic, 2021), and new hunting routes that respond to the changes they face (Inuit Circumpolar Council, 2017; Nunavut Climate Change Center, 2018; SIKU, 2020). Such examples of 'adaptation success' across Inuit Nunaat have been showcased and celebrated nationally and internationally (Youth Climate Report, 2019) and all are underpinned by Inuit knowledge and pivot on their right to self-determination. This is also embodied, for example, in Canada, the National Inuit Climate Change Strategy outlines the collective Canadian Inuit plan for climate action, centering on Inuit-determined priorities to protect their culture, language, and way of life, and guiding partners in how to work with Inuit on implementing this strategy (ITK, 2019). Their action on adaptation also spans scales from local to international. As far back as 1977, Inuit have been organized and involved at the international level. Inuit were present at the Rio Earth Summit and have participated in diverse but interrelated United Nations conventions to protect their homelands (e.g., UNFCCC, CBD, Stockholm

Convention). This history gives us unique insight and positions us as both leaders and partners with the ability to engage directly with governments, business, and others.

However, while Inuit are often recognized as leaders in adaptation, too often the academic literature ends there, citing 'successful Inuit-led adaptation to climate change' but not going further to explore towards what END this adaptation is designed. We have demonstrated leadership and set an example for the world in how to respond to change, but successful adaptation is not enough, it is not the end goal.

Central to their significant capacity to adapt is that it is done in recognition of the need to move beyond adaptation. Indeed, Inuit-led adaptation action is founded on the intention of contributing to and moving towards reformation and eventual transformation of systems to create a 'climate resilient' Arctic. This concept has surfaced in academic climate change literature and discussion and has begun to filter into the climate policy arena, especially within the context of the current COVID-19 pandemic that challenges us all to think about our world differently. With acknowledgement that reform and transformation is needed, the question remains, 'What does this look like?'

Inuit have an answer. System reform and transformation is grounded in self-determination. It is based in a human rights framework and rooted in Indigenous knowledge and culture. It recognizes and respects interconnectedness and builds this into solutions. It demands collaboration and true partnership towards action. And it comes from thinking big and across scales. Shaping this change calls for willingness and support to rethink the current economic and governance models that have failed us. For example, decentralizing governance and management, while it remains largely unconventional, has been shown to create some of the strongest systems we have. This is, in a large part, due to the way in which decentralization places more value and responsibility on the 'self' in self-determination. Decentralized processes in the Arctic have Indigenous knowledge holders playing a key and lead role in determining, defining, deciding how to work towards positive change.

Across Inuit Nunaat, examples of direct management and control over lands, territories and resources, have demonstrated that working from what is happening on the ground throughout their homelands, from their priorities and interests, has served to strengthen the health of their environment and their communities. For example, a comparative analysis on factors supporting and impeding Inuit food sovereignty between Alaska and the Inuvialuit Settlement Region found that the difference in outcomes within these regions is dependent on explicit respect for and recognition of the Inuit right of self-determination (Inuit Circumpolar Council Alaska, 2020). Furthermore, a new agreement achieved in Nunavut by the Qikiqtani Inuit Association related to the marine environment touted as an exemplary model for marine management is rooted in Inuit-determined structures and policies, and manifested by Inuit themselves (QIA, 2019).

Emphasis on decentralized management and substantial funding to do so at the grassroots level has been recognized by the IPCC previously in the SROCC. Ultimately, going beyond reform to system transformation requires, as Oren Lyons has stated, "value change for survival" (Lyons, 2020). Valuing decentralization, self-determination, Inuit knowledge, interconnectedness – core values held by Inuit – can move us in a climate-resilient direction.

[END BOX CCP6.2 HERE]

CCP6.3 Key Risks and Adaptation

CCP6.3.1 Key Risks

Key risks arising from changing climate hazards are presented in Table CCP6.6 (details in SMCCP6.4). Changing levels and magnitude of climate hazards translate into different levels of risks for ecosystems, industry, society and infrastructure (Figure CCP6.4) (see Meredith et al., 2019 Figures 3.5, 3.10 (Arctic), Figure 3.6 (Antarctic). In the Arctic, these risks are often also shaped by non-climatic factors (Huntington et al., 2019; Ford et al., 2021), including ongoing colonial legacies, land dispossession, landscape fragmentation, and resulting challenges in the valuing and meaningful use of Indigenous knowledge and local knowledge (Box CCP6.2) (Huntington et al., 2019; Kelman and Næss, 2019; Ford et al., 2020).

Available literature enabled assessment of particular polar assets based on projected future risk and including consideration of non-climatic compounding factors under 1°, 2°, 3° and 4°C global warming above pre-industrial including sea-ice ecosystems, marine mammals, sea birds, fisheries, infrastructure (Arctic only), local mobility (Arctic only), and coastal erosion (Arctic only) (Figure CCP6.5) (details in SMCCP6.4).

Table CCP6.5: Key risks and illustrative examples in polar regions identified through the processes described in Chapter 16 and SMCCP6.4.

Key Risk	Direct and indirect factors contributing to risk
KR1. Risk to marine ecosystems and species (CCP6.2.2; CCP6.2.3)	-Warming, marine heatwaves, sea-ice loss, glacial and ice sheet melt, ocean acidification, invasive species, harmful algae blooms -Narrow thermal niches, altered marine habitat, hampered calcification, higher corrosivity for $CaCO_3$ shell/skeleton, phenological mismatch, physiological/life history effects, sensitive food web relationships, reduced trophic (energy) transfer efficiencies, increased light availability, nutrient limitation, and changes to salinity, stratification, oxygen levels
KR2. Risk to terrestrial and freshwater ecosystems and species (CCP6.2.4)	-Warming, hydrological changes, terrestrial heat waves, change in rain and snow events, increased wild- and mega-fire events in Arctic, permafrost thaw, and erosion -Vegetation browning/greening, narrow thermal niches, physiological/ life history effects, sensitive food web relationships, parasites and disease
KR3. Risk to commercial and private infrastructure (CCP6.2.6)	-Permafrost freeze-thaw, extreme heat and precipitation, rapid warm-thaw events, storms, increased wave activity, storm surges, flooding, landslides and erosion. -Roads, airstrips, railways, ports, commercial buildings, private homes, ice cellars, traditional snow/ice/water travel routes, other infrastructure. -Permafrost freeze-thaw and SLR impacting cultural assets, including cultural heritage sites.
KR4. Risk to food and nutritional security (CCP6.2.5)	-Warming, ocean acidification, sea-ice loss, permafrost loss, changes to precipitation, wildfires, hydrological changes. -Access to marine areas increased, to coastal and terrestrial areas decreased; effects on subsistence and commercial species.
KR5. Increased polar shipping traffic with cascading risks for navigation, safety, ecosystems, and culture (CCP6.2.4; CCP6.2.5; Box CCP6.2; FAQ CCP6.1)	-Substantial reduction in sea-ice extent and thickness. -Marine subsistence species; coastal communities; Inuit hunters; ship operators; tourism operators; mining companies.
KR6. Increased mental health challenges and impacts on Indigenous Peoples and culture (CCP6.2.6.4; CCP6.2.7; CCP6.2.8. Box CCP6.2; FAQ CCP6.3)	-Warming temperature; heatwaves; ice changes; changes in snow cover; permafrost thaw; coastal erosion; changing landscapes.
KR7. Risk from polar change for global processes and SLR (FAQ CCP6.1)	-Reduction in Arctic sea-ice, sheets, and glaciers have implications for planetary albedo and ocean stratification and salinity, acceleration of global warming, potential effects on global overturning circulation and northern hemisphere weather patterns -cultural and resource connections to global sustainable development

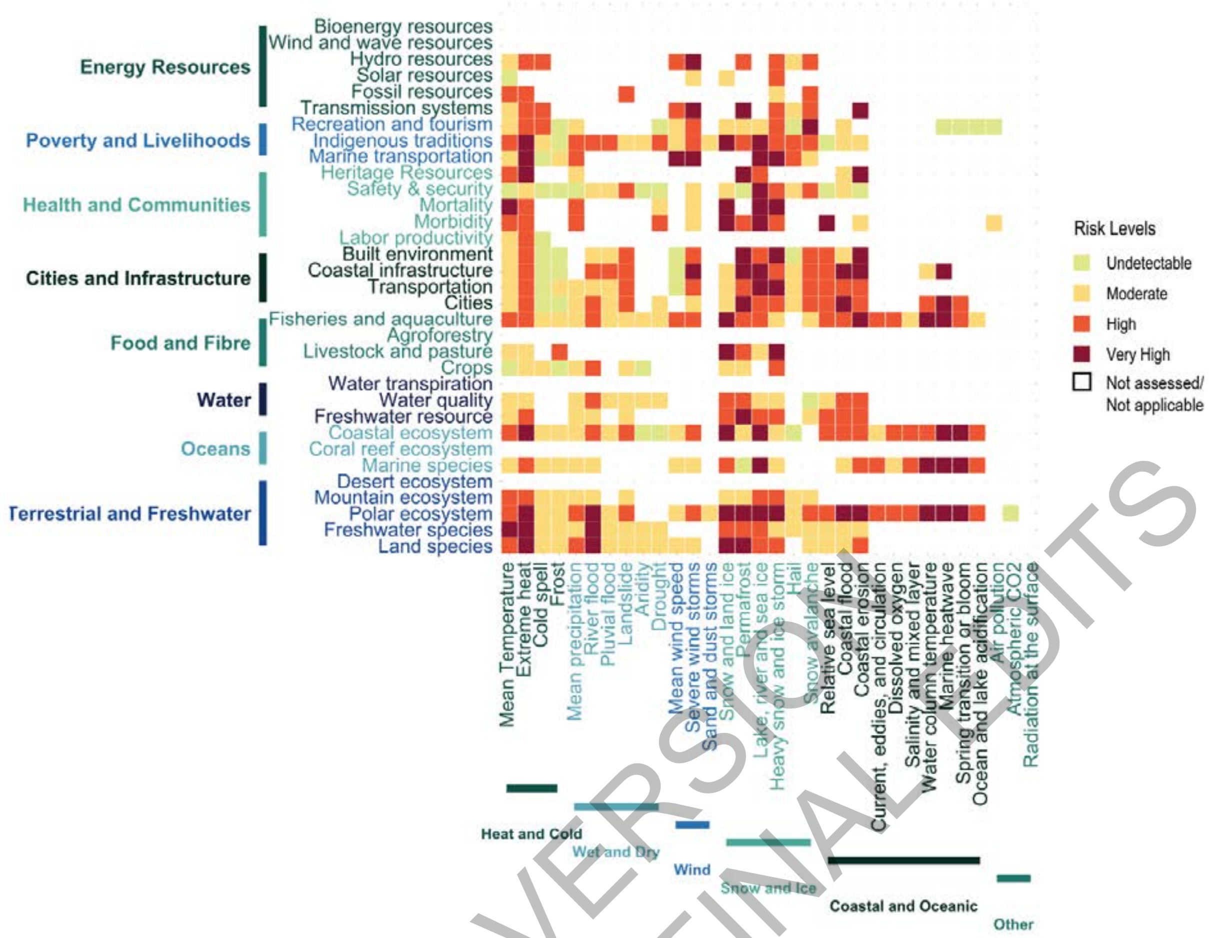

Figure CCP6.4: Rapid assessment for relative risk by sector (y-axis) and climate hazard (x-axis) for polar regions based on an assessment of asset-specific vulnerability and exposure across climate hazards (see SMCCP6.4 for methodological details). For each unique combination, the hazard by sector risk was ranked as very high (very high risk and high confidence), high (significant impacts and risk, high to medium confidence), medium (impacts are detectable and attributable to climate change, medium confidence), low/ not detected /positive (risk is low or not detectable). Blank cells are those where the assessment was not applicable or not conducted. Risks identified through the rapid assessment were further evaluated in the chapter assessments (see corresponding sector text for full assessment of risk and impacts).

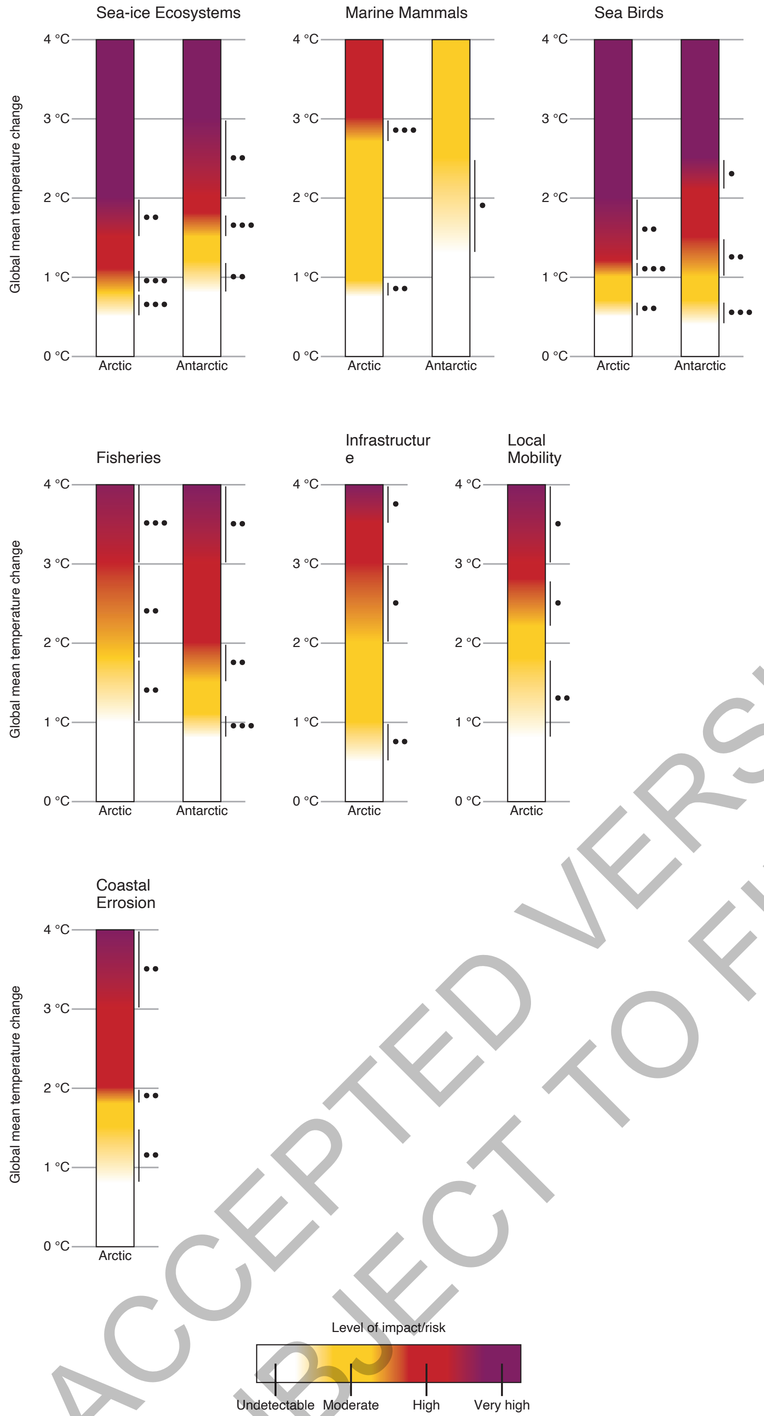

Figure CCP6.5: Burning ember of the relative risks to select assets in the Polar regions as a function of global mean surface temperature increase since pre-industrial times including: 1) sea-ice ecosystems, 2) marine mammals, 3) sea birds, 4) fisheries, 5) infrastructure (Arctic only), 6) local mobility (Arctic only), and 7) coastal erosion (Arctic only). The supporting literature and methods are provided in SMCCP6.5

CCP6.3.2 Adaptation

CCP6.3.2.1 Current adaptation

Across polar regions, adaptation responses to climate change impacts have ranged from rapid and incremental (e.g., shifting phenologies, alternative harvest or herding strategies) to large and transformative (e.g., switching livelihoods, social-ecological system transformation) (Figure CCP6.6). Some adaptation measures and opportunities induce novel risks to other sectors or systems resulting in cascading and compounding consequences that are sometimes hard to predict or prepare for (Huntington et al., 2015)

(Table CCP6.6). Adaptation planning and implementation is greater in the Arctic than Antarctic regions, in part due to disparate magnitudes of realized climate impacts and change between regions (Figure CCP6.2; Table CCP6.1), but also because of the differing governance systems in place (Meredith et al., 2019). In the Antarctic region, a climate action plan has been developed for terrestrial systems but not for the Southern Ocean (Meredith et al., 2019), although strategies for adapting to climate change have been proposed, including incorporation of precaution in decision-making (Constable et al., 2017). In the Arctic, climate change information is increasingly integrated into research, policy, and decision-making including incorporation of climate change projections, forecasts, and early warnings (AMAP, 2017; AMAP, 2018a; Marshall et al., 2019; Dorn and Zador, 2020; Hollowed et al., 2020; Stram et al., 2021).

The majority of adaptations in the Arctic are occurring at sub-regional levels in response to both observed and projected climate change, with evidence of increasing regional level action driven by climate planning processes of subnational governments (AMAP, 2017; Labbé et al., 2017; AMAP, 2018a; Canosa et al., 2020). Implemented adaptation includes alterations to building codes and infrastructure design (Shiklomanov et al., 2017; Flynn et al., 2019; Standards Council of Canada, 2020), surveillance (Ruscio et al., 2015; Ford and Clark, 2019; Meredith et al., 2019), information sharing (Berner et al., 2016), changes to survey and monitoring design (Stevenson and Lauth, 2019), hazard mapping (Flynn et al., 2019), use of new technologies (Tejsner and Veldhuis, 2018; Galappaththi et al., 2019), the development of regional and municipal adaptation plans (Labbé et al., 2017), shifting stocks and changes in fishery operations and location (Jørgensen et al., 2019; Fedewa et al., 2020; Thompson et al., 2020), alterations to subsistence harvesting activities (Anderson et al., 2018; Ford et al., 2018; Galappaththi et al., 2019), co-production of knowledge (Raymond-Yakoubian and Daniel, 2018), and application of Indigenous knowledge for resource management (Robards et al., 2018) and to monitor storms (Rosales et al., 2021; Simonee et al., 2021). Pan-Arctic and national-level adaptation remains limited (Ford et al., 2014; Canosa et al., 2020), although there have been few efforts to examine the nature of adaptation responses in Arctic regions and large gaps in understanding.

Illustrative examples of direct and cascading risks, enabling principles of climate resilience pathways, anticipated future conditions (with certainty levels and compounding risks for key sectors within polar regions are outlined in Table CCP6.6. A list of adaptation options responding directly to the challenges outlined for each sector, including an analysis of adaptation effectiveness and feasibility and cross referenced with key risks assessed in this chapter (Table CCP6.5) is provided in Figure CCP6.6

Table CCP6.6: Assessment of risks needing adaptation by sector in the polar regions.

Sector	**Direct and cascading risks**	**Enabling principles of climate resilience pathways**	**Anticipated future conditions / level of certainty**	**Compounding risks (non-climatic factors)**
Coastal settlements (CCP6.2.5)	Change in extent of sea-ice with more storm surges, thawing of permafrost, sea level rise, and coastal erosion	Local leadership and community-led initiatives to initiate and drive processes, responsive agencies, established processes for assessments and planning, geographic options	Increasing number of communities needing relocation (*medium confidence*), rising costs for mitigating erosion (*high confidence*)	Limitations of government budgets, other disasters that may take priority, policies deficiencies for addressing mitigation and relocation
Human health (CCP6.2.6)	Increased food insecurity, waterborne disease, emerging pathogens, injury and death, and negative mental health outcomes	Resources to support public programs; Indigenous self-determination; access to technology; supporting Indigenous knowledge systems; interdisciplinary and integrated decision-making	The intersection of social determinants of health will modify or mediate climate change impacts on health (*very high confidence*)	Underlying health conditions, advances in diagnosis and treatment, and other health system shocks (e.g., COVID)

 Transportation (aviation, rail, road, ice roads) (CCP6.2.4.3)	Permafrost thaw, sea-ice change, storm surge, coastal erosion, changing precipitation patterns (ice pellets, hail), and extreme events create risks to transportation infrastructure with consequences to navigation, economics, safety, and security	Financial and human resources for: climate resilient infrastructure research, development and implementation; improved weather, water, ice and climate forecasting at appropriate scales; improved communications infrastructure; local search and rescue	Limits to adaptation exist (*high confidence*), but strategic investments in technologically innovative infrastructure that offers mitigation co-benefits will greatly enhance adaptation effectiveness (*very high confidence*)	Level of local, regional, and national infrastructure development, commitment of national and state level government to sustainable development pathways, global economic and political trends, commodity prices, unforeseen system shocks
 Shipping (Box CCP6.1; FAQ CCP2)	Sea-ice reduction leading to increased shipping related to trade, tourism, fisheries, resource development, and re-supply with cascading risks from ships such as: increased under-water noise, potential introduction of invasive species, fuel spill risks, release of black carbon and air emissions, impacts to cultural resources, implications for subsistence hunting and food security, increased accidents and incidents	Financial support for ship-building technologies (e.g., low emission fuels, propulsion technologies, hull strength); development of robust multi-national agreements (in addition to existing agreements); inclusion of Indigenous Peoples in decision-making; investment in multi-national and longitudinal research on shipping impacts; and enhancing modern digital maritime charting	Ship traffic will continue to grow in polar regions (*high confidence*) with Arctic trade routes becoming increasing accessible (*very high confidence*) albeit with more challenging navigation due to increases in mobile ice in the near-term compared to late century when ice is expected to diminish completely during the shipping season (*high confidence*)	Geopolitical and sovereignty debates; shipping insurance premiums; global economic trends; commodity prices; national policies and politics; level of infrastructure investment; availability of search and rescue assets, and modern charting
 Infrastructure (CCP6.2.5)	Loss and damage to infrastructure from permafrost thaw affecting stability of ground; coastal erosion; SLR	Resources for assessments, mitigation, and where needed, relocation	Increasing cost to maintain infrastructure and greater demand for technological solutions to prevent damages (*high confidence*)	Strength of regional and national economies, other disasters that divert resources
 Non-renewable resource extraction (Arctic only) (CCP6.2.4.1)	Reduced sea-ice improves access to non-renewable resources in remote Arctic regions, while warming temperature and thawing permafrost affect production levels, quality, and reliability and season length of ice roads leading to increased operational costs	Investment in climate resilient infrastructure and low emission transportation (shipping) and investment in solar powered ships and low impact modular mining camp infrastructure	Increase in mining in newly accessible marine regions (*medium confidence)*, frequent false starts (i.e., due to climatic and non-climatic factors) (*high confidence*), and high levels of operational uncertainty (i.e., commodity prices, economic trends, climate risks) (*very high confidence*)	Commodity prices; global economic trends and shocks; Indigenous rights and decisions; changing regulatory environments, geopolitics, global demand for resources
 Tourism (CCP6.2.4.2)	Increased demand for polar tourism activities including development of 'last chance tourism' market; Increased tourism improves economic conditions but leads to increased environmental and cultural impacts	Financial resources for service and infrastructure development; Indigenous self-determination and development of co-management approaches for natural and cultural attractions;	Polar tourism demand will continue to increase, especially for cruise and yacht experiences (*high confidence*) and enhance risks related to ship groundings, accidents, and incidents (*medium confidence*)	Limited search and rescue capacity, poor infrastructure, aging expedition cruise ship fleet, uncharted waters, geological and sovereignty debates, global economic trends, unforeseen events (i.e., SARS, COVID-19)

		development of multi stakeholder/rightsholder tourism task teams		altering tourism demand patterns
 Reindeer herding (CCP6.2.3.1; 6.2.3.2; 6.2.5; Box CCP6.2)	Rain-on-snow events causing high mortality of herds, especially in the autumn season; shrubification of tundra pasture lowering forage quality	Flexibility in movement to respond to changes in pastures, secure land use rights; adaptive management; continued economic viability and cultural tradition; self-determination in decision-making; adequate support for communication and technological services; Indigenous Rights upheld and protected	Increased frequency of extreme events and changing forage quality adding to vulnerabilities of reindeer and herders (*high confidence*); adaptation limits are being approached	Change in market value of meat; overgrazing; land use policies affecting access to pasture and migration routes, property rights; cost of feed
 Commercial fisheries (CCP6.2.3)	Loss of sea-ice, warming waters, and MHWs transform ecosystems in the Arctic with impacts on fisheries including declines in multiple regions; changes to Antarctic ecosystems affect southern fisheries productivity and distribution	Implementation of adaptive management that is closely linked to monitoring, research, and low cost and inclusive public participation in decisions, high resolution forecast and projection tools, climate-informed survey and monitoring design	Changes in availability and location of fishery resources will impact fish operations in the eastern Bering Sea and Barents Sea as well as the Convention for the Conservation of Antarctic Marine Living Resources area. Declines in catch impact livelihoods, coastal communities, and pose a risk to regional and global food and nutritional security (*very high confidence*)	Changes in global demand for seafood, demand and markets, changes in gear, changes in policies affecting property rights. Changes due to offshore development and transportation
 Marine subsistence (CCP6.2.3; CCP6.2.3.1)	Changes in species distribution and abundance (not all negative); impediments to access of harvesting areas especially sea-ice; increased interactions with shipping; safety; changes in seasonality; reduced harvesting success and process of food production (processing, food storage; quality); threats to culture and food security	Systems of adaptive co-management that allow for species switching, changes in harvesting methods and timing, secure harvesting rights, communication and relationship building, co-production of knowledge	Changes in distribution and abundance of resources combined with more regulations related to species at risk. Adaptation at the local, individual, and household level under low mitigation scenarios will be costly and possibly undermined by the scale and pace of change, including climate shocks and extreme events (*medium confidence*)	Changes in cost of fuel, land use affecting access, food preferences, harvesting rights; colonialism, international agreements to protect vulnerable species
 Marine ecosystems (CCP6.2.1)	Warming, sea-ice loss, ocean acidification resulting in poleward contraction of polar zones, invasive species introduction, displacement of polar species, and restructuring of food webs	Reduce effects of external and compounding risks and increase application of ecosystem-based management to meet biodiversity and management goals. Conservation of genetic diversity and biodiversity to preserve resilience, and	Without institutional investment in sustaining climate resilience in ecosystems across sectors there is a high risk of failure (*high confidence*)	Novel and expanding activities in ice free areas (shipping; fishing), energy development and mineral extraction, increased tourism, global markets and demand for polar resources, population growth and community

		supplementation and assisted migration may be needed		relocation to coastal areas
 Terrestrial and Freshwater ecosystems (CCP6.2.2)	Warming, hydrology changes (reduced ice on lakes and rivers, flooding, snow) and permafrost thaw lead to impacts on polar terrestrial and freshwater systems, food webs, the distribution of polar fish, implications for peat systems with consequent changes on dependent animal assemblages and increasingly favorable conditions for parasites and pathogens. Increased risk of wildfires in the Arctic	Improving biodiversity and redundancy to enhance resilience. Efforts to minimize and prevent extinctions; preservation of ecosystem processes and habitats during critical life stages; coordinated governance; measures and planning that consider dynamic interactions within and among social and ecological systems are more effective	Without institutional investment in sustaining climate resilience in ecosystems across sectors there is a high risk of failure (*high confidence*). Arctic regions have greater understanding of resilience needs but coordination is not widespread. Antarctic has established action plans to identify key management needs for conserving terrestrial and freshwater biota.	Novel and expanding activities in ice free areas (shipping; fishing), energy development and mineral extraction, increased tourism, global markets and demand for polar resources, population growth and community relocation to coastal areas

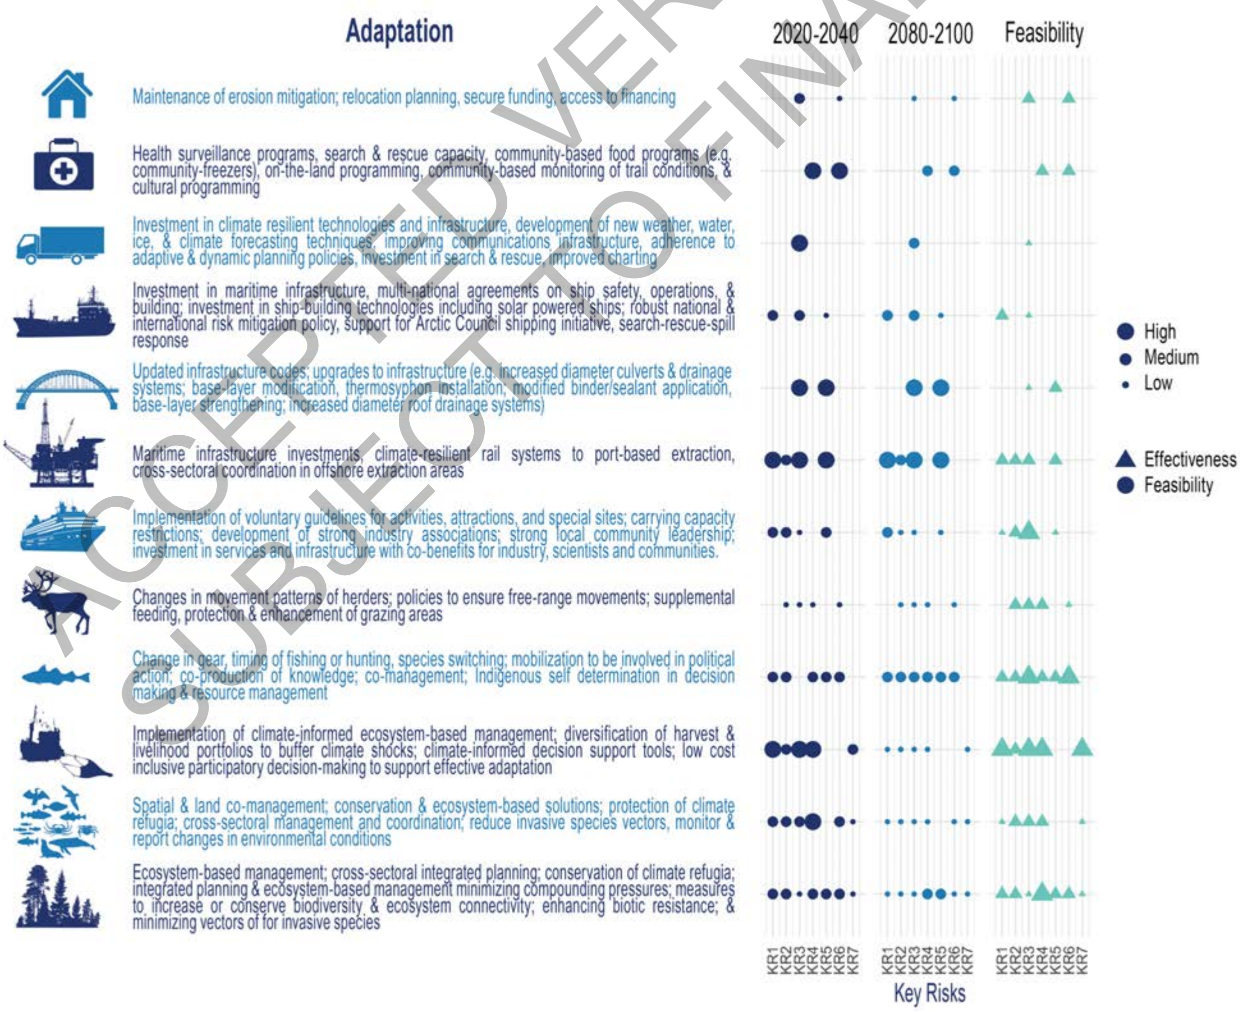

Figure CCP6.6: Assessment of feasibility and effectiveness of adaptation options by key risks in the polar regions (Table CCP6.6)

The need for self-determination for Indigenous Peoples and local communities in decision-making and cooperation across Arctic nations to manage a rapidly changing Arctic is increasingly recognized, particularly in a shipping and wildlife management context where climate impacts will be transboundary and multi-sectoral (Spence, 2017; Forbis and Hayhoe, 2018; Ford and Clark, 2019; Dawson et al., 2020) (CCP6.2.6; Box CCP6.2). Effective Indigenous and community-led adaptation efforts have been implemented across the Arctic to alleviate climate and non-climate stressors and build resilience through restoration and conservation (Huntington et al., 2017; Brattland and Mustonen, 2018; Hudson and Vodden, 2020; Mustonen and Feodoroff, 2020; Uboni et al., 2020; Huntington et al., 2021). For example, Indigenous knowledge and science has been used by the Skolt Sámi in Finland to attenuate warming, drought, and water quality impacts on salmonids through restoration of spawning and nursery habitats in the Vainosjoki river catchment (Brattland and Mustonen, 2018; Mustonen and Feodoroff, 2020; Ogar et al., 2020). This ecological restoration of damaged habitats for fish represents community-led actions. In Aasiaat, Greenlandic hunters have implemented community-based oceanographic and ecological monitoring to convey Indigenous knowledge observations of rapid change to the government and scientists. A special aspect of land use in the Russian North is the preservation of nomadic lifestyles of the Nenets and Chukchi (Mustonen and Mustonen, 2016), and while these traditional economies have undergone rapid change due to non-climate drivers, their land uses, observational frameworks and cultural matrixes remain of high importance in the context of climate change. Endemic responses (self-agency from within the culture) and Indigenous governance enable adaptation to the rapid and accelerating changes under way (Mustonen et al., 2018a). Therefore, community-based monitoring and inclusion of Indigenous knowledge in dialogue with science has been an effective mechanism to detect and respond to climate change.

CCP6.3.2.2 Adaptation gaps

In a study of adaptation progress across the Arctic from 2004−2019, 233 cases of adaptation were documented, with the majority of actions primarily behavioural and reactionary in nature and undertaken in the subsistence harvesting sector, with resource management, and infrastructure and transportation other prominent sectors where adaptation responses were documented to be occurring (Canosa et al., 2020). The study found few changes in the profile of adaptation over time, except for an increase in responses being motivated solely by climate impacts, and few cases of transformational change, although caution that a lack of data on adaptation actions makes documenting trends challenging. Human health is generally under-represented in adaptation initiatives, along with adaptations being developed within larger Arctic settlements (Ford et al., 2014; Canosa et al., 2020), and in many sectors decisions continue to be made without explicit inclusion of climate change impacts and risk in planning and design (*high confidence*) (Cherry et al., 2017; Lauta et al., 2018; Meredith et al., 2019). There is *limited evidence* of transformational adaptation taking place in the policy arena (e.g., U.S. Executive Order 13990, 2021), but many examples of how impacts and responses to climate change have transformed social-ecological connections, traditions, markets, trade, and livelihoods of Arctic residents and Indigenous Peoples (Ford et al., 2015).

CCP6.3.2.3 Maladaptation and limits to adaptation

In polar regions, multiple entities operate simultaneously to manage lands and resources, resulting in layered approaches and policies for the same sector or region, only some of which are synergistic and a few of which may counter each other (e.g., Southern Ocean: Solomonsz et al., 2021). Climate change and attendant uncertainty can undermine stakeholder confidence in management, leading to less effective management even when scientific understanding is stable (Mumby et al., 2017). In the Arctic, large landscapes, dispersed population centers, limited resources, and settler colonialism are structural barriers to effective planning, emergency response, and relief and recovery from climate impacts (*medium confidence*), which limit adaptation and sometimes exacerbate climate and non-climate pressures on social and ecological systems (Ford et al., 2015; Ford et al., 2020; Snook et al., 2020).

Adaptation strategies that are beneficial in the short term can result in long-term maladaptive outcomes. For Indigenous Peoples, strategies that fail to address colonialism, inequities, and injustices undermine effective adaptation (Canosa et al., 2020; Schipper, 2020; Ford et al., 2021). Large "responsiveness gaps" between impacts and implementation, approaches that fail to consider dynamic responses within social and ecological systems (which amplify or attenuate climate impacts), and a paucity of *a priori* planning can contribute to maladaptation (*high confidence*)(Pentz and Klenk, 2017; Turner et al., 2020b). For example, rationalization (privatization) can stabilize fisheries and incentivize long-term sustainability under stationary conditions, yet also promote low diversity in harvest (or livelihood) portfolios and when combined with behaviors to offset climate driven declines in yield (e.g., effort or price) rationalization can create lock-in to declining stocks, increasing the risk of income variability and collapse (Kasperski and Holland, 2013; Pinkerton and Davis, 2015; Holland et al., 2017; Ojea et al., 2017; Anderies et al., 2019; Fisher et al., 2021). Policies that foster stewardship yet also allow for diversification in fisheries may further attenuate climate shocks to individual fisheries (Kasperski and Holland, 2013; Fisher et al., 2021) and stabilize catches (e.g., US Bering Sea pollock fleet (Watson and Haynie, 2018)). Inclusive and participatory decision-making underpins long-term resilience to climate change (*medium confidence*)(Flynn et al., 2018; Ford et al., 2020), but a high cost of participation can disproportionately favor entities with strong investment, ample resources, and extreme viewpoints such that decision outcomes are not in the broad interest of polar societies (Lynham et al., 2017).

There are significant limits to adaptation in the polar regions related to the rate of warming and cascading changes that are occurring, which is equivalent to double and sometimes triple the global average depending on the region (Bush and Lemmen, 2019; IPCC, 2021). The rapid pace of change, such as sea-ice loss, can outpace ecological processes and induce substantial ecological shifts (CCP6.2)(*medium confidence*). The speed of climate change in the Arctic limits options for adaptation in communities who rely on a narrow resource base, when adaptation involves loss of culture and livelihoods, and when the costs of adaptation makes it infeasible (*medium confidence*) (Ford et al., 2015), such as for reindeer herding (Table CCP6.6; Figure CCP6.6; Figure CCP6.7) (Meredith et al., 2019). Adapting infrastructure in response to a rapidly changing cryosphere will be limited by available technologies and the relatively higher costs associated with updating infrastructure over vast polar regions (Schneider von Deimling et al., 2021).

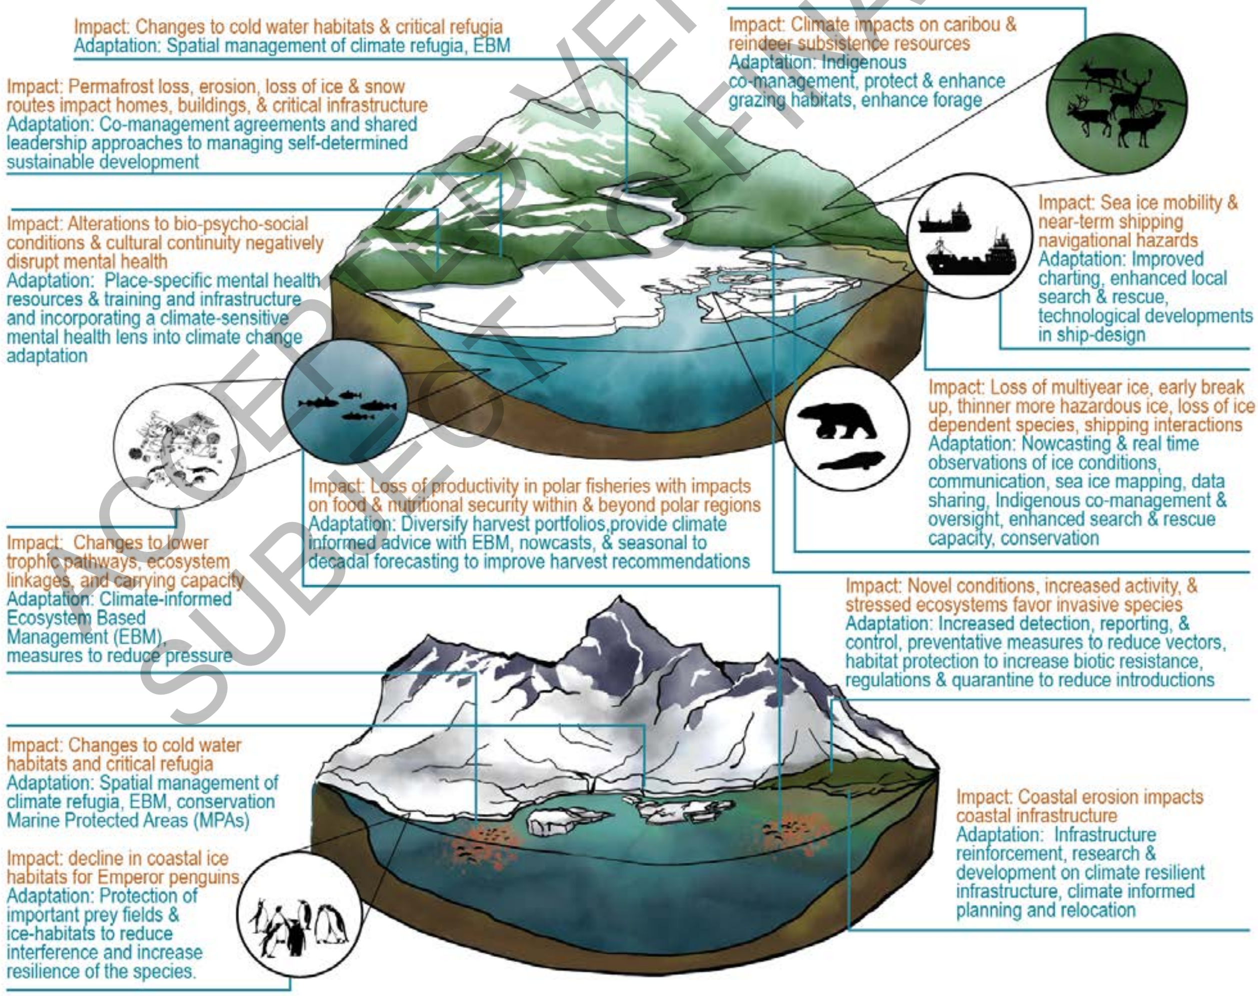

Figure CCP6.7: Climate change impacts, risks, and potential for adaptation in Arctic (upper panel) and Antarctic (lower panel) social ecological systems.

[START FAQ CCP6.4 HERE]

FAQ CCP6.4: When will climate change impacts in polar regions surpass our ability to adapt?

When environmental variability is within the range of the current adaptive management approaches, the social-ecological system can thrive. However, the rapidly changing polar systems are causing disruptions to societies, economies and ecosystems. The current management systems are yet to develop procedures for managing rapid change being experienced in warming waters, sea-ice declines, permafrost thaw and erosion, and poleward shifts in species. These challenges are expected to become more pronounced within a few decades rather than later this century.

Polar regions are naturally dynamic environments. Ecosystems in polar regions, and the people who rely on them, have adapted to natural variability and dynamic nature of polar environments. Fish populations in polar regions are known to exhibit cycles of productivity, and shift their distribution across hundreds of kilometers in response to changes in winter sea-ice cover and concomitant summer ocean conditions. Management of the productive fisheries in polar regions is also designed to allow for these changes, using adaptive and ecosystem based approaches that buffer populations from overexploitation and also stabilize fisheries, livelihoods, and food resources. Indigenous Peoples diversify their subsistence harvest across species and resources, and therefore similarly stabilize food and nutritional security. When environmental variability is within the range of these adaptive measures the social-ecological system can thrive. Thus, there are fundamental components in place in polar regions already to help ecosystems and people adapt to some degree of climate change. However, as climate change impacts like warming waters, sea-ice loss, permafrost thaw and erosion, systematically alter components of the system, shift species increasingly poleward, and disrupt linkages between species and people, the ability to adapt is reduced. There are critical tipping points (e.g., sea ice melt, permafrost thaw) where changes may cascade, self-reinforce and accelerate, outpacing adaptation actions and force natural and human systems irreversibly (on the scale of human existence) into novel regimes. The risk of crossing tipping points is greater and the probability much increased after mid-century under scenarios without global carbon mitigation (SSP5 8.5), where changes are largest and most rapid.

[END FAQ CCP6.4 HERE]

CCP6.4 Climate Resilient Development Pathways

The polar regions are expected to experience many economic development opportunities as a result of climate change, including increased accessibility for shipping and attractiveness for fisheries and tourism (CCP6.2.3.1, CCP6.2.4). For polar regions, equitable climate resilient development requires diverse perspectives in planning and implementation. In the Arctic, cultural, social and economic dimensions of Indigenous Peoples and local communities are critical (Ritsema et al., 2015; Huntington et al., 2021). For both poles, there are global cultural connections to polar systems (Roberts et al., 2021), along with important global and local needs for sustained ecosystems and their services, in the face of diminishing polar zonal conditions (Cavanagh et al., 2021; Murphy et al., 2021; Solomonsz et al., 2021).

Sustainable pathways integrating across sectors, and taking account of local and global connections, can be readily achieved in polar regions to balance trade-offs between economic, ecological, and socio-cultural imperatives, yet challenges remain (Murphy et al., 2021). Notably, terrestrial areas of greatest interest for infrastructure development, agriculture, and visitation potential are often also the same areas that have been identified as culturally and ecologically significant (PEW, 2016; Eliasson et al., 2017; Grant et al., 2021) (*high confidence*). Development of low impact shipping corridors in Arctic Canada is an example of an effective mechanism where climate resilient infrastructure can be prioritized and where regulation (voluntary and enforced) focused on cascading climatic risks can be implemented (Chénier et al., 2017; Dawson et al., 2020).

CCP6.4.1 Challenges to Climate Resilient Development Pathways

Decision-making in polar regions is complicated by globalization processes and the complexity of governance arrangements from local to global instruments and differing stakeholder perspectives and needs (Hughes et al., 2018; Stephen, 2018; Huntington et al., 2021; Murphy et al., 2021; Solomonsz et al., 2021). Substantial interest in and management of polar resources from non-polar states can lead to decision-making that lacks explicit consideration of local impacts and responses, thus reducing the effectiveness of adaptation, and in some cases causing maladaptation. Participatory decision-making is increasingly used in some sectors, but high costs of participation, a focus on consensus, and systematic erosion of resources can undermine outcomes (Mumby et al., 2017; Parlee and Wiber, 2018; Mendenhall et al., 2020). In the Arctic, the societal burden of climate change impacts and risks will manifest at the local level and thus the importance of local scale leadership and involvement in decision-making is essential for effective adaptation (AMAP, 2017).

Many losses and damages within Indigenous contexts are not able to be monetized but can be profound, such as loss of Indigenous languages (CAFF, 2013), loss of Indigenous knowledge associated with nomadic lifestyles and cultures (Box CCP6.2), and loss of geographical knowledge associated with an intimate knowledge of landscapes across seasons (Brattland and Mustonen, 2018), changing landscapes resulting in solastalgia and ecological grief (Cunsolo and Ellis, 2018), and some Indigenous practices and cultural assets, such as burial grounds, nomadic camp sites, graveyards, seasonal dwellings, and routes and pathways causing disruptions to mind and memory (Mustonen and Mustonen, 2016). Recognizing these intangible losses and damages is critical for understanding how to achieve climate resilience in the Arctic (Tschakert et al., 2019; Sawatzky et al., 2020).

For the Antarctic, the governance for managing climate impacts is emerging, particularly for terrestrial and nearshore habitats (*high confidence*) (Hughes et al., 2018; Chown and Brooks, 2019). However, it is poorly developed for marine ecosystems, despite its importance for decision-making (Trebilco et al., 2020; Goldsworthy and Brennan, 2021). A diversity of stakeholders are involved in developing evidence-based management for the region, which presents challenges for adaptation planning (Solomonsz et al., 2021), particularly in identifying sustainable practices in a changing environment (Constable et al., 2017; Brooks et al., 2018). Spatial management for enhancing the resilience of endemic polar biodiversity is increasingly proposed as the best option for managing risks of climate change (Chown and Brooks, 2019).

CCP6.4.2 Inclusive, Integrated Co-management

Inclusive, low-cost participatory decision-making can deliver equitable responses to climate change (*high confidence*). Land use, maritime activities, and subsistence fishery and other extracted resources in the polar regions are co-managed through multilateral and national government bodies. The capacity of governance systems in some Arctic regions to respond to climate change has strengthened recently (*high confidence*). Synthetic themes in adaptation for the Arctic have emerged from and since SROCC and include flexibility through diversity in livelihoods, and subsistence and harvest portfolios; co-management of resources; adaptive and ecosystem-based approaches; adoption of advanced technology, forecasts, and longer term projections to improve safety and resources management; and imperative need for low-cost, inclusive and participatory decision-making (Kasperski and Holland, 2013; Brattland and Mustonen, 2018; Parlee and Wiber, 2018; Galappaththi et al., 2019; Holsman et al., 2020; Huntington et al., 2021; Melbourne-Thomas et al., 2021; Mustonen and Van Dam, 2021). This was demonstrated in community-level adaptation by Pangnirtung Inuit to climate change impacts on fisheries (Galappaththi et al., 2019). Inclusive approaches to co-management, especially those that enable diverse perspectives, embrace conflict, and address equity and justice across power holders, can help alleviate the risk and promote solutions (Raymond-Yakoubian et al., 2017; Brattland and Mustonen, 2018; Parlee and Wiber, 2018; Raymond-Yakoubian and Daniel, 2018; Snook et al., 2020). Integration across levels of management and diverse regional perspectives can reduce climate risks and support equitable adaptation measures (Allison and Bassett, 2015; Raymond-Yakoubian et al., 2017; Raymond-Yakoubian and Daniel, 2018; Holsman et al., 2020).

Increased flexibility in management measures, greater investment in ecosystem monitoring, and more inclusive participatory methods and communication may help foster high levels of local investment and resilience and promote adaptive pathways (Cinner et al., 2016; Weymouth and Hartz-Karp, 2019), although explicit measures may be needed to reduce costs and increase representation, enhance transparency, embrace dissent, and clarify accountability are needed as these are not inherent outcomes (Lynham et al., 2017; Parlee and Wiber, 2018). Ecosystem-based management (EBM), which includes provisions aimed at sustaining critical connections within and among social and ecological systems, enhances resilience and attenuates climate impacts on ecosystems and provisioning services, e.g., EBM enhances climate resilience for Antarctic krill and Northeast Arctic cod fisheries (Troell et al., 2017; Meyer et al., 2020) and forestalls fishery collapse in the Bering Sea in the near-term (Holsman et al., 2020). Increasing likelihood of transboundary resources, interactions, and novel commerce may strain existing regulatory and international agreements suggests that *a priori* governance agreements that designed to manage climate risks and aimed at attenuating potential conflicts over resources and regions may be important for resolving these issues (Parlee and Wiber, 2018; Mendenhall et al., 2020).

CCP6.4.3 Enabling Climate Resilience in the Arctic: Self-determination and Indigenous Peoples' Rights

Climate change disproportionately impacts Indigenous Peoples (Box CCP6.2), which directly affects their livelihoods, health, and Sustainable Development Goal targets. For residents in the Arctic, a sustainable development pathway has been found to be highly effective if a self-determined development model is employed (*very high confidence*). Known determinants of Indigenous self-determined development in regions in the Arctic, include: 1) Indigenous self-determined decision-making (and inherent sovereignty); 2) effective and culturally legitimate institutions of government; 3) strategic vision and strategic thinking; and 4) public-spirited, nation-building leadership (Cornell and Kalt, 1992; Cornell and Kalt, 1998; Cornell and Kalt, 2007; Ritsema et al., 2015). For Indigenous Peoples, advances in recognition of self-governance, land and resource sovereignty, and resource co-management, particularly in the North American Arctic but also elsewhere, provide a strong basis for responding to climate impacts (Ford et al., 2015; Robards et al., 2018). These developments expand the solution space (Haasnoot et al., 2020) for responding to climate impacts, although historical and on-going forms of colonialism in research and government institutions continues to undermine Indigenous self-determination and reinforce climate change vulnerability (Marino and Lazrus, 2015; Whyte et al., 2019; Ford et al., 2020; Snook et al., 2020). Readiness for adaptation across Arctic nations continues to be challenged by a number of factors including the existence of pressing socio-economic challenges, institutional and governmental barriers, lack of meaningful inclusion of Indigenous knowledge in government planning and response, and lack of financial resources (Ford et al., 2015; Loring et al., 2016; AMAP, 2017; Ford et al., 2017; Birchall and Bonnett, 2019) (AMAP, 2018a). In Alaska, for example, the need to relocate high risk villages has been recognized by researchers, decision-makers, and communities themselves for some time, and while progress is being made in some locations (Ristroph, 2017), institutional barriers have generally resulted in negligible progress (Bronen and Chapin, 2013; Marino and Lazrus, 2015; Albert et al., 2018; Rosales et al., 2021).

CCP6.5 Summary and Conclusion

Rapid changes occurring in polar systems are clear and unequivocal, indicating that swift and effective responses are urgently needed to avoid substantial future impacts and reduce risks to polar social and ecological systems. Some underlying principles emerge from this assessment that appear fundamental to achieving climate resilient development in polar systems (Figure CCP6.8) because they could facilitate rapid, equitable and just responses to achieve climate resilience. These principles include having locally relevant and accessible tools and services (e.g., regional forecasts and projections) to support climate-informed decision-making, along with adequate and appropriate resourcing (including finance and integrated planning) for climate adaptation and for responding to emergencies. Effective decision-making processes integrate across sectors, all levels of governance, including through multinational instruments, and, most importantly, apply low cost and inclusive participatory processes to address gender, equitable and socially just outcomes. In the Arctic, there is evidence that overcoming colonialism through meaningful and explicit inclusion of Indigenous knowledge in research and resource management, as well as co-management and self-determination in decision-making, are effective measures to support equitable climate resilience across multiple sectors. Lastly, climate resilience is strongly dependent on both mitigation of climate change as well as effective adaptation to meet the challenges of unprecedented change in polar regions.

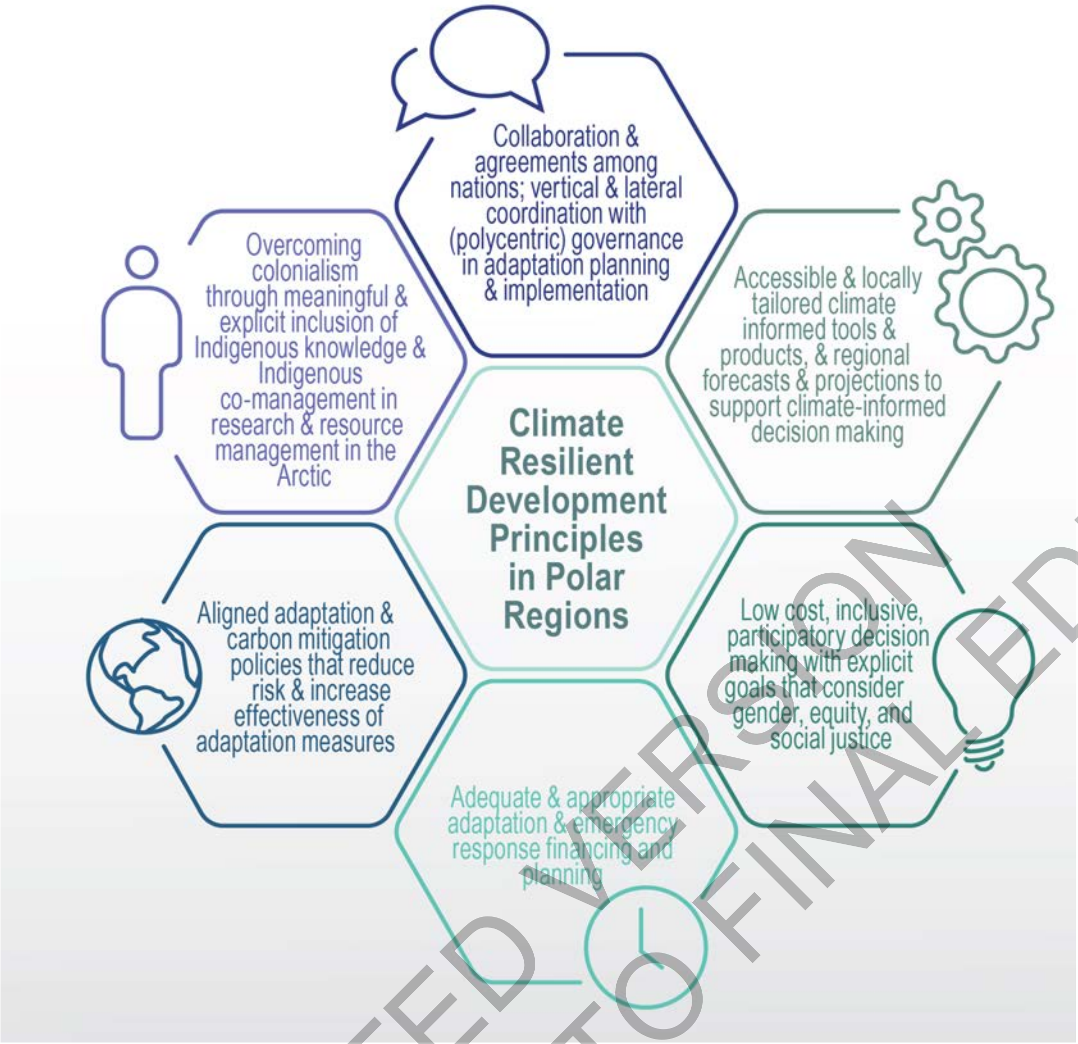

Figure CCP6.8: Six principles that support climate resilient pathways in the polar regions.

Date of Draft: 1 October 2021

Notes: TSU Compiled Version

Table of Contents

Executive Summary

Over 420 million ha of forest were lost to deforestation from 1990 to 2020; more than 90% of that loss took place in tropical areas (*high confidence*), threatening biodiversity, environmental services, livelihoods of forest communities and resilience to climate shocks (*high confidence*[1]). Forty five percent of the world's forested areas are in the tropics, and they are amongst the most important regulators of regional and global climate, natural carbon sinks and the most significant repositories of terrestrial biomass. They are of immeasurable value to biodiversity, ecosystem services, social and cultural identities, livelihoods, and climate change adaptation and mitigation {CCP7.2.1; CCP7.2.2; Box CCP7.2; Table CCP7.2}

Climate change affects tropical forests through warming and increased occurrence of extreme events such as droughts and heat waves, as well as more frequent fires, which increase tree mortality and reduce tree growth, limiting the ability of forests to regenerate (*high confidence*). Climate change is altering the structure and species composition of tropical tree communities (*high confidence*), including transitions from moist to drier forest in regions such as the Amazon (*high confidence*), and movement of species from lower to higher elevations (*high confidence*). Despite CO_2 fertilization, ongoing climate change has weakened the carbon sink potential of tropical forests in Amazonia and, to a lesser extent, in Africa and Asia (*medium confidence*). {CCP7.2.3; CCP7.3}

Large-scale tropical deforestation affects regional to continental scale climates with significant impacts on forest resilience (*high confidence*). Deforestation generally reduces rainfall and enhances temperatures with effects depending on scales (*high confidence*), while often increasing surface runoff (*medium confidence*). Continued deforestation-driven landscape drying and fragmentation will aggravate fire risk and reduce forest resilience, leading to savannization of the tropical forest biomes, in particular in combination with climate change (*high confidence*). {CCP7.3.6}

Implementing sustainable management strategies can improve the ability of tropical forest ecosystems to adapt to climate change (*high confidence)*, and the benefits of adaptation interventions often outweigh the costs (*medium confidence*). Adaptation of tropical forests to climate change provides an opportunity for tropical countries to develop forest policies that create incentives for environmental services such as carbon storage and biodiversity refugia. Forest restoration using a diverse mix of native species can help rebuild the climate resilience of tropical forests, but is best implemented alongside other sustainable forest management strategies and adaptation interventions (*high confidence*) {CCP7.5; Box CCP7.1}

Community-based adaptation, built on Indigenous Knowledge (IK) and Local Knowledge (LK) over centuries or millennia, is often identified as an effective adaptation strategy to climate change (*high confidence*). For successful adaptation of tropical forest communities, it is vital to consider IK and LK in addition to modern scientific approaches, together with consideration of non-climatic vulnerabilities (e.g., poverty, gender inequality and power asymmetries) (*high confidence*) Climate change vulnerability and adaptive capacity have a historical and geopolitical context, conditioned by value systems and development models. Transformative and sustainable practices are required for effective management of tropical forests (*high confidence*) {CCP7.4; Box CCP7.1}

Building resilience of tropical forests to climate change relies on adaptation in combination with reduction of direct and underlying drivers of deforestation and forest degradation (*high confidence*). Tropical deforestation is largely driven by agriculture, both from subsistence farming and industrial agriculture (e.g., oil palm, timber plantations, soybeans, livestock) (*high confidence*). While poverty and population growth combined with poor governance fuel subsistence agriculture (*high confidence*), industrial agriculture is often driven by international market forces for commodities and large-scale land acquisitions (*high confidence*). {CCP7.2.3}

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

Governance responses to addressing the direct and underlying drivers of deforestation have been inadequate to reduce pressures, yet the complexity of tackling drivers of forest loss and degradation is increasing as climate impacts on forests and ecosystems increase (*high confidence*). Transformative levers towards improving environmental governance and resilience of tropical forests include: incentivizing and building capacity for environmental responsibility and discontinuing harmful subsidies and disincentives; reforming segmented decision-making to promote integration across sectors and jurisdictions; pursuing pre-emptive and precautionary actions; managing for resilient social and ecological systems in the face of uncertainty and complexity; strengthening environmental laws and policies and their implementation; acknowledging land tenure and rights; and inclusive stakeholder participation (*medium confidence*). {CCP7.6}

CCP7.1 Introduction

Climate change is already impacting tropical forests around the world, including through distributional shifts of forest biomes, changes in species composition, biomass, pests and diseases and increase in forest fires (*high confidence*). These impacts are often compounded by non-climatic factors such as conversion of land for other uses, burning to clear land, mining, and road and infrastructure development. It is notable that, despite societal awareness and financial opportunities to restore forests (Brancalion and Chazdon 2017), tropical forests are increasingly threatened. For instance, the conversion of tropical forests to large-scale agricultural production (mainly soybeans, oil palm, maize, cotton, livestock), is amongst the strongest drivers of species richness decline of both flora and fauna, thereby impacting the adaptation opportunities of ecosystems and local people to climate change (IPBES 2018). Reducing direct and indirect drivers of deforestation and forest degradation is therefore critical to building, maintaining or enhancing the resilience of tropical forests against climate and non-climate drivers alike (*high confidence*).

With climate change-related drivers becoming increasingly important in the future, changes to tropical forests will most *likely*[2] be aggravated overall, although some tropical forests may temporarily benefit, physiologically, from higher temperatures and changes in precipitation patterns. To the degree to which forests are affected by climate change and other drivers, their resilience against these stressors is diminishing leading to a reduction in the regulating, supporting, provisioning and cultural ecosystem services they provide (Alroy 2017; Cadman et al. 2017; Pörtner et al. 2021) (Chapter 2) (*high confidence*). This, in turn, is affecting the lives and livelihoods of millions of people who depend on forests and their products, in particular forest dwelling communities, but also, via the teleconnections between forests and surrounding areas of influence, in socio-ecological systems outside the forests themselves.

While strong mitigation efforts are fundamental to minimizing future climate impacts on forests, forest management can be improved in many places in support of enhancing the resilience of tropical forests, often with significant co-benefits for carbon storage, biodiversity, food security and ecosystem services (*high confidence*). Sustainable management practices allow forests to be utilized, frequently with equally high or even higher productivity levels, while keeping their core functions intact. While there are numerous approaches to managing forests and forest landscapes sustainably, an element that appears to be critical are property rights and tenure arrangements allowing stewards of the land, including Indigenous Peoples, securing long-term access and utilization of forest resources *(medium confidence)* (Rahman and Alam 2016 and Naughton-Treves 2014).

The interconnections of climate risks and non-climate drivers facing tropical forests, their impacts on rates and extent of deforestation and forest degradation, loss of ecosystem services and biodiversity, leading to unsecured human well-being, contrasts with the sustainable forest management on protecting forest ecosystems and enhancing their resilience against these drivers are framed in Figure CCP7.1. The conceptual framework not only illustrates the complexity and scale of the challenge, but also provides opportunities to mitigate impacts at different scales, whereas eliminating the underlying drivers, both climate and non-climate related, must be the goal of policies and measures at global, national and subnational levels, involving state and non-state actors alike.

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term ‘*likely* range’ to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

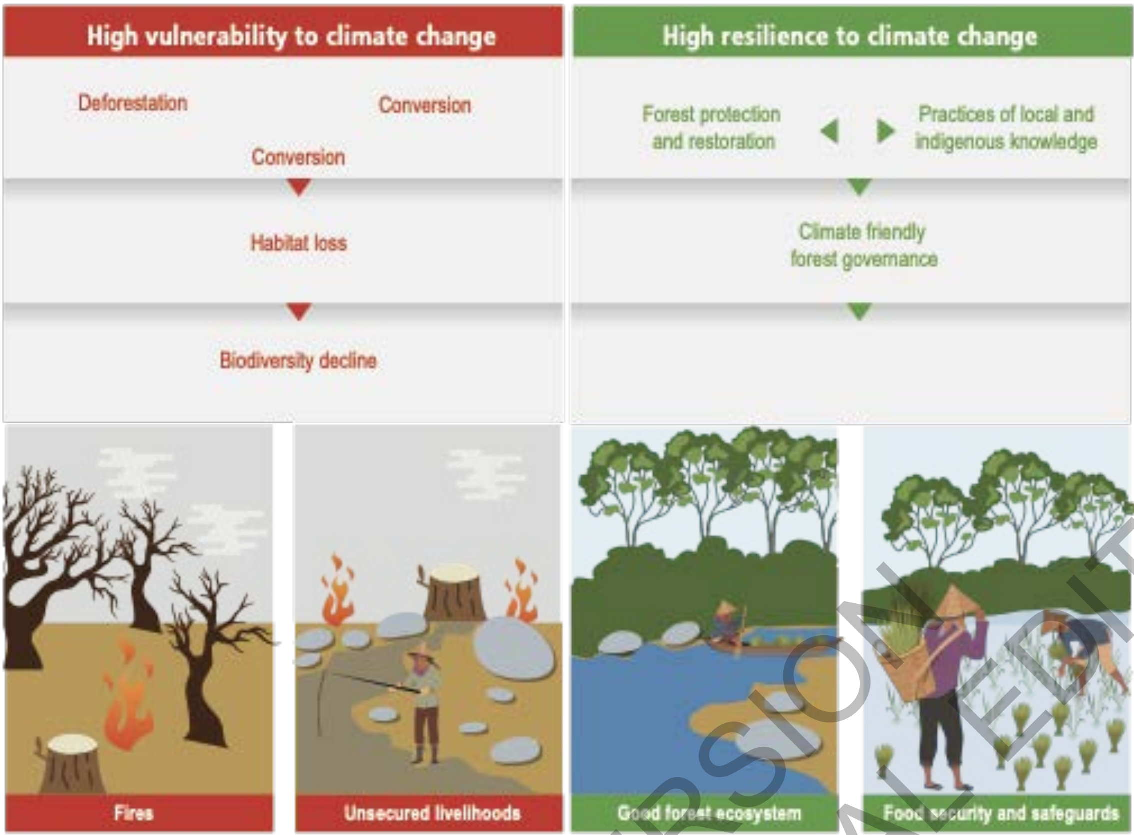

Figure CCP7.1: Impacts of climate change and human disturbances on tropical forests lead to high risk of biodiversity loss and uncertainty of livelihoods for the majority of forest dependent communities (left side). Good forest governance would increase the resilience of tropical forest through better adaptation and mitigation to climate change (right side)

Building on what has been presented in IPCC AR5, SR15, and SRCCL, section 7.2 of this Cross-Chapter Paper first briefly describes the types and extent of tropical forest ecosystems and then looks at current rates and drivers of deforestation and forest degradation. Section 7.3 presents current and projected climate change impacts on tropical trees and forests, focusing primarily on drought, heat and fires, looking from physiological responses to risks, projected climate change impact, and forest resilience. Section 7.4 addresses the impacts of climate change and tropical forest destruction on the livelihoods and well-being of communities and peoples living in or being strongly dependent upon tropical forests. This section includes a Box on Indigenous Knowledge and Local Knowledge and Community-based Adaptation. Section 7.5 assesses adaptation options for the sustainable management of tropical forests drawing upon the protection, management and restoration framework, and includes a Box on the connection between sustainable forest management and the United Nations Sustainable Development Goals. Section 7.6, finally, assesses opportunities and challenges of tropical forest governance to maintain and enhance resilience against climate change impacts on forests.

CCP7.2 The Current State of Tropical Forests

In the most recent Global Ecological Zones map produced by the Food and Agriculture Organization (FAO) for the year 2010, tropical vegetation has been defined as encompassing regions which are frost-free during all months in the year (FAO 2012). Further, the tropical vegetation has been sub-classified into tropical rainforest, tropical moist forest, tropical dry forest, tropical shrubland, tropical desert, and tropical mountain systems based on climate in combination with vegetation physiognomy and orographic zone (Table SMCCP7.1). IPCC has used the basic FAO classification in its National Greenhouse Gas Inventories Guidelines (IPCC 2019).

Since the FAO ecological zones represent potential biome extents, the present area under forest is assessed using the European Space Agency Climate Change Initiative Land Cover dataset (ESA 2017). The ESA dataset provides a direct mapping to IPCC land categories (e.g., "forest"), allowing for standardized and consistent reporting of existing forest and forest gain/loss in each ecological zone. The most extensive tropical ecological zone is the tropical rainforest (1,459 Mha or about 25% of all tropical ecological zones), followed by tropical desert (which is not further considered here), tropical moist forest, tropical shrubland, tropical dry forest and tropical mountain system (Table CCP7.1; Figure CCP7.2). Mangroves are not explicitly considered in the FAO classification. Tropical rainforest occurs largely in South America, Africa, and South and South East Asia, and is the most intact tropical forest biome (Table CCP7.1). Significant portions of tropical moist forest, which abuts tropical rainforest in many regions but experience a longer dry season, have been lost in most regions (Table CCP7.2). Tropical moist forest typically grades into the highly-threatened tropical dry forest ecological zone, of which only about a third exists under forest cover at present. Only about 44% of tropical mountain systems, which occur approximately above 1000 m above mean sea level, are presently under forest cover. While the FAO classification provides the potential tropical ecological zones (roughly, "vegetation types"), there are large differences in the extents of global tropical forest biomes which are still remaining as reported by different sources (Sayre et al. 2020; Ocón et al. 2021). These differences result from differences in biome definition, data source, the definition of "forest," and the method used for classifying remotely-sensed data. For example, the reported global area of tropical dry forests ranges from 105 Mha to 645 Mha (Pan et al. 2013; Bastin et al. 2017; Ocón et al. 2021).

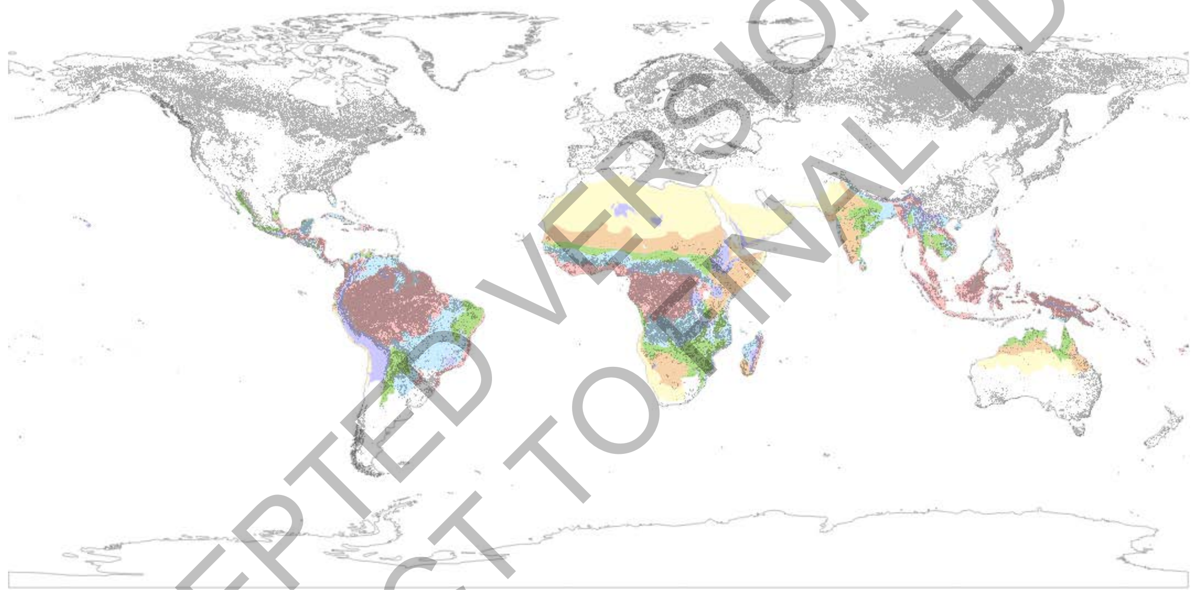

Figure CCP7.2: Colours represent tropical ecological zones as defined by the FAO (FAO 2012) Areas classified as "Forest" in the 2020 ESA Land Cover CCI Product (ESA 2017) are overlaid in grey.

Table CCP7.1: Areas in tropical ecological zones as defined by the FAO (FAO 2012). [1]Existing forest represents areas classified as "Forest" in the 2020 ESA Land Cover CCI Product (ESA 2017). All units are in million hectares, except where indicated.

Ecological zone	Africa	South America	North America	Asia	Australia	Oceania	**Global**	**Existing forest[1]**	**Existing forest (%)[1]**
Tropical rainforest	399	659	48	323	3	13	**1459**	**1140**	**78.2**

Tropical mountain system	147	188	16	90	0	2	**443**	**194**	**43.9**

CCP7.2.1 Distribution and Biodiversity of Tropical Forest Ecosystems

Tropical forests are indisputably the areas with highest biological diversity on Earth, both in absolute and density (species per area) terms (Plotkin et al. 2000). Estimates account that tropical forests harbor half or even more of world's biodiversity (Kier et al. 2009; Jenkins et al. 2013), even though this figure is highly uncertain owing to varying estimates of undescribed species (Mora et al. 2011). For example, it is estimated that there are at least 40,000, but possibly more than 53,000 tree species in tropical forests (Slik et al. 2015). A vast majority of this biodiversity and Indigenous Knowledge and Local Knowledge associated with its use remains poorly explored, presenting a vast unlocked genetic reserve at risk of loss, although many of today's important medicines, foods, and ecosystem products originate from tropical forests (Kouznetsov and Amado Torres 2008; Calderon et al. 2009), staple foods (Brondízio 2008; Isendahl 2011) (Maia and Mourão 2016).

Rates of global biodiversity loss in the past few decades have accelerated to levels that are, for some taxa, approaching the estimated rate of 75% of taxa extinction found in Earth's "big five" mass extinction events (Barnosky et al. 2011) (Díaz et al. 2019) (Davison *et al.*, 2021). Even though species-area relationships tend to overestimate extinction rates (He and Hubbell 2011). , there is evidence that species richness in tropical forests is alarmingly approaching or surpassing the taxa extinction value in this period (45% for dung beetles, 51% for lizards, 65% for ants, and 80% for mammals) should deforestation and habitat loss continue at the current pace (Alroy 2017) (Ceballos et al. 2017). Moreover, there is reasonable understanding that these numbers are underestimated and, as such, tropical forest loss and degradation alone will precipitate a sixth mass extinction event (Giam 2017). A total of 13 out of the 25 global biodiversity hotspots for conservation are located in tropical forests, such as Brazil's Atlantic Forest and India's Western Ghats/Sri Lanka (Myers et al. 2000). While forest loss and degradation have been the main cause of tropical biodiversity loss in the past, climate change now arises as a major threat not only for individual tropical forest species or taxa – as already observed for frogs (Pounds et al. 2006) - but for whole communities (Esquivel-Muelbert et al. 2019), and even entire tropical forest ecoregions (Lapola et al. 2018).

CCP7.2.2 Rates of Deforestation, Tropical Reforestation and Connections to Climate Resilience of Tropical Forests

More than 420 million ha of forest were lost globally in the 1990-2020 period due to deforestation, and more than 90% of that loss took place in tropical areas (FAO 2020). For the 2015-2020 period, the tropical deforestation rate decreased compared to 2010-2015, being estimated at 10.2 Mha yr-1 (FAO 2020). But reforestation and afforestation rates have also decreased, resulting in a tropical forests net loss rate of 7.3 Mha yr-1 in the 2015-2020 period. Overall, the net loss rate has slightly decreased (-4%) since 1990 (*high confidence*). However, a particularly high upward trend is observed in Central America and the Caribbean while a small increase (2%) is observed in the tropical zone of Africa, during the periods from 2010-2015 to 2015-2020 (see Table CPP7.2).

Table CCP7.2: Trends in net tropical forest loss, reforestation and expansion rates (1000 ha yr-1) from 2010-2015 to 2015-2020 periods by regions.

	Net loss rate			Reforestation rate			Forest expansion rate

CCP7.2.3 Drivers of Deforestation and Forest Degradation

Deforestation and forest degradation both affect carbon stocks, biodiversity loss and the provision of ecosystem services, leading to a reduction in resilience to climate change and exacerbating forest landscape vulnerability even in the absence of direct anthropogenic action (*high confidence*) (Barlow et al. 2016; Aleixo et al. 2019; X. Feng et al. 2021; Saatchi et al. 2021). There is also clear evidence of deforestation influencing temperatures and the hydrological cycle at local to regional scales resulting in reduced precipitation and evaporation and increased runoff relative to unaffected areas (*high confidence*) [CCP7.3.6] (Jia et al. 2019; Douville et al. 2021). Negative trends in biodiversity and ecosystems are predicted to undermine 80% of the Sustainable Development Goals targets related to poverty, hunger, health, water, cities, climate, oceans and land(IPBES 2019). Therefore, besides GHG mitigation, reducing the driving forces leading to deforestation and forest degradation is of the utmost importance for forest resilience, biodiversity protection, avoiding regional climatic changes and the provision of critical ecosystem services, and communities whose livelihoods depend on forests (*high confidence*) (Curtis et al. 2018; IPBES 2019; Jia et al. 2019; Seymour and Harris 2019; Pörtner et al. 2021; Saatchi et al. 2021).

Drivers of deforestation and forest degradation can be distinguished between proximate (i.e. direct) and underlying (i.e. indirect). Direct drivers, such as agriculture (including crops, livestock and plantation forestry), infrastructure development (which often provides access to intact forests and catalyzes deforestation), or timber extraction, are place-based and visible. They are influenced by underlying driving forces, such as demographic, economic, technological, political and institutional, or cultural factors, which typically form complex interactions and act at multiple scales, frequently without any direct connection to the areas of forest loss (Geist and Lambin 2002).

Agriculture is by far the largest direct driver of tropical deforestation, with great differences between commercial and subsistence farming and large variation across regions (Figure CCP7.3). Over 80% of tropical deforestation between 2000 and 2010 was caused by agriculture, proportionally ranging from ca. 75% in Africa and Asia to ca. 95% in the Americas (FAO and UNEP 2020), but both the scale of deforestation and the relative contribution of different drivers have changed considerably over time (*high confidence*) (Hosonuma et al. 2012; Curtis et al. 2018; Seymour and Harris 2019; FAO and UNEP 2020).

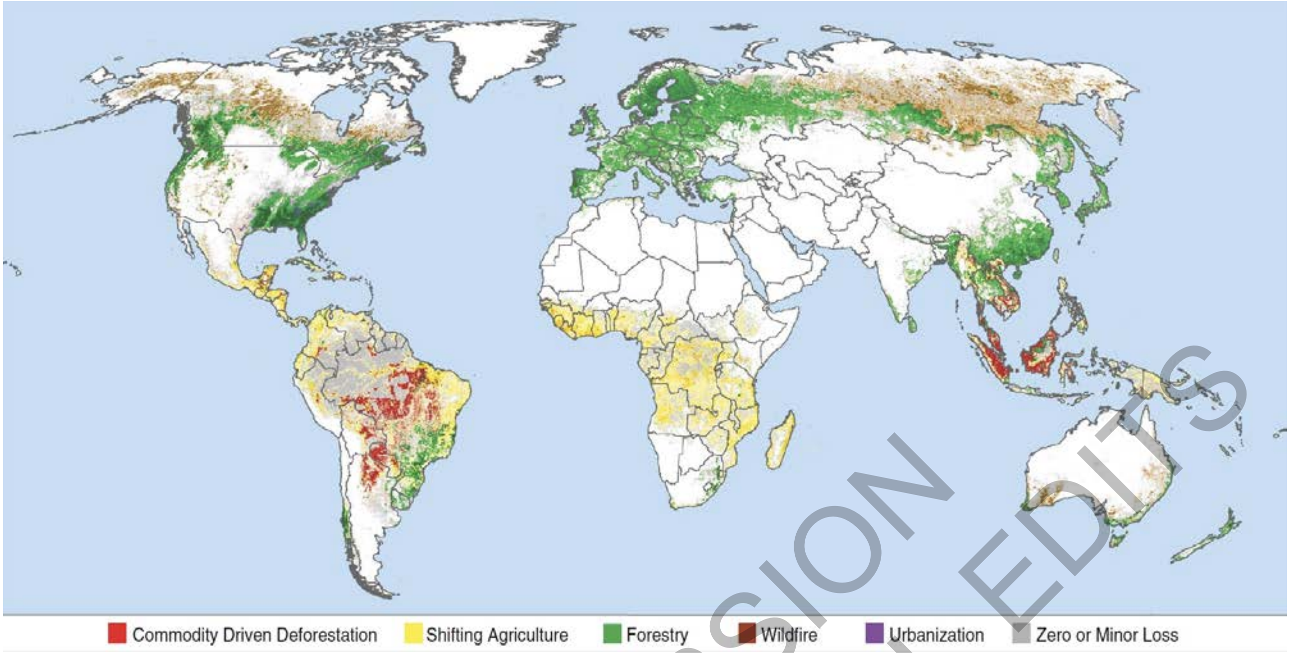

Figure CCP7.3: Primary drivers of forest cover loss for the period 2001 to 2015. Darker color intensity indicates greater total quantity of forest cover loss. While some tropical forest cover loss is temporary, a large portion is related to deforestation. Source: (Curtis et al. 2018). Reprinted with permission from AAAS.

Forest degradation is more difficult to track, but can have large negative effects on carbon storage, provision of ecosystem services, and biodiversity (B. W. Griscom et al. 2017; Houghton and Nassikas 2017). A recent analysis suggests that forest degradation is increasing and is now surpassing deforestation rates in the Brazilian Amazon (Aparecido Trondoli Matricardi et al. 2020). As with deforestation, drivers of forest degradation differ by region, such that timber extraction was by far the most important degradation driver in Latin America and Asia, whereas in Africa wood fuel consumption contributed to about half of forest degradation between 2000 and 2010 (Hosonuma et al. 2012).

Though not as visible as direct drivers, indirect or underlying causes can greatly influence direct drivers, and must be addressed to reduce pressures on forests (*high confidence*) (e.g. FAO 2016b; Fehlenberg et al. 2017; Pendrill et al. 2019b; Bos et al. 2020; Junquera et al. 2020; Ken et al. 2020; Kissinger 2020; Siqueira-Gay et al. 2020; Hoang and Kanemoto 2021). Next to population growth, poverty and insecure land tenure (Ariti et al. 2015; Arevalo 2016; FAO 2016a; Ken et al. 2020; Siqueira-Gay et al. 2020; Verma et al. 2021), many developing tropical countries identify weak forest sector governance and institutions, lack of cross-sectoral coordination, and illegal activity (related to weak enforcement) as critical underlying drivers (FAO 2016a; Ken et al. 2020; Kissinger 2020) [CCP7.6].

International and market forces, particularly commodity markets and, increasingly, large-scale land acquisitions are also key underlying drivers (*high confidence*) (Assunção et al. 2015; Henders et al. 2015; Conigliani et al. 2018; Ingalls et al. 2018; Garrett et al. 2019; Pendrill et al. 2019b; Kissinger 2020; Neef 2020; Hoang and Kanemoto 2021) [WG2 Chapter 5.13]. Deforestation related to commodity imports is increasing, illustrating the growing influence of global markets in deforestation dynamics (Henders et al. 2015). Although some of this production is consumed domestically, 29–39% of deforestation was driven by international trade, primarily from Europe, China, the Middle East and North America (Pendrill et al. 2019a). While many developed countries, China and India have achieved net domestic forest gains, their consumption patterns have increased deforestation embodied in their imports to varying degrees, frequently from biodiversity hotspots (Hoang and Kanemoto 2021). Fifty percent (50%) of the biodiversity loss associated with consumption in developed economies occurs outside their territorial boundaries (Wilting et al. 2017). The increasing prominence of medium- and large-scale clearings of forest between 2000–2012, particularly in Southeast Asia and South America suggests the growing need for policy interventions targeting industrial-scale agricultural commodity producers (Austin et al. 2017). However, countries have been slow to address underlying drivers such as international demand for agricultural commodities. A review of 43 countries' REDD+ readiness documents found that proposed policy interventions largely missed the agricultural drivers identified (Salvini et al. 2014). An assessment of policy responses to rubber and coffee production highlights the challenges governments face in identifying correlations between the direct drivers and related underlying drivers, with international drivers being the most challenging to address (Kissinger 2020).

CCP7.3 Current and Projected Climate Change Impacts on Tropical Forests (Drought, Temperature, Extreme Events)

While early dynamic global vegetation models predicted biome shifts and contractions of tropical forests, more recent efforts have focused on biome changes at more regional scales, or on functional aspects of tropical forests, such as plant physiological and phenological changes, drought-related mortality, population dynamics, interspecies interactions and community responses, ecohydrology, risk of fire and related impacts, soil nutrient and microbe-plant interactions. Climate change is expected to increase temperatures across the tropics, with attendant variability in rainfall, and more extreme events such as intense storms, droughts and wildfires (Zelazowski et al. 2011; Malhi et al. 2014; Brando et al. 2019). This could be expected to have structural and functional impacts on tropical forest biomes (Malhi et al. 2014; Adams et al. 2017). This section looks at responses of tropical trees and forests to current and future climate-change related pressures, focusing on physiological responses including growth, mortality and regeneration, fire risk, and ecological vulnerability, as well as on climate effects of tropical forest loss.

CCP7.3.1 Tropical Tree Physiological Responses to Climate Change

With rising temperatures and atmospheric carbon dioxide, possibly accompanied by greater variability in soil moisture availability, a key question is how tropical forest trees respond physiologically (especially photosynthesis and respiration which determine net growth rates) and how well they can acclimate (i.e., able to adapt) to climate change (Dusenge et al. 2019). Key climate factors influencing tree growth on pan-tropical forests are precipitation, solar radiation, temperature amplitude and relative soil moisture (Wagner et al. 2014).

The temperature response of photosynthetic carbon uptake in tropical trees seems remarkably similar across moist and dry forest types as well as for light-demanding, fast-growing species compared to shade-tolerant, slow-growing species (Slot and Winter 2017). It is generally agreed that photosynthesis in tropical species can acclimate to moderate levels of warming but beyond this there would be no net gain in carbon (Slot and Winter 2017). The factor that limits photosynthesis in different tropical forests will depend on water-availability. In water-limited dry forests, photosynthesis may decline largely due to stomatal closure, while in wet forests, the decline may largely be driven by warming-related changes to leaf biochemistry (Slot and Winter 2017). A recent modelling approach suggests that the limits of photosynthetic thermal acclimation may be an increase of about 2˚C, in terms of maximum tolerated temperature, with enhanced tree mortality beyond this level of warming (Sterck et al. 2016).

A critical concern for plant function has been that higher temperatures will enhance respiration rates, potentially resulting in tropical forests becoming net carbon sources (rather than photosynthesis driven carbon sinks) (Gatti et al. 2021). Some studies suggest that excessive respiration is less of a concern as respiration rates can acclimate to elevated temperatures over time (Lombardozzi et al. 2015; Pau et al. 2018). Thermal acclimation of respiration has been shown in a seasonally dry neotropical forest (Slot et al. 2014), while models indicate that increases in plant respiration could halve by the end of the 21st century through acclimation, thereby partly ameliorating the potential release of carbon from tropical forests (Vanderwel et al. 2015). A contrary view is that plant physiological processes, such as the photosynthesis in tropical canopy trees, are already functioning at levels close to or beyond their thermal optimum limits and that any further temperature increase would turn them from a sink into a carbon source (Mau et al. 2018)
One of the most pressing questions regarding forest responses to increasing atmospheric CO2 levels is whether trees experience enhanced growth rates as a result of the so-called CO2 fertilization effect [Box 2.3

in IPCC SRCCL]. Observed changes in the terrestrial carbon sink and process-based vegetation models indicate that tropical vegetation response to CO2 fertilization (Schimel et al. 2015) is combined to other factors such as nitrogen deposition and length of the growing season, while aerosol-induced cooling may also have played a role in enhancing carbon sink [Box 2.3 in IPCC SRCCL]. Contrastingly, evidence for CO2 fertilization of growth in individual tropical tree species is generally lacking or controversial (Silva and Anand 2013), or not as substantial as expected (Sampaio et al. 2021). It is however widely agreed that the intrinsic water-use efficiency of a tree, i.e. the amount of carbon assimilated as biomass per unit of water used, increases under elevated atmospheric CO2 levels due to the regulation of stomata (cells on the leaf surface which regulate the exchange of water and gases between the plant and the atmosphere) (Van Der Sleen et al. 2015; Bartlett et al. 2016; Rahman and Alam 2016; Keeling et al. 2017). Tropical dry forests (c. 1000mm annual rainfall) exhibit changes in water-use efficiency (WUE), relative to CO2, at least twice as much as do tropical moist forests (c. 4000mm rainfall) (Adams et al. 2019).

Other key components in the forest system are plant-microbe-soil nutrient interactions, which play major roles in carbon cycling and plant photosynthetic response to increased atmospheric CO_2 and warming (Zhang et al. 2014; Singh and Singh 2015; Du et al. 2019). Phosphorus is generally a limiting factor in tropical forest soils though this may be species-specific (Ellsworth et al. 2017; Turner et al. 2018). Mycorrhizal fungi (both arbuscular and ectomycorrhizal) play major roles in water acquisition of host plant and their responses to drought in dry tropical forest (Lehto and Zwiazek 2011) as well as in the capture and transfer of nutrients, especially N (which may otherwise become limiting), to host plants. Climate change factors can thus be expected to alter the nature of soil-plant interactions with consequences for the species composition and biodiversity of tropical ecosystems (Pugnaire Francisco et al. ; Terrer et al. 2019)

CCP7.3.2 Climate-Related Mortality and Regeneration in Tropical Forests

Drought-related mortality of tropical trees shows complex patterns which could change forest community structure and composition with cascading effects on biodiversity (McDowell et al. 2020). During drought, the mortality rate is enhanced in larger-sized trees in tropical forests (as is the case with all forests globally) with significant impacts on forest structure, carbon storage and regional hydrology (Bennett et al. 2015). The mortality rate of neotropical moist forest trees appears to be consistently increasing since the 1980s (McDowell et al. 2020) with plant functional types such as softwood, pioneer and evergreen species suffering higher mortality during years of extreme drought (Aleixo et al. 2019). Large trees (>30 cm dbh) in tropical dry forests have much lower mortality rates than those reported for tropical moist forests (Suresh et al. 2010). Contrary to expectation, during prolonged droughts in these dry forests, deeper-rooted tree species are more *likely* to die than shallow-rooted ones, which are more adapted to changes in soil moisture content, because of water depletion in the deepest unsaturated zone (Chitra-Tarak et al. 2018).

Regeneration of tropical tree seedlings and their response to a changing climate is inadequately understood. Experimental work suggests that tropical moist forest tree seedlings and saplings can acclimate photosynthetically to moderate levels of warming and, unlike adults, may even exhibit increased growth rates (Cheesman and Winter 2013; Slot and Winter 2018) Some moist forest seedlings also show plasticity to recurrent drought episodes by enhancing their growth rates when favorable moisture conditions return, while others fail to respond (O'Brien et al. 2017). The nature of response also seems to be mediated by neighborhood diversity, with greater plasticity in more diverse communities (O'Brien et al. 2017). Seedlings in tropical dry forests subject to burning show enhanced growth rates post-fire and within two years attain similar height of seedlings in unburnt areas (Pulla et al. 2015), though the environmental drivers of seedling growth post-fire are not well understood (Bhadouria et al. 2017).

The net outcome of the population dynamics processes of growth, mortality and regeneration is change in species composition as a consequence of a changing climate. In the Amazon forests, dry habitat-affiliated genera have become more abundant among the newly recruited trees, while the mortality of moist habitat-affiliated genera has increased at places where the dry season has intensified most, thus driving a slow shift towards a drier forest type (Esquivel-Muelbert et al. 2019). A similar multi-decadal shift in West-African forest species composition towards more dry-affiliated species as a response to long-term drying has been recorded (Aguirre-Gutiérrez et al. 2020). While upward shifts in the tree line and in the range of individual tree species have been recorded at several temperate mountain regions, evidence from the tropics is rare. A large-scale study from 200 plot inventories of >2000 tree species across a ~3000m elevation gradient in the

Andean tropics and sub-tropics has shown that the relative abundances of tree species from lower, warmer locations were increasing at these sites indicating that "thermophilization of vegetation" (increased domination of plant species from warmer locations) was indeed taking place as expected (Fadrique et al. 2018) [Section 2.5.4.2.1 in Chapter 2].

CCP7.3.3 Fire Risks from Climate Change in Tropical Forests

Temperature rise and prolonged droughts increase the danger of fires in drained peatlands and tropical forests in South East Asia and the Amazon (da Silva et al. 2018; Pan et al. 2018; Sullivan Martin et al. 2020), resulting in large carbon emissions, which reached 11.3 Tg CO_2 per day during September-October 2015 (Huijnen et al. 2016; Yin et al. 2020) and changes in forest composition and biodiversity (Asner et al. 2000; Hoffmann et al. 2003) *(high confidence*). In many cases, tree mortality due to fire is poorly recorded in the literature, but the available data suggests that fire-induced mortality has increased in recent years (Figure CCP7.2) (Malhi et al. 2014; Brando et al. 2019) *(high confidence*). While large forest and peat fires used to be associated mainly with El Niño Southern Oscillation (ENSO) events, there is now evidence that tropical rainforests in Indonesia may experience higher fire danger from increased temperatures even during non-drought years due to high evaporation rates of fragmented forests (Fernandes et al. 2017; McAlpine et al. 2018). The droughts of 2007 and 2010 in the Amazonian region caused 12% and 5% of the southeastern Amazon forests to burn, respectively, as compared to <1% of these forests burning during non-drought years (Brando et al. 2014; da Silva Júnior et al. 2019; Pontes-Lopes et al. 2021). Moreover, degraded forests in Ghana are more vulnerable to fires during droughts (Dwomoh et al. 2019).

Factors other than solely climate also interact in enhancing the danger of tropical forest fires. For instance, the extent of burned area of rainforests in Borneo has shown that subsurface hydrology, (i.e., hydrological drought), interacts with meteorological drought and, hence, fires have become more intense in recent decades following the progressive desiccation of the island over the past century (Taufik et al. 2017). Bornean forest fire risk also increased through the interaction of drought with land use conversion for logging, oil palm and tree plantations, and human settlements (Sloan et al. 2017). Similarly, simulations of future fire risks in the Amazon show that extensive land use change under the RCP 8.5 scenario results in 4 to 28-fold enhanced area of forest burned by fire by 2080-2100, as compared to 1990-2010, whereas on a RCP 4.5 scenario the area burned would be enhanced by 0.9 to 5.4-fold (Le Page et al. 2017).

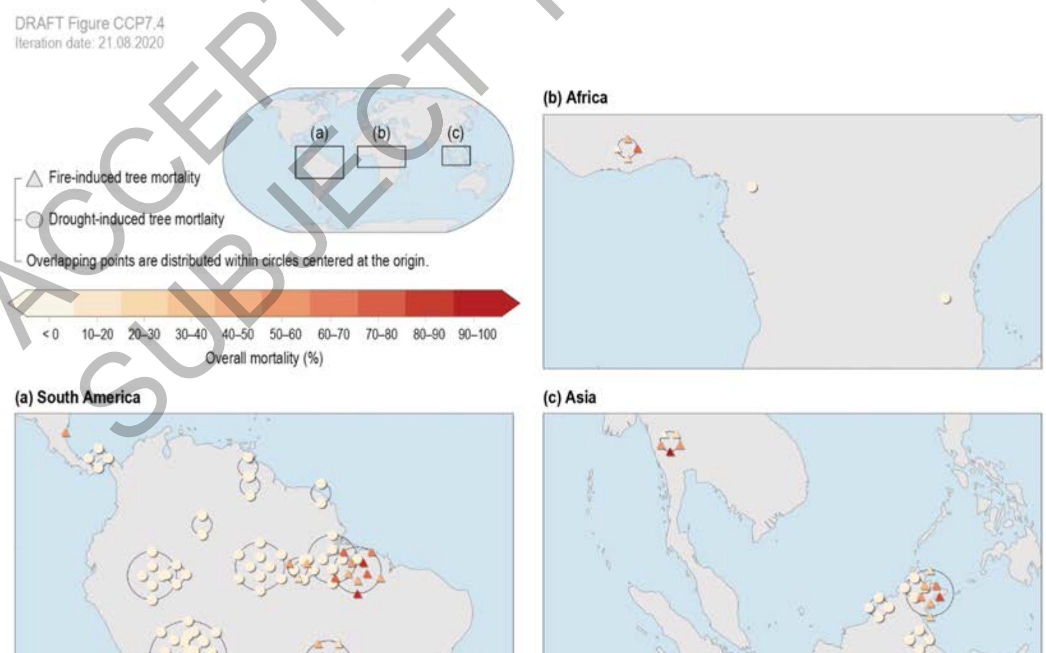

Figure CCP7.4: Documented instances of tree mortality in tropical moist forests due to fire (1992-2016) and drought (1982-2005). These occurrences were associated with anomalies in precipitation and temperature over the study period. Adapted from (Brando et al. 2019).

CCP7.3.4 Current climate risks for tropical forests

Impacts of climate change on tropical forest cover seem to correlate with climatic zone. Natural selection of drought tolerant species is observed in tropical dry forests under a prolonged water deficit environment (Stan and Sanchez-Azofeifa 2019). Tropical montane forests are highly sensitive to warming and associated changes in cloud cover and moisture, with evidence that such forests are already being impacted through "browning" (loss of biomass) from increased warming since the 1990s (Krishnaswamy et al. 2014).

Besides higher temperatures, current climate risks also depend on regional responses to a variety of climate events. For example, tropical biomes across the three continents may respond differently to ENSO events in terms of carbon fluxes and balance. During the 2015-2016 ENSO event, different processes were dominant for the carbon fluxes anomaly in the tropical regions. In Asian forests this anomaly was primarily derived from enhanced fire occurrence, in African forests through increased ecosystem respiration (from higher temperatures), and in South American forests by ecophysiological effects, through the gross primary production (GPP) expressed as reduced carbon uptake (Liu et al. 2017; van Schaik et al. 2018). It has also been shown that the probability of drought spells at the beginning and end of the rainy season is higher in the areas with the highest deforestation (Leite-Filho et al. 2019). Furthermore, it has been observed that Amazon rainforest resilience is being lost faster in regions with less rainfall and in parts of the rainforest that are closer to human activity (IPCC 2014; Seiler et al. 2015) (CCP7.3.6). Conversely, it has been pointed out, on the basis of vegetation indices, that temperature has a greater influence on resilience than does precipitation, and tropical forests are more resilient to climate change when they are more diverse (Feng et al. 2021) (CCP7.3.6).

Biomes such as seasonally dry tropical forests subject to higher variability in rainfall or other climatic factors may be more resilient to fire and drought (Pulla et al. 2015; Liu et al. 2017), though there could be changes in species distributions as a result of disturbances (Allen et al. 2017). A regime of long-term, high rainfall variability seems to be critical in determining the overall resilience of tropical forests and savannas to climate disturbances (Ciemer et al. 2019), highlighting the heterogeneity of the tropical landscape to climate risk. Similarly, forest composition, nutrient limitations, and biodiversity can influence forest resilience to disturbances. Recent evidence suggests that the degree of forest disturbance also affects the mechanisms through which biodiversity influences forest functioning (Schmitt et al. 2020). Neotropical secondary forests also showed high resilience by maintaining their biomass through high productivity and rates of recovery following major disturbances (Poorter et al. 2016). However, the possibility of tropical forests reaching "tipping points" in their resilience and experiencing rapid die-off cannot be ruled out (Verbesselt et al. 2016).

CCP7.3.5 Projected Impacts of Climate Change on Tropical Forest

Climate change projections indicate increased warming and changes in rainfall patterns in the tropical region as elsewhere globally (IPCC AR6 WG1). These would have impacts on carbon stocks (Mitchard 2018; Hubau et al. 2020), water availability (Tamoffo et al. 2019), and structure and diversity (Malhi et al. 2014; McDowell et al. 2020) in tropical forests, amplified by deforestation (CCP7.3.6).

Tropical forests are critical repositories of global carbon; living tropical trees are estimated to hold 200-300 Pg C or about one-third of the levels in the atmosphere (Mitchard 2018). CMIP5 and CMIP6 Earth System Models (ESM) project an increasing future tropical carbon sink, which is particularly strong in the scenarios with more pronounced increase in atmospheric CO2 concentration (Koch et al. 2021). However, major uncertainties regarding the ecophysiological processes governing carbon turnover and tree mortality under a changing climate (Hartmann et al. 2015; Pugh et al. 2020), and the ecosystem-level responses of tropical forests to elevated atmospheric CO2 (Körner 2009) explain the contrast between observational data and modeling results (Rammig and Lapola 2021). Observational data show that structurally intact old-growth tropical forests have been net sinks of atmospheric carbon in recent decades, but there is evidence that the capacity of such intact tropical forests to build up carbon stock may be limited as biomass peaked during the 1990s and has since weakened by 30% in the Amazon since the 1990s (high confidence), mainly due to increased tree mortality and faster carbon turnover, and the African tropical forest sink following this trend since about 2010 (Hubau et al. 2020; Gatti et al. 2021). From a peak pan-tropical (Amazonia, Africa and Southeast Asia) forest sink of 1.26 Pg C yr-1 during the 1990s, it is projected to decline to an uptake of only 0.29 Pg C yr-1, reaching zero, in the Amazon, during the 2030s (Hubau et al. 2020). This decline will possibly be driven by the reduced rates of forest carbon uptake from the weakening global CO2 fertilization effect mediated by limiting soil nutrient, and reduced water availability and higher temperatures during extreme droughts (Qie et al. 2017; Fleischer et al. 2019; Wang et al. 2020), reinforced by deforestation and forest degradation [IPCC SRCCL, 2019].

Offline (uncoupled) vegetation models simulations indicate that the extensive tropical and subtropical forests of the Americas could gradually transit towards a savanna-like vegetation with the most pronounced shifts (of up to 600km northward) from relatively stable forests to savanna-forest transitions occurring in the eastern Amazonian region (Huntingford et al. 2013; Anadon et al. 2014; Nobre et al. 2016) depending largely on the yet uncertain strength of the CO_2 fertilization effect and future dry season length, with important feedbacks on the flux of moisture from the forest to the atmosphere (Delphine Clara Zemp et al. 2017). More limited simulations for Central American rainforests under RCP 4.5 and 8.5 also support a transition in some areas to lower biomass tropical dry forest and savanna-like vegetation (Lyra et al. 2017). Such transitions from one biome type to another will cause major changes in forest structure, species compositions and overall biodiversity. Additionally, the difficulty of species to migrate through highly fragmented tropical forested regions (such as West Africa or South and Southeast Asia) and “non-analogue climates”, under a climate change scenario, poses extra pressure on tropical biodiversity to adapt and survive (Pörtner et al. 2021). Even in expansive tracts of forests such as in the Amazon, climate change is expected to become more important than deforestation by 2050 in causing the loss of tree species (Gomes et al. 2019). Tropical mountain biodiversity hotspots (e.g., Andes, Himalayas) are particularly vulnerable to species loss due to elevation range shifts (Sekercioglu et al. 2008). Under a 2°C increase scenario, a substantial reduction of tropical montane cloud forest in Kenya is estimated (Los et al. 2019).

CCP7.3.6 Climate Responses to Tropical Deforestation and Links to Forest Resilience

Since AR5 there has been meaningful advancement in understanding the climate effects of deforestation and concomitant changes in forest ecosystem resilience. The IPCC Special Report on Climate Change and Land (Jia et al. 2019) and IPCC AR6 WG1 (Douville et al. 2021) both describe significant climate-related changes resulting from tropical deforestation (*high confidence*).

Deforestation generally reduces rainfall and enhances temperatures and landscape dryness; effects that increase with the scale of forest loss, whereas reforestation and afforestation generally reverses these effects (*high confidence*) (Lawrence and Vandecar 2015; Alkama and Cescatti 2016; Khanna et al. 2017; Jia et al. 2019; Staal et al. 2020; Douville et al. 2021; Hofmann et al. 2021; Leite-Filho et al. 2021). There is also *medium evidence* from observations and modeling that deforestation enhances surface runoff (Douville et al. 2021). Whereas quantitative information is much more limited for other tropical regions, past deforestation in the Amazon has led to a small reduction in rainfall of -2.3 to -1.3%, shortening and delay of the wet season, and an estimated 4% increase in dryness (Leite-Filho et al. 2020; Staal et al. 2020; Douville et al. 2021).

Modeling studies estimate that large-scale tropical deforestation will contribute to average warming of the deforested areas with $+0.61 \pm 0.48$°C and will lead to large changes in diurnal temperature ranges due to a reduction of nocturnal cooling (*medium confidence*) (Jia et al. 2019). Large-scale deforestation will also strongly decrease average regional precipitation and evapotranspiration and further delay the onset of the wet season, enhancing the chance of dry spells and intensifying dry seasons, but the magnitude of the decline depends on the scale and type of land-cover change (*high confidence*) (Delphine Clara Zemp et al. 2017; Jia et al. 2019; Douville et al. 2021; Gatti et al. 2021).

Continued forest landscape drying and fragmentation in connection with deforestation may also enhance surface flow variability (Farinosi et al. 2019; Souza et al. 2019) and will aggravate the risk of forest dieback (D. C. Zemp et al. 2017), elevate forest flammability (Alencar et al. 2015) and increase fire incidence (*high* *confidence*) (Aragão et al. 2018; Jia et al. 2019; Silveira et al. 2020; dos Reis et al. 2021), ultimately leading to savannization of many tropical rainforests (Sales et al. 2020). However, compositional heterogeneity and diversity of forest assemblages increases resilience against climate-enhanced forest degradation (Réjou-Méchain et al. 2021).

For the Amazon, deforestation (ca. 40% of the region) in combination with climate change will raise the prospect of passing a tipping point leading to large-scale savannization of the rainforest biome, but but uncertain remains that this will take place in the 21st century (Nobre et al. 2016; Jia et al. 2019; Douville et al. 2021). However, considering that the Amazon has already lost ca. 20% of its forests (Nobre et al. 2016), crossing the tipping point may not only create savannas of the deforested parts but may also result in precipitation reductions of 40% in non-deforested parts of the western Amazon due to a breakdown of the South American monsoonal circulation and the subsequent western cascade of precipitation and evapotranspiration (Boers et al. 2017). Other effects of forest degradation include loss of ecosystem services, biodiversity, carbon storage, and indigenous culture (Watson et al. 2018; Strassburg et al. 2019; Gatti et al. 2021), as well as potentially reduced hydropower capacity and agricultural production (Sumila et al. 2017) and increases in tropical diseases (Husnina et al. 2019).

The dearth of data for tropical forest regions other than the Amazon makes assessments of deforestation-related changes in temperature, precipitation and streamflow difficult (*high confidence*) and hampers estimates of tropical forest ecosystem health, biodiversity loss and vulnerability to current and future climatic and other pressures (*high confidence*). There is, hence, a strong need for increased investment in relevant data and research to narrow the knowledge gaps (Davison et al. 2021). Nonetheless, conclusions based on a newly developed tropical vulnerability index synthesizing remotely sensed land use and climate information indicate that forests in the Americas are already reaching critical levels to multiple stressors, while forests in Asia reveal vulnerability primarily to land-use change and African forests still show relative resilience to climate change (Saatchi et al. 2021).

CCP7.4 Social-Economical Vulnerabilities of Indigenous Peoples and Local Communities Living in Tropical Forests

Around 800 million people live in or in the immediate vicinity of tropical forests (Keenan 2015). Short-term impacts of climate change on biodiversity will exacerbate the inequalities affecting those livelihoods which heavily rely on forests (Pörtner et al. 2021).

Livelihoods, gender, land use change and dependency on forest resources for food, fuel, housing and other needs have been identified as key elements of vulnerability in Indigenous Peoples and rural communities in Africa and South America (high confidence) (Nkem et al. 2013; Field et al. 2014; Newton et al. 2016; Pearse 2017; IPBES 2018; Pörtner et al. 2021). Socio- economic vulnerability varies depending on the level of dependency of forest food consumption (Rowland et al. 2017), livelihood strategies and settlement patterns. In Cameroon (Nkem et al. 2013), nomadic hunter-gatherers and sedentary communities showed differences in their vulnerability, driven by their preferences in forest settlement locations for farming, hunting, fishing, gathering, trapping, and maintaining livestock.

Increasing temperatures, extreme climatic events, drought and fire will affect the proportion and frequency of forest resources availability. In communities of tropical America, Asia and Africa, social vulnerability factors identified include: deforestation pressures for agriculture expansion to cope with climate-induced food shortages, conflicts over access to forest land as a result of uncontrolled fire induced by higher drought frequency and severity, the availability of wild game, the work capacity, and the time consumed in work and gender-based differences (Blaser and Organization 2011; Bele et al. 2013; IPCC 2014). Although the size and quality of harvest in crops and Non-Timber Forest Products (NTFPs) will be affected, the literature reports the use of NTFPs, hunting, and fishing is less sensitive to climate change, and relevant for household incomes (Bele et al. 2013; Djoudi et al. 2013; Newton et al. 2016; Onyekuru and Marchant 2016). Data from tropical forests document the contribution of NTFPs to local livelihoods (Issaka 2018), with well-established NTFPs such as Brazil nut (Bertholletia excelsa), Rattan (Calamus and Daemonorops species), Rubber (Hevea species), Açai (Euterpe oleracea) showing promise for sustainable harvesting strategies which could reduce socio-economic vulnerability (Blaser et al. 2021).

The decrease of tropical forest area due to land use change will put additional pressures, threatening livelihood practices, traditional land arrangements, and customary rights of forest-dependent communities and impacting the Sustainable Development Goals (SDG) of Climate action and Life on Land (Djoudi and Brockhaus 2011; Tiani et al. 2015; Hurlbert et al. 2019). Globalized trade relations, agricultural expansion, illegal activities and violent conflicts have been identified as important non-climatic drivers of forest degradation (*high confidence*) (Barr and Sayer 2012; Rist et al. 2012; Shanley et al. 2012; Ruiz-Mallén et al. 2017; IPBES 2018; IPBES et al. 2018). Globally, about 70% of tropical forest areas occur outside protected areas. In Latin America and the Caribbean, Indigenous Peoples and local communities have predominant ownership of tropical forest lands, while in West and Central Africa and Asia, forested areas are largely State-owned with exacerbating problems of governance, inequity and conflict with customary land tenure systems (Blaser and Organization 2011).

Further research by experts and local stakeholders and Indigenous Peoples is required to design more accurate and comprehensive indicators (Huong et al. 2019). Solid evidence shows important knowledge and experiences that Indigenous Peoples and local communities contribute to disaster risk reduction and management (IPBES 2018a). Recognizing the land rights of Indigenous Peoples is among the most cost-effective actions to address climate and biodiversity risks, according to FAO and FILAC (2021). In Indigenous Peoples' forest lands in the Amazon basin, deforestation rates are up to 50% lower than in other forested areas (Ding et al. 2016), and indigenous management is correlated with reduced carbon emissions (Blackman and Veit 2018). Indigenous authors and local authors have pointed out the role of traditional systems of governance, knowledge and belief systems in the resilience of Indigenous Peoples and rural communities in the Amazonian and Andean region, by regulating seed access and the conservation of agrobiodiversity and tropical forest (Camico et al. 2021; Panduro Meléndez et al. 2021). In Philippines, the traditional land use system Muyong, promote sustainable agroforestry management based on customary land laws (Camacho et al. 2016). Participation of local stakeholders and the inclusion of a gender perspective contribute to prioritizing resource allocation and the development of effective legal frameworks for adaptation (Shah et al. 2013; Tiani et al. 2015; Ihalainen et al. 2017; Collantes et al. 2018). There is a need to combine quantitative and qualitative methods, and increase research efforts to integrated approaches; including multiscalar and interdisciplinary assessments of vulnerability (Djoudi et al. 2013; Guidi et al. 2018; FAO and CIFOR 2019).

[START BOX CCP7.1 HERE]

Box CCP7.1: Indigenous Knowledge and Local Knowledge and Community-Based Adaptation

Purely scientific knowledge, albeit indispensable, is insufficient to address climate change. Indigenous Knowledge systems, embedded in social and cultural structures, are integral to climate resilience and adaptation (*high confidence*) (Ajani 2013; Tengö et al. 2014; Hiwasaki et al. 2015; Roue and Nakashima 2018)[AR5 WG2 12.3.3, 14.3.1, 20.4.2 , SRCCL 4.8.1, 4.8.2, SR15 4.3.5]. Indigenous knowledge and local knowledge (IK and LK) and community-based adaptation (CbA) have received increasing recognition across all sectors (*high confidence*) (Reid and Huq 2014; Wright et al. 2014; MOSTE 2015)[SRCCL 4.1.6, 5.3.5, SR15 Box 4.3] (Figure Box CCP7.1.1). Forest Indigenous knowledge is closely linked to traditional land-use practices and local governance (Roberts et al. 2009); it is embodied in art, rituals, food, agriculture and customary laws, among others (Hiwasaki et al. 2015; Camico et al. 2021). CbA is a community led process based on its desires, priorities, knowledge and capacities; which empowers people as central players in climate change adaptation (Reid et al. 2009) [SRCCL 5.3.5].

CbA is related with concepts such as community and adaptive collaborative forest management. These approaches acknowledge the importance of cultural and socio-economic ties between communities and forests, along with community's authority and responsibility for forest sustainable management (Ajani 2013; Ellis et al. 2015; Torres et al. 2015).

Role of IK and LK and CbA for Climate Change Adaptation in Tropical Forests

Local forest and Indigenous forest management systems have developed over long time periods; generating social practices and institutions that have supported livelihoods and cultures for generations (*high confidence*) (Seppälä 2009; Martin et al. 2010; Parrotta and Agnoletti 2012; Camico et al. 2021).

Archaeological evidence shows that humans have manipulated tropical forests for at least 45 thousand years (*high confidence)*. Indigenous Peoples usually consider themselves as parts of socio-ecosystems, protecting the forest by maintaining healthy socio-ecological relationships and successfully adapting to environmental change (Speranza et al. 2010; Swiderska et al. 2011; Parrotta and Agnoletti 2012; Uprety et al. 2012; Mistry et al. 2016; Roberts et al. 2017) [AR5 WG2 12.3.2].

CbA ensures community engagement in bottom-up management and adaptation approaches (Simane and Zaitchik 2014; Keenan 2015). IK and LK and CbA can enhance adaptation in many ways, including through knowledge generation, ecosystem monitoring, climate forecasting, increased resilience and response to climate extremes and slow onset events (Speranza et al. 2010) [AR5 WG2 12.3.3; SRCCL 4.8.2] (Figure Box CCP7.1.1).

Integration of IK and LK Systems, CbA and Modern Scientific Systems

Several authors have highlighted the need to foster a respectful a dialogue between IK and LK and modern science towards a holistic research model (*high confidence*) (Berkes 2010; Ajani 2013; Tengö et al. 2014; Roue and Nakashima 2018)[AR5 WG2 12.3.3, 14.2.2]; but few ecological studies have attempted this integration (Keenan 2015; Vadigi 2016). Examples in tropical forest ecosystems include topics such as monitoring climate impacts; local climates; seed, water and land management resilience-increasing practices and climate threats to traditional agriculture (Parrotta and Agnoletti 2012; Fernández-Llamazares et al. 2017; Camico et al. 2021; Panduro Meléndez et al. 2021). A growing number of methods are available to help this dialogue [SRCCL 7.5.1] (Reid et al. 2009; Tengö et al. 2014; Tengö et al. 2017; Roue and Nakashima 2018)(Figure Box CCP7.1.1). While there is expanding interest among decision-makers, researchers, Indigenous Peoples and civil society on IK and LK (Hiwasaki et al. 2015; Maillet and Ford 2016), gaps remain regarding links between place-and-culture dimensions and adaptive capacities (Ford et al. 2016).

Enhancing Adaptive Capacity Through IK and K and CbA: Lessons Learned

Useful lessons can be drawn from experience to effectively incorporate IK and LK and CbA in adaptation strategies. A number of barriers to adaptation have also been recognized (Figure Box CCP7.1.1). Considering that IK and LK is increasingly threatened by colonization, acculturation, dispossession of land rights, and environmental and social change, among others [AR5 WG2 12.3.3; SR5 4.3.5] (Seppälä 2009) highlighted the importance of supporting community efforts to document, vitalize and protect it. It is essential to consider goals, identity and livelihood priorities of Indigenous Peoples and local communities, including those beyond natural resource management (Reid et al. 2009; Diamond and Ansharyani 2018; Zavaleta et al. 2018). Adaptation processes are more *likely* to be transformational when they are locally driven (*medium confidence*: *medium evidence, high agreement*) (Chung Tiam Fook 2015; Chanza and De Wit 2016). This requires adaptive institutional frameworks, capable of navigating the complex dynamic of socio-ecosystems (*medium confidence*: *medium evidence, high agreement*) (Locatelli et al. 2008; Simane and Zaitchik 2014)[AR5 WG2 12.3.2; SR15 5.3.1]. It is important to consider power relations and priority differences to avoid causing social disruption and inequality. "We need to keep asking: Who benefits? Who loses? Who is empowered? Who is disempowered?" (Reid et al. 2009).

Finally, vulnerability and adaptive capacity have a historical and geopolitical context, conditioned by value systems and development models. Forest management strategies must take into account the wider picture if they seek to be not just temporally effective (at best), but transformative and sustainable over time (*high confidence)* (Chung Tiam Fook 2015; Chanza and De Wit 2016).

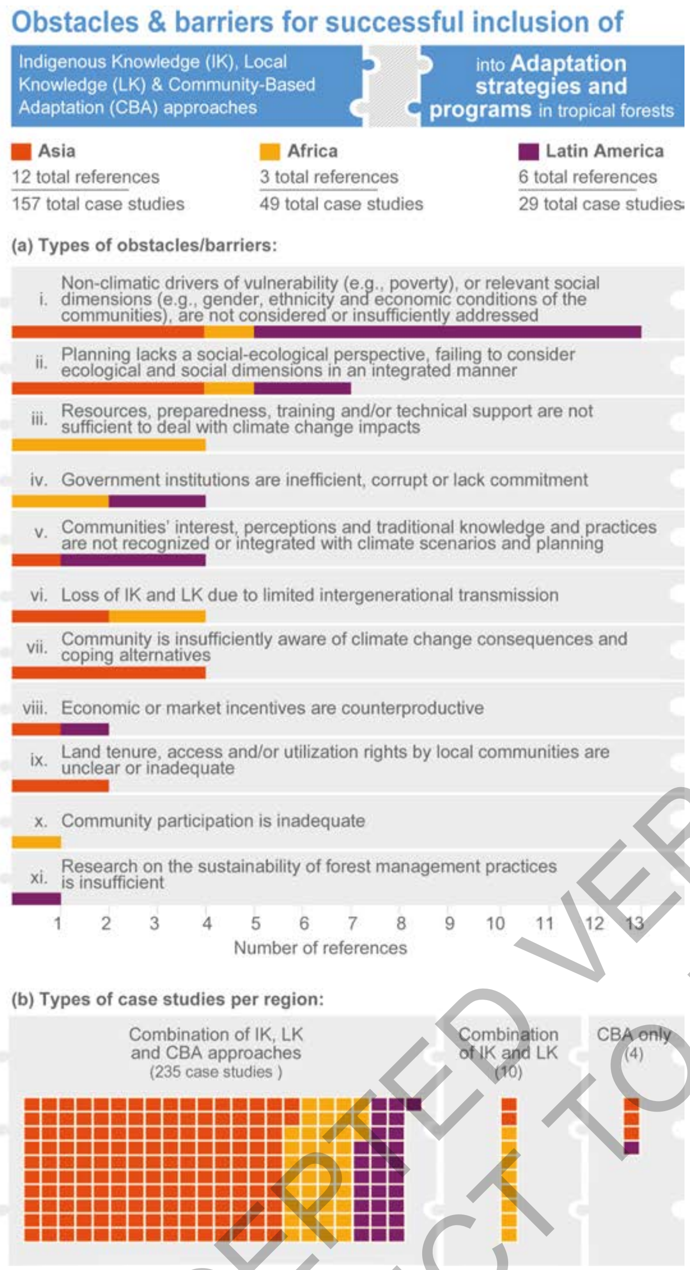

Figure Box CCP7.1.1: Main obstacles and barriers reported for successful IK and LK and CBA approaches in adaptation strategies and programs for tropical forests.
Panel (a): Obstacles and barriers ranked by the number of references in which they were identified. (One reference can identify more than one barrier, so numbers of references by barrier are not additive). Panel (b): Distribution of cases studies according to approach (IK and LK, CBA or a combination of both). One reference can include one or more case studies. See countries included by continent and references in the Supplementary Material (SMCCP7.2)

[END BOX CCP7.1 HERE]

CCP7.5 Adaptation Options, Costs, and Benefits

Ecological adaptation and other spontaneous responses to climate change are discussed in (Settele et al. 2015) and [AR6WGII_Ch2]). Here we consider the role of humans in managing the adaptation of tropical forests to climate change. The focus is on human-assisted adaptation options that help to maintain tropical forest ecosystems and not on the use of forests to supply provisioning services, such as timber, which is covered in [AR6 WGII_Ch5]. Forest management and agroforestry are discussed, but only with regard to their role in contributing to the adaptation of tropical ecosystems now and in the future. Maintaining ecosystems has a range of co-benefits for humans including through 'ecosystem-based adaptation' these are explored in [Chapter 1 Box 1.3; Cross-Chapter Box NATURAL in Chapter 2, Box CCP7.2]. Although there are a number of potentially valuable response options, it is clear that certain hazards, such as heat waves, may be impossible to manage at the forest community level and require long-term interventions at the landscape scale. Similarly, it will be difficult for forest managers to adapt to indirect climate-related ecosystem disturbances such as loss of pollination agents, invasive species, or pest and diseases outbreaks (Allen et al. 2010; Anderegg et al. 2020). Equally important in adapting to increased pressure from climate change are efforts to minimize disturbance from non-climatic stress factors (e.g. overharvesting, pollution, and land use change (Malhi et al. 2014; Keenan 2015; Barlow et al. 2016; Pörtner et al. 2021). Under some emissions scenarios, projected climate change impacts are of such severity that no adaptation measure is *likely* to protect natural forest systems, e.g. with warming of 4 ˚C, some tropical forests are at risk of die-back from high temperature (Malhi et al. 2014; Settele et al. 2015; Trumbore et al. 2015).

Actions to protect the extent or reduce the disturbance pressure on forest systems contribute to the capacity of these systems to respond to climate change (increasing resistance and resilience) (*high confidence*) (Millar et al. 2007; Schmitz et al. 2015; Settele et al. 2015; Sakschewski et al. 2016; Hisano et al. 2018). Furthermore, if implemented sufficiently well, efforts to manage and restore forests also improve the capacity of forest systems to respond to future climate stressors (increasing resilience and responsiveness). Table CCP7.3 gives an overview of adaptation strategies for tropical forests within the framework of protect, manage, restore (Sayer et al. 2003; Pörtner et al. 2021). In assessing the available adaptation options, it can be useful to distinguish between actions focused on protecting forest extent, managing biodiversity, managing ecosystem function, or restoring ecosystem services (Seppälä 2009), Figure CCP7.5 and Table CCP7.4 give a detailed assessment of the major adaptation options in this context. Beyond these specific interventions, and in several cases underpinning them, there is an increasing awareness that effective management and adaptation of tropical forests requires an appreciation of IKLK and community-based adaptation in order for implementation to be meaningful, these approaches are assessed in [Box CCP7.1]

CCP7.5.1 Adaptation Options at Different Scales

To retain functioning tropical forests, adaptation will need to take place across many scales from individual stands, to interconnected landscapes, and upwards to regional and global policy changes. From a global perspective the most effective adaptation and mitigation option is to reduce and reverse the loss of area in tropical forest ecosystems (Alkama and Cescatti 2016; B. W. Griscom et al. 2017). Maximizing tropical forest extent has well described benefits in mitigating CO2 emissions and in the role of forests regulating global climate (*high confidence*) (Smith et al. 2014). For nations with tropical forests, adaptation is largely achieved through sustainable management of forested areas, enforcing the land rights/land tenure of Indigenous Peoples, and through establishment of Protected Areas (Table CCP7.4; (Seppälä 2009; Pörtner et al. 2021)). Some of this is achieved through schemes incentivizing landowners to retain tree cover for the express purpose of mitigating climate change impacts (e.g. PES, REDD+). For nations outside of the tropics, there is a need to regulate the global drivers of forest loss, such as the consumption of agricultural commodities and of non-sustainable forest products (including timber) (CCP7.3; (CCP 7.3; Henders et al. 2015 Nolte et al., 2017, Pendrill et al., 2019).

At a landscape scale, increasing forest cover and maintaining biodiversity-friendly land-use outside forests increases ecosystem resilience to climate change (and other disturbances) and allows for climate-driven species migration e.g. Table CCP7.3- protect; (Schmitz et al. 2015; Aguirre and Sukumar 2016)). Ensuring forested areas are large and/or interconnected including the use of specific climate refugia and climate corridors is recommended for climate adaptation (*high confidence*) (Schmitz et al. 2015; Settele et al. 2015; Simmons et al. 2018; Pörtner et al. 2021). For habitats or species pushed to the edge of their range, area-based conservation needs to take account of the future climate space and facilitate movement of species through connectivity or assisted migration (Seppälä 2009; Schmitz et al. 2015; Pörtner et al. 2021). Maintaining functioning forest ecosystems is vital due to biophysical, biological (biodiversity-driven) and socioeconomic interactions that contribute to ecosystem resilience (Pielke Sr et al. 2011; Malhi et al. 2014; Lawrence and Vandecar 2015; Alkama and Cescatti 2016; Sakschewski et al. 2016). Protecting forested areas can be achieved through vertical integration of policies at national, subnational and local levels and effective stakeholder empowerment (Meijer 2015). Community-based and ecosystem-based adaptation approaches provide an overall strategy to help achieve these goals [Cross-Chapter Box NATURAL in Chapter 2] (Locatelli et al. 2010; Cerullo and Edwards 2019). In addition to conservation of tropical forests, restoration and afforestation can be effective climate adaptation measures (e.g. Table CCP7.3- restore)

(Arora and Montenegro 2011; Perugini et al. 2017). The technical requirements for such adaptation measures are similar to those required for forest landscape restoration (Mansourian and Vallauri 2005; Mansourian et al. 2017; Shimamoto et al. 2018; Philipson et al. 2020). Agricultural intensification has been proposed as one method to reduce pressure on remaining forested land, although the overall carbon impact of such approaches must be considered (Cross-Chapter Box 6 in SRCCL, Shukla et al. 2019; Cerri et al. 2018; Kubitza et al. 2018).

At the forest community level, adaptation options aim to protect the forest microenvironment and retain biodiversity through forest management (e.g. Table CCP7.3- manage; (Keenan 2015; Jactel et al. 2017)). In Protected Areas this would typically involve reinforcing existing conservation objectives through adaptive management (Salafsky et al. 2001; Ellis et al. 2015; Tanner-McAllister et al. 2017; Hagerman and Pelai 2018), including support for natural regeneration (Chazdon et al. 2016). It is also possible to improve forest cover and interconnectivity through restoration or afforestation. There are many technical guides to improve the implementation and success rate of such approaches (Table CCP7.4) (Lamb and Gilmour 2003; Shimamoto et al. 2018; Strassburg et al. 2019)) and funding support specifically aimed at climate change adaptation and mitigation (e.g. REDD+). In some instances, climate change can alter climate suitability to the extent that managers need to allow for a transition to a new habitat type (e.g. from tropical forest to savanna), adaptive management can help recognize and facilitated these transitions (Seppälä 2009; Schmitz et al. 2015; Lapola et al. 2018). Depending on local conditions it will be necessary to adapt to specific stress factors that are *likely* to increase in prevalence or severity due to climate change, e.g. heat waves, drought events and forest fires (Allen et al. 2010; Malhi et al. 2014; Seidl et al. 2017). Although it is typically not possible to link individual events or adaptation measures to climate change; the effectiveness of technical interventions has been illustrated in a broader forest management context. Table CCP7.4 assesses the costs and benefits of different adaptation options based on the available literature. However, it should be noted that there is lack of information on many potential adaptation interventions, especially in the context of tropical forests (Locatelli et al. 2010; Bele et al. 2015; Keenan 2015; Hagerman and Pelai 2018). The sections below and Figure CCP7.5 offer a framework for optimizing management of complex tropical forest ecosystems within a landscape context, through a range of interconnected adaptation options.

CCP7.5.2 Adaptation Response Options

Forests will be affected by several climate change impacts that will require forest management towards fulfilling four objectives: maintain forest area; facilitate biodiversity adaptation; maintain healthy functioning forest ecosystems; and restore ecosystem services (including productive capacity) (Seppälä 2009), which complement the more conventional approaches to protect, manage and restore forests (Sayer et al. 2003). This is dependent on location-specific conditions that are defined by the type of forest and land tenure regimes or dominant actors across forest landscapes. The analysis here proposes 10 adaptation responses that focus on the adaptation potential of tropical forests to climate change and are linked to the management objectives identified (Figure CCP7.5). Each response option (1–10) implies variable economic costs and benefits, influenced by location-specific conditions, including several important non-monetized benefits. The figure suggests the most relevant situations in which the different response options hold greater potential to meet the forest management objectives for addressing expected climate change impacts.

This assessment considers the economic costs and benefits of 10 response options in their contribution to adaptation of tropical forests to climate change impacts but also includes non-market costs that are more difficult to quantify (e.g. cultural values), which are borne by different stakeholders (Chan et al. 2016; Pascual et al. 2017). Similarly, benefits also include the social and environmental benefits that result from adaptation options over extended time horizons. Economic costs and benefit-cost ratios suggest the short-term economic potential of different options, but responsibly designed adaptation measures involving a combination of different response options and embracing a long-time horizon have the potential to provide significant social and climate benefits over the coming 50 years or more.

Table CCP7.3: Overview of adaptation strategies for tropical forests. This table includes key policy frameworks and common management approaches with potential for adapting native forests to increased disturbance from climate hazards. Details on each management approach and the associated literature are given in Table CCP7.4: Costs and Benefits of Adaptation Options in Tropical Forests.

	Strategy	Expected contribution to climate adaptation
Protect	Protected Areas	Maintaining forest extent builds resistance and resilience to climate change (Seppälä et al., 2009; Schmitz et al., 2015).
	Area-based conservation / Climate refugia	Where forests are under threat from progressive warming, protection of less disturbance prone areas (e.g. higher altitude stands) allows for migration and recolonization improving the ability of the whole ecosystem to respond to climate change (Schmitz et al., 2015; Pörtner et al., 2021).
	Buffer zones	Maintaining buffer zones around protected forests builds resistance and resilience to climate change and allows for adjustment of boundaries, under future conditions (Seppälä et al., 2009; Schmitz et al., 2015).
	Avoid deforestation	Reducing loss of trees due to non-climate stressors, protects forest extent and builds resistance and resilience to climate change (Locatelli et al., 2010; Smith et al., 2019).
	Public education / awareness	Publicizing the role of forests in supporting human society can reduce anthropogenic pressures on forested areas (Seppälä et al., 2009; Hagerman & Pelai, 2018).
Manage	Vulnerability assessment and monitoring programs	Recognising changes in climate and in disturbance regimes allows for other management interventions, such as area-based conservation and assisted migration, to be implemented (Schmitz et al., 2015; Hagerman & Pelai, 2018).
	Adaptive management / climate services	Adaptive management along with information on the changing climate can improve the capacity of forest managers to respond to climate change (Seppälä et al., 2009; Tanner-McAllister et al., 2017).
	Strengthen land tenure	Strong land tenure, e.g. for Indigenous Peoples, often leads to more sustainable management of forested areas, so building resistance and resilience of climate change (Porter-Bolland et al., 2012; Garnett et al., 2018).
	Conserve biodiversity, promote mixed stands	Within managed forests, using diverse planting stock and managing for biodiversity improves resilience to disturbances from future climate changes (Keenan, 2015; Pörtner et al., 2021).
	Fire prevention and management	The use of fire suppression, fire breaks, controlled burning and water table maintenance can build resistance to climate change driven wildfires, in both managed and natural systems (Stephens et al., 2013; Musri et al., 2020; Bowman et al., 2020).
	Sustainable forest management	Within managed forests, vegetation control to manage tree density and stand conditions can build resistance to climate driven disturbance such as fire (Seppälä et al., 2009; Pörtner et al., 2021).
Restore	Increase connectivity	Providing connection corridors between forested areas builds resilience and helps the system response to climate change. This can include thermal corridors that allow for species migration under progressive climate change (Schmitz et al., 2015; Hagerman & Pelai, 2018).
	Forest restoration / assisted natural regeneration	Forest restoration helps restore forest extent and connectivity, and can reduce edge pressure, improving resilience and the capacity to respond to future climate stressors. In some cases, assisted migration and the use of planting stock selected for tolerance to climate change may be appropriate (Locatelli et al., 2015a; Pörtner et al., 2021).
	Agroforestry / trees on farm	In degraded areas, such as buffer zones and mosaic landscapes, planted trees can reduce resource pressure on intact forest, improve soil conservation, regulate temperature and water cycles, and increase resilience through ecological processes (Jose, 2009; Lasco et al., 2014).
	Indigenous and Local knowledge of ecosystems	Incorporating Indigenous and Local knowledge can improve the ability to protect and sustainably manage forest systems so building resilience (Seppälä et al., 2009; Porter-Bolland et al., 2012).

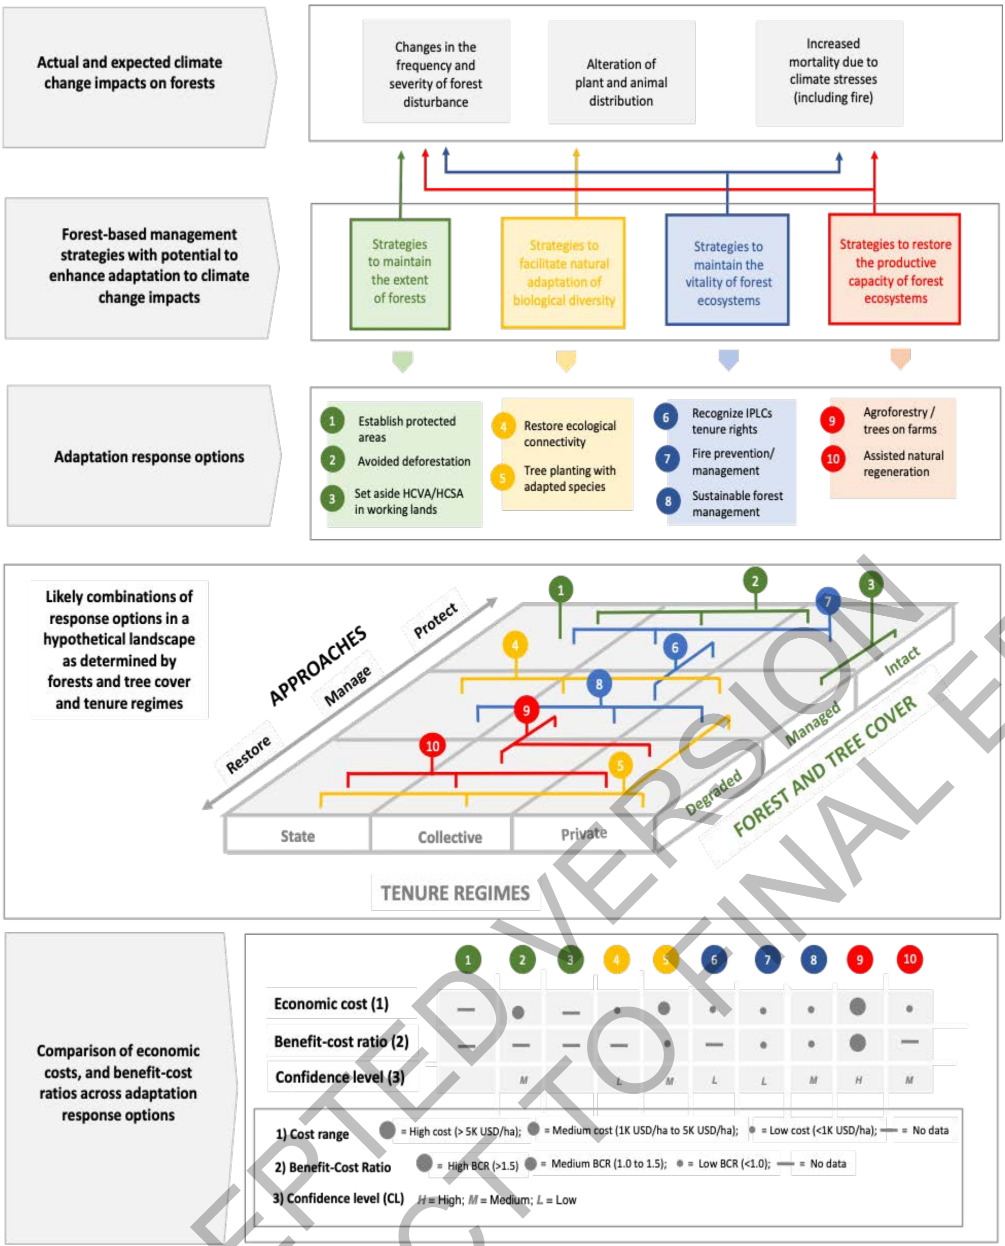

Figure CCP7.5: Framework to assess adaptation response options in tropical forests by adopting a landscape perspective as determined by types of forests and tree cover across different tenure regimes. Notes: HCVA = High Conservation Value Areas; HCSA = High Carbon Stock Areas; IPLC = Indigenous Peoples and Local Communities. The information supporting this figure originates from an extensive literature review that is included in this section, Table CCP7.4. The assessment of confidence levels is based on the judgement of the authors based on the reviewed literature and follows IPBES guidelines.

CCP7.5.3 Costs

The cost of implementing adaptation options varies widely and will change based on the location, time horizon, and who bears the cost. As a result, most existing estimates are offered in broad ranges that include only partial cost estimates. Here we group the adaptation costs into three categories, low (<USD1000/ha), medium (between USD1000/ha and USD5000/ha) and high cost options (>USD5000/ha).

- Low cost options are those estimated to cost less than USD 1000 per ha and include recognition of tenure rights of Indigenous Peoples and local communities (Hatcher 2009), restoring ecological connectivity (Crossman and Bryan 2009; Torrubia et al. 2014), fire prevention and management (Bronson W Griscom et al. 2017; Arneth et al. 2019), assisted natural regeneration (Cury and Carvalho

2011; Lira et al. 2012; MMA 2017; Silva and Nunes 2017), and sustainable forest management (Boltz et al. 2001; Holmes et al. 2002; Pokorny and Steinbrenner 2005; Medjibe and Putz 2012; Singer 2016).
- Medium cost options are those estimated to cost between USD 1000 and USD 5000 per ha and include estimates for tree planting (Rodrigues 2009; Campos-Filho et al. 2013; Silva and Nunes 2017; Nello et al. 2019) and avoided deforestation (Kindermann et al. 2008; Overmars et al. 2014; Smith et al. 2019).
- High cost options are those estimated to cost more than USD 5000 per ha and include actions associated with agroforestry systems, particularly the most biodiverse systems (Raes et al. 2017; Nello et al. 2019).
- Costs per hectare are either not available or vary too widely for several options, including protected areas (Balmford and Whitten 2003; Bruner et al. 2004), and high value conservation areas in working lands (Naidoo and Adamowicz 2006). Bronson W Griscom et al. (2017) provided recent estimated costs for many of the above adaptation options; in most cases these costs are much lower than other estimates referenced here, which are particularly focused on tropical forest landscapes.

While economic costs constitute an important factor in determining the feasibility of options, there are other factors that have an important influence on the viability of the options including opportunity costs, transaction costs, and social feasibility, which are not included in this analysis. For example, options such as recognition of rights for Indigenous Peoples and local communities can be a low-cost option but often face political opposition (RRI 2021) including from some conservation organizations; fire prevention and management require political coordination across multiple governance levels (Fonseca-Morello et al. 2017); and sustainable forest management can be seen as a less attractive option when compared to other more profitable land uses (Köthke 2014). Table CCP7.4 offers a more detailed assessment of the costs included, along with a reference to the costs for society.

CCP7.5.4 Benefits

Estimates of economic benefits across options tend to vary greatly, largely based on the scale of operations, and the market and institutional contexts in which they are implemented. The longer-term non-monetary benefits tend to be larger than has been acknowledged in the past (Chan et al. 2016; Pascual et al. 2017; UNEP 2021). The shorter-term horizon of the economic benefits of adaptation options suggest that benefit-cost ratios of investments are higher in more biodiverse agroforestry systems in comparison with simpler ones (Miccolis et al. 2016), and agroforestry system benefits are comparatively higher compared with commercial tree planting depending on the species (Table CCP7.4 (Nello et al. 2019)).

All the objectives here support not only a large number of local people in fulfilling their livelihoods, but often provide services to distant urban populations as well. The benefits differ according to which of the four forest landscape management objectives is prioritized (Table CCP7.4):

- objectives that seek to maintain the extent of forests contribute to improved landscape continuity, persistence of species and metapopulations (including floral recruitment) (Nordén et al. 2014), maintaining hydrological cycles (Creed et al. 2011), and avoiding surface temperature increases (Perugini et al. 2017). In many cases High Conservation Value Areas (HCVAs) are based on the presence of threatened or endemic species or dense, carbon-rich forest ecosystems (e.g. primary forest) (Jennings et al. 2003).
- objectives that prioritize natural regeneration and adaptation of biological diversity allow greater opportunity for climate refugia (Morelli et al. 2017; Simmons et al. 2018), provide increased dispersal opportunities for different species (Christie and Knowles 2015), increase flora and fauna diversity, and may provide small benefits in reducing warming (Arora and Montenegro 2011).
- objectives to maintain and enhance the quality and persistence of vital forest ecosystems contribute to securing the provision of habitat, maintain soil structure and fertility, and regulate water quantity and quality (Imai et al. 2009; Putz et al. 2012).
- objectives that prioritize the restoration of ecological productivity of degraded forest ecosystems and landscapes contribute to increased biodiversity conservation, soil structure and fertility, nutrient cycling, water infiltration/water recharge, erosion control and climate regulation (Seppälä 2009; Shimamoto et al. 2018; Pörtner et al. 2021).

CCP7.5.5 Strategic Approaches to Combine Response Options

While adaptation costs and benefits of response options differ, their benefit-to-cost ratios are almost always positive, particularly in the longer term (Müller and Sukhdev 2018; Chausson et al. 2020; Seddon et al. 2020; Baste et al. 2021). However, implementation of adaptation actions can be economically unviable if the benefits accrue over longer periods of time because development banks apply much higher discount rates to low income countries than the standard rates (Watkiss 2015). Achieving conditions that do not disincentivize against, and rather encourage investments in nature-based solutions to protect, sustainably manage, or restore tropical forest landscapes is therefore critical to enhancing their implementation (UNEP 2021).

In addition, implementation of response options should consider equity aspects to ensure that the costs and benefits of actions within a landscape are equitably distributed among public institutions, private enterprise, and civil society (Verdone 2015). Strategic approaches to restoring ecosystems can increase conservation gains and reduce costs (Shimamoto et al. 2018; Strassburg et al. 2019). Cost-effective solutions that consider multiple costs and benefits need a "compromise solution" between short and long-term social and economic gains. Pursuing spatial allocations for adaptation options has the potential to deliver greater benefits at lower costs, therefore aligning aims for tropical forest adaptation, species conservation, and climate mitigation targets with the interests of farmers under short and long time horizons (Beatty et al. 2018).

Table CCP7.4: Costs and Benefits of Adaptation Options in Tropical Forests.

Climate change impact	Adaptation measures	Expected contribution to adaptation	Context/Location of implementation	Economic costs	Costs to society	Benefits for forest ecosystems	Benefits/Impacts to people
1. Forest management strategies to maintain the extent of forests							
Changes in the frequency and severity of forest disturbance	Avoid deforestation	Forests counteract wind-driven degradation of soils, and contribute to soil erosion protection and soil fertility enhancement for agricultural resilience (Locatelli *et al.* 2015a). The impact of reduced deforestation may be higher when the large biophysical impacts on the water cycle (and thus drought) are taken into account (e.g. (Alkama and Cescatti 2016)). Reducing deforestation and habitat alteration contribute to limiting infectious diseases (e.g. malaria) (Karjalainen *et al.* 2010). Avoiding deforestation contributes to climate change mitigation due to reduced carbon emissions (Smith *et al.* 2019).	In private lands (individual and collective) and in state lands, in areas with larger presence of intact forests or mosaic agriculture and forest lands under management.	500-2600 USD ha^{-1} (Kindermann *et al.* 2008; Overmars *et al.* 2014; Smith *et al.* 2019). (1) 20-200 USD ha^{-1} (Bronson W Griscom *et al.* 2017; Arneth *et al.* 2019) (global estimate).	Opportunity costs associated with different alternatively productive land uses (Kindermann *et al.* 2008).	Landscape continuity, persistence of species and metapopulations (including floral recruitment) (Nordén *et al.* 2014). Maintained hydrology (Creed *et al.* 2011), and flood mitigation. Avoided surface temperature increases (Perugini *et al.* 2017) Protects other regulatory functions of forests, with positive impacts on human health.	Potential to affect the lives of 1-25 million people globally (low confidence) (Keenan 2015; UNISDR and CRED 2015; Smith *et al.* 2019).
	Protect and/or increase the size and number of protected areas, especially in 'high-value' areas	Protected areas play a key role for improving adaptation (Lopoukhine *et al.* 2012; Watson *et al.* 2014), through reducing water flow, stabilizing rock movements, creating physical barriers to coastal erosion, improving resistance to fires, and buffering storm damages. Primary forests sustain tropical biodiversity (Gibson *et al.* 2011), thus protecting intact forests preserves current patterns of biodiversity (Schmitz *et al.* 2015). (2)	Mainly established in state lands where there is dominance of intact forests, in some cases overlapping with Indigenous territories.	Costs include recurrent management costs, system wide costs, and establishment costs. The cost per ha decreases with increased area (Balmford and Whitten 2003; Bruner *et al.* 2004).	Potential land use and tenure conflicts over protected area expansion. 'High value' areas are often priority areas for human activity (e.g. lowlands) (Venter *et al.* 2014). Management costs (Bruner *et al.* 2004).	May create additional dispersal corridors and support metapopulations for forest species increasing ecosystem resilience (Nordén *et al.* 2014). Improved hydrology (Creed *et al.* 2011) Protected areas contribute to income generation through tourism (Snyman and Bricker 2019).	Empirical studies of protected areas that use impact evaluation methods, provide evidence that parks help increase household incomes (Mullan *et al.* 2009), poverty alleviation and environmental sustainability (Andam *et al.* 2010).

	Set aside High Value Conservation Areas (HVCA) and High Carbon Stock Areas (HCSA) in working lands	Setting aside HCVA and HCSA within agriculture or tree-crop plantations has benefits for preserving endemic species, and some ecological services (e.g. pollination services from insects)) (Scriven *et al.* 2019) (3)	Established in private intact and managed forest lands often allocated to mid- and large-scale plantations.	Opportunity costs to landowners who would lose working land/productive area to HCVA or HCSA. Management costs (Naidoo and Adamowicz 2006).	□Opportunity costs to landowners who would lose working land/productive area to HCVA or HCSA. □Management costs (Naidoo and Adamowicz 2006).	□In many cases HCVA are based on the presence of threatened or endemic species or dense, carbon-rich forest ecosystems (e.g. primary forest) (Jennings *et al.* 2003).	HCVA also provide ecosystem services, and therefore can contain valuable economic benefits; forests provide for some basic needs of local communities (health and subsistence) as well as traditional/ cultural identity (Seppälä 2009; Karjalainen *et al.* 2010).
2. Forest management strategies to facilitate adaptation of biological diversity							
Alteration of plant and animal distribution	Restore ecological connectivity through the establishment of corridors	Conserve biodiversity by enabling natural migration of species to areas with more suitable climates (Malcolm *et al.* 2002), maintaining connectedness, especially between various protected areas, and ensuring that different stages of forest development are present (Seppälä 2009). Building corridors creates landscape permeability for plant and animal movement (Schmitz *et al.* 2015).	Corridors are implemented in managed lands across state, collective and private tenure regimes circumscribed to specific project targeted areas.	60-1294 USD ha^{-1} (in USD 2019) (Crossman and Bryan 2009; Torrubia *et al.* 2014)	□Land use opportunity costs, financial costs of land acquisition and restoration (Naidoo and Adamowicz 2006). Research and pilot costs of different corridor connection methods (Naidoo and Adamowicz 2006).	□Landscape connectivity allows greater opportunity for climate refugia (Morelli *et al.* 2017; Simmons *et al.* 2018) and the restoration of ecosystem patches of native forests can provide dispersal opportunities for different species using alternate successional stages (Christie and Knowles 2015). □Improved hydrology.	Ecosystem services could be enhanced (e.g., hydrological benefits, soil conservation, health, recreational and cultural benefits through establishment and restoration of green spaces).
	Mixed planting with native species tree planting, with consideration of intraspecific genetic diversity of seedlings	Reforestation is an important climate change adaptation response option (Reyer *et al.* 2009; Locatelli *et al.* 2015b; Ellison *et al.* 2017), and can potentially help a large proportion of the global population to adapt to climate change and related natural disasters. Native tree planting aimed at increasing resilience should include planting genotypes tolerant of drought,	Tree planting is implemented in degraded lands across different state, collective and private lands	Planting of seedlings 978-3450 USD ha^{-1} (in USD 2019) (Chabaribery *et al.* 2008; Rodrigues 2009; Campos-Filho *et al.* 2013; MMA 2017; Silva and	Loss of water yield (at least on an annual average basis) due to increased evapotranspiration Reforestation helps maintaining base flow during the dry season may reduce the	□Better water retention capacity; reduced risk of erosion, landslides □Carbon gain. □Increases both flora and fauna biodiversity. □In cases of reforestation/afforestation, small benefits in reducing warming are expected	Reforestation/afforestation has the potential to impact the lives of >25 million people globally (Medium confidence) (Reyer *et al.* 2009; UNISDR and CRED 2015; Sonntag *et al.* 2016; Bronson W Griscom *et al.* 2017; Smith *et al.* 2019) (global estimate). No availability

		insects and/or disease, as well as increasing the genetic diversity within species used for planting and recognizing provenance. Tree planting should avoid conversion of natural ecosystems including grasslands and savannahs (Bond and Zaloumis 2016).		Nunes 2017; Nello *et al.* 2019) 20-200 USD ha^{-1} (Arneth *et al.* 2019), for reforestation and forest restoration (Bronson W Griscom *et al.* 2017) (global estimate).	amount of water available for people downstream (Ellison *et al.* 2017). Research costs on genetic varieties and Implementation	(Arora and Montenegro 2011). □Increased potential for adaptive evolutionary responses within populations to the varied effects of climate change (drought, disease, etc.) (Puettmann 2014).	of information on differentiated impacts from reforestation and afforestation.
3. Forest management strategies to maintain the vitality of forest ecosystems							
Changes in the frequency and severity of forest disturbance	Recognizing the rights of Indigenous Peoples and local communities	Granting tenure rights to Indigenous people has potential to maintain forest, and ensure provision of ecosystem services, thus supporting local strategies for adaptation to climate change threats (Porter-Bolland *et al.* 2012)	Recognizing local tenure rights takes place in land belonging to Indigenous Peoples and local communities across all different forest and trees conditions	0.05-9.96 USD ha^{-1} (Hatcher 2009). Include the costs of mapping, delimitation, and titling. (RRI 2021) estimates the following costs: US$5 per ha for large projects, $22.5 per ha for medium, sub-national projects, and US$50 per ha for small investments.	□Costs to local populations for protecting forest lands, and opportunity costs for avoiding land conversion (Hajjar *et al.* 2016).	□Landscape continuity, persistence of species and metapopulations (including floral recruitment) (Nordén *et al.* 2014).	Some estimates indicate that Indigenous people manage or have tenure rights over at least ~38 million km^2 (Garnett *et al.* 2018) (global estimate). Recognition of rights often translates into positive social and environmental benefits (RRI 2021), yet they may differ depending on local conditions
Increased mortality due to climate stresses (including fire)	Within production forests, practice sustainable logging by embracing reduced-impact	Some production forests can retain most ecosystem functions and services, and a similar species richness of animals, insects, and plants to that found in nearby old-growth forest but can be more susceptible to defaunation and fire (Edwards *et al.* 2014). Sustainable	SFM is undertaken at a large scale in public forests allocated as concessions, and at smaller scales in private and	70 to 160 USD ha^{-1} (Singer 2016) 169-345 USD ha^{-1} (in USD 2019) (Boltz *et al.* 2001; Holmes *et al.* 2002; Pokorny	□The tendency of interventions is a (direct or indirect) reduction of diversity because the natural interest of the forest owner is to favor	□Secures the provision of species habitat □Soil structure and fertility □Regulates water quantity and quality □Carbon storage (Imai *et al.* 2009)	The benefits of Sustainable Forest Management have the potential to affect the lives of >25 million people globally (low confidence) (UNISDR and CRED

	logging (RIL) and other practices	Forest Management plays a role in adaptation by ensuring that through long-term forest management the diversity of forests is maintained as well as benefits from forest resource use (Putz *et al.* 2012). Improved forest management positively impacts adaptation by limiting the negative effects associated with pollution (of air and fresh water), diseases, and exposure to extreme weather events and natural disasters (e.g., (Smith *et al.* 2014)) [4]	community forests lands	and Steinbrenner 2005; Medjibe and Putz 2012) \$20-\$200 ha^{-1} (Bronson W Griscom *et al.* 2017; Arneth *et al.* 2019) (global estimate)	commercial species.		2015; Smith *et al.* 2019) (global estimate)
	Reduce the incidence of fire hazard and improve fire management	As fire hazard increases in some forests with climate change, adaptation measures to reduce fire hazard will be needed (Seppälä 2009).	Fire prevention and management is practiced in private lands (individual and collective) and state lands across managed and intact forest lands	<\$20 ha^{-1} (Bronson W Griscom *et al.* 2017; Arneth *et al.* 2019) (global estimate)	Costs of fuel management and prescribed burns. Costs of implementing fire management plans with many groups of stakeholders (Stephens *et al.* 2013).	• Avoids forest degradation and deforestation. • Prevents biodiversity and species loss. • Protects local livelihoods and cultural values.	>5.8 million people affected by wildfire globally; max. 0.5 million deaths per year by smoke globally (medium confidence) (Johnston *et al.* 2012; Doerr and Santín 2016; Smith *et al.* 2019) (global estimate)
4. Forest management strategies to restore the productive capacity of forest ecosystems							
Increased mortality due to climate stresses	Assisted natural regeneration in degraded forest landscapes	Forest landscape restoration positively affects the structure and function of degraded ecosystems (Shimamoto *et al.* 2018). Forest restoration may enhance connectivity between forest areas and help conserve biodiversity hotspots (Locatelli *et al.* 2015a; Ellison *et al.* 2017; Dooley and Kartha 2018). Forest restoration may improve ecosystem functionality and services, provide microclimatic regulation for people and crops, wood and fodder as safety nets, soil erosion protection	Tree regeneration takes place in more degraded lands across different types of tenure regimes in public, community and private lands	Assisted natural regeneration 180-980 (USD ha^{-1} (in USD 2019) (Cury and Carvalho 2011; Lira *et al.* 2012; MMA 2017; Silva and Nunes 2017)	Opportunity costs of alternative land uses, costs of maintaining regenerating landscapes (e.g. exclusion plots), costs of facilitated dispersal or seeding (Naidoo and Adamowicz 2006).	• Uses microclimatic changes from regeneration to create emergent landscape restoration from available and present species in soil seed banks or dispersive capacity of local habitat patches. • Increases potential area and influence of forest ecosystems even into marginal matrix habitat (Chazdon and Guariguata 2016).	The benefits of regeneration of degraded landscapes has the potential to impact the lives of >25 million people globally (Medium confidence) (Reyer *et al.* 2009; UNISDR and CRED 2015; Sonntag *et al.* 2016; Bronson W Griscom *et al.* 2017; Smith *et al.* 2019) (global estimate)

		and soil fertility enhancement (Locatelli *et al.* 2015a). Land restoration can reduce future risks (e.g. by protecting against hazards) and current vulnerability (e.g. by diversifying livelihoods) (Pramova *et al.* 2019). Natural forest regeneration contributes to climate mitigation through carbon removals (Lewis *et al.* 2019), and this would imply less need for climate adaptation					
Changes in the frequency and severity of forest disturbance	Expand agroforestry systems (AFs) in buffer zones and mosaic landscapes	Agroforestry reduces pressure on intact forests and can enhance ecosystem services at the landscape level (Jose 2009). It can also help to increase resilience to pests and diseases through ecological processes (Miccolis *et al.* 2016). Agroforestry can reduce vulnerability to hazards like wind and drought, particularly for subsistence farmers (Thorlakson and Neufeldt 2012).	Agroforestry has a large potential in collective forest lands, both managed and degraded	7150-22575 USD ha^{-1} (n USD 2019) (Raes *et al.* 2017; Nello *et al.* 2019)	Opportunity costs of other land uses. Costs of engaging in markets and/or developing markets for agroforestry products. Risks of market saturation and supply/demand inconsistencies. (Torres *et al.* 2010; Mercer *et al.* 2014)	Biodiversity (habitat, migratory corridors, gene flow) Soil structure and fertility, nutrient cycling Water infiltration/ water recharge, erosion control Buffer strips can reduce the resource pressures on native ecosystems by providing income and resources for people (Vieira *et al.* 2009).	Potential to improve farmers' livelihoods and quality of life of 2,300 million people globally (medium confidence) (Lasco *et al.* 2014; Smith *et al.* 2019) (global estimate)

Table Notes:
This table draws on Appendix 6.1-6.4 from Seppala et al. 2009, pp. 71-77
(1) Agricultural expansion is the major driver of deforestation in developing countries. Cost of reducing deforestation is based on opportunity cost of not growing the most common crop in developing countries (Maize) for six years to reach tree maturity, with yield of 8 t ha^{-1} (high); 5 tons ha^{-1} (medium) & 1.5 t ha^{-1} & price of USD 329 t^{-1}. Also, reduced deforestation practices have relatively moderate costs, but they require transaction and administration costs (Kindermann *et al.* 2008; Overmars *et al.* 2014).
(2) May not deal with displacement of wild species due to climate change
(3) Fragments of disconnected HCVAs have less value to preserve ecological services
(4) Forest management strategies may decrease stand-level structural complexity and may make forest ecosystems more susceptive to natural disasters like wind throws, fires, and diseases (Seidl *et al.* 2017)

[START BOX CCP7.2 HERE]

Box CCP7.2 Contribution of sustainable tropical forest management to the SDGs

There is increasing evidence of positive impacts of resilient tropical forests, biodiversity, and sustainable forest management in achieving SDGs as illustrated in Table Box CCP72.1. However, there is also risk of unintended consequences based on conflicts between the use of forest-based goods and services and effects on tropical forest resilience, ecosystem services, and biodiversity (Baumgartner 2019). For instance, substitution of fossil fuels and non-renewable resources with bio-based products can lead to deforestation and the loss of biodiversity (Carrasco 2017) (Cross-Working-Group Box BIOECONOMY in Chapter 5). Deforestation as a result of increased agricultural production and productivity could hamper efforts in addressing long term food security, particularly for forest dependent people (Newton et al. 2016); CCP7.2.3). Synergies and trade-offs depend very much on local contexts and are therefore presented in exemplary form.

IFAD (2016) estimated that there are 640 million people living below the poverty line in rural areas of 43 tropical countries. Poor communities rely on ecosystem services for their subsistence livelihoods, and often they have limited capacity to adapt to change, making them more vulnerable to climate change and other forms of changes (Bhatta 2015). Managing forests sustainably benefits both urban and rural communities, including provision of food and fiber, on watershed hydrology, agroforestry production, among others (Powell et al. 2013; Dawson et al. 2014) (Clark and Nicholas 2013) (Mbow et al. 2014)) (Table Box CCP7.2.1).

Table Box CCP7.2.1: Examples from sustainable tropical forest management (STFM) in achieving SDGs.

SDGs	Contribution of STFM to the Goals	Adaptation Interventions	Supporting references
1 No Poverty	Area of forest land with legal property status held by communities	In Mexico, community forest management (CFM) has played a pivotal role in forest cover and biodiversity conservation in the region where timber production and processing generates income and thereby offers a way out of poverty for families in communities with rights to forests.	(Ellis et al. 2015)
	Improve incomes through selling forest products or by generating employment for the poorest	Non-timber forest products (NTFPs) are a significant source for socio-economic, employment and income generation, particularly for tribal people.	(Kumar 2015)
	Improve income through valuation of ecosystem services	In Cambodia, contribution of forest resources should be integrated into payment for ecosystem services schemes, in order to provide more diversified income streams, insulating indigenous people from shocks and stressors.	(Nhem 2018)
2 Zero Hunger	Forests also provide food, which improves food security and nutrition	In Cameroon, forest fruits provide important macro- and micronutrients lacking from the family diets of rural people. Association between tree cover and the dietary diversity of children in the communities of 21 countries across Africa.	(Fungo et al. 2015) ; (Ickowitz et al. 2014)
3 Good Health & Wellbeing	Medicinal plants contribute to emotional and spiritual wellbeing	Medicinal plants and the associated Bhutanese traditional medicine (BTM) are protected by the country's constitution and receive both government support and acceptance by the wider public. These medicinal plants have been one of the drivers of the 'Gross National Happiness (GNH)' and biodiscovery projects in Bhutan.	(Wangchuk and Tobgay 2015)

	Health co-benefits of preserving biodiversity	In the Brazilian Amazon, interventions targeted specifically at preserving biodiversity in protected areas generate health co-benefits. From the perspectives of malaria, acute respiratory infection (ARI), and diarrhea, results suggest that the public health benefits of strict PAs may offset some of their local costs. Nature is doing its part by providing a form of (human) capital for the rural poor and the politically voiceless.	(Bauch et al. 2015)
4 Quality Education	Inclusive education that builds and reinforces positive attitudes to forest	Encouraging and enabling pro-forest behavior as well as strengthening education systems that respect, nurture and enable Indigenous knowledge and local knowledge.	(Kanowski 2019) (Tengö 2017) (Vaidyanathan 2014)
		The value of social capital for maintaining sustainability of community forest management includes, among others, individual characteristics, procedural knowledge and access to information. Initiatives to manage natural resources are *likely* to be more successful if the forest management program initiators consider several factors that influence the capacity development of resource users.	(Lee 2017)
5 Gender Equality	Within genders, other characteristics such as class, race, caste, culture, wealth, age and ethnicity influence responses and affect the impact of climate variability and change on livelihoods	Despite challenges, Nepal's community forestry policy is considered one of the most progressive, as it allows women to exercise equal rights with men in the management and utilization of community forests. Furthermore, women-only forestry groups have registered many success stories.	(Lama et al. 2017); (Agarwal 2015)
6 (Clean Water & Sanitation)	Regulate water supply, water quality and water purification	Evidence from the Hindu Kush Himalayas require improved upstream-downstream integration, transboundary cooperation and greater coordination of implementation of different SDGs. Greater efforts are required to make the communities struggling on the frontline of sustainable forest management more climate resilient. Forest concessions can make a positive contribution to this by minimizing the negative impacts of harvesting operations on water access and by employing appropriate restoration techniques as required by the concession contract and national legislation.	(Scott C.A. 2019); (Amezaga 2019) (Bruggeman et al. 2015),
7 (Affordable & clean energy)	Energy transitions	Decreased reliance on traditional wood fuels and increased use of forest-derived modern fuels (e.g. biofuel) are generally synergistic with achieving other SDGs, such as livelihoods strategies. However, modern wood fuels need improved stoves to ensure the energy is clean.	(Jagger 2019) ; (Simangunsong et al. 2017)

8 (Decent work and economic growth)	Stimulating economic growth and minimizing forest loss	Synergy potentials exist where growth strategies and associated policies target the forest section with NTFPs from natural forests, ecotourism and payments for environmental services.	(Stoian 2019)
		Community forestry enterprises have the potential to make significant contributions by providing a solid institutional framework to efficiently translate SDGs into actions. It also improves forest management, social cohesion and rural incomes amongst local communities in developing countries.	(Aryal 2020); (Vázquez-Maguirre 2020); (Baynes 2015)
9 (Industry innovation & infrastructure)	Integration of small-scale business into value chains and markets	Strategies in relation to sustainable supply chains and tropical forest protection, i.e. Unilever and Instituto Centro de Vida (ICV), demonstrate both alignment and variability between and within organizations. Associated incentives could help balance the burden of responsibility for implementation between global and local actors of promoting zero deforestation.	(Delabre et al. 2020)
10 (Reduced Inequalities)	Reduction in the number of poor households	Results from Waseda-Bridgestone Initiative for Development of Global Environment (W-BRIDGE Initiative) in South Kalimantan province through capacity building delivered by academic partners. This initiative also increased land area ownership from 0.28 to 1.23 ha per household.	(Hiratsuka 2019)
	Protect the workers and communities long-term and economic well-being	Rural agrarian communities in low-latitude tropical forests (e.g., communities in Southeast Asia, South America, Central Africa) adapting to chronically hotter temperatures in common ways, such as adjusting when and how they work. Decision-makers should develop an understanding of these behavioral adaptations that are already being adopted before establishing broader adaptation strategies.	(Masuda 2019)
11 (Sustainable Cities and Communities)	Upstream forests influence water supplies to cities	Watershed condition is associated with measurable health outcomes downstream. Maintaining natural capitals within watersheds is an important public health investment especially for populations with low levels of built capital.	(Herrera et al. 2017)
		Evidence from Marikina Watershed Integrated Resources Development Alliance in the Philippines working together with all stakeholders to restore Marikina Watershed to reduce disaster risk and urban resilience.	(Devisscher 2019)
		Synergies delivered through sound urban forestry approaches could benefit not only urban dwellers but also forest communities. Community groups have also taken responsibility for urban forestry in the absence of strong government commitment.	(Konijnendijk 2018)
12 (Responsible Consumption & Production)	Generates materials for sustainable consumption	Forest concessionaires can also increase the repurposing of waste to improve sustainable consumption. For instance, the logging company Congolaise Industrielle des Bois produces electricity from sawmill wood waste.	(Tegegne et al. 2019)

13 (Climate Action)	Enhance resilience and adaptive capacities to climate change through forest management	Mixed agroforestry systems offer opportunities to simultaneously meet the water, food, energy and income needs of densely populated rural and peri-urban areas in Indonesia.	(van Noordwijk et al. 2016)
	Carbon-based conservation	Payment for carbon-based conservation (eg. REDD+, Green Climate Fund) protecting peatlands from avoidable human impacts for favourable return from carbon conservation investments.	(Roucoux et al. 2017)
		REDD+ has mixed impacts on communities' socio-ecological resilience. On one hand, increases in network ties and participation in decision-making would enhance potential for local adaptability. However, restrictions on local forest practices could limit communities' ability to manage uncertainty.	(Hajjar 2021)
14 (Life Below Water)	Support numerous ecosystem services	Complex root systems serve as shelter as they protect juvenile fish from predators as well as provide food and nutrients for fish.	(Friess 2019)
		Mangroves contribute to fisheries production and have become one of the higher carbon stocks compared to other forests. The mangroves system of the Zambezi River Delta, Mozambique confirms the consistency of substantial C stocks typical of mangroves across a relatively large and hydrologically diverse area.	(Stringer 2015)
	Protection for aquatic macroinvertebrates habitats	The riparian canopy of the tropical forest is significantly able to maintain in-stream temperature that is important to aquatic macroinvertebrates. The study of Gunung Tebu, Malaysia showed high diversity and abundance of steams invertebrates as the natural habitats are minimally impacted.	(Md rai 2014)
15 (Life on Land)	Community monitoring of their own forests or forest within communal jurisdiction, sustainable certification	Mainstreaming SFM in vast tracts of forest, thereby increasing the share of forest area under a forest management plan, including the proportion of forest area certified under independent forest certification schemes.	(van Hensbergen 2016)
		Even with tension between the management of resources for local goals and the need for public good values, still there are some communities that maintain strong control over their lands and resources in achieving desirable conservation outcomes and willing to see large tracts of land set aside, i.e. areas held to be sacred.	(Sayer et al. 2015); (Sheil 2015)
16 (Peace, justice and strong institutions)	Addressing complexity of implementing conservation policy	Target 16.7 calls for responsive, inclusive participatory and representative decision-making at all levels. Decentralization in forest governance observed through community-based/collaborative forest management depends on the strength of underlying land tenure and use rights, as well as capacity to benefit from those rights.	(Baynes 2015) ; (McDermott 2019) ;(Myers 2017) ;(Nunan 2018)
		By 2021, Thailand plans to increase use of renewable and alternative energy by 25% including energy crops. Adequate forest protection is critical, as increasing demand for energy crops may drive demand for expanding agricultural production into	(Phumee 2018)

		public forests, benefitting some SDGs and threatening others.	
	Modern technologies in forest management control	Technologies including remote sensing and Geographic Information System (GIS) are interrelated as they support management actions in global forest resources management thus reducing exploitation through monitoring and evaluation activities.	(Beckline 2017)
	Governance laws and policies provide access to justice for all	The Forest Stewardship Council (FSC) and the program for the Endorsement of Forest Certification (PEFC) significantly contribute to ensuring the legality of the timber supply chain. The (FAO 2018b) considers the proportion of forest with secure tenure rights for forest dependent people and the local community in ensuring equal rights to economic resources for all.	(Gabay 2019)
17(Partnership for the goals)	Co-benefits derived from tropical forest conservation	Raising awareness of the interconnectedness of tropical forests and the SDGs through multi-disciplinary collaboration will support more informed decisions of social, cultural, economic and policy interest.	(Swamy 2018) ; (Bukoski et al. 2018)
	Voluntary Partnership Agreements (VPAs) stabilize and reproduce the very forest governance regime	In Ghana, the adoption of the VPA resulted in an improved Timber Legality Assurance System (TLAS), strengthened Social Responsibility Agreements (SRA) enforcement, updated forest management plans, artisanal milling strategies and technical transparent timber dights allocations.	(Hansen 2018)
	Central bureaucracies promote forest benefits: countering conservation	Forest Management Units (FMUs) could be utilized to support conservation-oriented regimes with worldwide interests as well as domestic production-oriented regimes. For example, FMUs might potentially link up with global and domestic timber certification regimes under the Multistakeholder Forestry Programme (MFP3) imitative.	(Sahide 2016)

[END BOX CCP7.2 HERE]

CCP7.6 Governance of tropical forests for resilience and adaptation to climate change

Deforestation and forest degradation in tropical forests has grown in prominence as priorities for environmental governance in the face of climate change, given the large share of forest and land use GHG emissions in the national profiles of tropical forest countries (*high confidence*) (Butt et al. 2015; IPCC 2019). This is reflected in Parties' Nationally Determined Contributions to the Paris Climate Agreement (UNFCCC 2021). Significant investments in REDD+ readiness, improved forest monitoring, assessments of drivers of deforestation and, forest degradation and related policy responses, and stakeholder engagement have occurred over the past decade in countries across Africa, Asia-Pacific, and Latin America and the Caribbean (Hein et al. 2018; UN-REDD Programme 2018; World Bank 2018). Fifty three percent of countries use highest quality remote sensing data for forest monitoring and reporting, covering 93% of forest cover (Nesha et al. 2021). However, improved monitoring has not yet translated into forest governance effectiveness. Since the New York Declaration on Forests was endorsed in 2014, average annual humid tropical primary forest loss has accelerated by 44% (NYDF 2019). Policy responses towards conservation and ecosystem resilience are found to be insufficient to stem the direct and indirect drivers of nature deterioration (*high confidence*) (IPBES 2019). For governance measures to be effective, it is necessary to alter the direct and underlying drivers that are leading to forest destruction or impeding the implementation of sustainable forest management practices and actions to restore degraded forests (*high confidence*) (CCP7.2.3; CCP7.5; UNFCCC, 2013).

Private sector commitments to reduce deforestation impacts in their commodity supply chains are growing, but evidence of impact is slim and inconclusive (Garrett et al. 2019; NYDF 2019). Half of the biodiversity loss associated with consumption in developed economies occurs outside their territorial boundaries (Wilting et al. 2017), and trends in international trade in land-based production systems are increasing, with greatest impacts on tropical forests (Nyström et al. 2019; Hoang and Kanemoto 2021). In addition, in some cases the impacts of financialization (e.g. correlation of commodity prices with stock market dynamics rather than pure demand) are found to be larger than those related to timber and agricultural commodity production dynamics (Girardi 2015; Ouyang and Zhang 2020); cross-reference to Chapter-5.13). Such factors present challenges for governance and policy responses.

The complexity of tackling drivers of forest loss and degradation will increase as climate impacts on forests and ecosystems intensify in the context of incomplete information and limited understanding of risks (Helbing 2013; Hughes et al. 2013; Springmann et al. 2018; Tu et al. 2019), necessitating novel approaches to forest governance for resilience (Keenan 2015; Spathelf et al. 2018). Therefore, governance—defined as efforts that seek to influence the relationship between existing social processes and governance arrangements by using regulatory processes, mechanisms, and organizations (Agrawal et al. 2018) is a crucial process to convene stakeholders for decisions (FAO 2018a).

This section describes seven levers that support transformative environmental governance towards resilience of tropical forests by tackling the underlying indirect drivers, offering policy solutions and governance challenges and opportunities. The first five build on IPBES (2019) whereas the remaining two are drawn from the governance literature as highly relevant variables specific to the tropical forest context due to their prominence in the international frameworks developed over the past ten years (Table CCP7.5). Monitoring and finance are embedded in multiple levers. The levers include:

1) developing incentives and increased capacity for environmental responsibility (particularly in relation to global targets such as the SDGs, Aichi Biodiversity Targets and the Paris Agreement) and discontinuing harmful subsidies and disincentives;
2) reforming sectoral and segmented decision-making to promote integration across sectors and jurisdictions to mainstream environmental objectives across institutions within and among all relevant sectors;
3) pursuing pre-emptive and precautionary actions in regulatory and management institutions and businesses to avoid, mitigate and remedy the deterioration of nature, and monitor outcomes;
4) managing for resilient social and ecological systems in the face of uncertainty and complexity;
5) strengthening environmental laws and policies and their implementation, and the rule of law more generally (Pörtner et al. 2021);
6) acknowledging land tenure and rights to recognize the need of bringing human rights considerations into the climate change regime; and,
7) enhancing inclusive stakeholder participation to ensure effective, efficient and equitable outcomes (Pasgaard et al. 2016).

While the first five levers are relevant to environmental governance more broadly, the exploration of these levers in Table CCP7.5 is more specific to governance for forest resilience, drawing upon insights related to each transformation lever. Next to the governance solutions being implemented currently, indications of future challenges/opportunities related to resilience in tropical forests are explored based on examples from the recent literature.

Table CCP7.5: Levers of transformative change to tackle the underlying indirect drivers of forest deterioration for resilience.

Levers of transformative change	Barriers	Current governance and policy solutions and potential future challenges and opportunities with an orientation towards resilience in tropical forests
1. Incentives and capacity-building	• Population growth and corruption counteract governance effects (Enrici and Hubacek 2016; Busch and Ferretti-Gallon 2020; Fischer et al. 2020) • Macroeconomic development favoured over ecosystem service provision-environment ministries under resourced and politically weak compared to those for economic and natural resource development (UNEP 2019) • Though food systems are the major driver, many interconnected food system activities and effects do not have established governance regimes to address them (Clapp and Scott 2018). • Reliance on non-state market-based approaches (e.g. zero-net deforestation) has not achieved necessary impact against stated targets, reporting is lacking (Lambin et al. 2018; Global Canopy 2019) • Finance for forest mitigation is less than 1.5% of total since 2010 (Partners 2019), and amount for forest adaptation is even less (Micale et al. 2018)	**Current policy solutions** • REDD+ and Payments for ecosystem services (PES) • Corporate supply chain commitments (WWF and BCG 2021) • Product certification and forest certification have mixed results in addressing deforestation (Blackman et al. 2018; van der Ven et al. 2018) • Agricultural credit restrictions (Assunção et al. 2020) • Protected areas and area-based conservation measures (OECMs) (Maxwell et al. 2020) • Clear performance indicators and monitoring systems to assess performance (Agrawal et al. 2018) **Future policy challenges/opportunities** • Policies that insulate the forest frontier from the influence of high commodity prices (Busch and Ferretti-Gallon 2020) • Project-level biodiversity responses linked to broader jurisdictional biodiversity targets (Simmonds et al. 2020) • Ecological fiscal transfers to base portions of intergovernmental fiscal transfers on ecological indicators (Busch et al. 2021) • Financial disclosure on risks, divestiture, environment-related investment mandates (Halvorssen 2021) • Identification of means for the forest-based bioeconomy (wood fuel, timber) to be sustained (Dieterle and Karsenty 2020) • Incentives towards less emissions-intensive inputs in manufactured products, such as bamboo (van der Lugt et al. 2018) • Reducing imports of embedded deforestation (role of land-use telecoupling) (Gardner et al. 2019) • Supply chain traceability and public reporting (Gardner et al. 2019; Global Canopy 2019)
2. Cross-sectoral cooperation	• Inherent vertical and horizontal fragmentation of policy arena • Challenge of silos between ministries (Nilsson et al. 2016) • Policy integration has a stronger chance of reforming existing policies and competing sectors than coordination, but is challenged to overcome sectoral fragmentation and reach international actors and markets (Kissinger et al. 2021)	**Current policy solutions** • Policy coordination and integration (Candel and Biesbroek 2016) • Jurisdictional and landscape approaches in targeted regions and commodity sectors/supply chains (Reed et al. 2017; von Essen and Lambin 2021) **Future policy challenges/opportunities** • Theories of change applied and testing of policy effectiveness (Meehan et al. 2019; Bager et al. 2021) • Whole-of-government approaches to change mandates across ministries • Mainstreaming climate change into sectoral policies (Di Gregorio et al. 2017)

		• Policy mixes implemented as a bundle, policy instrument selection attuned to complexity of the problem (Henstra 2015; Head 2018)
3. Pre-emptive action	• Complexity of the issues for any specific level of jurisdiction to grapple with, scale mismatches (temporal, spatial and institutional), institutional inertia (Bai et al. 2016) • Reliance on path dependency rather than innovation (Beland Lindahl et al. 2017; Peters et al. 2018; Wieczorek 2018) • Agenda setting and framing influences political and policy responses (Soto Golcher et al. 2018) • Problem denial and blame avoidance on the part of decision-makers (Howlett and Kemmerling 2017).	**Current policy solutions** • GHG emission cap-and-trade systems and carbon pricing (Green 2021) • Moratoria • Identifying thresholds of concern, when critical thresholds of fast-changing variables are triggered, and nonlinear responses erode the resilience of ecosystems (such as in the case of changing forest fire regimes) (Gillson et al. 2019) • Reduce loss and waste of biomass • Change in consumption patterns, sharing and reuse • Shareholder divestiture due to climate/forest and biodiversity risk (Halvorssen 2021)
4. Decision-making in the context of resilience and uncertainty	• Scope of problem identification limited (Beland Lindahl et al. 2017) • Increasingly complex and networked world increases risks, but reduces our ability to understand and manage these risks (Helbing 2013; Tu et al. 2019)	**Current policy solutions** • Forecasting, scenarios of future climate and forest condition, socio-economic dimensions, science-policy dialogue (Bele et al. 2015) and thresholds for ecosystem shifts due to mortality (tipping points) (Verbesselt et al. 2016). **Future policy challenges/opportunities** • Interdisciplinary and transdisciplinary approaches to data gathering and policy design (Keenan 2015) • 'Robust' decision-making approaches for adaptive forest management (Hörl et al. 2020) • Maintain diversity and redundancy, manage connectivity, and slow variables and feedbacks (Biggs et al. 2012) • Measurement and disclosure of climate and ecosystem risk (NBIM 2021)
5. Environmental law and implementation	• 69% of agricultural conversion of tropical forests *likely* illegal between 2013-2019 (Dummett et al. 2021) • 90% of countries (of 31 assessed), identify weak forest sector governance and institutions, conflicting policies beyond the forest sector, and illegal activity main underlying drivers (Kissinger et al. 2012); corruption and illegality are identified as key factors in increasing forest loss (Piabuo et al. 2021). • Implementation and enforcement of environmental laws falls far short; primary obstacle is political will (UNEP 2019)	**Current policy solutions** • Environmental laws and regulations (Head 2018) • Trained prosecutors • Citizen rights to information (Bizzo and Michener 2017) **Future policy challenges/opportunities** • Capacity and willingness to engage iterative processes for continuous effort in transparency and accountability (in implementing the Extractive Industry Transparency Initiative)(Lujala 2018) • Regulatory frameworks as enablers to motivate and hold private sector initiatives to account (test effectiveness) (Begemann et al. 2021) • Nested and multilevel governance arrangements (Ravikumar et al. 2015) • Diagnosing the political drivers of decision making through political economy assessment (Fritz et al. 2014)

	• Conflicting legal instruments, lack of clarity in implementation, monitoring and evaluation, responsibilities are poorly defined and fragmented across multiple agencies (Ranabhat et al. 2018) • Lack of sanctions, transparency and accountability (Bai et al. 2016; Enrici and Hubacek 2016) • Open-ended decision-making exacerbates political asymmetries (Holley and Sofronova 2017)	
6. Lend tenure/rights	• Though recognition of indigenous self-determination is growing, many cases of legal recognition still lack full authority to govern (UN-DESA 2021) • Free Prior Informed Consent (FPIC)	**Current policy solutions** • Legal and constitutional recognition of rights, collective/communal rights (Safitri 2015; Blackman et al. 2017; Gebara 2018) • Indigenous land demarcation (Baragwanath and Bayi 2020). • Community-based forest management (Pelletier et al. 2016) **Future policy challenges/opportunities** • Forest protection /climate and biodiversity is strongest when indigenous people hold collective legal titles to their lands (IPCC 2019) (In Latin America, deforestation rates are about 50% lower in Indigenous territories than in other forested areas) (FAO and FILAC 2021).
7. Participation and stakeholder inclusion	• Governments increasingly rely on highly autonomous semi-public or private organizations for policy results, which weakens control of the process (Howlett et al. 2015), yet mediating between diverse values and interests of citizens, consumers, business, community is a determinant of policy effectiveness (Peters et al. 2018). • Growing legal restrictions on civil society involvement in governance and access to funding (UNEP 2019) • Institutional practices of stakeholder consultation in REDD+ not well operationalized (criteria and transparency often lacking) (Fujisaki et al. 2016)	**Current policy solutions** • Multistakeholder dialogue combined with moratoria (e.g. Brazilian soy moratorium) (Gibbs et al. 2015) • Community-based monitoring (Slough et al. 2021) **Future policy challenges/opportunities** • Collaborative networks (Thomas et al. 2018) • Re-evaluating agency, social structures and the distribution of power to uphold rights (I. Delabre et al.) • Community engagement correlated to secure rights to resources (Pham et al. 2015)

[START FAQ CCP7.1 HERE]

FAQ CCP7.1: How is climate change affecting tropical forests and what can we do to protect and increase their resilience?

Global warming, droughts, extreme rainfalls, and sea-level rise cause significant impacts on tropical forests.

In addition to climate change, tropical forests are experiencing non-climatic stressors. Conversion of forest into large scale agriculture land and exploitation of timber and non-timber forest products are increasing pressure and amplifying the impacts of climate change on the remaining areas of tropical forests. These include biodiversity decline, increases of fires, large scale ecosystem transformation, e.g., into savannah in South Eastern Amazon, and increasing carbon emissions due to deforestation, forest conversion and forest degradation. Further, loss of forest resources leads to the decline of livelihoods of Indigenous Peoples and local communities. All nations need to collaborate to implement collective actions to protect tropical forests.

Tropical forests are essentially important for the health of planet Earth. Tropical forests in Asia, Africa, and South America regulate carbon, water, and chemical cycles, which maintain a healthy climate and nutrient cycles for supporting life. Tropical forests are home to two-thirds of our world's biodiversity, although they cover only about 13 percent of the land on Earth but it is not exactly known how many millions of living creatures, such as microorganisms, insects, amphibians, snakes, fish, birds, mammals, and primates, live in tropical forests.

Approximately 1.3 billion people directly depend upon tropical forest resources to survive. Others are indirectly dependent upon the health and provisioning of ecosystem services and goods from tropical forests. The forests provide many kinds of economic products, such as timber, medicines, and food, recreational services, such as nature trekking, bird and wildlife watching, to mention a few. Indigenous People and other forest-dependent communities have shown extraordinary knowledge on how to manage forest resources to meet their subsistence needs without causing forest degradation. This forest culture and wisdom are broken when the rate of forest extraction changes into unplanned and unsustainable large-scale transformation.

Deforestation and land-use changes in tropical forests cause not only physical and biological changes on flora and fauna but also rapid changes in cultures harming forest peoples. A degraded tropical forest is prone and more vulnerable to climate change. An increase in temperature in lowlands creates an unfavorable condition for optimum growths of many kinds of plant species, which affects, as well, several agricultural plants. Coffee farmers, for example, are forced to open new forest frontiers in highland areas to meet an optimum temperature for the growth of coffee.

The onset and duration of dry and rainy seasons also changes. A prolonged wet season has excessive rains, which causes flash floods and substantially disturbs a fruiting cycle of many plant species. Due to high rainfall and high humidity, most flowers of forest trees fail to mature, and hence essentially deplete fruit production. Most trees in tropical forests require a short period of a dry season in order to have a mass fruiting season. On the other hand, a prolonged dry season causes soils to dry in deeper layers, higher atmospheric demand for water vapor and enhanced forest fires. In the tropical humid forests, the majority of forest fires are anthropogenic. In Southeast Asia, peat fires cause large carbon emissions and haze pollution, which harms locals and people in neighboring countries. The impact on tropical forest comes also from the rise of sea level rise which due to changes in salinity and sedimentation rates, and the expansion of inundated areas leads to the decline of mangrove productivity.

Projected impacts of climate change on the tropical forest might be detrimental to safeguards of local communities and a significant number of flora and fauna in the tropics. In South-Eastern Amazon, reduction in precipitation, due to changes in the climate pattern, associated with intense deforestation and land cover change are leading to reduction of productivity in the remaining forest areas, and might lead to a large-scale change in the forest structure, which can become a savannah. In Southeast Asia, in particular in Indonesia and Malaysia, prolonged dry seasons associated with the El Niño phenomenon cause extensive peat fires, releasing large amounts of carbon dioxide, and creating various health problems related to haze pollution. Furthermore, climate change interacts with deforestation for agriculture (crops, livestock and plantation forestry), logging, mining or infrastructure development exacerbating temperature and rainfall changes resulting in more degradation.

Climate change together with forest fragmentation and deforestation also harms wildlife. For example, the orangutan, an endemic species to tropical peat forests in Kalimantan and Sumatra, is classified as critically endangered. Many other endemic and unknown species of flora in tropical forests are in the same condition, and could experience a mass extinction at a more rapid rate than the previous five mass extinctions on Earth. About 1.3 million Indigenous Peoples depending on the natural resources of the tropical forest would suffer from cultural disruption and livelihood change due to forest loss.

To protect tropical forests a collective action of all nations is needed. It requires a global effort to stop deforestation and the conversion of tropical forests. The role of Indigenous Peoples and local communities as forest keepers must be strengthened. Economic incentives for protecting tropical forests, among other strategies, could facilitate collective actions towards a sustainable management of tropical forests. Sustainable, effective and just strategies to increase the resilience of tropical forests need to consider the complex political, social and economic dynamics involved, including the goals, identity and livelihood priorities of Indigenous Peoples and local communities beyond natural resource management. Strategies can benefit from integrating knowledge and know-how from traditional cultures, fostering transitions towards more sustainable systems.
