7.2.6.2 Immobility and Resettlement in the Context of Climatic Risks

Immobility in the context of climatic risks can reflect vulnerability and lack of agency (i.e., inability to migrate), but can also be a deliberate choice (high confidence). Research since AR5 shows that immobility is best described as a continuum, from people who are financially or physically unable to move away from hazards (i.e. *involuntary immobility*) to people who choose not to move (i.e. voluntary immobility) because of strong attachments to place, culture, and people (Nawrotzki and DeWaard, 2018); (Adams, 2016);(Farbotko and McMichael, 2019);(Zickgraf, 2019);(Neef et al., 2018);(Suckall et al., 2017);(Ayeb-Karlsson et al., 2018);(Zickgraf, 2018);(Mallick and Schanze, 2020). Involuntary immobility is associated with individuals and households with low adaptive capacity and high exposure to hazard and can exacerbate inequality and future vulnerability to climate change (Sheller, 2018), including through impacts on health (Schwerdtle et al., 2018). Voluntary immobility represents an assertion of the importance of culture, livelihood and people to wellbeing, and is of particular relevance for Indigenous Peoples (Suliman et al., 2019).

Planned relocations by governments of settlements and populations exposed to climatic hazards are not presently commonplace, although the need is expected to grow in coming decades. Examples include relocations of coastal settlements exposed to storm and erosion hazards, as well as smaller numbers of cases of flood-prone settlements in river valleys, and these examples suggest that organized relocations are expensive, contentious, create multiple challenges for governments, and generate short- and longer term disruptions for the people involved (high agreement, medium evidence) (Ajibade et al., 2020);(Henrique and Tschakert, 2020);(Desai et al., 2021).

Examples of relocations of small Indigenous communities in coastal Alaska and villages in the Solomon Islands and Fiji suggest that relocated people can experience significant financial and emotional distress as cultural and spiritual bonds to place and livelihoods are disrupted (Albert et al., 2018);(Neef et al., 2018);(McMichael and Katonivualiku, 2020);(McMichael and Katonivualiku, 2020);(McMichael et al., 2021);(Piggott-McKellar et al., 2019);(Bertana, 2020). Voluntary relocation programs offered by US state governments in communities damaged by 2012's Hurricane Sandy have been subject to multiple studies, and these show participants' longer term economic outcomes, social connections and mental wellbeing can compare either favourably or unfavourably with non-participants for a range of reasons unrelated to the impacts of the hazard event itself (Bukvic and Owen, 2017);(Binder et al., 2019);(Koslov and Merdjanoff, 2021),

[START BOX 7.4 HERE]

Box 7.4: Gender Dimensions of Climate-related Migration

Migration decision-making and outcomes – in both general terms and in response to climatic risks – are strongly mediated by gender, social context, power dynamics, and human capital (Bhagat, 2017);(Singh and Basu, 2020);(Rao et al., 2019a);(Ravera et al., 2016). Women tend to suffer disproportionately from the negative impacts of extreme climate events for reasons ranging from caregiving responsibilities to lack of control over household resources to cultural norms for attire (i.e. saris in South Asia) (Belay et al., 2017);(Jost et al., 2016). In many cultures, migrants are most often able-bodied, young men (Call et al., 2017);(Heaney and Winter, 2016). Women wait longer to migrate because of higher social costs and risks (Evertsen and Van Der Geest, 2019) and barriers such as social structures, cultural practices, lack of education, and reproductive roles (Belay et al., 2017);(Afriyie et al., 2018);(Evertsen and Van Der Geest, 2019)).

Research critiques the tendency to portray women as victims of climate hazards, rather than recognizing differences between women and the potential for women to use their agency and informal networks to negotiate their situations (Eriksen et al., 2015);(Ngigi et al., 2017);(Pollard et al., 2015);(Rao et al., 2019b);(Ravera et al., 2016). Migration can change household composition and structure, which in turn affect the adaptive capacity and choices of those who do not move (Rao et al., 2019a);(Rao et al., 2019b);(Singh, 2019). When only male household members move, the remaining members of the now female-headed household must take on greater workloads and their vulnerability may increase (Goodrich et al., 2019);(Rao et al., 2019b);(Rigg and Salamanca, 2015), leading to increased workload and greater vulnerability for those left behind (Arora et al., 2017);(Bhagat, 2017);(Flat ø et al., 2017);(Lawson et al., 2019). It can, however, also increase women's economic freedom and decision-making capacity, enhance their agency (Djoudi et al., 2016);(Rao, 2019) and alter the gendered division of paid work and care and intra-household relations (Rigg et al., 2018);(Singh and Basu, 2020), a process that may reduce household vulnerability to extreme climate events (Banerjee et al., 2019b).

[END BOX 7.4 HERE]

7.2.6.3 Connections Between Climate-related Migration and Health

The number of assessable peer-reviewed studies that make connections between climate-related migration and health and wellbeing is small and merits further encouragement. The health outcomes of migrants generally, and of climate-migrants in particular, vary according to geographical context, country, and the particular circumstances of migration or immobility (Hunter and Simon, 2017; Hunter et al., 2021) (Hunter et al., 2021); (Schwerdtle et al., 2020). Such linkages are best described as "multidirectional", with studies suggesting that healthy individuals may be more likely to migrate internationally in search of economic opportunities than people in poorer health except during adverse climatic conditions, when migration rates may change across all groups; and, that migrants may have different long-term health outcomes than people born in destination areas, potentially displaying a range of positive and negative health outcomes compared to non-migrants (Kennedy et al., 2015);(Dodd et al., 2017); (Hunter and Simon, 2017);(Riosmena et al., 2017). Refugees and other involuntary migrants often experience higher exposure to disease and malnutrition, adverse indirect health effects of changes in diet or activity, and increased rates of mental health concerns attributable to sense of loss or to fear (Schwerdtle et al., 2018);(Torres and Casey, 2017) as well as due to interruption of health care, occupational injuries, sleep deprivation, non-hygienic lodgings and insufficient sanitary facilities, heightened exposure to vector- and water-borne diseases, vulnerability to psychosocial, sexual, and reproductive issues, behavioural disorders, substance abuse and violence (Farhat et al., 2018);(Wickramage et al., 2018). Linkages between climate migration and the spread of infectious disease are bidirectional; migrants may be exposed to diseases at the destination to which they have lower immunity than the host community; in other cases, migrants could introduce diseases to the receiving community (McMichael, 2015). Thus, receiving areas may have to pay greater attention to building migrant sensitive health systems and services (Hunter and Simon, 2017). Further, the risk of migration leading to disease transmission is exacerbated by weak governance and lack of policy to support public health measures and access to medicines (Pottie et al., 2015).

7.2.7 Observed Impacts of Climate on Conflict

7.2.7.1 Introduction

In AR5, conflict was addressed in Chapter 12 on Human Security. The chapter concluded that some of the factors that increase the risk of violent conflict within states are sensitive to climate change (medium evidence, medium agreement), people living in places affected by violent conflict are particularly vulnerable to climate change (medium evidence, high agreement) and that climate change will lead to new challenges to states and will increasingly shape both conditions of security and national security policies (medium evidence, medium agreement). The evidence since AR5 has strengthened the evidence for these findings and allowed statements to be made on direct associations between increased risk of conflict and climate change. AR5 characterised the major debate within the field: authors supporting an association between climate anomalies and conflict that can be extrapolated into the future (e.g. (Hsiang et al., 2013);(Hsiang and Marshall, 2014);(Burke et al., 2015a) and authors that argue that these associations are not so universal, breaking down when contextual, scale and political factors are introduced (e.g. (Buhaug et al., 2014);{Buhaug, 2016, Climate Change and Conflict: Taking Stock.

Consistent with AR5 findings, there continues to be little observed evidence that climatic variability or change cause violent inter-state conflict. In intra-state settings, climate change has been associated both with the onset of conflict, particularly in the form of civil unrest or riots in urban settings (high agreement, medium evidence). {Ide, 2020, Multi-method evidence for when and how climate-related disasters contribute to armed conflict risk} as well as with changes in the duration and severity of existing conflicts (Koubi, 2019) Climate change is conceptualised as one of many factors that interact to raise tensions (Boas and Rothe, 2016) through diverse causal mechanisms (Mach et al., 2019);(Ide et al., 2020) and as part of the peace-vulnerability and development nexus (Barnett 2019)(Abrahams, 2020);(Buhaug and von Uexkull, 2021). New areas of literature assessed in this report include the security implications of responses to climate change, and the gendered dynamics of conflict and exposure to violence under climate change, and civil unrest in urban settings. The impact of violent conflict on vulnerability is not addressed in this chapter, but does arise in other chapters [8.3.2.3; 17.2.2.2]. Other chapters address non-violent conflict over changing availability and distribution of resources, for example, competing land uses and fish stocks shifting to different territories [5.8.2.3; 5.8.3, 5.9.3, 5.13; 9.8.1.1; 9.8.5.1]. A commonly used definition of armed conflict is conflicts involving greater than 25 battle-related deaths in a year; this number represents the Uppsala Conflict Data Program threshold for inclusion in their database, a core resource in this field.

Climatic conditions have affected armed conflict within countries, but their influence has been small compared to socio-economic, political and cultural factors (Mach et al., 2019) (high agreement, medium evidence). Inter-group inequality, and consequent relative deprivation can lead to conflict, and the negative impacts of climate change lower the opportunity cost of involvement in conflict (Buhaug et al., 2020);(Vestby, 2019). Potential pathways linking climate and conflict include direct impacts on physiology from heat, or resource scarcity; indirect impacts of climatic variability on economic output, agricultural incomes, higher food prices, increasing migration flows; and the unintended effects of climate mitigation and adaptation policies (Koubi, 2019);(Busby, 2018);(Sawas et al., 2018).Relative deprivation, political exclusion and ethnic fractionalisation and ethnic grievances (Schleussner et al., 2016);(Theisen, 2017) are other key variables. Research shows that factors such as land tenure and competing land uses interacting with market-driven pressures and existing ethnic divisions produce conflict over land resources, rather than a scarcity of natural resources caused by climate impacts such as drought. (*high agreement, medium evidence*) (Theisen, 2017); (Balestri and Maggioni, 2017);(Kuusaana and Bukari, 2015);[also Box 8.3]

7.2.7.2 Impacts of Climate Change and Violent Conflict

Positive temperature anomalies, and average increases in temperature over time, have been associated with collective violent conflict in certain settings (medium agreement, low evidence). Helman and Zaitchik (2020) find statistical associations between temperature and violent conflict in Africa and the Middle East that are stronger in warmer places and identify seasonal temperature effects on violence. However, they are unable to detect the impact of regional temperature increases on violence. For Africa, Van Weezel (2019) found associations between average increases in temperature and conflict risk. Caruso et al (2016) found an association between rises in minimum temperature and violence; through the impact of temperature on rice yields [also Box 9.4]. However, the associations between temperature and violence are weak compared to those with political and social factors (e.g. (Owain and Maslin, 2018) and research focuses on areas where conflict is already present and, as such, is sensitive to bias (Adams et al., 2018). There is a body of literature that finds statistical associations between temperature anomalies and interpersonal violence, crime and aggression in the Global North, predominantly in the United States (e.g. (Ranson, 2014);(Mares and Moffett, 2019);(Tiihonen et al., 2017);(Parks et al., 2020)[14.4.8]. However, authors have cautioned against extrapolating seasonal associations into long-term trends, and against focusing on individual crimes rather than wider social injustices associated with climate change and its impacts (Lynch et al., 2020).

Variation in availability of water has been associated with international political tension and intra-national collective violence (low agreement, medium evidence). Drought conditions have been associated with violence due to impacts on income from agriculture and water and food security, with studies focusing predominantly on sub-Saharan Africa and the Middle East (Ide and Frohlich, 2015);(De Juan, 2015);(Von Uexkull et al., 2016);(Waha et al., 2017);(Abbott et al., 2017);(D'Odorico et al., 2018). A small set of published studies has argued inconclusively over the role of drought in causing the Syrian civil war (Gleick, 2014);(Kelley et al., 2015);(Selby et al., 2017) [also 16.2.3.9]. In general, research stresses the underlying economic, social and political drivers of conflict. For example, research on conflict in the Lake Chad region has demonstrated that the lake drying was only one of many factors including lack of development and infrastructure (Okpara et al., 2016);(Nagarajan et al., 2018);(Tayimlong, 2020). Fewer studies examine the relationship between flooding (excess water) and violence and often rely on migration as the causal factor (see below). However, some studies have shown an association between flooding and political unrest (Ide et al., 2020). [also 4.3.6, 12.5.3, Box 9.4].

Extreme weather events can be associated with increased conflict risk (low agreement, medium evidence). There is the potential for extreme weather events and disasters to cause political instability and increase the risk of violent conflict, although not conclusively (Brzoska, 2018). Post-disaster settings can be used to intensify state repression (Wood and Wright, 2016) and to alter insurgent groups' behaviour (Walch, 2018). Different stakeholders use disasters to establish new narratives and alter public opinion (Venugopal and Yasir, 2017). However, some research has demonstrated how post-disaster activities have had positive impacts on the social contract between people and the state, reducing the risk of conflict by strengthening relations between government and citizens and strengthened citizenship of marginalized communities (Siddiqi, 2018; (Pelling and Dill, 2010; Siddiqi, 2019). However, post-disaster and disaster-risk related activities in of themselves, have limited capacity to support diplomatic efforts to build peace (Kelman et al., 2018)

7.2.7.3 Causal Pathways Between Climate Change Impacts and Violent Conflict

Increases in food price due to reduced agricultural production and global food price shocks are associated with conflict risk and represent a key pathway linking climate variability and conflict (medium confidence).

Rises in food prices are associated with civil unrest in urban areas among populations unable to afford or produce their own food, and in rural populations due to changes in availability of agricultural employment with shifting commodity prices (Martin-Shields and Stojetz, 2019). Under such conditions, locally specific grievances, hunger, and social inequalities can initiate or exacerbate conflicts. Food price volatility in general is not associated with violence, but sudden food price hikes have been linked to civil unrest in some circumstances (Bellemare, 2015);(McGuirk and Burke, 2020);(Winne and Peersman, 2019). In urban settings in Kenya, Koren et al (2021) found an association between food and water insecurity that is mutually reinforcing and associated with social unrest (although insecurity in either one on its own was not). Analysing global food riots 2007-2008, and 2011, Heslin (2021) stresses the role of local politics and pre-existing grievances in determining whether people mobilise around food insecurity [also Chapter 5].

Climate-related internal migration has been associated with experience of violence by migrants, the prolongation of conflicts in migrant receiving areas and civil unrest in urban areas *(medium agreement, low evidence)*. Research points to the potential for conflict to serve as an intervening factor between climate and migration. However, the nature of the relationship is diverse and context specific. For example, displaced people and migrants may be associated with heightened social tensions in receiving areas through mechanisms such as ecological degradation, reduced access to services, and a disturbed demographic balance in the host area (Rüegger and Bohnet, 2020). Ghimire et al (2015) observed that an influx of flood-displaced people prolonged conflict by causing a lack of access to services for some of the host population and feelings of grievance. Migration from drought-stricken areas to local urban centres has been used to suggest a climate trigger for the Syrian conflict (e.g.(Ash and Obradovich, 2020)). However, this link has been strongly contested by research that contextualizes the drought in wider political economic approaches and existing migration patterns (De Châtel, 2014);(Fröhlich, 2016);(Selby, 2019) [16.2.3.9].

There is some evidence of an association between climate-related rural-to-urban migration and the risk of civil unrest (medium agreement, low evidence). Petrova (2021) found that while migration in general was associated with increased protests in urban receiving areas, the relationship did not hold for hazard-related migration. In other settings, the association of civil unrest with in-migration was found to depend on the political alignment of the host state with the capital (Bhavnani and Lacina, 2015), previous experience of extreme climate hazards (Koubi et al., 2021) and previous experience of violence in migrants (Linke et al., 2018). Climate-related migrants have reported higher levels of perception, and experience, of violence in their destination (Linke et al., 2018);(Koubi et al., 2018). There has been no association established between international migration and conflict. The literature highlights how unjust racial logics generate spurious links between climate migration and security (Fröhlich, 2016);(Telford, 2018).

7.2.7.4 Gendered Dimensions of Climate-related Conflict

Structural inequalities play out at an individual level to create gendered experiences of violence (high agreement, medium evidence). Violent conflict is experienced differently by men and women because of gender norms that already exist in society and shape vulnerabilities. For example, conflict deepens gendered vulnerabilities to climate change related to unequal access to land and livelihood opportunities (Chandra et al., 2017). Motivations for intergroup violence may be influenced by constructions of masculinity, for example the responsibility to secure their family's survival, or pay dowries (Myrttinen et al., 2017), and gendered roles may incentivize young men to protest or to join non-state armed groups during periods of adverse climate (Myrttinen et al., 2015), (Myrttinen et al., 2017);(Anwar et al., 2019);(Hendrix and Haggard, 2015);(Koren and Bagozzi, 2017). Research has found a positive correlation between crop failures and suicides by male farmers who could not adapt their livelihoods to rising temperatures (Bryant & Garnham 2015; (Kennedy and King, 2014); (Carleton, 2017).

Extreme weather and climate impacts are associated with increased violence against women, girls and vulnerable groups (high agreement, medium evidence). During and after extreme weather events, women, girls and LGBTQI people are at increased risk of domestic violence, harassment, sexual violence and trafficking (Le Masson et al., 2019);(Nguyen, 2019);(Myrttinen et al., 2015);(Chindarkar, 2012). For example, early marriage is used as a coping strategy for managing the effects of extreme weather events (Ahmed et al., 2019)and women are exposed to increase risk of harassment and sexual assault as scarcity and gender-based roles cause them to walk longer distances to fetch water and fuel (Le Masson et al., 2019). Within the household, violence may arise from changing gender norms as men migrate to find work in post-disaster settings may lead to violent backlash or heightened tensions (Stork et al., 2015) and men's use of negative coping mechanisms, such as alcoholism, when unable to meet norms of providing for the household (Anwar et al., 2019);(Stork et al., 2015). Rates of intimate partner violence have been found to increase with higher temperatures (Sanz-Barbero et al., 2018).

7.2.7.5 Observed impacts on non-violent conflict and geopolitics

Climate adaptation and mitigation projects implemented without taking local interests and dynamics into account have the potential to cause conflict (high agreement, medium evidence). Reforestation or forest management programs driven by reducing emissions through deforestation, land zoning and managed retreat due to sea level rise have been identified as having the potential to cause friction and conflict within and between groups and communities (de la Vega-Leinert et al., 2018);(Froese and Schilling, 2019). Conflict may arise when there is resistance to a proposed project, where interventions favour one group over another, projects undermine livelihoods or displace populations (e.g. (Nightingale, 2017);(Sovacool et al., 2015);(Sovacool, 2018) Corbera, 2017; Hunsberger 2018) [also 4.6.8, 5.13.4, 14.4.7.3]. In addition to conflict generated by the poor implementation of land-based climate mitigation and adaptation projects, Gilmore and Buhaug (2021) highlight the links between climate policy and conflict through potential effects on economic growth and unequal distribution of economic burdens, and fossil fuel markets. There is a small literature that draws attention to potential security of nuclear proliferation, if nuclear is increasingly employed as a low-carbon energy source (e.g. (Parthemore et al., 2018);(Bunn, 2019).

Economic and social changes due to changes in sea ice extent in the Arctic are anticipated to be managed as part of existing governance structures (high agreement, medium evidence). The opening-up of the Arctic and associated geopolitical manoeuvring for access to shipping routes and sub-sea hydrocarbons is often highlighted as a potential source of climate conflict (e.g. Koivurova, 2009; (Åtland, 2013);(Tamnes and Offerdal, 2014). Research assessed in AR5 focused on the potential for resource wars and Arctic land grabs. However, research since AR5 is less sensationalist in its approach to Arctic security, focusing instead on the practicalities of polycentric Arctic governance under climate change, the economic impacts of climate change, protecting the human security of Arctic populations whose autonomy is at risk (Heininen and Exner-Pirot, 2020), understanding how different regions (e.g. EU) are positioning themselves more prominently in the Arctic space (Raspotnik & Østhagen, 2019), and Arctic Indigenous People's understanding of security (Hossain, 2016) [also Chapter 3, Chapter 14, CCP6. IPCC SROCC]

7.3 Projected Future Risks under Climate Change

7.3.1 Projected Future Risks for Health and Wellbeing

7.3.1.1 Global Impacts

Climate change is expected to significantly increase the health risks resulting from a range of climate-sensitive diseases and conditions, with the scale of impacts depending on emissions and adaptation pathways in coming decades (very high confidence). Sub-sections 7.3.1.2 to 7.3.1.11 assess available studies on future projections for risks associated with specific climate sensitive diseases and conditions previously described in Section 7.2.1. In the case of diabetes, cancer, injuries, mosquito-borne diseases other than dengue and malaria, rodent borne diseases, and most mental illnesses, insufficient literature was found to allow for assessment. Adaptation pathways and options for managing such risks are detailed in Section 7.4.

Even in the absence of further warming beyond current levels, the proportion of the overall global deaths caused by climate sensitive diseases and conditions would increase marginally by mid-century (high confidence). Studies that incorporate climate forcing project an additional 250,000 deaths per year by mid-century due to climate-sensitive diseases and conditions, and under high-emissions scenarios, over 9 million additional deaths per year by 2100 (*high confidence*). Two global projections of climate change health impacts were conducted since AR5. The first focused on cause-specific mortality for eight exposures for 2030 and 2050 for a mid-range emissions scenario (A1b) and three scenarios of economic growth (WHO, 2014). The study estimated that the climate change projected to occur by 2050 (compared to 1961-1990) could result in an excess of approximately 250,000 deaths per year, dominated by increases in deaths due to heat (94,000, mainly Asia and high-income countries), childhood undernutrition (85,000, mainly Africa, also Asia), malaria (33,000, mainly Africa), and diarrheal disease (33,000, mainly Africa and Asia). Overall, more than half of this excess mortality is projected for Africa. Near term projections (2030) are predominantly for childhood undernutrition (95 200 out of 241 000 total excess deaths) (Figure 7.8). The second study focused on all-cause mortality associated with warming under both a high emissions scenario (RCP 8.5) and a low emissions scenario (RCP4.5). Under the high emissions scenario, and accounting for population growth, economic development, and adaptation, an increase of approximately 85 excess deaths per 100,000 population per year by the end of the century was projected, for a total annual excess of 9,250,000 per year based on United Nations Department of Economic and Social Affairs population projections. The authors estimate that removing adaptation and projected economic growth increased the estimate by a factor of 2.6.

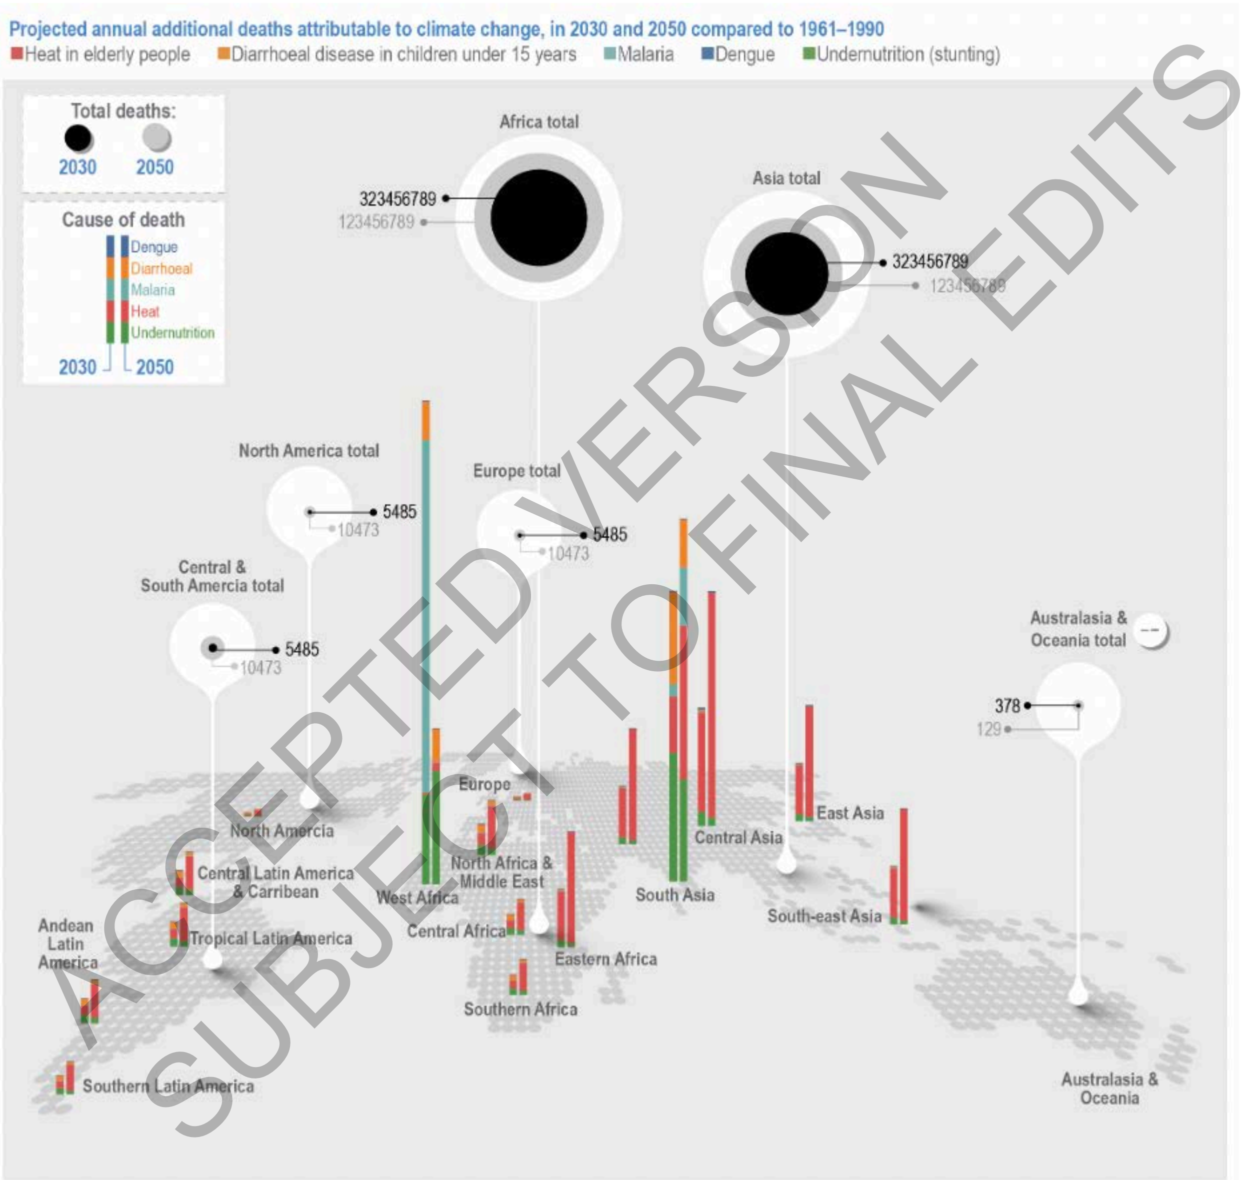

Figure 7.8: Projected additional annual deaths attributable to climate change, in 2030 and 2050 compared to 1961-1990 (WHO, 2014)

Temperature increases are projected to exceed critical risk thresholds for six key climate-sensitive health outcomes, highlighting the criticality of building adaptive capacity in health systems and in other sectors that influence health and well-being (high confidence). Recently reported research illustrates the temperature thresholds at which the following health risks change under three SSP-based adaptation scenarios: heat-related morbidity and mortality; ozone-related mortality; malaria incidence rates; incidence rates of Dengue and other diseases spread by *Aedes sp*. mosquitos; Lyme disease; and West Nile fever (Ebi et al., 2021a). As shown in Figure 7.9, adaptation under SSP1, SSP2, and SSP3 significantly alters the warming thresholds at which risks accelerate, with SSP1, an adaptation scenario that emphasizes international cooperation toward achieving sustainable development, having the greatest potential to avoid significant increases in risks under all but the highest levels of warming. SSP2 describes a world with moderate challenges to adaptation and mitigation. SSP3 describes a world with high challenges to adaptation and mitigation. In the figure, transitions are based on the peer-reviewed literature projecting risks for each of the health outcomes. Projections for time slices were changed to temperature increase above pre-industrial based on the climate models and scenarios used in the projections. The black dots are levels of confidence, from very high (four dots) to low (one dot).

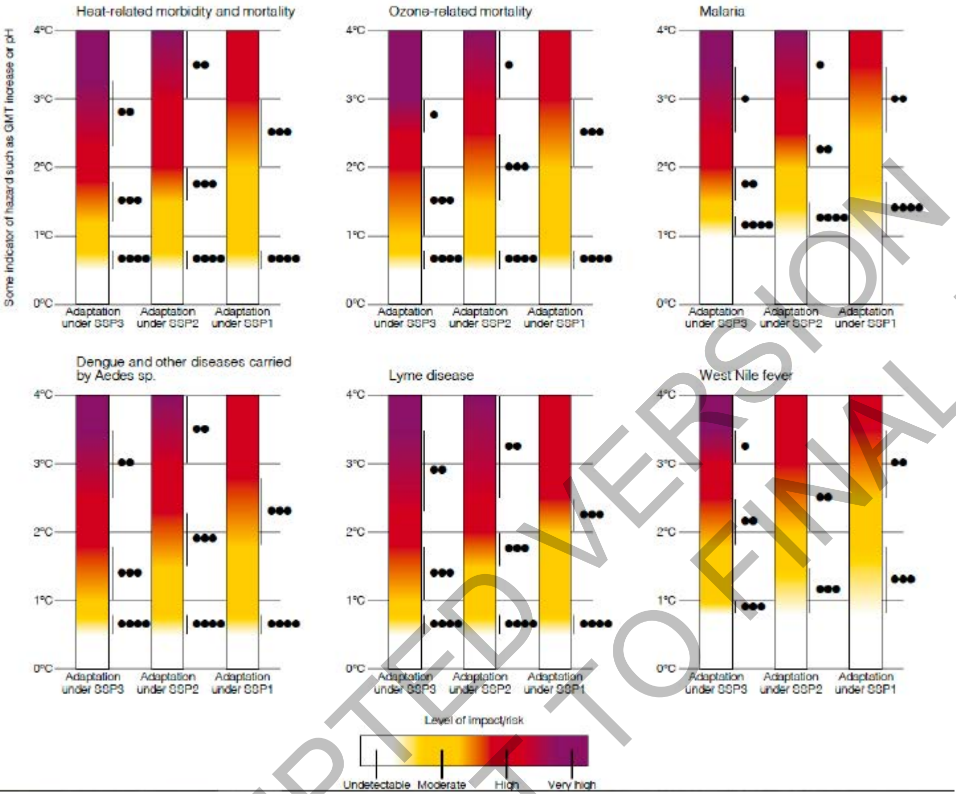

Figure 7.9: Change in risks for six climate-sensitive health outcomes by increases in temperature above pre-industrial levels, under adaptation scenarios (Ebi et al., 2021a)

7.3.1.2 Projected Changes in Heat- and Cold-related Exposure and Related Outcomes

This section considers the broad impacts of projected changes in heat- and cold-related exposure and related outcomes including mortality and work productivity. Several of the most common heat and cold-related specific health outcomes (e.g., cardiovascular disease) are assessed individually in later sections of this chapter.

Population heat exposure will increase under climate change (very high confidence). Since AR5 there has been considerable progress with quantifying the future human exposure to extreme heat (Schwingshackl et al., 2021), especially as determined by different combinations of Shared Socioeconomic Pathways (SSP) and Representative Concentration Pathways (RCP) (Chambers, 2020);(Cheng et al., 2020);(Jones et al., 2018);(Liu et al., 2017);(Ma and Yuan, 2021);(Russo et al., 2019). For example, Table 7.1 shows projections of population exposure to heatwaves, as expressed by the number of person days, for the period 2061- 2080 aggregated by geographical region and SSP/RCP. At the global level, projected future exposure increases from approximately 15-million person-days for the current period to 535 billion person-days for the high population growth under the high greenhouse gas SSP3-RCP8.5 scenario, while for the low population growth/high urbanization and business as usual SSP5-RCP4.5 scenario, the exposure is substantially lower at 170 billion person-days. Spatial variations in future heatwave frequency and population growth play out in the form of significant geographical contrasts in exposure with the largest increases projected for low latitude regions such as India and significant portions of Sub-Saharan Africa where increases in heatwave frequency and population are expected. Over East Asia and especially eastern China, exposures are projected to rise, with the effect of increases in heatwave frequency exceeding the countering effect of projected reductions in population, especially in non-urban areas. Further, for North America and Europe, where rural depopulation is projected, the predominant driver of increases in exposure is urban growth (Jones et al., 2018).

Table 7.1: Projected exposure in millions of person days by region under different RCP/SSP combinations {Supplementary material in: Jones, B., Tebaldi, C., O'Neill, B.C., Olsen K, Gao, J.. (2018) Avoiding population exposure to heat-related extremes: demographic change vs climate change. Climatic Change 146, 423–437 (2018). https://doi.org/10.1007/s10584-017-2133-7

Comparisons of heatwave exposure for 1.5°C and 2.0°C warming for different SSPs indicate strong geographical contrasts in potential heatwave risk (high confidence). One global level assessment for a 1.5°C warming projects that low-human development index countries will experience exposure levels equal to or greater than the exposure levels for very high-human-development index countries under a 2°C warming {Russo, 2019, Half a degree and rapid socioeconomic development matter for heatwave risk}. The same assessment also finds that holding global warming below 1.5°C, in tandem with achieving sustainable socioeconomic development, (e.g., SSP1 as opposed to SSP4), yields reduced levels of heatwave exposure, especially for low-human development index countries, particularly across sub-Saharan Africa (Russo et al., 2019). Similar findings were apparent in other global level assessments, such that global exposure to extreme heat increases almost 30 times under a RCP8.5/SSP3 combination, with the average exposure for Africa 118 times greater than historical levels, in stark contrast to the four-fold increase projected for Europe. Compared to a RCP8.5/SSP3 scenario, exposure was reduced by 65% and 85% under RCP4.5/SSP2 and RCP2.6/SSP1 scenarios, respectively (Liu et al., 2017).

Regional level assessments of changes in population heat exposure for Africa, Europe, the US, China and India corroborate the general findings at the global level – the impact of warming is amplified under divergent regional development pathways (e.g., SSP4 - inequality) compared to those fostering sustainable development (e.g., SSP1 - sustainability) (high confidence). (Rohat et al., 2019a);(Weber et al., 2020), (Broadbent et al., 2020);(Dahl et al., 2019);(Harrington and Otto, 2018);(Rohat et al., 2019b);(Vahmani et al., 2019);(Huang and et al., 2018);(Zhang et al., 2020a);(Liu et al., 2017). For some regions, such as Europe, changes in exposure are projected to be largely a consequence of climate change, while for others, such as Africa and to a lesser extent Asia, Oceania, North and South America, the interactive effects of demographic and climate change are projected to be important (Jones et al., 2018);(Liu et al., 2017);(Russo et al., 2016);(Ma and Yuan, 2021) (*medium confidence*).

Compared to research that estimates the temperature only impacts of climate change on heat-related mortality (see below), the number of studies that explicitly model mortality responses considering various combinations of Shared Socioeconomic Pathways (SSP) and Representative Concentration Pathways (RCP) is small and mostly restricted to the country or regional level. These studies point to increases in heat-related mortality especially amongst the elderly across a range of SSPs with the greatest increases under SSP5 and RCP8.5 (Rail et al., 2019);(Yang et al., 2021).

Estimates of heat-related mortality based solely on changes in temperature point to elevated levels of global and regional level mortality compared to the present with the magnitude of this increasing from RCP4.5 through to RCP8.5 (high confidence). (Ahmadalipour and Moradkhani, 2018);(Cheng et al., 2019);(Kendrovski et al., 2017);(Lee et al., 2020);(Limaye et al., 2018);(Morefield et al., 2018). Further support comes from the projection that heat-related health impacts for a 2°C increase in global temperatures will be greater than those for a 1.5°C warming (*very high confidence*) (Dosio et al., 2018);(Mitchell et al., 2018);(King and Karoly, 2017);(Vicedo-Cabrera et al., 2018a).

Estimates of future mortality that incorporate adaptation, using a variety of temperature adjustment methods, indicate increases in heat-related mortality under global warming, albeit at lower levels than the case of no adaptation (high confidence). (Anderson et al., 2018);(Gosling et al., 2017);(Guo et al., 2018);(Honda and Onozuka, 2020);(Vicedo-Cabrera et al., 2018b);(Wang et al., 2018b). Whether adaptation is considered or not, the consensus is Central and South America, Southern Europe, Southern and Southeast Asia and Africa will be the most affected by climate change related increases in heat-related mortality (*high confidence*). Similarly, projections of the impacts of future heat on occupational health, worker productivity and workability point to these regions as problematic under climate change (*high confidence*) (Andrews et al., 2018);(de Lima et al., 2021);(Dillender, 2021);(Kjellstrom et al., 2018);(Orlov et al., 2020);(Rao et al., 2020);(Tigchelaar et al., 2020), especially for occupations with high exposure to heat, such as agriculture and construction. This accords with the findings from independent projections of population heat-exposure as outlined above (*high confidence*).

The effect of climate change on productivity is projected to reduce GDP at a range of geographical scales (high confidence). (Borg et al., 2021);(Oppermann et al., 2021);(Orlov et al., 2020); For example, measuring economic costs using occupational health and safety recommendations, it was estimated that RCP8.5 would result in a 2.4% reduction in global GDP, compared to a 0.5% reduction under RCP2.6 (Orlov et al., 2020). For the USA, it was estimated that the total hours of labour supplied declined ~0.11 (±0.004) % per °C increase in global mean surface temperature for low-risk workers and 0.53 (±0.01) % per °C increase for high-risk workers exposed to outdoor temperatures (Hsiang et al., 2017). Further, a systematic review of the literature indicates that extreme heat exacts a substantial economic burden on health systems, which bears implications for future heat-attributable health care costs (Wondmagegn et al., 2019).

Since AR5 there has been an increase in the understanding of the extent to which a warming world is likely to affect cold/winter related health impacts. Future increases in heat-related deaths are expected to outweigh those related to cold (high confidence). (Aboubakri et al., 2020);(Achebak et al., 2020);(Burkart et al., 2021);(Huber et al., 2020b);(Martinez et al., 2018);(Rodrigues et al., 2020);(Vardoulakis et al., 2014);(Weinberger et al., 2017);(Weinberger et al., 2018a);(Weitensfelder and Moshammer, 2020). However, strong regional contrasts in heat- and cold-related mortality trends are *likely* under a RCP8.5 scenario with countries in the global north experiencing minimal to moderate decreases in cold related mortality while warm climate countries in the global south are projected to experience increases in heat-attributable deaths by end of century (Gasparrini et al., 2017);(Burkart et al., 2021)Projections of the magnitude of change in the temperature related burden of disease do however demonstrate great variability, due to the application of a wide range of climate change, adaptation and demographic scenarios (Cheng et al., 2019).

A particular focus since AR5 has been the impact of climate change on cities (see AR6 Chapter 6). Heat risks are expected to be greater in urban areas due to changes in regional heat exacerbated by 'heat island' effects (high confidence). (Doan and Kusaka, 2018);(Heaviside et al., 2016);(Li et al., 2021);(Rohat et al., 2019a);(Rohat et al., 2019c);(Varquez et al., 2020);(Wouters et al., 2017);(Zhao et al., 2021), with intra-urban scale variations in heat exposure attributable to land cover contrasts and urban form and function (Avashia et al., 2021);(Jang et al., 2020);(Macintyre et al., 2018);(Schinasi et al., 2018) . However, further research is required to establish the health implications of increasing chronic slow-onset extreme heat (Oppermann et al., 2021), in addition to the acute health outcomes of urban heat island - heatwave synergies under climate change. The latter is particularly important as studies that address urban heat island – heatwave interactions have mainly focused on changes in urban heat island intensity (e.g. (Ramamurthy and Bou-Zeid, 2017);(Scott et al., 2018). Whether significant urban mortality anomalies arise from the interplay of heatwaves and urban heat islands largely remains an open question although at least one study demonstrated higher urban compared to rural mortality rates during heatwaves (Ruuhela et al., 2021). Yet, the benefits of the winter urban heat island (UHI) effect for cold related mortality remain largely unexplored but one study for Birmingham, UK indicates the winter UHI will continue to have a protective effect in future climate (Macintyre et al., 2021).

7.3.1.3 Projected impacts on vector-borne diseases

The distribution and abundance of disease vectors, and the transmission of the infections that they carry, are influenced both by changes in climate, and by trends such as human population growth and migration, urbanization, land-use change, biodiversity loss, and public health measures. Each of these may increase or decrease risk, interact with climate effects, and may contribute to emergence of infectious disease, although there are few studies assessing future risk of emergence (Gibb et al., 2020). Unless stated otherwise, the assessments below are specifically for the effects of climate change on individual diseases, assuming other determinants remain constant.

There is a high likelihood that climate change will contribute to increased distributional range and vectorial capacity of malaria vectors in parts of Sub-Saharan Africa, Asia, and South America (high confidence) In Nigeria, the range and abundance of *Anopheles* mosquitoes are projected to increase under both lower (RCP2.6) and especially under higher emissions scenarios (RCP8.5) due to increasing and fluctuating temperature, longer tropical rainfall seasons and rapid land use changes (Akpan et al., 2018). Similarly, vegetation acclimation due to elevated atmospheric CO_2 under climate change will likely increase the abundance of *Anopheles* vectors in Kenya (Le et al., 2019). Distribution of *Anopheles* may decrease in parts of India and Southeast Asia, but there is an expected increase in vectorial capacity in China (Khormi and Kumar, 2016). In South America, climate change is projected to expand the distributions of malaria vectors to 35-46% of the continent by 2070, particularly species of the *Albitarsis* Complex (Laporta et al., 2015).

Malaria infections have significant potential to increase in parts of Sub-Saharan Africa and Asia, with risk varying according to the warming scenario (medium confidence). In Africa, where most malaria is due to the more deadly *Plasmodium falciparum* parasite, climate change is likely to increase the overall transmission risk due to the likely expansion of vector distribution and increase in biting rates (Bouma et al., 2016);(M'Bra et al., 2018);(Nkumama et al., 2017);(Ryan et al., 2015b) ; (Tompkins and Caporaso, 2016a). The projected effect of climate change varies markedly by region, with projections for West Africa tending to indicate a shortening of transmission seasons and neutral or small net reductions in overall risk, whereas studies consistently project increases in Southern and Eastern Africa, with potentially an additional 76 million people at risk of endemic exposure (10-12 months per year) by the 2080s (Nkumama et al., 2017);(Ryan et al., 2015b);(Semakula et al., 2017);(Zaitchik, 2019);(Leedale et al., 2016);(Murdock et al., 2016);(Yamana et al., 2016);(Ryan et al., 2020). In Sub-Saharan Africa, malaria case incidence associated with dams in malaria-endemic regions will likely be exacerbated by climate change, with significantly higher rates projected under RCP 8.5 in comparison to lower-emission scenarios (Kibret et al., 2016). Incidence of malaria in Madagascar is projected to increase under RCPs 4.5 through 8.5 (Rakotoarison et al., 2018). Distribution of *P. vivax* and *P. falciparum* malaria in China is likely to increase under RCPs higher than 2.6, especially RCP8.5 (Hundessa et al., 2018). In India, projected scenarios for the 2030s under RCP4.5 indicate changes in the spatial distribution of malaria, with new foci and potential outbreaks in the Himalayan region, southern and eastern states, and an overall increase in months suitable for transmission overall, with some other areas experiencing a reduction in transmission months (Sarkar et al., 2019).

Rising temperatures are likely to cause poleward shifts and overall expansion in the distribution of mosquitoes Aedes aegypti and Ae. albopictus, the principal vectors of dengue, yellow fever, chikungunya and zika (high confidence). Globally, the population exposed to disease transmission by one or other of these vectors is expected to increase significantly due to the combination of climate change and non-climatic processes including urbanization and socio-economic interconnectivity, with exposure rates rising under higher warming scenarios (Kamal et al., 2018);(Kraemer et al., 2019). For example, approximately 50% of the global population is projected to be exposed to these vectors by 2050 under RCP6.0 (Kraemer et al., 2019). The effect of climate change alone is projected to increase the population exposed to *Ae. aegypti* by 8-12% by 2061–2080 (Monaghan et al., 2018), and its abundance is projected to increase by 20% under RCP 2.6 and 30% under RCP 8.5 by the end of the century (Liu-Helmersson et al., 2019) (Figure 7.10) Exposure to transmission by *Ae. albopictus* specifically would be highest at intermediate climate change scenarios and would decrease in the warmest scenarios (Ryan et al., 2019). Under scenarios other than RCP2.6, most of Europe would experience significant increases in exposure to viruses transmitted by both vectors (Liu-Helmersson et al., 2019).

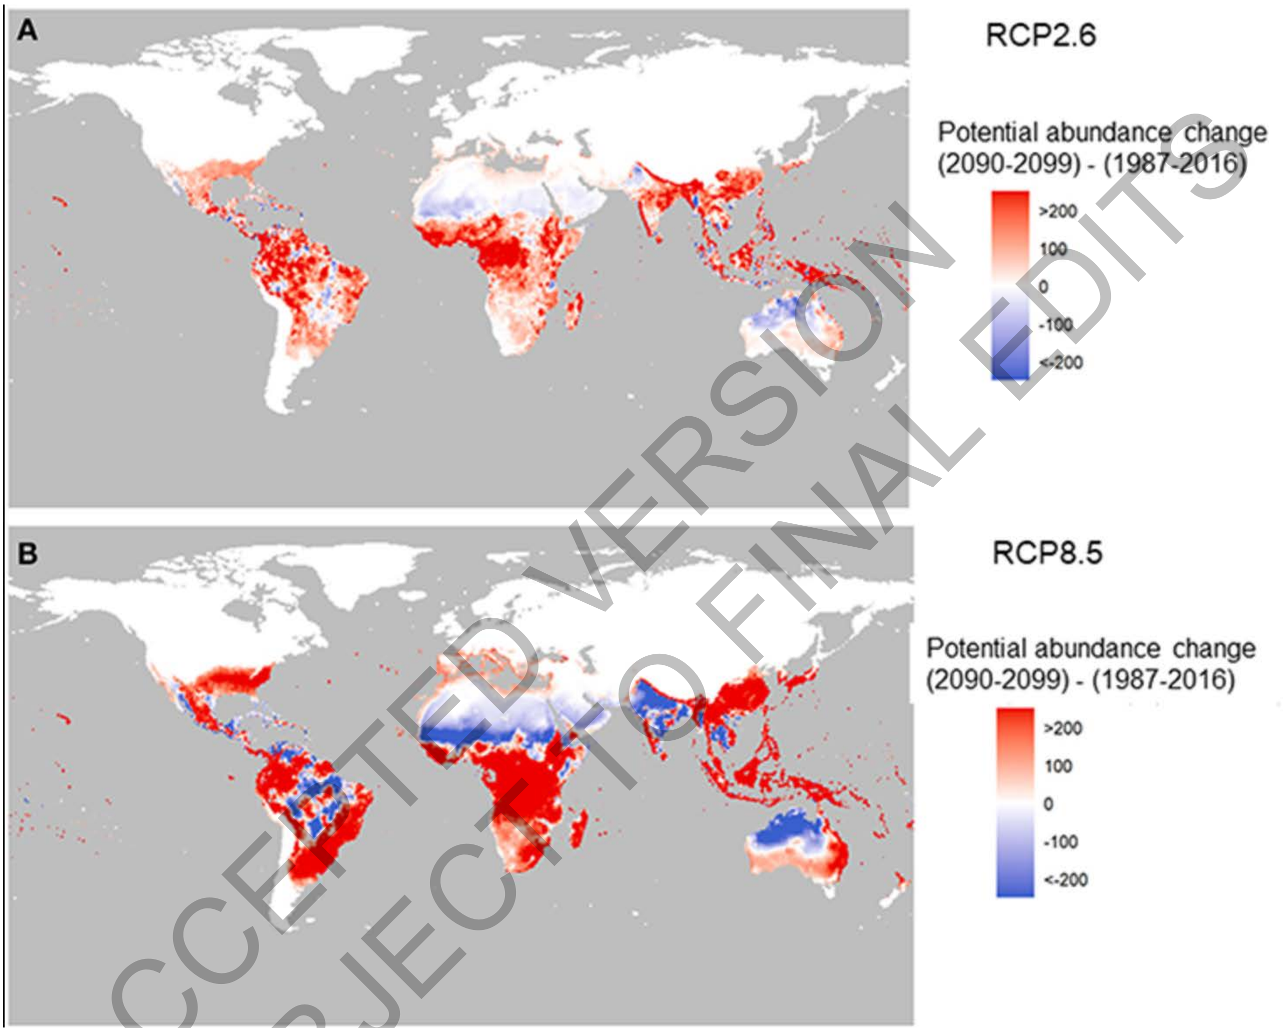

Figure 7.10: Projected change in the potential abundance of *Aedes aegypti* over the twenty-first century (2090-2099 relative to 1987-2016) (Liu-Helmersson et al., 2019)

Climate change is expected to increase dengue risk and facilitate its global spread, with the risk being greatest under high emissions scenarios (high confidence). Future exposure to risk will be influenced by the combined effects of climate change and non-climatic factors such as population density and economic development (Akter et al., 2017). Overall, risk levels are expected to rise on all continents (Akter et al., 2017);(Messina et al., 2015);(Rogers, 2015);(Liu-Helmersson et al., 2016);(Messina et al., 2019). Compared to 2015, an additional 1 billion people are projected to be at risk of dengue exposure by 2080 under an RCP4.5/SSP1 scenario, 2.25 billion under RCP6.0/SSP2, and 5 billion under RCP8.5/SSP3 (Messina et al., 2019). In North America, risk is projected to expand in north-central Mexico, with annual dengue incidence in Mexico increasing by up to 40% by 2080, and to expand from US southern states to mid-western regions, with annual dengue incidence in Mexico increasing by up to 40% by 2080 (Proestos et al., 2015);(Colon-Gonzalez et al., 2013). In China, under RCP8.5, dengue exposure would increase from 168 million people in 142 counties to 490 million people in 456 counties by the late 2100s (Fan and Liu, 2019). In Nepal, dengue fever is expected to expand throughout the 2050s and 2070s under all RCPs (Acharya et al., 2018). In Tanzania, there is a projected shift in distribution towards central and north-eastern areas and risk intensification in nearly all parts of the country by 2050 (Mweya et al., 2016). Dengue vectorial capacity is projected to increase in Korea under higher RCP scenarios (Lee et al., 2018a).

There are insufficient studies for assessment of projected effects of climate change on other arboviral diseases, such as chikungunya and zika. Zika virus transmits under different temperature optimums than does dengue, suggesting environmental suitability for zika transmission could expand with future warming (low confidence).
(Tesla et al., 2018)

Climate change can be expected to continue to contribute to the geographical spread of the Lyme disease vector Ixodes scapularis *(high confidence) and the spread of tick-borne encephalitis and Lyme disease vector* Ixodes ricinus *in Europe (medium confidence).* In Canada, vector surveillance of the black-legged tick *I. scapularis* identified strong temperature effects on the limits of their occurrence, on recent geographic spread, temporal coincidence in emergence of tick populations, and acceleration of the speed of spread (Clow et al., 2017);(Cheng et al., 2017). In Europe, increasing temperatures over the period 1950-2018 significantly accelerated the life cycle of *Ixodes ricinus* and contributed to its spread (Estrada-Peña and Fernández-Ruiz, 2020). Under RCP4.5 and RCP8.5 scenarios, projections indicate a northward and eastward shift of the distribution of *I. persulcatus and I. ricinus,* vectors of Lyme disease and tick-borne encephalitis in Northern Europe and Russia, with an overall large increase in distribution in the second half of the current century (Popov and Yasyukevich, 2014);(Yasjukevich et al., 2018) and increases in intensity of tick-borne encephalitis transmission in central Europe (Nah et al., 2020).

Climate change is projected to increase the incidence of Lyme disease and tick-borne encephalitis in the Northern Hemisphere (high confidence) (see also Figure 7.3). The basic reproduction number (R0) of *I. scapularis* in at least some regions of Canada is projected to increase under all RCP scenarios (McPherson et al., 2017). In the United States, a 2°C warming could increase the number of Lyme disease cases by over 20% over the coming decades, and lead to an earlier onset and longer length of the annual Lyme disease season (Dumic and Severnini, 2018);(Monaghan et al., 2015).

Climate change is projected to change the distribution of schistosomiasis in Africa and Asia (high confidence), with a possible increase in global land area suitable for transmission (medium confidence). A global increase in land area with temperatures suitable for transmission by the three main species of *Schistosoma* (*S. japonicum*, *S. mansoni* and *S. haematobium)* is projected under the RCP4.5 scenario for the periods 2021–2050 and 2071–2100 (Yang and Bergquist, 2018) but regional outcomes are expected to vary. In Africa, shifting temperature regimes associated with climate change are expected to lead to reduced snail populations in areas with already high temperatures, and higher populations in areas with currently low winter temperatures (Kalinda et al., 2017);(McCreesh and Booth, 2014). Infection risk with *Schistosoma mansoni* may increase by up to 20% over most of eastern Africa over the next 20-50 years but decrease by more than 50% in parts of north and east Kenya, southern South Sudan and eastern PDRC (McCreesh et al., 2015), with a possible overall net contraction (Stensgaard et al., 2013). In China, currently endemic areas in Sichuan Province may become unsuitable for snail habitats, but currently non-endemic areas in Sichuan and Hunan/Hubei provinces may see new emergence (Yang and Bergquist, 2018). In addition to the projected effects of temperature described above, distribution and transmission of schistosomiasis will also be affected positively or negatively by changes in the availability of freshwater bodies, which were not included in these models.

7.3.1.4 Projected impacts on water-borne diseases

Climate change will contribute to additional deaths and mortality due to diarrheal diseases in the absence of adaptation (medium confidence) (see Figure 7.3*).* Risk factors for future excess deaths due to diarrheal diseases are highly mediated by future levels of socio-economic development and adaptation. An additional 1°C increase in mean average temperature is expected to result in a 7% (95% CI, 3%-10%) increase in all-cause diarrhoea (Carlton et al., 2016), and an 8% (95% CI, 5%-11%) increase in the incidence of diarrheic *E. coli* (Philipsborn et al., 2016)*,* and a 3% to 11% increase in deaths attributable to diarrhoea (WHO, 2014). WHO Quantitative Risk Assessments for the effects of climate change on selected causes of death for the

2030s and 2050s project that overall deaths from diarrhoea should fall due to socioeconomic development, but that the effect of climate change under higher emission scenarios could cause an additional 48,000 deaths in children aged under 15 years in 2030 and 33,000 deaths for 2050, particularly in Africa and parts of Asia. In Ecuador, projected increases in rainfall variability and heavy rainfall events may increase diarrhoea burden in urban regions (Deshpande et al., 2020). A limit in the assessable literature is a lack of studies in the highest risk areas (Liang and Gong, 2017);(UNEP, 2018).

Climate change is expected to increase future health risks associated with a range of other waterborne diseases and parasites, with effects varying by region (medium confidence). Waterborne diseases attributable to protozoan parasites including *Cryptosporidium* spp and *Giardia duodenalis (intestinalis)* are expected to increase in Africa due to increasing temperatures and drought (Ahmed et al., 2018);(Efstratiou et al., 2017). Recent data suggest a poleward expansion of *Vibrios* to areas with no previous incidence, particularly in mid- to high- latitude regions in areas where rapid warming is taking place (Baker-Austin et al., 2017). The number of *Vibrio*-induced diarrhoea cases per year increased in past decades in the Baltic Sea region, and the projected risk of vibriosis will increase in northern areas, where waters are expected to become warmer, more saline due to reduced precipitation, and have higher chlorophyll concentrations (Escobar et al., 2015);(Semenza et al., 2017).

The risk of Campylobacteriosis and other enteric pathogens could rise in regions where heavy precipitation events or flooding are projected to increase (medium confidence). In Europe, the risk of Campylobacteriosis and diseases caused by other enteric pathogens could also rise in regions where precipitation or extreme flooding are projected to increase (Agency, 2017), although incidence rates may be further mediated by seasonal social activities (Rushton et al., 2019);(Williams et al., 2015b). Accelerated releases of dissolved organic matter to inland and coastal waters through increases in precipitation are expected to reduce the potential for solar UV inactivation of pathogens and increase risks for associated waterborne diseases (Williamson et al., 2017). The combined relative risk for waterborne campylobacteriosis, salmonellosis and diseases due to Verotoxin-producing Escherichia coli was estimated to be 1.1 (i.e. a 10% increase) for every 1°C in mean annual temperature, while by the 2080s, under RCP8.5, annual rates of cryptosporidiosis and giardiasis could rise by approximately 16% due to more severe precipitation events (Brubacher et al., 2020);(Chhetri et al., 2019).

7.3.1.5 Projected impacts on food-borne diseases

The prevalence of Salmonella *infections are expected to rise as higher temperatures enable more rapid replication (medium confidence)*. Research from Canada finds a very strong association of salmonellosis and other food-borne diseases with higher temperatures, suggesting that climate change could increase food safety risks ranging from increased public health burden to emergent risks not currently seen in the food chain (Smith and Fazil, 2019). In Europe, the average annual number of temperature-related cases of salmonellosis under high emissions scenarios could increase by up to 50% more than would be expected on the basis of on population change alone, by 2100 (Lake, 2017);(Agency, 2017). Warming trends in the southern US may lead to increased rates of Salmonella infections (Akil et al., 2014).

7.3.1.6 Projected impacts on pollution and aeroallergens related health outcomes

Global air pollution-related mortality attributable directly to climate change – the human health climate penalty associated with climate-induced changes in air quality - is likely to increase and partially counteract any decreases in air pollution-related mortality achieved through ambitious emission reduction scenarios or stabilisation of global temperature change at 2°C (medium confidence). Demographic trends in aging and more vulnerable population are likely to be important determinants of future air quality – a human health climate penalty *(high confidence)*.

Poor air quality contributes to a range of non-communicable diseases including cardiovascular, respiratory, and neurological, commonly resulting in hospitalisation or death. This section considers the possible risks for health of future climate-related changes in ozone and particulate matter (PM). The climate penalty, the degree to which global warming could affect future air quality, is better understood for ozone than particulate matter (von Schneidemesser et al., 2020). This is because increases in air temperature enhance ozone formation via associated photochemical processes (Archibald et al., 2020);(Fu and Tian, 2019). The association between climate and particulate matter is complex and moderated by a diverse range of PM components as well as formation and removal mechanisms (von Schneidemesser et al., 2020), added to which is uncertainty about future climate related PM sources such as wildfires (Ford et al., 2018) and changes in aridity (Achakulwisut et al., 2019). As noted in Chapter 6 of the WG1 report, future air quality will largely depend on precursor emissions, with climate change projected to have mixed effects. Because of the uncertainty of how natural processes will respond, there is low confidence in the projections of surface ozone and PM under climate change (Szopa et al., 2021 – Chapter 6, IPCC AR6 WGI). This bears implications for the levels of confidence in projections of the health climate penalty associated with climate-induced changes in air quality (Orru et al., 2017), (Orru et al., 2019);(Silva et al., 2017).

There is a rich literature on global and regional level projections of air quality-related health effects arising from changes in emissions. Comparatively few studies assess how changes in air pollution directly attributable to climate change are likely to affect future mortality levels. Projections indicate that emission reduction scenarios consistent with stabilisation of global temperature change at 2°C or below would yield substantial co-benefits for air quality related health outcomes(Chowdhury et al., 2018b); (von Schneidemesser et al., 2020);(Silva et al., 2016c);(Markandya et al., 2018);(Orru et al., 2019);(Shindell et al., 2018) (*high confidence*). For example, by 2030, compared to 2000, it was estimated that globally and annually 289,000 PM2.5 - related premature deaths could have been avoided under RCP 4.5 compared to 17,200 PM2.5 - related excess premature deaths under RCP 8.5(Silva et al., 2016c). Further, and notwithstanding estimated reductions in global PM2.5 levels and an associated increase in the number of avoidable deaths, the benefits of following a low emissions pathway are expected to be apparent by 2100, with avoidable deaths estimated at 2.39 million deaths per year under RCP4.5. This contrasts with the 1.31 million estimated under RCP8.5. A few projections of the health related climate-penalty indicate a possible increase in ozone and PM2.5 - associated mortality under RCP8.5 (Doherty et al., 2017);(Orru et al., 2019);(Silva et al., 2017).

At the global level for PM2.5, annual premature deaths due to climate change were projected to be 55,600 (−34,300 to 164,000) and 215,000 (−76,100 to 595,000) in 2030 and 2100, respectively, countering by 16% the projected decline in PM2.5 -related mortality between 2000 and 2100 without climate change (Silva et al., 2017). Similarly for ozone , the number of annual premature ozone-related deaths due to climate change were projected to be 3,340 in 2030 and 43,600 in 2050, with climate change accounting for 1.2% (14%) of the annual premature deaths in 2030 (2100) (Silva et al., 2017). These global level projections average over considerable geographical variations (Silva et al., 2017). Projections of the climate change effect on ozone mortality in 2100 were greatest for East Asia (41 deaths per year per million people), India (8 deaths per year per million people) and North America (13 deaths per year per million people). For PM2.5, mortality was projected to increase across all regions except Africa (−25,200 deaths per year per million people) by 2100, with estimated increases greatest for India (40 deaths per year per million people), the Middle East (45 deaths per year per million people), East Asia (43 deaths per year per million people) and the Former Soviet Union (57 deaths per year per million people). Overall, higher ozone-related health burdens were projected to occur in highly populated regions and greater PM2.5 health burdens were projected in high PM emission regions (Doherty et al., 2017).

For Central and Southern Europe, climate change alone could result in an 11% increase in ozone-associated mortality by 2050. However, projected declines in ozone precursor emissions could reduce the EU-wide climate change effect on ozone-related mortality by up to 30%; the reduction was projected to be approximately 24% if aging and an increasingly susceptible population were accounted for in projections to 2050 (Orru et al., 2019). For the US in 2069, the impact of climate change alone on annual PM2.5 and ozone-related deaths were estimated to be 13,000 and 3,000 deaths respectively, with heat-driven adaptation of air conditioning accounting for 645 and 315 of the PM2.5 and ozone related annual excess deaths, respectively (Abel et al., 2018). An aging population as a determinant of future air quality related mortality levels. An aging population along with an increase in the number of vulnerable people may work to offset the decrease in deaths associated with a low emission pathway (RCP4.5) and possibly dominate the net increase in deaths under a business as usual pathway (RCP8.5) (Chen et al., 2020) ;(Doherty et al., 2017);(Hong et al., 2019);(Schucht et al., 2015).

Complementing the longer-term changes in air quality arising from climate change are those associated with air pollution sensitive short-term meteorological events, such as heatwaves. Studies of individual heat events

(Garrido-Perez et al., 2019);(Johansson et al., 2020);(Kalisa et al., 2018);(Pu et al., 2017);(Pyrgou et al., 2018);(Schnell and Prather, 2017);(Varotsos et al., 2019) and systematic reviews (Anenberg et al., 2020) provide evidence for synergistic effects of heat and air pollution. However, the health consequences of a possible additive effect of air pollutants during heatwave events were heterogeneous, varying by location and moderated by socio-economic factors at the intra-urban scale (Analitis et al., 2014);(Fenech et al., 2019);(Krug et al., 2020);(Pascal et al., 2021);(Schwarz et al., 2021);(Scortichini et al., 2018). This, combined with the challenges associated with projecting future concentrations of health-relevant pollutants during heatwave events (Jahn and Hertig, 2021);(Meehl et al., 2018) makes it difficult to say with any certainty that synergistic effects of heat and poor air quality will result in a heatwave-air pollution health penalty under climate change.

The burden of disease associated with aeroallergens is anticipated to grow due to climate change (high confidence). The incidence of pollen allergy and associated allergic disease increases with pollen exposure, and the timing of the pollen season and pollen concentrations are expected to change under climate change (Beggs, 2021);(Ziska et al., 2019), (Ziska, 2020). The overall length of the pollen season and total seasonal pollen counts/concentrations for allergenic species such as birch (Betula) and ragweed (Ambrosia) are expected to increase as a result of CO_2 fertilization and warming, leading to greater sensitization (Hamaoui-Laguel et al., 2015);(Lake et al., 2017);(Zhang et al., 2013). Changes in pollen levels for several species of trees and grasses are projected to increase annual emergency department visits in the US by between 8% for RCP4.5 and 14% for RCP8.5 by the year 2090 (Neumann et al., 2019) with the exposure to some pollen types estimated to double beyond present levels in Europe by 2041-2060 (Lake et al., 2017). The prospect of increases in summer thunderstorm events under climate change (Brooks, 2013) may hold implications for changes in the occurrence of epidemic thunderstorm asthma (Bannister et al., 2021);(Emmerson et al., 2021);(Price et al., 2021). Similarly projected alterations in hydroclimate under climate change may bear implications for increased exposure to mould allergens in some climates (D'Amato et al., 2020); (Paudel et al., 2021).

7.3.1.7 Cardiovascular diseases

Climate change is expected to increase heat-related cardiovascular disease (CVD) mortality by the end of the 21st century, particularly under higher emission scenarios (high confidence). Most modelling studies conducted since AR5 project higher rates of heat-related CVD mortality throughout the remainder of this century(Huang and et al., 2018);(Li et al., 2015);(Li et al., 2018);(Limaye et al., 2018);(Zhang et al., 2018a);(Silveira et al., 2021a); (Yang et al., 2021). CVD mortality in Beijing, China could increase by an average of 18.4%, 47.8%, and 69.0% in the 2020s, 2050s, and 2080s, respectively, under RCP 4.5, and by 16.6%, 73.8% and 134%, respectively, under RCP 8.5 relative to a 1980s baseline (Li et al., 2015). Projections of temperature-related mortality from CVD for Beijing in the 2080s varying depending on RCP and population assumptions (Zhang et al., 2018a). Projections for Ningo, China, suggest heat-related years of life lost could increase significantly in the month of August, by between 3 and 11.5 times greater over current baselines by the 2070s, even with adaptation (Huang and et al., 2018). Yang and colleagues project that heat-related excess CVD mortality in China could increase to approximately 6% (from a 2010 baseline of under 2%) by the end of the century under RCP 8.5 and to over 3% under RCP 4.5 (Yang et al., 2021). The future burden of temperature-related myocardial infarctions (MI) in Germany is projected to rise under high emissions scenarios (Chen et al., 2019), while in the eastern US, Limaye et al. (2018) projected an additional 11,562 annual deaths (95% CI: 2,641–20,095) by mid-century due to cardiovascular stress in the population 65 years of age and above. CVD mortality in Brazil is projected to increase up to 8.6% by the end of the century under RCP 8.5, compared with an increase of 0.7% for RCP 4.5 (Silveira et al., 2021a).

It is important to note that the assessed studies typically take an observed epidemiological relationship and apply future temperature projections (often derived from regional climate projections), to these relationships. Because the relationships between temperature and CVD death are influenced by both climatic and non-climatic factors (such as population fitness and aging), future projections are highly sensitive to assumptions about interactions between climate, population characteristics, and adaptation pathways. Changes in air quality because of climate change are an additional important factor. For example, an assessment of future annual and seasonal excess mortality from short-term exposure to higher levels of ambient ozone in Chinese cities under RCP 8.5 projected approximately 1,500 excess annual CVD deaths in 2050 (Chen et al., 2018).

To the extent possible, the relationships reported above reflect changes derived from changes in heat exposure driven by climate change, and not changes in population demographics or air pollution exposure.

Climate change could impact CVD through other pathways, including exposure to fine dust. For example, Achakulwisut and colleagues found that adult mortality attributable to fine dust exposure in the American southwest could increase by 750 deaths per year (a 130% increase over baseline) by the end of the century under RCP 8.5 (Achakulwisut et al., 2018).

7.3.1.8 Maternal, foetal, and neonatal health

Additional research is needed on future impacts of climate change on maternal, foetal and neonatal health. Maternal heat exposure is a risk factor for several adverse maternal, foetal, and neonatal outcomes (Kuehn and McCormick, 2017), including foetal growth (Sun et al., 2019) and congenital anomalies (Haghighi et al., 2021). There is very limited research on this subject, an exception being Zhang et al. 2020 (Zhang et al.) that projected an 34% increase in congenital health disease risk in the US in 2025 and 2035 based on increased maternal extreme heat exposure.

7.3.1.9.1 Malnutrition

Climate change is projected to exacerbate malnutrition (high confidence). Climate change attributable moderate and severe stunting in children less than 5 years of age was projected for 2030 across 44 countries to be an additional 570,000 cases under a prosperity and low climate change scenario (RCP2.6) to one million cases under a poverty and high climate change scenario (RCP8.5), with the highest effects in rural areas.(Lloyd, 2018). Future disability-adjusted life years (DALYs) lost due to protein-energy undernutrition and micronutrient deficiencies without climate change have been projected to increase between 2010 and 2050 by over 30 million. With climate change (RCP8.5), DALYs were projected to increase by nearly 10%, with the largest increases in Africa and Asia (Sulser et al., 2021).

The projected risks of hunger and childhood underweight vary under the five SSPs, with population growth, improvement in the equality of food distribution, and income-related increases in food consumption influencing future risks (Ishida et al., 2014);(Hasegawa et al., 2015). A review of 57 studies projecting global food security to 2050 under the SSPs concluded that global food demand was expected to increase by 35% to 56% between 2010 and 2050, with the population at risk of hunger expected to change by −91% to +8% (van Dijk et al., 2021);(van Dijk et al., 2021). Taking climate change into account changed the ranges slightly but with no statistical differences overall.

7.3.1.9.2 Climate Change, Carbon Dioxide, Diets, and Health

Climate change could further limit equitable access to affordable, culturally acceptable, and healthy diets (high confidence). Climate impacts on agricultural production and regional food availability will affect the composition of diets, which can have major consequences for health. Variable by region and context, healthy diets are an outcome of the four interconnected domains of sustainable food systems, namely ecosystems, society, economics, and health (Drewnowski et al., 2020);(Fanzo et al., 2020). Climate change limits the potential for healthy diets through adverse impacts on natural and human systems that are disproportionately experienced by low-income countries and communities (FAO et al., 2021). Climate-driven droughts, floods, storms, wildfires, and extreme temperatures reduce food production potential by diminishing soil health, water security, and biological and genetic diversity (Macdiarmid and Whybrow, 2019). Models project that climate-related reductions in food availability, specifically fruit and vegetables, could result in an additional 529,000 deaths a year by 2050 (Springmann et al., 2016b).

Diets reliant on marine fisheries and fish also face complex climate-driven challenges (Hollowed et al., 2013). Rapidly warming oceans (Cheng et al., 2020) limit the size of many fish and hamper their ability to relocate or adapt; many commonly consumed fish, like sardines, pilchards, and herring could face extinction due to these pressures (Avaria-Llautureo et al., 2021). Other fisheries models project end of century pollock and Pacific cod fisheries decreasing by >70% and >35% under RCP 8.5 (Holsman et al., 2020). Climate-driven increases in marine mercury concentrations (Booth and Zeller, 2005) and harmful algal blooms (Jardine et al., 2020) could impact dietary quality and human health.

Global crop and economic models project higher cereal prices of up to 29% by 2050 under RCP 6.0, resulting in an additional 183 million people in low-income households at risk of hunger (Hasegawa et al., 2018). Climate impacts on human health disrupt agricultural labour, food supply chain workers, and ultimately regional food availability and affordability. A recent meta-analysis focused on Sub-Saharan Africa and Southeast Asia combined metrics of heat stress and labour to project that a 3°C increase in global mean temperature, without adaptation or mechanization, could reduce agricultural labour capacity by 30-50%, leading to 5% higher crop prices and a global welfare loss of $136 billion (de Lima et al., 2021).

The nutritional density of wheat, rice, barley, and other important food crops, including of protein content, micronutrients, and B-vitamins, is affected negatively by higher CO_2 concentrations (*very high confidence*). (SRCCL, 2019 5.4.3);(Smith and Myers, 2018). Projections indicate negative impacts on human nutrition of rising CO_2 concentrations by mid- to late-century (Medek et al., 2017);(Smith and Myers, 2018);(Weyant et al., 2018);(Zhu et al., 2018);(Beach et al., 2019). Staple crops are projected to have decreased protein and mineral concentrations by 5-15% and B vitamins up to 30% when the concentrations of CO_2 double above pre-industrial (Ebi and Loladze, 2019);(Beach et al., 2019);(Smith and Myers, 2018). Without changes in diets and accounting for nutrient declines in staple crops, a projected additional 175 million people could be zinc deficient and an additional 122 million people could become protein deficient (Smith and Myers, 2018).Weyant et al. (2018) projected that CO_2-related reductions in crop zinc and iron levels could result in 125.8 million DALYs lost globally, with South-East Asian and sub-Saharan African countries most affected. Zhu et al. (2018) estimated 600 million people at risk from reductions in the protein, micronutrient, and B-vitamin content of widely grown rice cultivars in Southeast Asia.

The combined effect of CO_2 and rising temperatures because of climate change could result in a 2.4% to 4.3% penalty on expected gains by mid-century in nutritional content because of technology change, market responses, and the fertilization effects of CO_2 on yield (Beach et al., 2019). These penalties are expected to slow progress in achieving reductions in global nutrient deficiencies, disproportionately affecting countries with high levels of such deficiencies.

7.3.1.10 Projected impacts on harmful algal blooms, mycotoxins, aflatoxins, and chemical contaminants

Harmful algal blooms are projected to increase globally, thus increasing the risk of seafood contamination with marine toxins (high confidence). (Authority) et al., 2020);(Gobler et al., 2017);(Barange et al., 2018);(SRCCL, 2019);(Wells et al., 2020). Climate change impacts on oceans could generate increased risks of ciguatera poisoning in some regions *(medium confidence).* Studies suggest that rising sea surface temperatures could increase rates of ciguatera poisoning in Spain (Botana, 2016), and other parts of Europe {EFSA, 2020, Climate change as a driver of emerging risks for food and feed safety`, plant`, animal health and nutritional quality.

Mycotoxins and aflatoxins may become more prevalent due to climate change (medium agreement, low evidence). Models of aflatoxin occurrence in maize under climate change scenarios of +2 °C and +5 °C in Europe over the next 100 years project that aflatoxin B1 may become a major food safety issue in maize, especially in Eastern Europe, the Balkan Peninsula and the Mediterranean regions (Battilani, 2016). The occurrence of toxin-producing fungal phytopathogens has the potential to increase and expand from tropical and subtropical into regions where such contamination does not currently occur (Battilani, 2016).

Climate change may alter regional and local exposures to anthropogenic chemical contaminants (medium agreement, low evidence). Changes in future occurrences of wildfires could lead to a 14 percent increase in global emissions of mercury by 2050, depending on the scenarios used (Kumar et al., 2018a). Mercury exposure via consumption of fish may be affected by warming waters. Warming trends in the Gulf of Maine could increase the methyl mercury levels in resident tuna by 30 percent between 2015 and 2030 (Schartup et al. (2019). An observed annual 3.5 percent increase in mercury levels was attributed to fish having higher metabolism in warmer waters, leading them to consume more prey. The combined impacts of climate change and the presence of arsenic in paddy fields are projected to potentially double the toxic heavy metal content of rice in some regions, potentially leading to a 39 percent reduction in overall production by 2100 under some models (Muehe et al., 2019).

7.3.1.11 Mental Health and Wellbeing

Climate change is expected to have adverse impacts on wellbeing, some of which will become serious enough to threaten mental health (very high confidence). However, changes (Hayes and Poland, 2018) in extreme events due to climate change, including floods {Baryshnikova, 2019 #3530} , droughts (Carleton, 2017) and hurricanes (Kessler et al., 2008);(Boscarino et al., 2013), (Boscarino et al., 2017) ; (Obradovich et al., 2018), which are projected to increase due to climate change, directly worsen mental health and wellbeing, and increase anxiety (*high confidence)*. Projections suggest that sub-Saharan African children and adolescents, particularly girls, are extremely vulnerable to negative direct and indirect impacts on their mental health and wellbeing (Atkinson and Bruce, 2015);(Owen et al., 2016). The direct risks are greatest for people with existing mental disorders, physical injuries, impacts on respiratory, cardiovascular and reproductive systems, with indirect impacts potentially arising from displacement, migration, famine and malnutrition, degradation or destruction of health and social care systems, conflict, and climate-related economic and social losses (*high to very high confidence*) (Burke et al., 2018);(Curtis et al., 2017);(Hayes et al., 2018); (Serdeczny et al., 2017);(Watts et al., 2019). Demographic factors increasing vulnerability include age, gender, and low socioeconomic status, though the effect of these will vary depending on the specific manifestation of climate change; overall, climate change is predicted to increase inequality in mental health across the globe (Cianconi et al., 2020). Based on evidence assessed in Section 7.2 of this chapter, future direct impacts of increased heat risks and associated illnesses can be expected to have negative implications for mental health and wellbeing, with outcomes being highly mediated by adaptation, but there are no assessable studies that quantify such risks. There may be some benefits to mental health and wellbeing associated with fewer very cold days in the winter; however, research is inconsistent. Any positive effect associated with reduced low-temperature days is projected to be outweighed by the negative effects of increased high temperatures (Cianconi et al., 2020).

Human behaviors and systems will be disrupted by climate change in a myriad of ways, and the potential consequences for mental health and wellbeing are correspondingly large in number and complex in mechanism (high confidence). For example, climate change may alter human physical activity and mobility patterns, in turn producing alterations in the mental health statuses promoted by regular physical activity (Obradovich and Fowler, 2017);(Obradovich and Rahwan, 2019). Climate change may affect labour capacity, because heat can compromise the ability to engage in manual labor as well as cognitive functioning, with impacts on the economic status of individual households as well as societies (Kjellstrom et al., 2016);(Liu, 2020). Migrations and displacement caused by climate change may worsen the wellbeing of those affected (Vins et al., 2015);(Missirian and Schlenker, 2017). Climate change is expected to increase aggression through both direct and indirect mechanisms, with one study predicting a 6% increase in homicides globally for a 1°C temperature increase, although noting significant variability across countries (Mares and Moffett, 2016). Broad societal outcomes such as economic unrest, political conflict, or governmental dysfunction assessed in sections 7.3.5 may undermine mental health of populations in the future (*medium confidence*). Food insecurity presents its own severe risks for mental health and cognitive function (Jones, 2017).

7.3.2 Migration and displacement in a Changing Climate

Future changes in climate-related migration and displacement are expected to vary by region and over time, according to: (1) region-specific changes in climatic drivers, (2) changes in the future adaptive capacity of exposed populations, (3) population growth in areas most exposed to climatic risks, and (4) future changes in mediating factors such as international development and migration policies (high agreement, medium evidence). (Gemenne and Blocher, 2017);(Cattaneo et al., 2019);(McLeman, 2019) Assessed in this section are future risks associated with changes in the frequency and/or severity of storms, floods, droughts, extreme heat, wildfires and other events assessed in section 7.2 that currently affect migration and displacement patterns; as well as the impacts of emerging hazards, including average temperature increases that may affect the habitability of settlements in arid regions and the tropics, and sea level rise and associated hazards that threaten low-lying coastal settlements. Studies assessed here consider projected changes in future exposure to hazards over a variety of geographical and temporal periods, with some considering changes in population numbers in exposed areas. However, the uneven distribution of exposure of age cohorts is typically overlooked in existing research. For example, people younger than age 10 in the year 2020 are projected to experience a nearly fourfold increase in extreme events under 1.5C of global warming, and a fivefold increase under 3C warming; such increases in exposure would not be experienced by a person of the age of 55 in 2020 in their remaining lifetime under any warming scenario (Thiery et al., 2021).

7.3.2.1 Region-specific changes in climatic risks

As outlined in 7.2, the most common drivers of observed climate-related migration and displacement are extreme storms (particularly tropical cyclones), floods, extreme heat, and droughts (high confidence). The future frequency and/or severity of such events due to anthropogenic climate change are expected to vary by region according to future GHG emission pathways [IPCC 2021 Chapter 12; Regional Chapters, this report], with there being an increased potential for compound effects of successive or multiple hazards (e.g., tropical storms accompanied by extreme heat events, (Matthews et al., 2019). Table 7.2 summarizes anticipated changes in future migration and displacement risks due to sudden-onset climate events, by region (and by sub-regions for Africa and Asia, where climatic risks vary within the region).

Table 7.2: Projected changes in sudden-onset climate events associated with migration and displacement, by region

Region	**Main directions of current migration flows (from (Abel and Sander, 2014))**	**Current climatic drivers of migration & displacement [7.2.6.1]**	**Expected changes in drivers (*including confidence statements*) from IPCC 2021 TS 4.3.1-4.3.2**
Asia	East and Southeast Asia: Within countries and between countries within same region. South and Central Asia: Within countries and between countries within same region; from South Asia to Middle East, North America, Europe. West Asia: Within countries and between countries within the same region; to Europe	Floods, extreme storms, extreme heat	Increased risk of flooding in East, North, South & Southeast Asia due to increases in annual mean precipitation (*high confidence*) and extreme precipitation events in East, South, West Central, North & Southeast Asia (*medium confidence*); uncertainty regarding future trends in cyclones (current trend = decreased frequency, increased intensity); higher average temperatures across region (*high confidence*)
Africa	Within countries and between countries within the same region; to Europe and the Middle East	Floods, droughts, extreme heat	Decrease in total annual precipitation in northernmost and southernmost parts of Africa (*high confidence*); west-to-east pattern of decreasing-to-increasing annual precipitation in West Africa and East Africa (medium confidence); increased risk of heavy precipitation events that trigger flooding, across most parts of Africa (*medium confidence*); increased aridity and drought risks in North Africa, southern Africa and western parts of West Africa (*medium-high confidence*)
Europe	Within countries and between countries in same region	Floods	Increased risk of floods across all areas of Europe except Mediterranean areas (high confidence); higher risks of drought, fire weather in Mediterranean areas (high confidence)
North America	Within countries and between countries in same region	Floods; tropical cyclones (US Atlantic & Caribbean coast);	Increased frequency of heavy precipitation events across most areas (high confidence); tropical cyclones to become more severe (medium confidence); increased risk of drought

		tornadoes; wildfires	and fire weather in central and western North America
Central and South America	Within countries and between countries in same region; to North America, Europe	Floods (Central and South America; extreme storms (Central America)	Increases in mean annual precipitation and extreme precipitation events with higher risks of floods in most areas of South America (*medium confidence*); increased risk of droughts in northeastern and southern South America and northern Central America (*medium confidence*); tropical cyclones becoming more extreme (*medium confidence*)
Australasia	Displacement within countries	Wildfires	Increases in fire weather across Australia and New Zealand (*medium confidence*)
Small island states	Within and between countries in same region (e.g., Pacific Islands to Australia & New Zealand; Caribbean islands to USA)	Extreme storms	Potentially fewer but more extreme tropical cyclones (medium confidence)

In low-lying coastal areas of most regions, future increases in mean sea levels will amplify the impacts of coastal hazards on settlements, including erosion, inland penetration of storm surges and groundwater contamination by salt water, and eventually lead to inundation of very low-lying coastal settlements (high confidence). (Diaz, 2016);(Hauer et al., 2016);(Neumann et al., 2015);(Rahman et al., 2019);(Pörtner et al., 2019) Projections of the number of people at risk of future displacement by sea level rise range from tens of millions to hundreds of millions by the end of this century, depending on (1) the sea level rise scenario or RCP selected, (2) projections of future population growth in exposed areas and (3) the criteria used for identifying exposure. These latter measures can include estimates of populations situated within selected elevations above sea level (with 1m, 2m and 10m being common parameters), populations situated in 1-in-100 year floodplains, or populations in areas likely to be entirely inundated under specific RCPs (Neumann et al., 2015);(Hauer et al., 2016);(Merkens et al., 2018);(McMichael et al., 2020);(Hooijer and Vernimmen, 2021). As an illustrative example, an estimated 267 million people (error range = 197-347 million at 68% confidence level) worldwide lived within 2m of sea level in 2020, 59% of whom reside in tropical regions of Asia (Hooijer and Vernimmen, 2021). At a 1m increase in sea level and holding coastal population numbers constant, the number of people worldwide living within 2m of sea level expands to 410 million (error range = 341-473 million). However, it is *unlikely* that coastal population growth rates will remain constant at global or regional scales in future decades. At present, coastal cities in many regions have relatively high rates of population growth due to the combined effects of in-migration from other regions and natural increase, with coastal areas of Africa having the highest projected future population growth rates (Neumann et al., 2015);(Hooijer and Vernimmen, 2021); see also Box 7.5. Further complicating future estimates is that many large coastal cities are situated in deltas with high rates of subsidence, meaning that locally experienced changes in relative sea level may be much greater than sea level rise attributable to climate change, thereby further increasing the number of people exposed (Edmonds et al., 2020);(Nicholls et al., 2021).

Sea level rise is not presently a significant driver of migration in comparison with hazards assessed in 7.2.6, but it has been attributed as a factor necessitating the near-term resettlement of small coastal settlements in Alaska, Louisiana, Fiji, Tuvalu, and the Carteret Islands of Papua New Guinea (Marino and Lazrus, 2015);(Connell, 2016);(Hamilton et al., 2016; Nichols, 2019). In coastal Louisiana, communities tend to resist leaving exposed settlements until approximately 50% of available land has been lost (Hauer et al., 2019). Movements away from highly exposed areas may have longer-term demographic implications for inland settlements (Hauer, 2017), but this requires further study. Based on the limited empirical evidence available, sea level rise does not appear to currently be a primary motivation for international migration originating in small island states in the Indian and Pacific Oceans; economic considerations and family reunification appear to be the dominant current drivers (McCubbin et al., 2015);(Stojanov and Du, 2016);(Heslin, 2019);(Kelman et al., 2019). However, climatic drivers of migration are anticipated to take on a much greater causal role in migration decisions in coming decades (Thomas et al., 2020), and may discourage return migration to small island states (van der Geest et al., 2020). Even under best-case sustainable development scenarios, rising sea levels and associated hazards create risks of involuntary displacement in low-lying coastal areas and should be expected to generate a need for organized relocation of populations where protective infrastructure cannot be constructed (Horton and de Sherbinin, 2021) (Hamilton et al., 2016) . In high emissions scenarios, low-lying island states may face the long-term risk of becoming functionally uninhabitable, creating the potential for a new phenomenon of climate-induced statelessness (Piguet, 2019);(Desai et al., 2021).

[START BOX 7.5]

Box 7.5: Uncertainties in projections of future demographic patterns at global, regional and national scales

Projections of future numbers of people exposed to climate change-related hazards described in this chapter and elsewhere in this report are heavily influenced by assumptions about population change over time at global, regional, and national scales. One challenge concerns global and regional variability of baseline data for current populations, which is typically aggregated from national censuses that vary considerably in terms of frequency, timing, and reliability, especially in low-income countries. A number of gridded mapping dataset initiatives emerged in recent years to support population-environment modelling research at global and regional levels, common ones being the Gridded Population of the World, the Global Rural Urban Mapping Project, and LandScan Global Population dataset (McMichael et al., 2020). For future population projections at national levels, researchers commonly draw upon data generated by the Population Division of the United Nations Department of Economic and Social Affairs, which publishes periodic projections for future fertility, mortality, and international migration rates for over 200 countries, the most recent projections being for the period 2020 to 2100 (Division and Population, 2019). There have been debates among demographers regarding the precision of DESA projections, with some debate over whether these overestimate or underestimate future population growth in some regions (Ezeh et al., 2020). Population growth rates are highly influenced by socio-economic conditions, meaning that future population levels at local, national, and regional scales are likely to respond to relative rates of progress toward meeting the Sustainable Development Goals (Abel et al., 2016). The Shared Socio-economic Pathways used in climate impacts and adaptation research include a variety of assumptions about future mortality, fertility, and migration rates, and provide a range of population growth scenarios that diverge after the year 2030 according to future development trajectories (Samir and Lutz, 2017) and which are then further modified and downscaled by researchers for national-level studies. Understanding of future risks of climate change will benefit from continued efforts by the international community to collect and share data on observed population numbers and trends, and to work toward better projected data for population characteristics that strongly influence vulnerability to climate risks, such as gender, age, and indigeneity.

[END OF BOX 7.5]

Increased frequency of extreme heat events and long-term increases in average temperatures pose future risks to the habitability of settlements in tropical and sub-tropical regions, and may in the long term affect migration patterns in exposed areas, especially under high emissions scenarios (medium agreement, low evidence). Greater research into the specific dynamics between extreme heat and population movements is required in order to make an accurate assessment of this risk. Recent studies suggest that future increases in average temperatures could expose populations across wide areas of the tropics and subtropics to ambient temperatures for extended periods each year that are beyond the threshold for human habitability (Pal and Eltahir, 2016);(Im et al., 2017);(Xu et al., 2020). This effect would be amplified in urban settings where heat-island effects occur and create heightened need for air conditioning and other adaptation measures. In addition to risks associated with average temperature changes, Dosio et al (2018) project that at 1.5°C warming, between 9% and 18% of the global population will be regularly exposed to extreme heat events at least once in 5 years, with the exposure rate nearly tripling with 2°C warming. How these changes in exposure to high temperatures will affect future migration patterns, particularly among vulnerable groups, will depend heavily on future adaptation responses (Horton and de Sherbinin, 2021). Multiple country-level studies assessed in section 7.2 observe existing associations between extreme heat, its impacts on agricultural livelihoods, and changes in rural-to-urban migration flows in parts of South Asia and sub-Saharan Africa. A study conducted in Indonesia, Malaysia, and the Philippines suggests that an increased risk of heat stress would likely influence migration intentions of significant numbers of people (Zander et al., 2019).

7.3.2.2 Interactions with non-climatic determinants and projections of future migration flows

Only a very small number of studies have attempted to make systematic projections of future regional or global migration and displacement numbers under climate change. Key methodological challenges for making such projections include the availability of reliable data on migration within and between countries, definitional ambiguity in distinguishing climate-related migration from migration undertaken for other reasons, and accounting for the future influence of non-climatic factors. The most reliable example of such studies to date is a World Bank report by Rigaud et al (2018) generated projections of future internal population displacements in South Asia, sub-Saharan Africa,, and Latin America by 2050 using multiple climate and development scenarios, resulting in a very large range of possible outcomes (from 31 to 143 million people being displaced, depending on assumptions). An important outcome is the study's emphasis on how the potential for future migration and displacement will be strongly mediated by socio-economic development pathways in low- and middle-income countries. Consistent with this, Hoffmann et al (2020) used metaregression-based analyses to project that future environmental influences on migration are likely to be greatest in low- and middle-income countries in Latin America and the Caribbean, Sub-Saharan Africa, the Middle East and most of continental Asia.

Research reviewed in AR4 and AR5 observed that at higher rates of socio-economic development, the in situ adaptive capacity of households and institutions rises, and climatic influences on migration correspondingly decline. Recent evidence adds further support for such conclusions (high confidence). (Kumar et al., 2018b);(Mallick, 2019);(Gray et al., 2020) (Box 7.5). Population growth rates are currently highest in low-income countries (Division and Population, 2019), many of which have high rates of exposure to climatic hazards associated with population displacement, further emphasizing the importance of socio-economic development and adaptive capacity building. Although country-specific scenarios for socio-economic development and population are embedded in SSPs, research into future migration flows under climate change has not to date made great use of these. One of the few studies to do so found that safe and orderly international migration tends to increase wealth at regional and global scales in all SSP narratives, which in turn reduces income inequality between countries (Benveniste et al., 2021). International barriers to safe and orderly migration may potentially impede progress toward attainment of objectives described in the Sustainable Development Goals and increase exposure to climatic hazards in low- and middle income countries (McLeman, 2019);(Benveniste et al., 2020).

7.3.3 Climate Change and Future Risks of Conflict

Climate change may increase susceptibility to violent conflict, primarily intrastate conflicts, by strengthening climate-sensitive drivers of conflict *(medium confidence).* Section 7.2.7 demonstrated how climate variability and extremes affect violent conflict through food and water insecurity, loss of income, and loss of livelihoods. Risks are amplified by insecure land tenure, competing land uses and weather-sensitive economic activities, when they occur in the context of weak institutions and poor governance, poverty, and inequality (7.2.7). These known, climate-sensitive risk factors allow projections of where conflict is more likely to arise or worsen under climate change impacts (see Chapters 1, 4, 5, 6, 16) (Mach et al., 2020). However, there is also the potential for new causal pathways to emerge as climate changes beyond the variability observed in available datasets and adaptation limits are met (Theisen, 2017);(Mach et al., 2019);(von Uexkull and Buhaug, 2021).

Future violent conflict risk is highly mediated by socio-economic development trajectories (high confidence). Development trajectories that prioritise economic growth, political rights, and sustainability are associated with lower conflict risk (medium confidence, low evidence). Hegre et al (2016) forecast future conflict under the SSPs) and found that SSP1, which prioritises sustainable development is associated with lower risks of conflict. Using data from sub-Saharan Africa, Witmer et al (2017) forecast conflict along the SSPs and find that any increases in conflict that may be associated with climate change could be offset by increases in political rights. Strong predictors of future conflict are a recent history of conflict, large populations, and low levels of socio-economic development (Hegre and Sambanis, 2006) ; (Blattman and Miguel, 2010).

Increases in conflict-related deaths with climate change have been estimated but results are inconclusive (high agreement, medium evidence). Some studies attempted to attribute observed conflict outbreaks to changes in the physical environment and quantify future conflict risk associated with climate change (von Uexkull and Buhaug, 2021);(Theisen, 2017). Burke et al (2015b) concluded that with each one standard deviation increase in temperature, interpersonal conflict increased by 2.4% and intergroup conflict by 11.3%. However, this kind of approach has been criticised for its statistical methods and underrepresenting the known role that socioeconomic conditions and conflict history play in determining the prevalence of violence (Buhaug et al., 2014);(van Weezel, 2019);(Abel et al., 2019). Forecasting armed conflict is used as a heuristic policy tool rather than a representation of the future (Cederman and Weidmann, 2017) and forecasts have limitations. What constitutes, and is experienced as, a hazard will shift over time as societies adapt to climate change (Roche et al., 2020), the drivers of conflict change over time. The SSPs assume economic convergence between countries and do not reflect growth disruptions (e.g. commodity price shocks) that are often a key conflict risk factor (Dellink et al., 2017);(Buhaug and Vestby, 2019);(Hegre et al., 2021).

Asia represents a key region where the peace, vulnerability, and development nexus has been analysed. In Central, South, and South East Asia, there are large numbers of people exposed to the changing climate (Busby et al., 2018);(Vinke et al., 2017);(Reyer et al., 2017). South Asia is one of the least peaceful regions in the world with intra-state communal conflict, international military conflict, and political tension (Wischnath and Buhaug, 2014);(Huda, 2021), and many of the factors that drive conflict risk (large populations and high levels of inequality) are present (Nordqvist and Krampe, 2018). Despite these risks, studies in this region also support the case for environmental peacebuilding and resource sharing, as it relates to transboundary water sharing(Berndtsson and Tussupova, 2020);(Huda and Ali, 2018); Sections 4.3.6; 7.4.5.2).

In Asia, there is little evidence of weather-related impacts on conflict risk or prevalence, but the region is understudied in general (Wischnath and Buhaug, 2014);(Nordqvist and Krampe, 2018). Climate stressors may have contributed, in part, to local level conflicts in Bangladesh and Nepal (Sultana et al., 2019) and intensified water use conflict in peri-urban areas (Roth et al., 2019). There is the potential for climate change to stretch the effectiveness of transboundary water agreements by raising regional geopolitical tensions (Atef et al., 2019);(Scott et al., 2019) or to generate water use conflicts between hydropower and irrigation within countries (Jalilov et al., 2018). Climate change may impact on conflict by affecting food security (Caruso et al., 2016);(Raghavan et al., 2019). There may be greater military involvement in humanitarian response to cyclones, flooding, and to other impacts of climate change that might contribute to increased instability (Pai, 2008) ; (Busby and Krishnan, 2017).

7.4 Adaptation to Key Risks and Climate Resilient Development Pathways

With proactive, timely, and effective adaptation, many observed and projected risks for human health and wellbeing, health systems, and those associated with migration and conflict, can be reduced or potentially avoided (high confidence). Given the key health risks identified in this chapter, adaptation that increases resilience and sustainability will require moving beyond incremental adaptation and to sustained, adaptive management (Ebi, 2011);(Hess et al., 2012) with the goal of transformative change. This includes differentiating adaptation to climate variability from adaptation to climate change (Ebi and Hess, 2020). Health adaptation efforts are increasingly aiming to transition to building climate-resilient and environmentally sustainable health systems (WHO, 2015b);(WHO, 2020a) and healthcare facilities, emphasizing service delivery, including climate-informed health policies and programs, management of the environmental determinants of health; emergency preparedness and management; and health information systems, including health and climate research, integrated risk monitoring and early warning systems, and vulnerability, capacity, and adaptation assessments (Marinucci et al., 2014);(Mousavi et al., 2020);; (Organization, 2015);(CDC, 2019);(WHO, 2020a).

Migration can contribute to or work against adaptation goals and progress, depending on the circumstances under which it occurs. Policies that support safe and orderly movements of people, protect migrant rights, and facilitate flows of financial and other resources between sending and receiving communities are consistent with adaptive capacity building and building sustainability, and are part of climate resilient development pathways.

Adaptation to prevent climate from exacerbating conflict risk involves meeting development objectives encapsulated in the SDGs. Conflict-sensitive adaptation, environmental peacebuilding, and climate-sensitive peace building offer promising avenues to addressing conflict risk, but their efficacy is yet to be demonstrated through effective monitoring and evaluation (Gilmore et al., 2018). Associations between environmental factors and conflict are weak in comparison to socio-economic and political drivers. Therefore, meeting the SDGs, including Goal 16 on Peace, justice, and strong institutions represent unambiguous pathways to reducing conflict risk under climate change (Singh and Chudasama, 2021). Analysing peace rather than taking conflict for granted (Barnett, 2019) improving focus on gender within peacebuilding (Dunn and Matthew, 2015);(UNEP, 2021), and understand how natural resources and their governance interact with peacebuilding (Krampe et al., 2021) present key elements of climate resilient development pathways for sustainable peace.

As documented across this chapter, there is a large adaptation deficit for health and wellbeing, with climate change causing avoidable injuries, illnesses, disabilities, diseases, and deaths (high confidence). Implementation of health adaptation has been incremental because of significant constraints, primarily relating to financial and human resources, and because of limited research funding on adaptation (Berrang-Ford et al., 2021). Current global investments in health adaptation are insufficient to protect the health of populations and communities *(high confidence)* from most climate-sensitive risks, with large variability across and within countries and regions (UNEP, 2018). Climate change adaptation in health is <1% of international climate finance despite health being a priority sector in 54% of NDCs featuring adaptation (UNEP, 2018).

As climate change progresses and the likelihood of dangerous risks to human health continue to increase (Ebi et al., 2021a), there will be greater pressure for more transformational changes to health systems to reduce future vulnerabilities and limit further dangerous climate change. Transformational resilience would need parallel investments in social and health protections, including achieving the SDGs, coupled with investments in mitigation (Ebi and Hess, 2020). Further, investments in mitigating greenhouse gas emissions will not only reduce risks associated with dangerous climate change but will improve population health and wellbeing through several salutary pathways.

This chapter section identifies and assesses specific elements in adapting to risks identified in 7.2 and 7.3 and opportunities for fostering sustainability and pursuing climate resilient development pathways.

7.4.1 Adaptation Solution Space for Health and Wellbeing

The solution space is the space within which opportunities and constraints determine why, how, when, and who adapts to climate change (Chapter 1). *There is increased understanding of exposure and vulnerabilities to climate variability and change, and of the capacities to manage the health risks, of the effectiveness of adaptation (including a growing number of lessons learned and best practices), and of the co-benefits of mitigation policies and technologies (high confidence).*

Effectively preparing for and managing the health risks of climate change requires considering the multiple interacting sectors that affect population health and the effective functioning of health systems (high confidence). Given the wide range of causal pathways through which climate change affects environmental and social systems resulting in health impacts, a systems-based approach can promote identifying, implementing, and evaluating solutions that support population health and health systems in the short and longer-term (high agreement, medium evidence). Such an approach provides insights into policies and programs that promote health and wellbeing via multiple sectors (e.g. water and food safety and security), and can ensure that health policies do not have adverse consequences in other sectors (Organization, 2015);(Ebi and Otmani del Barrio, 2017);(Wright et al., 2021).

Figure 7.11 illustrates the context within which risks to health outcomes and health systems emerge because of climate change. The figure presents the emergence of risk from interactions between specific types of climatic hazards and exposure and vulnerability to those hazards, and the responses taken within the health sector. The figure illustrates also how health risks are situated within larger interactions between the health system and other sectors and systems, with underlying enabling conditions making adaptation and transformation possible. Within this context, response options can decrease the impacts of climate change on human health, wellbeing, and health systems by 1) reducing exposure to climate-related hazards; 2) reducing vulnerability to such hazards; and 3) strengthening health system responses to future risks. Such approaches are described as "Lateral Public Health" and emphasize the importance of involving community members and stakeholders in the planning and coordination of activities (Semenza, 2021);(Semenza, 2011). Lateral public health strives for community engagement (e.g., through access to technology in decision making, such as low-cost air sensors for wildfire smoke) in preparedness and response.

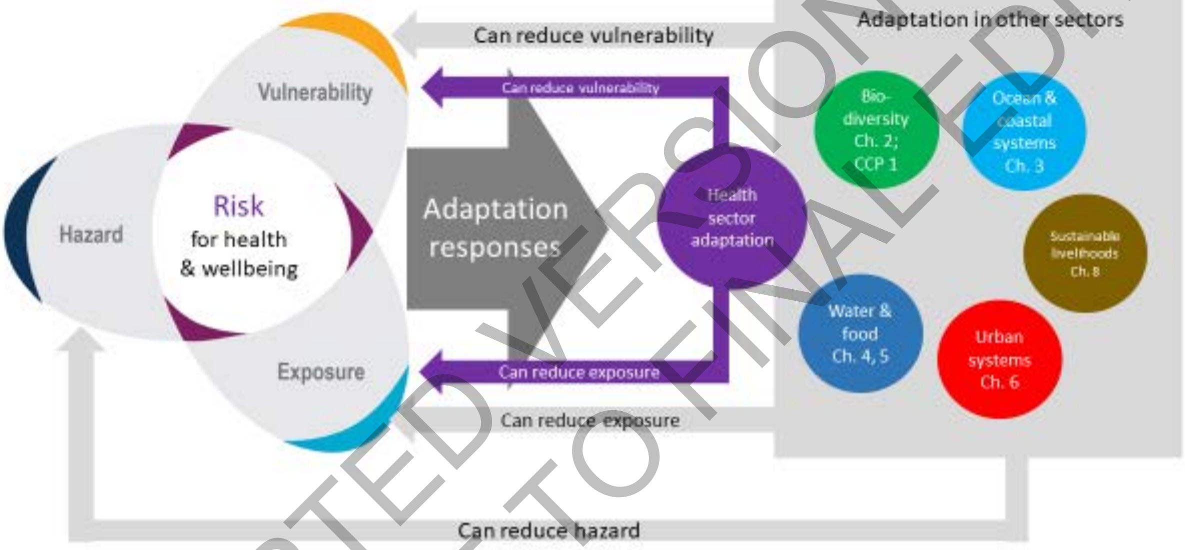

Figure 7.11: Context within which adaptation responses to climatic risks to health are implemented, in the frame of interactions between health and multiple other sectors..

Effective health risk management incorporates the magnitude and pattern of future climate risks as well as potential changes in factors that determine vulnerability and exposure to climate hazards, such as determinants of healthcare access, demographic shifts, urbanization patterns, and changes in ecosystems (very high confidence). Climate change is associated with shocks and stresses that can affect the capacity and resilience of health systems and healthcare facilities (WHO, 2020a). Figure 7.12 illustrates some possible extents to which the capacity of health systems could be reduced when exposed to a stress or shock, and possible pathways forward, from collapse to transformation. The subsequent sections assess adaptation and mitigation options to facilitate building the resilience of health systems and healthcare facilities to recover better than before or to transform.

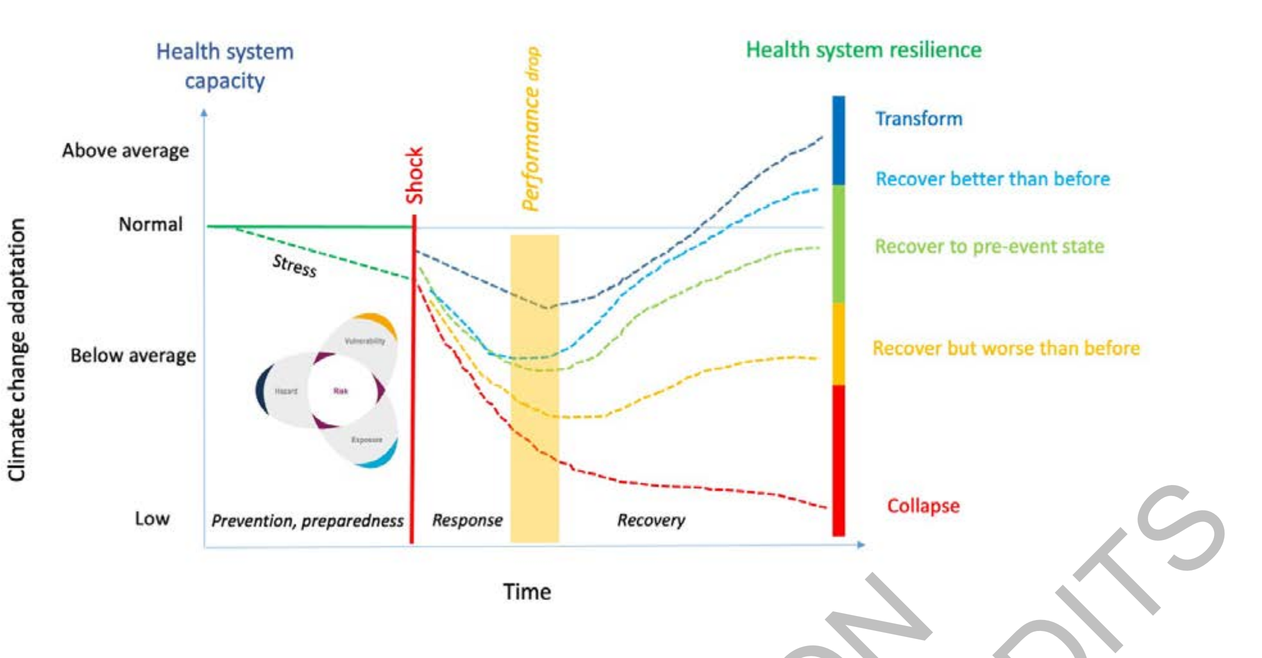

Figure 7.12: Health systems capacity and resilience to climate change-related shocks and stresses (from WHO 2020).

7.4.2 Adaptation Strategies, Policies and Interventions for Health and Wellbeing

7.4.2.1 Current state of health adaptation

Analysis of the Nationally Determined Contributions (NDC) to the Paris Agreement to determine how health was incorporated, including impacts, adaptation, and co-benefits, concluded that most low- and middle-income countries referred to health in their NDC (Dasandi et al., 2021). Figure 7.14 shows the degree of health engagement; this engagement is based on indicators measuring the specificity and detail of health references within the country NDC. Many vulnerable countries had high engagement of the health sector in the country NDC. However, this analysis did not determine whether the ambition expressed was sufficient to address the health adaptation needs.

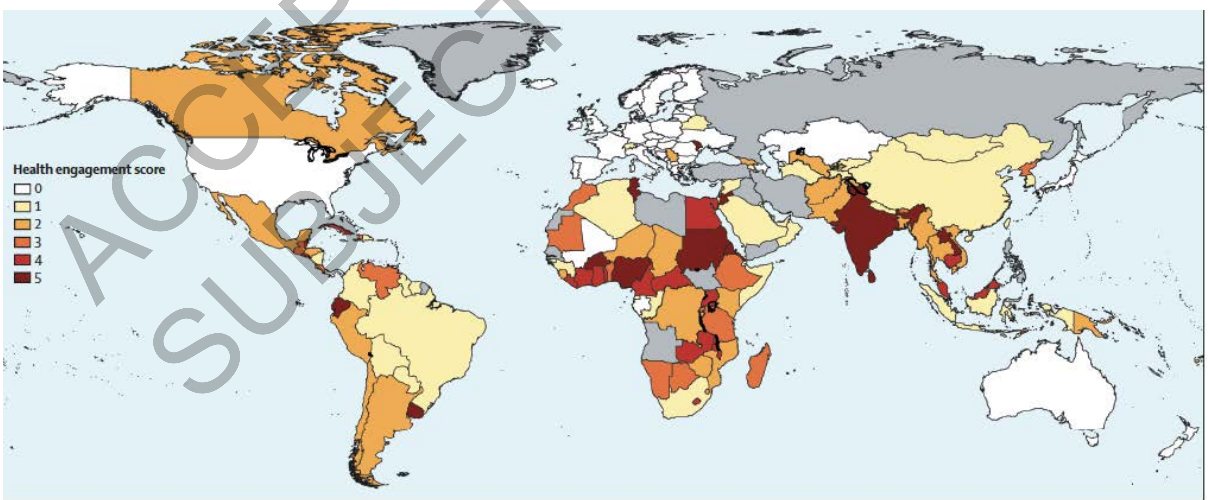

Figure 7.13: Health engagement score in NDCs by country. Source: Dasandi et al. 2021 (Dasandi et al., 2021)

The 2018 WHO Health and Climate Change Survey, a voluntary national survey sent to all 194 WHO member states, to which 101 responded, found that national planning on health and climate change is advancing, but the comprehensiveness of strategies and plans need to be strengthened; implementing action on key health and climate change priorities remains challenging; and multisectoral collaboration on health and climate change policy is evident, with uneven progress (Watts et al., 2021). Approximately 50% of respondent countries had developed national health and climate strategies, over 2/3 within the preceding five years, and 48/101 had conducted a health vulnerability and adaptation assessment (Watts et al., 2019). However, most countries reported only moderate or low levels of implementation, with financing cited as the most common barrier due to a lack of information on opportunities, a lack of connection by health actors to climate change processes and a lack of capacity to prepare country proposals. A review of public health systems in 34 countries found that only slightly more than half considered climate change impacts and adaptation needs (Berry et al., 2018).

Given the key health risks identified in this chapter, adaptation that increases resilience requires sustained, adaptive management (Ebi, 2011);(Hess et al., 2012) with the goal of transformative change. This includes differentiating adaptation to climate variability from adaptation to climate change (Ebi and Hess, 2020). Health adaptation efforts are increasingly aiming to transition to building climate-resilient and environmentally sustainable health systems (WHO, 2015b);(WHO, 2020a) and healthcare facilities, emphasizing service delivery, including climate-informed health policies and programs, management of the environmental determinants of health; emergency preparedness and management; and health information systems, including health and climate research, integrated risk monitoring and early warning systems, and vulnerability, capacity, and adaptation assessments (Marinucci et al., 2014);(Mousavi et al., 2020);(Organization, 2015);(CDC, 2019);(Organization, 2020). Previous and current projects funded by a range of groups, such as bilateral and multilateral development partners, include addressing key enabling conditions (e.g., leadership and governance) and developing the capacity of the health workforce to manage and govern changing risks. Because the health risks of climate change often vary within a country, sub-national assessments and plans are needed to help local authorities protect and promote population health in a changing climate (Aracena et al., 2021);(Basel et al., 2020);(Schramm et al., 2020a).

7.4.2.2 Adaptation in health policies and programs

Health policies were historically not designed or implemented taking into consideration the risks of climate change and as currently structured are likely insufficient to manage the changing health burdens in coming decades (very high confidence). The magnitude and pattern of future health burdens attributable to climate change, at least until mid-century, will be determined primarily by adaptation and development choices. Current and future emissions will play an increasing role in determining attributable burdens after mid-century. Increased investment in strengthening general health systems, along with targeted investments to enhance protection against specific climate-sensitive exposures (e.g., hazard early warning and response systems, and integrated vector control programs for vector-borne diseases) will increase resilience, if implemented to at least keep pace with climate change (*high confidence*). Investments to address the social determinants of health can reduce inequities and increase resilience (*high confidence).* (Thornton et al., 2016) ; (Marmot et al., 2020) (Wallace et al., 2015 measured as health, aging, retirement, are predictors of mortality and disability, with cross-country differences.) (Semenza and Paz, 2021)

Peer-reviewed publications of health adaptation to climate change in low- and middle-income countries have typically focused on flooding, rainfall, drought, and extreme heat, through improving community resilience, disaster risk reduction, and policy, governance, and finance (Berrang-Ford et al., 2021);(Scheelbeek et al., 2021). Health outcomes of successful adaptation have included reductions in infectious disease incidence, improved access to water and sanitation, and improved food security. Figure 7.14 shows a Sankey diagram of climate hazards, adaptation responses, and health outcomes, where CSA is climate-smart agriculture. The figure highlights the range of health adaptation responses that are discussed in more detail earlier in this chapter and demonstrates the potential health benefit of adaptation efforts that affect a broad range of health determinants.

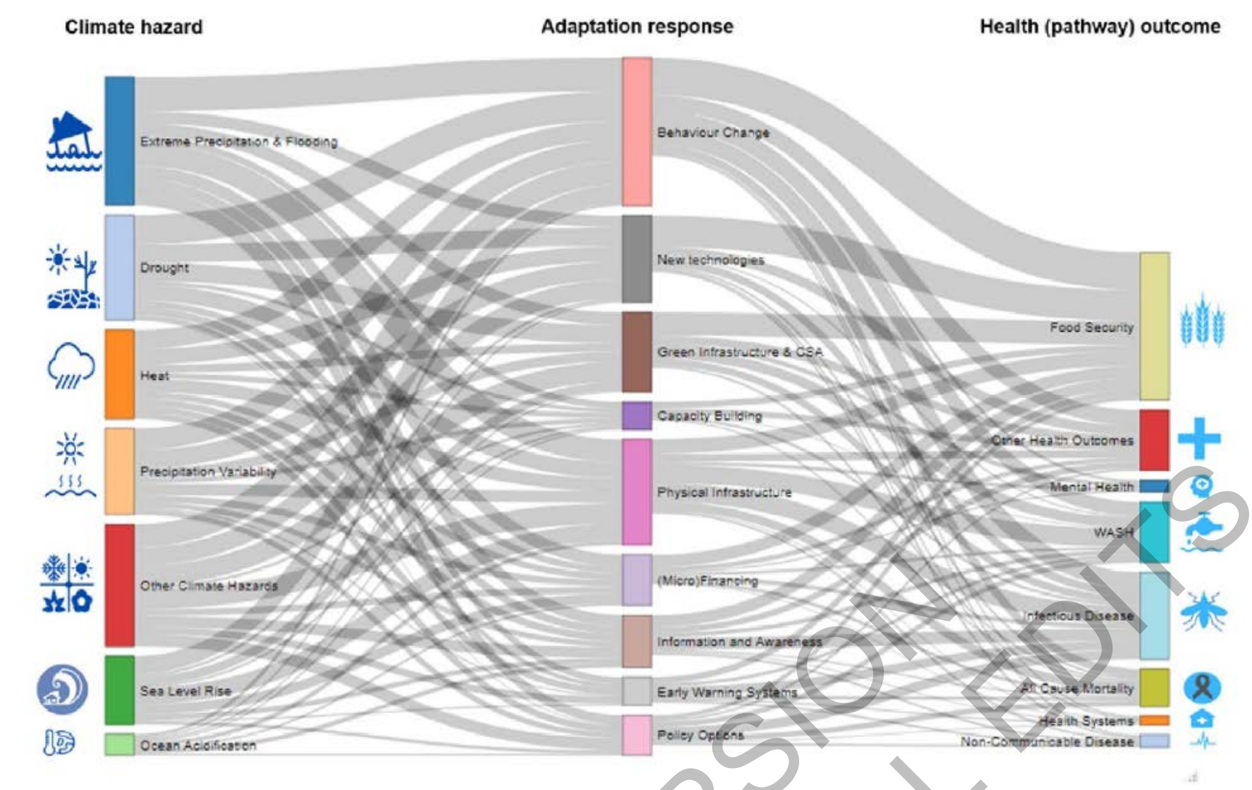

Figure 7.14: Sankey diagram of climate hazards, adaptation responses, and health outcomes. CSA is climate-smart agriculture. Source: Scheelbeek et al. 2021 (Scheelbeek et al., 2021).

Questions of the feasibility and effectiveness of health adaptation options differ from those in other sectors because public health is a societal enterprise that cuts across many different spheres of society. Consequently, there are dependencies that lie outside the jurisdiction of the health sector. All the health risks of a changing climate currently cause adverse outcomes, with policies and programs implemented in at least some health programs in some places. Policies and programs are continuously modified to increase effectiveness; this should accelerate in a changing climate. Improvements are needed as more is understood about disease aetiology, changing socioeconomic and environmental conditions, obstacles to uptake, and other factors.

A feasibility and effectiveness assessment was conducted of six adaptation strategies often used and recommended by the UN to respond to malnutrition risks, combining a literature review and expert judgment assessment of 80 peer-reviewed studies (UNSCN 2010; Tirado et al 2013; methods adapted from de Coninck et al. (2018) and Singh et al (2020). Nineteen indicators of six dimensions of feasibility (economic, technical, social, institutional, environmental, and geophysical) were considered. The lead time to initiate and expected longevity of each option were examined. Feasibility was defined as how significant the reported barriers were to implement a particular adaptation option. Highly feasible options were those where no or very few barriers were reported. Moderately feasible were those where barriers existed but did not have a strong negative effect on the adaptation option (or evidence was mixed). Low feasibility options had multiple barriers reported that could block implementation. Effectiveness ratings were based on expert consultation and reflected the potential of the adaptation option to reduce risk. The final effectiveness and feasibility scores were categorized as high, medium, or low, and reflect the combined results of all studies for a given adaptation option (Table 7.3). The assessed studies and categorizations are included as Supplementary Materials for this chapter.

Table 7.3: Feasibility and effectiveness assessments of multisectoral adaptation for food security and nutrition

Climate change impacts on food security and nutrition	Adaptation option	Evidence	Agreement	Feasibility Dimensions						Effectiveness	Enablers			
				Eco	Tec	Inst	Soc	Env	Geo		Women empowerment	Education	HDP Nexus	Rights-based approach & good governance
KEY RISK: Malnutrition in all its forms linked to decline in food availability and increased cost of healthy food	Climate-resilient, nutrition-sensitive and agroecological food production	Robust	High	M	M	H	L	H	H	Moderate	HR	HR	HR	HR
	Sustainable and healthy diets (local, equitable, diverse)	Robust	High	H	H	H	M	H	L	High	HR	HR	LR	LR
	Access to health, nutrition services and healthy environments (Water and sanitation)	Medium	High	M	M	M	H	M	L	Moderate	HR	HR	MR	HR
	Early warning systems to prevent adverse effects on nutrition	Robust	Medium	H	M	M	H	H	L	High	LR	HR	HR	LR
	Nutrition-sensitive social protection	Robust	High	H	H	L	L	H	H	High	HR	HR	MR	HR
	Nutrition-sensitive risk reduction, risk sharing and insurance	Medium	Low	L	H	L	H	H	NA	Low	MR	MR	LR	MR

Table Notes:
Abbreviations: Ec: Economic; Tec: Technical; Inst: Institutional; Soc: Socio-cultural; Env: Environmental; Geo: Geophysical. HR: high relevance, MR: medium relevance, LR: low relevance. NA = Not applicable/insufficient evidence

Policies and programs for climate-sensitive health outcomes are only beginning to incorporate the challenges and opportunities of climate change, although this is critical for increasing resilience. The fundamentals of many policies and programs in a changing climate will remain the same: implementing infectious disease control programs, preventing heat-related mortality and morbidity, and reducing the burden of other climate-related health endpoints, but activities will need to explicitly account for climate change to continue to protect health. Even with such attention to climate change, regrettably, there are limits to the feasibility and effectiveness of health adaptation options for some of these programs. For example, there are limits to adaptation to extreme heat, controlling emerging infectious diseases, and controlling cascading risk pathways.

As discussed in Chapter 1.4.2 and Chapter 1.5, an adaptation option is feasible when it is capable of being implemented by one or more relevant actors. In the health sector, the World Health Organization, UNICEF, and other organizations provide technical expertise to Ministries of Health, who then provide national to local healthcare and public health services. Generally, the question is less of overall feasibility, given the range of potential adaptation options that have yet to be fully explored and implemented, but more of readiness to buy-in to the adaptation efforts required from health and other sectors. In specific contexts, feasibility also depends on governance capacity, financial capacity, public opinion, and the distribution of political and economic power (Chapter 17). In other words, adaptation to climate change health impacts is broadly feasible with adequate investment and engagement, although this has yet to materialize, and in specific contexts, feasibility is contingent and time-varying and needs to be assessed at national to sub-national scales. For example, a scoping review in the Pacific region noted the following areas where further and significant investment and support are needed to increase feasibility of climate and health action: i) health workforce capacity development; ii) enhanced surveillance and monitoring systems; and iii) research to address priorities and their subsequent translation into practice and policy (Bowen et al., 2021). Vulnerability, adaptation, and capacity assessments include consideration of the feasibility and effectiveness of priority health adaptation options and can help decision makers identify strategies for enhancing adaptation feasibility in specific contexts.

7.4.2.3 Adaptation options for vector-borne, food-borne, and water-borne diseases

Integrated vector control approaches are crucial to effectively manage the geographic spread, distribution, and transmission of vector-borne diseases associated with climate change (high confidence). Some of the projected risks of climate change on VBD can be offset through enhanced commitment to existing approaches to integrated case management and integrated vector control management (Cissé et al., 2018);(Confalonieri et al., 2017);(Semenza and Paz, 2021). Important components include enhanced disease surveillance and early warning and response systems that can identify potential outbreaks at sub-seasonal to decadal time scales (J. and R., 2020);(Semenza and Zeller, 2014)(Table 7.4). In many cases, the exposure dynamics of VBD are strongly influenced by socio-economic dynamics that should be considered when developing and deploying adaptation options (UNEP, 2018). This is especially the case in low-income countries. For example, insufficient access to sanitation and presence of standing water are important determinants of the presence of *Ae. aegypti* populations and pathogens that cause visceral leishmaniasis (*L. donovani* and *L. infantum*) in urban and peri-urban areas; and low housing quality and lack of refuse management are associated with higher rodent infestation. Strategies expected to have important health co-benefits include those that support health systems strengthening; improve access to health coverage; increase awareness and education; and address underlying conditions of uneven development and lack of adequate housing and access to water and sanitation systems in areas endemic to mosquito-borne diseases (Semenza and Paz, 2021); Cross-Chapter Box ILLNESS in Chapter 2).

Adaptation options for climate-related risks for water-borne and food-borne diseases are strongly associated with wider, multi-sectoral initiatives to improve sustainable development in low-income communities (high confidence). Effective measures include improving access to potable water and reducing exposure of water and sanitation systems to flooding and extreme weather events (Brubacher et al., 2020);(Cisse, 2019) (Table 7.4). This requires focusing on farm-level interventions that limit the spread of pathogens into adjacent waterways, preventing the ongoing contamination of water and sanitation systems, and the promotion of food-safe human behaviours (Levy et al., 2018);(Nichols et al., 2018). It is also important to implement well-targeted and integrated WASH interventions, including at schools and ensuring proper disposal of excreta and wastewater. Cities can integrate regional climate projections into their engineering models, to produce lower-risk source waters, to increase the resilience of water and sanitation technologies and management systems under a range of climate scenarios. Technologies can help abstract source waters from depth, introduce or increase secondary booster disinfection, design or modify systems to reduce residence times within pipes, and/or coat exposed pipes (Levy et al., 2018). Other efficient interventions include source water protection, promoting water filtration, testing the presence of waterborne pathogens in shellfish, trade restrictions and improvement of hygiene at all levels (Semenza and Paz, 2021). Needed actions include early warning and response systems, strengthening the resilience of communities and health systems, and promoting water safety plans and sanitation safety plans (Brubacher et al., 2020);(Cisse, 2019);(Ford and Hamner, 2018);(Lake and Barker, 2018);(Levy et al., 2018);(Nichols et al., 2018);(Organization and Association, 2009);(Organization, 2016);(Organization, 2018b);(Semenza, 2021);(Rocklöv et al., 2021).

.

Table 7.4: Summary of adaptation options for key risks associated with climate-sensitive vector-, water- and food-borne diseases

Key risk	Geographic region(s) at higher risk	Consequence that would be considered severe, and to whom	Hazard conditions that would contribute to this risk being severe	Exposure conditions that would contribute to this risk being severe	Vulnerability conditions that would contribute to this risk being severe	Adaptation options with high potential for reducing risk	Selected key references
Vector-borne diseases	Global	Increase in the incidence of some vector-borne diseases such as malaria, dengue, and other mosquito-borne diseases, in endemic areas and in new risk areas (e.g., cities, mountains, northern hemisphere)	Increased climatic suitability for transmission (e.g., enhanced vectorial capacity through a temperature shift)	Large increases in human exposure to vectors driven by growth in human and vector populations, globalization, population mobility, and urbanization	Few effective vaccines, weak health systems, ineffective personal and household protections, susceptibility to disease, poverty, poor hygiene conditions, insecticide resistance, behavioral factors	Improved housing, better sanitation conditions and self-protection awareness. Insecticide treated bednets and indoor spraying of insecticide. Broader access to healthcare for the most vulnerable. Establishment of disease surveillance and early warning systems for vector-borne diseases. Cross-border joint control of outbreaks. Effective vector control. Targeted efforts to develop vaccines.	(Cissé et al., 2018);(Semenza, 2021);(J. and R., 2020)
Water-borne diseases	Mostly low- and middle-income countries (Africa and Asia); small islands; global for *Vibrios*	Increase in the occurrence and intensity of waterborne diseases such as *Vibrios* (particularly *V. cholerae*), diarrheal diseases, other water-borne gastro-intestinal illnesses	Substantial changes in temperature and precipitation patterns, increased frequency and intensity of extreme weather events (e.g., droughts, storms, floods), ocean warming and acidification	Large increases in exposure, particularly in areas with poor sanitation, flood-prone areas, and favourable ecological environments for waterborne disease pathogens	Poor hygiene conditions, lack of clean drinking water and safe food, flood and drought prone areas, vulnerabilities of water and sanitation systems	Improved water, sanitation and hygiene conditions and better surveillance system. Improved personal drinking and eating habits, behaviour change	(Brubacher et al., 2020);(Ford and Hamner, 2018);(Lake, 2018);(Levy et al., 2018);(Nichols et al., 2018);(Rocklöv et al., 2021)
Food-borne diseases	Global	Increase in the occurrence and intensity of foodborne diseases such as *Salmonella* and *Campylobacter,*	Substantial changes in temperature and precipitation patterns, increased frequency and intensity of	Large increases in exposure, particularly in areas with poor sanitation, flood-prone areas and favourable ecological	Poor hygiene conditions; lack of clean drinking water and safe food; flood and drought prone areas. Vulnerabilities in water and sanitation systems, food storage	Improved water, sanitation and hygiene conditions and better surveillance system. Improved personal drinking and eating habits, behaviour change. Improved food storage, food	(Brubacher et al., 2020);(Ford and Hamner, 2018);(Lake, 2018);(Levy et al., 2018);(Nichols et

		including in high-income countries	extreme weather events (e.g., droughts, storms, floods), ocean warming and acidification	environment for foodborne disease pathogens	systems, food processes, food preservation, and cold chain/storage	processing, food preservation, cold chain/storage	al., 2018);(Rocklöv et al., 2021)

7.4.2.4 Adaptation options for heat-related morbidity and mortality

Adaptations options for heat refer to strategies implemented at short time scales such as air conditioning and heat action plans, including heat warning systems and longer-term solutions such as urban design and planning and nature -based solutions (Table 7.5).

To date, air conditioning is the main adaptation approach for mitigating the health effects of high temperatures, especially in relation to cardiorespiratory health (Madureira et al., 2021). However, air conditioning may constitute a maladaptation because of its high demands on energy and associated heat emissions, especially in high-density cities (Eriksen et al., 2021);(Magnan et al., 2016);(Schipper, 2020) and also lead to 'heat inequities' as this is not an affordable or practical option for many (Jay et al., 2021);(Turek-Hankins et al., 2021). Heat action plans (HAP) link weather forecasts with alert and communication systems and response activities, including public cooling centres, enhanced heat-related disease surveillance, and a range of individual actions designed to reduce the health effects of extreme heat events such as seeking shade and altering the pattern of work (McGregor et al., 2015). While well designed and operationalisable HAPs possess the potential to reduce the likelihood of mortality from extreme heat events (*medium confidence*) (Benmarhnia et al., 2016);(Heo et al., 2019b);(Martinez-Solanas and Basagana, 2019);(Martinez et al., 2019);(De'Donato et al., 2018);, full process and outcome based evaluations of HAPs and their constituent components are lacking, (Boeckmann and Rohn, 2014);(Chiabai et al., 2018b);(Boeckmann and Rohn, 2014);(Nitschke et al., 2016; Diaz et al., 2019);(Benmarhnia et al., 2016);(Heo et al., 2019a), (Heo et al., 2019b)); (Ragettli and Roosli, 2019). Evaluations of heatwave early warning systems as a component within HAPs show inconsistent results in terms of their impact on predicting mortality rates (Nitschke et al., 2016);(Benmarhnia et al., 2016);(Heo et al., 2019a), (Heo et al., 2019b)); (Ragettli and Roosli, 2019);(Martinez et al., 2019);(De'Donato et al., 2018);{;(Weinberger et al., 2018b), indicating climate-based heat warning systems, which use a range of heat stress metrics (Schwingshackl et al., 2021), are not sufficient as a stand-alone approach to heat risk management (*high confidence*). To support HAP and heat risk related policy development, identification and mapping of heat vulnerability 'hot spots' within urban areas have been proposed (Chen et al., 2019); (Hatvani-Kovacs et al., 2018)

A multi-sectoral approach, including the engagement of a range of stakeholders will likely benefit the response to longer term heat risks, through implementation of measures such as climate sensitive urban design and planning that mitigates urban heat island effects (high confidence). (Ebi, 2019), (Jay et al., 2021);(Alexander et al., 2016);;(Levy, 2016);(Masson et al., 2018);(McEvoy, 2019);(Pisello et al., 2018). In the shorter-term, potentially localized solutions can include awnings, louvers, directional reflective materials, altering roof albedo), mist sprays, evaporative materials, green roofs and building facades and cooling centres (Jay et al., 2021);(Macintyre and Heaviside, 2019);(Spentzou et al., 2021);(Takebayashi, 2018). Nature-based solutions (NbS) to reduce heat that offer co-benefits for ecological systems include green and blue infrastructure (e.g., urban greening/forestry and the creation of water bodies) (Koc et al., 2018);(Lai et al., 2019);(Shooshtarian et al., 2018);(Ulpiani, 2019);(Zuvela-Aloise et al., 2016), (Hobbie and Grimm, 2020). The implementation of climate-sensitive design and planning can be constrained by governance issues;(Jim et al., 2018) and the benefits are not always evenly distributed among residents. Implementation of climate-sensitive design and NbS does, however, need to be carried out within the context of wider public health planning because water bodies and moist vegetated surfaces provide suitable habitats for a range of disease vectors;(Nasir et al., 2017);(Tian et al., 2016);(Trewin et al., 2020). Solutions recommended for managing exposure to heat in outdoor workers include improved basic protection (including shade, planned rest breaks), heat-appropriate personal protective equipment, work scheduling for cooler times of the day, heat acclimation, improved aerobic fitness, access to sufficient cold drinking water, and on-site cooling facilities and mechanisation of work (Morabito et al., 2021);(Morris et al., 2020);(Varghese et al., 2020);(Williams et al., 2020).

Most adaptation options were developed in high- and middle-income countries, and typically require significant financial resources for their planning and implementation. Studies are needed of the benefits of Indigenous and non-Western approaches to managing and adapting to extreme heat risk. Recently published reviews of approaches to heat adaptation outline the nature and limitations of a range of cooling strategies with optimal solutions for a number of settings recommended (Jay et al., 2021);(Turek-Hankins et al., 2021).

Table 7.5: Summary of adaptation options for key health risks associated with heat.

Key risk	Geographic region	Consequence that would be considered severe, and to whom	Hazard conditions that would contribute to this risk being severe	Exposure conditions that would contribute to this risk being severe	Vulnerability conditions that would contribute to this risk being severe	Adaptation options with high potential for reducing risk	Selected key references
Heat-related mortality and morbidity and mental illness	Global but especially where temperature extremes beyond physical and mental health and thermal comfort threshold levels are expected to increase	Substantial increase in heat-related mortality and morbidity rates, especially in urban centres (heat island effect) and rural areas (outside workers), outdoors in general (sports and related activities) and for people suffering from obesity, weak cardiovascular capacity /physical fitness. Increased risk of respiratory diseases and cardiovascular diseases (CVD) mortality. Loss of economic productivity. Substantial increase in mental illness compared to base rate.	Substantial increase in frequency and duration of extreme heat events, especially in cities where heat will be exacerbated by urban heat island effects. Unintended increases in urban temperatures from anthropogenic heat (vehicles, air conditioning, urban metabolism) Increased number of days with high temperatures in non-urban settings such as agricultural areas.	Large increases in urban heat and population heat exposure driven by demographic change (e.g., aging) and increasing urbanization. Exposure will increase amongst agricultural and construction workers	Mortality/morbidity: Increases in the number of very young and elderly, and of those with other health conditions such as lack of physical fitness, obesity, diabetes and associated comorbidities, lack of adaptation capacity Mental illness: Lack of air conditioning. Lack of access to health care systems and services	Heat warning systems. Improved building and urban design (including green and blue infrastructure), passive cooling systems acknowledging that not all will have access to air conditioning. Broader understanding of heat hazard and better access to public health systems for the most vulnerable. Application where possible of renewable energy sources. Communication around drinking, availability of clean water, via simple effective water purification systems in low water quality settings, and water spray cooling. Mental health support.	(Benmarhnia et al., 2016);(Chen et al., 2019); (Jay et al., 2021);(Heo et al., 2019b);(Martinez-Solanas and Basagana, 2019);(Morabito et al., 2021);(Schwingshackl et al., 2021)

7.4.2.5 Adaptation options for air pollution

As noted in 7.3.1.6, air pollution projections indicate ambitious emission reduction scenarios or stabilisation of global temperature change at 2ºC or below would yield substantial co-benefits for air quality-related health outcomes. Improvements in air quality could be achieved by the deliberate adoption of a range of adaptation options to complement mitigation measures such as decarbonisation (e.g. renewable energy, fuel switching, energy efficiency gains, carbon capture storage and utilization) and negative emissions technologies (e.g. bioenergy carbon capture and storage, soil carbon sequestration, afforestation and reforestation, wetland construction and restoration).

Adaptation options for air pollution include implementing ozone precursor emission control programmes, developing mass transit/efficient public transport systems in large cities, encouraging car-pooling and cycling and walking (active transport), traffic congestion charges, low emission zones in cities and integrated urban planning, implementing NbS such as the green infrastructure for pollutant interception and removal, managing wildfire risk regionally and across jurisdictional boundaries, developing air quality warning systems, altering activity on high pollution days, effective air pollution risk communication and education, wearing protective equipment such as face masks, avoiding solid fuels for cooking and indoor heating, ventilating and isolating cooking areas, and using portable air cleaners fitted with high-efficiency particulate air filters (Abhijith et al., 2017);(Carlsten et al., 2020);(Cromar et al., 2020);(Ding et al., 2021);(Holman et al., 2015);(Jennings et al., 2021);(Kelly et al., 2021);(Kumar et al., 2019);(Masselot et al., 2019);(Ng et al., 2021);(Riley, 2021);(Voordeckers et al., 2021);(Xu et al., 2017)(Table 7.6). While the range of air pollution adaptation options is potentially extensive, barriers may need to be overcome to achieve successful implementation, including financial, institution, political/inter- and intra-governmental and social barriers (Barnes et al., 2014);(Ekstrom and Bedsworth, 2018);(Fogg-Rogers et al., 2021);(Schumacher and Shandas, 2019).

Table 7.6: Summary of adaptation options for key health risks associated with air pollution.

Key risk	Geographic region	Consequence that would be considered severe, and to whom	Hazard conditions that would contribute to this risk being severe	Exposure conditions that would contribute to this risk being severe	Vulnerability conditions that would contribute to this risk being severe	Adaptation options with high potential for reducing risk	Selected key references
Air pollution related health	Global but especially in regions with existing poor air quality particularly in relation to particulate matter and ozone. Greatest climate change driven ozone related mortality is expected for East Asia and North America. For particulate matter the highest climate and air quality related mortalities are projected for India, the Middle East, Former Soviet Union and East Asia	Substantial increase in air pollution-related mortality and morbidity rates, especially in urban centres related to both severe pollution episodes and longer-term deterioration of air quality. People particularly vulnerable include those with respiratory tract infections and respiratory and cardiovascular disease. Increase in mental illness (depression) as a result of poor air quality and visibility.	Non-achievement of emission reduction targets. Substantial increase in frequency and duration of meteorological conditions conducive to the build-up of both primary and secondary air pollutants (e.g. greater frequency of calm atmospheric 'blocking' conditions) and no long term improvement in air quality at a range of geographical scales (global to the local). Increase in frequency and intensity of wildfires and dust storms. Increase in the	Large increases in exposure to air pollutants driven by demographic change (e.g., aging) and increasing urbanization. For arid regions increases in exposure to dust storms. Areas adjacent/downwind of major wildfires. For urban populations intensifying urban heat islands and enhanced formation of secondary pollutants	Increases in the number of very young and elderly, and those with respiratory or cardiovascular conditions and lack of adaptation capacity (e.g., reduce reliance on solid fuel for cooking/heating) Mental illness: Lack of access to health care systems and services	Air quality management policies, air quality warning systems, efficient and cheap mass transit systems, integrated urban planning, (including NBS and green infrastructure) Broader understanding of air pollution hazard and better access to public health systems for the most vulnerable. Application where possible of renewable energy sources to reduce emissions.	(Carlsten et al., 2020);(Doherty et al., 2017);(Jennings et al., 2021);(Kumar et al., 2019);(Orru et al., 2017; Orru et al., 2019) (Schumacher and Shandas, 2019);(Silva et al., 2017);(Voordeckers et al., 2021)

			intensity of urban heat islands especially in the summer and the occurrence of ozone episodes due to anomalously high urban temperatures.				

7.4.2.6 Multisectoral Adaptation for Nutrition

Adaptation to reduce the risk of malnutrition requires multi-sectoral, integrated approaches (very high confidence). Adaptation actions include access to healthy, affordable diverse diets from sustainable food systems *(high confidence)*; a combination of access to health -including maternal, child and reproductive health-, nutrition services, water and sanitation (*high confidence*); access to nutrition-sensitive and shock-responsive social protection (*high confidence*); early warning systems (*high agreement*), risk sharing, transfer, and risk reduction schemes such as insurance index-based weather insurance *(medium confidence)*. (Mbow et al., 2019);(Swinburn et al., 2019; UNICEF/WHO/WBG, 2019);(FAO et al., 2021);(Macdiarmid and Whybrow, 2019);(Liverpool-Tasie et al., 2021);(Fakhri, 2021). Common enablers across adaptation actions that enhance the effectiveness and feasibility of the adaptation include: education, women and girls' empowerment (*high confidence*), rights-based governance, and peace-building social cohesion initiatives such as the framework of the Humanitarian Development and Peace Nexus *(medium confidence).*

Nutrition-sensitive and integrated agroecological farming systems offer opportunities to increase dietary diversity at household levels while building local resilience to climate-related food insecurity (high confidence). (Bezner Kerr et al., 2021);(IPES-Food, 2020);(Altieri et al., 2015) especially when gender equity, racial equity, and social justice are integrated (Bezner Kerr et al., 2021). Adaptation responses include a combination of healthy, culturally appropriate, and sustainable food systems and diets, soil and water conservation, social protection schemes and safety nets, access to health services, nutrition-sensitive risk reduction, community-based development, women's empowerment, nutrition-smart investments, increased policy coherence, and institutional and cross-sectoral collaboration *(high agreement, medium evidence)* (FAO et al., 2018);(Mbow et al., 2019);(Pozza and Field, 2020);(FAO et al., 2021) (Table 7.7). Nutrition security can be enhanced through consideration of nutrient flows in food systems (Harder et al., 2021).This 'circular nutrient economy' perspective highlights the potential for adaptations throughout the food supply chain, including sustainable production practices that promote nutrient diversity and density, processing, storage, and distribution that conserves nutrition, equitable access and consumption of available, affordable, appropriate, and healthy foods, and waste management that supports nutrient recovery (Harder et al., 2021);(Boon and Anuga, 2020);(FAO et al., 2021);(Pozza and Field, 2020);(Ritchie et al., 2018). Traditional, Indigenous, and small-scale agroecology and regional food systems provide context-specific adaptations that promote food and nutrition security as well as principles of food sovereignty and food systems resilience (HLPE, 2020);(Bezner Kerr et al., 2021);(IPES-Food, 2020);(IPES-Food, 2018).

Adaptive social protection programs and mechanisms that can support food insecure households and individuals include cash transfers or public work programs, land reforms, and extension of credit and insurance services that reduce food insecurity and malnutrition during times of environmental stress (Carter and Janzen, 2018), (Johnson et al., 2013); (Alderman, 2016). For example, children from families participating in Ethiopia's Productive Safety Net Program experienced improved nutritional outcomes, partly due to better household food consumption patterns and reduced child labor (Porter and Goyal, 2016). School feeding programs improve nutritional outcomes, especially among girls, by promoting education, and by reducing child pregnancy and fertility rates (Bukvic and Owen, 2017). Adaptive social protection is most effective when it combines climate risk assessment with disaster risk reduction and wider socioeconomic development objectives (Davies et al., 2013).

Transformative approaches towards healthier, more sustainable, plant-based diets require integrated strategies, policies, and measures, including economic incentives for the agroecological production and equitable access to and consumption of more fruits, vegetables, and pulses, inclusion of sustainability criteria in dietary guidelines, labelling, public education programs and promoting collaboration, good governance, and policy coherence {Glover, 2019, Principles of innovation to build nutrition-sensitive food systems in South Asia

Table 7.7: Summary of adaptation options for key risks associated with malnutrition

Key risk	Geographic region	Consequence that would be considered severe, and to whom	Hazard conditions that would contribute to this risk being severe	Exposure conditions that would contribute to this risk being severe	Vulnerability conditions that would contribute to this risk being severe	Adaptation options with high potential for reducing risk	Selected key references
Malnutrition due to decline in food availability and increased cost of healthy food	Global, with greater risks in Africa, South Asia, Southeast Asia, Latin America, Caribbean, Oceania	Substantial number of additional people at risk of hunger, stunting, and diet-related morbidity and mortality, including decreased mental health and cognitive function. Micro- and macronutrient deficiencies. Severe impacts on low-income populations from LIMICs. Risks especially high to groups that suffer greater inequality and marginalization.	Climate changes leading to reductions in crop, livestock, or fisheries yield, including temperature and precipitation changes and extremes, drought, and ocean warming and acidification	Large numbers of people in areas and markets particularly affected by climate impacts on food security and nutrition	High levels of inequality (including gender inequality), substantial numbers of people subject to poverty or violent conflict, in marginalized groups, or with low education levels. Slow economic development. Ineffective social protection systems, nutrition services, and health services.	Multi-sectoral approach to nutrition-sensitive adaptation and disaster risk reduction / management, including food, health, and social protection systems. Inclusive governance involving marginalized groups. Improved education for girls and women. Maternal and child health, water and sanitation, gender equality, climate services, social protection mechanisms.	(Glover and Poole, 2019);(Mbow et al., 2019);; (Swinburn et al., 2019)

7.4.2.7 Adaptation options for risks to mental health

Adaptation options for reducing mental health risks associated with extreme weather include preventive and post-event responses (high confidence). (Brown et al., 2017); {Cohen, 2019 #3534},(James et al., 2020) (Table 7.8). Responses include improving funding and access to mental health care, which is under-resourced (WHO, 2019); surveillance and monitoring of psychosocial impacts of extreme weather events; community-level planning for mental health as part of climate resilience planning (Clayton et al., 2017); and mental health and psychological first aid training for care providers and first responders (Hayes et al., 2018);(O'Donnell et al., 2021);(Hayes et al., 2018; Taylor, 2020);(Morgan et al., 2018);(Sijbrandij et al., 2020). Legislation can ensure access to services as well as establish a regulatory framework (Ayano, 2018). Advanced disaster risk planning reduces post-event mental health challenges. One example is from China, where pre-planning of temporary shelters resulted in significantly lower rates of anxiety, depression, and PTSD in the aftermath of flooding among displaced people who accessed them (Zhong et al., 2020). Key elements of successful initiatives include coordinated planning and action between key regional agencies and governments, with a focus on improving accountability and removing barriers to implementation and subsequent access to programs (Ali et al., 2020). As an example, following the 2019/2020 Australian bushfires, the federal government allocated funds to support mental health through free counselling for those affected, increased access to tele-health, extended hours for mental health services and programs designed specifically for youth (Newnham et al., 2020).

Because mental health is fundamentally intertwined with social and economic wellbeing, adaptation for climate-related mental health risks benefits from wider multi-sectoral initiatives to enhance wellbeing, with the potential for co-benefits to emerge (high confidence). Improvements in education, quality of housing, safety, and social protection support enhance general wellbeing and make individuals more resilient to climate risks (Lund et al., 2018);(Hayes et al., 2019). Among Indigenous Peoples, connections to traditional culture and to place are associated with health and wellbeing (Bourke et al., 2018) as well as with resilience to environmental change (Ford et al., 2020). As an example of the connection between infrastructure improvements and mental health, a study of domestic rainwater harvesting initiatives to promote household water security also improved mental health in participating households (Mercer and Hanrahan, 2017). Adaptive urban design that provides access to healthy natural spaces – an option for reducing risks associated with heat stress – also promotes social cohesion and mitigates mental health challenges *(high confidence)* (Buckley et al., 2019);(Clayton et al., 2017);(Jennings and Bamkole, 2019);(Liu et al., 2020b);(Mygind et al., 2019);(Marselle et al., 2020).

Table 7.8: Summary of adaptation options for key risks associated with mental health

Key Risk	Geographic region	Consequence that would be considered severe, and to whom	Hazard conditions that would contribute to this risk being severe	Exposure conditions that would contribute to this risk being severe	Vulnerability conditions that would contribute to this risk being severe	Adaptation options with high potential for reducing risk	Selected key references
Mental health impacts in response to floods, storms, and fires	Global; some areas at greater risk for storms, flooding, or wildfires	Substantial increase in mental illness compared to base rate	Increased frequency of major storms, weather-related flooding, or wildfires	Low-lying areas, dry areas, urban areas	Physical infrastructure that is vulnerable to extreme weather, inadequate emergency response and mental health services, social inequality	Improved urban infrastructure, warning systems, and post-disaster social support, improving funding and access to mental health care; improved surveillance and monitoring of mental health impacts of extreme weather events; climate change resilience planning in the mental health system (including at a community level); and mental health first aid training for care providers and first responders	(Ali et al., 2020);(Ayano, 2018);(Buckley et al., 2019);(Clayton et al., 2017);(Hayes et al., 2019);(James et al., 2020);(Sijbrandij et al., 2020)

7.4.2.8 Adaptation options to facilitate non-heat early warning and response systems

Early warning systems are a potentially valuable tool in adapting to climate-related risks associated with infectious diseases when based on forecasts with high skill and when there are effective responses within the time frame of the forecast (high confidence). Through advanced seasonal weather forecasting that draws upon established associations between weather/climate and infection/transmission conditions, conditions conducive to disease outbreaks can be identified months in advance, providing time to implement effective population health responses (Morin et al., 2018). Most current early warning systems are focused on malaria and dengue, but there are examples for other diseases, such as an early warning system developed for *Vibrios* monitoring in the Baltic Sea (Semenza et al., 2017). An early warning system for dengue outbreaks in Colombia based on temperature, precipitation, and humidity successfully detected 75% of all outbreaks between one and five months in advance, detecting 12.5% in the same month (Lee et al., 2017b). Dengue warning systems in Brazil, Malaysia, and Mexico have generated satisfactory results (Hussain-Alkhateeb et al., 2018). An effective early warning system for malaria was implemented in the Amhara region of Ethiopia (Merkord et al., 2017).

Early warning systems are effective at detecting and potentially reducing food security and nutrition risks (high confidence). Examples of proven systems include the USAID Famine Early Warning System, FAO's Global Information and Early Warning System, and WFP's Corporate Alert System. Such systems are fundamental for anticipating when a crisis might occur and setting priorities for interventions (Funk et al., 2019). Financial investments to develop early warning systems are cost-effective and reduce human suffering (Choularton and Krishnamurthy, 2019) (*high confidence*). For instance, during the 2017 drought-induced food crisis in Kenya, 500,000 fewer people required humanitarian assistance than would have been expected based on past experiences; this was largely due to timely and effective interventions triggered by the early warning (Funk et al., 2018).

Early warning systems have been established for other climate-sensitive health outcomes, such as respiratory diseases associated with air pollution (Shih et al., 2019);(Li and Zhu, 2018);(Yang and Wang, 2017). Early warning systems for non-heat extreme weather and climate events, such as storms and floods, are designed to protect human health and wellbeing; disaster risk management organizations and institutions typically communicate these warnings through their networks. Research is ongoing to extend the time period for warnings.

7.4.2.9 Incorporating Disaster Risk Reduction into Adaptation

Integrating health into national disaster risk management plans has wider benefits for resilience and adaptation to climate change risks (high confidence). (UNFCCC, 2017a);(Watts et al., 2019). Disaster risk reduction (DRR), including disaster preparedness, management and response, is widely recognized as important for reducing health consequences of climate-related hazards and extreme weather events (Keim, 2008);(Phalkey and Louis, 2016). A systematic review by Islam et al., (2020) identified multiple, ongoing challenges to integrating climate adaptation and DRR at global and national levels, including a lack of capacity among key actors and institutions, a lack of coordination and collaboration across scales of government, and general lack of funding – challenges that are particularly relevant for the health sector. Global events, including climate-related extreme events and public health emergencies of international concern (for example, Ebola, MERS and COVID-19) have influenced the development of national public health preparedness and response systems and attracted significant investment over the last two decades (Khan et al., 2015);(Murthy et al., 2017);(Watson et al., 2017). The Sendai Framework for Disaster Risk Reduction and the International Health Regulations establish important global and regional goals for increasing health system resilience, and reducing health impacts from biological hazards and extreme climate events (Aitsi-Selmi et al., 2015);(Maini et al., 2017);(UNFCCC, 2017b);(Wright et al., 2020). There are explicit links between the health aspect of the Sendai Framework and UN Sustainable Development Goals 1, 2, 3, 4, 6, 9, 11, 13, 14, 15 and 17 (Wright et al., 2020). More specifically, reducing the number of disaster-related deaths, illnesses and injuries, as well as damage to health facilities are key indicators for achieving the goals set out in the Sendai Framework (UNFCCC, 2017b).

The intersection of health and multisectoral disaster risk reduction and management, generally described as as Health Emergency and Disaster Risk Management (Health-EDRM), encompasses multisectoral approaches from, epidemic preparedness and response including the capacities for implementing the International Health Regulations (IHR, 2005), health systems strengthening and health systems resilience (Lo Iacono et al., 2017);(Organization, 2019);(Wright et al., 2020). Health-EDRM costs to governments are notably lower than the cost of inaction (Peters et al., 2019). Additional per capita costs in low-income countries have been estimated to range from 4.33 USD (capital) and 4.16 USD (annual recurrent costs), and in upper middle-income countries to an additional 1.35 USD in capital costs and 1.41 USD in extra annual recurrent costs (Peters et al., 2019). Adopting a Health-EDRM approach supports the systematic integration of health and multisectoral DRM to ensure a holistic approach to health risks and assists alignment of action in health security, climate change and sustainable development (Chan and Peijun, 2017);(Dar et al., 2014);(Organization, 2019);(Wright et al., 2020).

Climate-informed Health-EDRM is crucial for the climate resilience of health systems (Organization, 2015), particularly to account for additional risks and uncertainties associated with climate change and allow for well-planned, effective and appropriate DRM and adaptation (Watts et al., 2018a);(WHO, 2013);(Organization, 2015). Potential coherent approaches to addressing climate change and disaster risks to health include: strengthening health systems; vulnerability and risk assessments that incorporate disaster and climate change risk; building resilience of health systems and health infrastructure; and climate-informed EWSs (Banwell et al., 2018);(Phalkey and Louis, 2016). However, a review of DRR projects including climate change in South Asia found that the health sector was the least represented with only 2% of 371 projects relating to health (Mall et al., 2019) indicating a need to strengthen the incorporation of climate change in Health-EDRM. Current tracking under the Sendai Framework of Disaster Risk Reduction 2015-2030 shows that most countries (particularly low-income countries and lower-middle income countries) still lack robust systems for integrated risk monitoring and early warning (UNEP, 2018). The incorporation of disaster risk reduction and management strategies into climate adaptation for health and health systems at local scales is particularly important, given that it is at local scales where health services are most often delivered and where knowledge of specific needs and challenges is often greater (Amaratunga et al., 2018) (Schramm et al., 2020a). Indigenous knowledge has been shown to be valuable in disaster risk reduction, with particularly strong evidence existing for drought risk reduction in sub-Saharan Africa (Fummi et al., 2017; Muyambo et al., 2017) (Dube and Munsaka, 2018);(Macnight Ngwese et al., 2018). In the US, disaster risk reduction strategies that draw upon traditional knowledge and local expertise are being incorporated into climate adaptation planning for health in a number of Indigenous communities under the "Climate-ready Tribes Initiative" (Schramm et al., 2020b).

7.4.2.10 Monitoring, Evaluation and Learning

Monitoring, evaluation and learning (MEL) can assess the ability of nations and communities to prepare for and adequately respond to the health risks of climate change over time (high confidence). (Boyer et al., 2020). MEL describes a process that includes baseline assessment, prioritizing actions and activities, identifying key indicators to track, ongoing data collection, and periodically considering new information (Kruk et al 2015). MEL determines whether adaptation options achieved their goals and whether resources were used effectively and efficiently (Boyer et al., 2020). One of the challenges for MEL in the context of adaptation is that climate risks vary as a function of time, location, socio-economic development, demographics, and activities in other sectors (Ebi et al., 2018a). MEL indicators in the health sector need to account for factors related to governance, implementation, and learning as well as for exposures, impacts, and programmatic activities, all of which are context dependent and are often outside the health sector (Boyer et al., 2020);(Ebi et al., 2018a);(Fox et al., 2019).

No universal standardized approach exists for monitoring or evaluating adaptation activities in the health sector (high confidence). Candidate indicators of climate change health impacts and adaptation activity, typically at the national level, are available (Bowen and Ebi, 2017);(Cheng and Berry, 2013);(Kenney et al., 2016);(Navi et al., 2017);(Organization, 2015). Indicators are best grouped by category of activity, i.e., vulnerability, risk, and exposure; impacts; and adaptation and resilience (Ebi et al., 2018a). As health adaptation expands, enhanced monitoring will be needed to ensure that scientific advances are translated into policy and practice. A promising initiative that emerged since the AR5 is the *Lancet Countdown*, which represents a global effort at tracking various indicators of exposures, impacts, adaptation activities, finance, and media activity related to climate change and health (Watts et al., 2018a), although this effort is principally focused on monitoring and does not explicitly focus on evaluation adaptation efforts or learning from adaptation efforts.

Community-based monitoring of adaptation responses to health impacts, especially in Indigenous Peoples, has not been widely undertaken, despite its potential to improve monitoring of, and local adaptation to, environmental change (Kipp et al., 2019). The health sector has been particularly weak at recognizing climate impacts on and adaptation needs of Indigenous peoples and in engaging Indigenous Peoples in monitoring progress (Ford et al., 2018, (David-Chavez and Gavin, 2018); (Ramos-Castillo et al., 2017). Successful adaptation to the health impacts of climate change in Indigenous Peoples requires recognition of their rights to self-determination, focusing on Indigenous conceptualizations of wellbeing, prioritizing Indigenous knowledge, and understanding the broader agenda of decolonization, health, and human rights (*high confidence)* (Ford and King, 2015);(Green and Minchin, 2014);(Hoy et al., 2014);(Jones, 2019);(Jones et al., 2014);(Mugambiwa, 2018);(Nursey-Bray and Palmer, 2018).

Indicators should capture measures of processes that drive adaptation readiness, including leadership, institutional learning, and intersectoral collaboration (Boyer et al., 2020);(Ford and King, 2015), as well as outcome measures such as presence of programming known to reduce risks (Ebi et al., 2018a). Additionally, indicators related to scaling up of effective interventions, relying on implementation science frameworks are important (Damschroder et al., 2009);(Theobald et al., 2018 2020, Using Implementation Science For Health Adaptation: Opportunities For Pacific Island Countries);(Ebi et al., 2018a);(Fox et al., 2019). Measuring impacts attributable to climate change could be addressed with a combination of indicators related to overall health system performance and population vulnerability (Ebi et al., 2017);(Ebi et al., 2018a).

7.4.3 Enabling Conditions and Constraints for Health and Wellbeing Adaptation

7.4.3.1 Governance, Collaboration, and Coordination

Effective governance institutions, arrangements, funding, and mandates are key for adaptation to climate-related health risks (high confidence). Without integration and collaboration across sectors, health adaptation can become siloed, leading to less effective adaptation or even maladaptation (Magnan et al., 2016);(Fox et al., 2019). Integration and collaboration include working laterally across national government departments and agencies, as well as vertically, from national agencies to local governments, and with the private sector, academia, NGOs, and civil society. In this context, top-down policy design and implementation are complemented by bottom-up approaches that engage community actors in program design, and draw upon their local practices, perspectives, opinions, and experiences. Opportunities exist to better integrate public health into climate change discourse and policymaking processes and strengthen public health partnerships and collaborative opportunities (Awuor et al., 2020). Creating networks, integration across organizations and jointly developed policies can facilitate cross-sectoral collaboration (Bowen and Ebi, 2017).

7.4.3.2 Multisectoral Collaborations

Multisectoral collaborations aimed at strengthening the health sector can generate multiple co-benefits in other sectors (high agreement, medium evidence). Solutions for health and wellbeing risks described in 7.2 and 7.3 often have their origins in sectors that include water, sanitation, agriculture, food systems, social protection systems, energy, and key components of urban systems such as housing and employment (Organization, 2015);(Bowen et al., 2014b);(Machalaba et al., 2015);(Confalonieri et al., 2015);(Bowen et al., 2014a);(Semenza, 2021).Climate resilient development pursued in these other sectors, and in cooperation with the health sector, simultaneously increases the potential for adaptation and climate resilience in terms of health and wellbeing *(high confidence)* (Ahmad et al., 2017); (Watts et al., 2018b);(Levy and Patz, 2015);; (Organization, 2018b);(Chiabai et al., 2018a); (Dudley et al., 2015);(Zinsstag et al., 2018);(Sherpa et al., 2014).

7.4.3.3 Financial Constraints

Financial constraints are the most referenced barrier to health adaptation and so scaling up financial investments remains a key international priority (very high confidence). (Wheeler and Watts, 2018) (UNFCCC, 2017a). AR5 estimated the costs of adaptation in developing countries at between US$70 billion and US$100 billion annually in the year 2050, but these are likely to be a significant underestimate, particularly in the years 2030 and beyond (UNEP, 2014). National surveys conducted by the World Health Organization identified financial constraints as a major barrier to the implementation of health adaptation priorities (WHO, 2019);(Watts et al., 2021). Novel research drawing on global financial transaction data suggests that in 2019, global financial transactions with the potential to deliver adaptation in the health and healthcare sector reached US$18.4 billion, driven by transactions in high- and upper-middle income countries, with investment in Africa, South-East Asia, and the Eastern Mediterranean mostly stagnant (Watts et al., 2021).

There has been limited participation of the health sector in international climate financing mechanisms (Martinez and Berry, 2018). Of 149 projects listed in the Adaptation Fund database in October 2020, a large number were broad based initiatives that may have considerable indirect benefits for health systems, such as enhanced disaster preparedness and food security, but none were explicitly aimed at strengthening health systems or directed funds through ministries of health. A review of projects funded by the major multilateral climate funds showed that less than 1.5% of dispersed adaptation funding, and less than 0.5% of overall funding has been allocated to projects aimed at protecting health (WHO, 2015a).A survey of national public health organization representatives from a mix of low-, middle- and high-income countries found that a lack of political commitment, insufficient coordination across sectors, and inadequate funding for public health-specific adaptation initiatives were common barriers to building climate resilience (Marcus and Hanna, 2020). Under-investment in climate-specific initiatives in health systems coincides with persistent under-investment in health care more generally, especially in low- and middle-income countries (Schaferhoff et al., 2019).

Adaptation financing often does not reach places where the climate-sensitivity of the health sector is greatest (Weiler, 2019). Financial constraints in Africa are one of the key reasons for slow implementation of health adaptation measures (Nhamo and Muchuru, 2019). Strengthening health systems in vulnerable countries has the potential to reduce current and future economic costs related to environmental health risks, thus enabling reinvestment in the health system and sustainable development (WHO, 2020b);(Organization, 2015). Robust and comprehensive climate and health financing builds first on core health sector investments (Organization, 2015). Other potential opportunities for resource mobilization include health-specific funding mechanisms, climate change funding streams, and investments from multi-sectoral actions and actions in health-determining sectors (Organization, 2015). Incorporating climate change and health considerations into disaster reduction and management strategies could improve funding opportunities and increase potential funding streams (Aitsi-Selmi et al., 2015). Reinforcing cross-sectoral governance mechanisms maximizes health co-benefits and economic savings, by allowing for multisectoral costs and benefits to be comprehensively considered in decision-making (Belesova et al., 2016); (WHO, 2020b);(Organization, 2015). An additional financial need concerns health research, the existing funding for which does not match what is needed to support the implementation of the combined objectives of the UN 2030 Agenda for Sustainable Development, the Sendai Framework for Disaster Risk Reduction; and the Paris Agreement (Green and Minchin, 2014; Ebi, 2016);(Green et al., 2017)

7.4.3.4 Perceptions of Climate Change Risks and Links to Adaptation

Adaptation decisions and responses to climate change can be influenced by perceptions of risks, which are shaped by individuals' characteristics, knowledge, and experience (medium agreement, medium evidence). Institutional and governmental responses are critical for adapting to climate-related risks in health and other sectors, but individual responses also are relevant, such as choosing to implement adaptation measures. Individual responses are in turn affected not only by capabilities but also by perceptions that climate change is real and requires a response (Ogunbode et al., 2019). Perceptions of climate risks are formed by experiences of changes in local weather and extreme weather events (Sattler et al., 2018), (Sattler et al., 2020);(van der Linden, 2015),observations of environmental changes (Hornsey et al., 2016), experiences of and knowledge about climate change impacts (Ngo et al., 2020);(van der Linden, 2015), and individual characteristics such as values and worldviews (Poortinga et al., 2019) (*high agreement, medium evidence*). Risk perceptions include both logical assessments about the likelihood and severity of climate change impacts, and affective feelings about those impacts. On average, affective measures of risk perception are more strongly associated with disaster preparation than cognitive measures (Bamberg et al., 2017);(van Valkengoed and Steg, 2019).

In addition to perceptions of risk, the likelihood that an individual will implement behavioural adaptations, or support relevant public policy, is affected by subjective assessments of the response options (Bamberg et al., 2017); (van Valkengoed and Steg, 2019);(Akompab et al., 2013), (Carman and Zint, 2020);(Hornsey et al., 2016);(Brenkert-Smith et al., 2015).

Efficacy beliefs, social norms, and subjective resilience also affect adaptation behaviour (medium confidence), which has implications for communication about the need for climate adaptation. Efficacy beliefs represent the belief in one's ability to carry out particular action(s) and the belief that the action(s) will have the desired outcome. Belief that one is personally able to complete a behavior is moderately associated with engaging in disaster preparations (Navarro et al., 2021); (van Valkengoed and Steg, 2019) and with adaptation intentions (Burnham and Ma, 2017). *Collective efficacy*, the belief that a group of people working together can achieve a desired outcome, is important for participating in community adaptation behaviors (Bandura, 1982);(Chen, 2015);(Thaker et al., 2015). Related to this is *response efficacy*, a belief that a behavior will achieve its desired outcome, which is also moderately associated with engaging in disaster preparations (van Valkengoed and Steg, 2019). Collective efficacy can potentially be developed by strengthening communication networks and social ties within a community (Haas et al., 2021);(Jugert et al., 2016). Norms describing the adaptation strategies of others in a community, particularly those with high social status, can either facilitate or inhibit individual adaptation decisions (Neef et al., 2018);(Smith et al., 2021).

Distinct from efficacy beliefs, subjective resilience is a more general optimism or belief about one's ability (Jones, 2019);(Khanian et al., 2019). Subjective resilience (Clare et al., 2017) can influence preferred responses to climate change via assessment of one's ability to engage in specific response options. Identities can influence assessment of subjective resilience. Place attachment, having a strong emotional connection to a particular location, is weakly associated with disaster preparation (Brügger et al., 2015). In some cases, place attachment may inhibit adaptive responses, either by reducing perceptions of risk, or by making people reluctant to leave an area that is threatened (De Dominicis et al., 2015);(van Valkengoed and Steg, 2019). Place attachment can also contribute to enhanced community resilience (Khanian et al., 2019);(Jones, 2019);(Wang et al., 2021).

7.4.4 Migration and Adaptation in the Context of Climate Change

7.4.4.1 Linkages between Migration, Adaptation, Household Resilience

AR5 (Chapter 17 Human Security) concluded that migration is often, though not in all situations, a potential form of adaptation initiated by households. *Subsequent research indicates that the circumstances under which migration occurs, and the degree of agency under which household migration decisions are made, are important determinants of whether migration outcomes are successful in terms of advancing the wellbeing of the household and providing benefits to sending and receiving communities (high confidence).* (Adger et al., 2015);(Cattaneo et al., 2019); Cross-Chapter Box MIGRATE in Chapter 7]. Evidence from refugee studies and general migration research indicates that higher agency migration, in which migrants have mobility options, allows migrants greater opportunities for integrating into labour markets at the destination, makes it easier to remit money home, and generally creates conditions for potential for benefits for migrant households and for sending and receiving communities (Migration, 2019). Bilateral agreements that facilitate labour migration have been identified as being especially urgently needed for Pacific small island states (Weber, 2017).

Adaptive migration and the implied assumption that people can or should simply move out of harm's way is not a substitute for investment in adaptive capacity building (high agreement). (Bettini and Gioli, 2016). Climate-related migration, and especially involuntary displacement, often occurs only after *in situ* adaptation options have been exhausted and/or where government actions are inadequate (Adger et al., 2015);(Ocello et al., 2015); Cross-Chapter Box MIGRATE in Chapter 7). The threshold at which household adaptation transitions from *in situ* measures to migration is highly context specific and reflects the degree of exposure to specific climate risks, mobility options and the socio-economic circumstances of the household and the local community (McLeman, 2017);(Adams and Kay, 2019);(Semenza and Ebi, 2019) [also Cross-Chapter Box MIGRATE in Chapter 7]. A consistent theme in the research literature reviewed for all sections of this chapter is that proactive investments in health, social, and physical infrastructure, including those not aimed specifically at climate risks, build societal adaptive capacity and household resilience. In turn, expanding the range of adaptation options available to households and increases the likelihood that, when migration does occur, it does so under conditions of high agency that lead to greater chances of success. In communities where climate-related migration and/or relocation is occurring or may be likely to occur, policymaking and planning benefits from understanding the cultural, social and economic needs of exposed populations helps in the identification of responses and policies that build resilience (Adams and Kay, 2019).

7.4.4.2 Climate, Migration and linkages to Labour Markets and Social Networks

Adaptive climate-related migration is often closely related to wage-seeking labour migration (medium confidence). Because of the circumstances under which they move, climate-related migrants' destination and labour market choices, and the returns from migration, may be more heavily constrained than are those of other labour migrants (Jessoe et al., 2018);(Wrathall and Suckall, 2016).Within low- and middle-income countries, rural-urban migrant networks are important channels for remittances that may help build socio-economic resilience to climate hazards (Porst and Sakdapolrak, 2020), with higher levels of wage-seeking labour participation observed in climate-sensitive locales in South Asia (Maharjan et al., 2020). Local level research in China and South Asia shows, however, that the potential for remittances to generate improvements in household level adaptive capacity or resilience is highly context specific, has significant gender dimensions, and depends on such factors as the nature of the hazard, the distance migrated, and the length of time over which remittances are received (Banerjee et al., 2019a; Banerjee et al., 2019b). Social networks are a key asset in helping climate migrants overcome financial and structural impediments to their mobility, but these have their limits, particularly with respect to international migration (Semenza and Ebi, 2019). Since AR5, greater restrictions have emerged on movement between many low- and high-income countries (not including those necessitated by public health measures during the COVID-19 pandemic), a trend that, if it continues, would generate additional constraints on destination choices for future climate migrants (McLeman, 2019). Transnational diasporic connections are a potential asset for building resilience in migrant-sending communities highly exposed to climatic risks, with migrants' remittances potentially providing resources for long term resilience building, recovery from extreme events, and reducing income inequality (Bragg et al., 2018);(Mosuela et al., 2015);(Obokata and Veronis, 2018);(Shayegh, 2017);(Semenza and Ebi, 2019). Safe and orderly labour migration is consequently a potentially beneficial component of wider cross sectoral approaches to building adaptive capacity and supporting sustainable development in regions highly exposed to climate risks (McLeman, 2019).

7.4.4.3 Attitudes Toward Climate Migration

The success of climate-related migration as an adaptive response is shaped by how migrants are perceived and how policy discussions are framed (high agreement, medium evidence). The possibility that climate change may enlarge international migrant flows has in some policy discussions been interpreted as a potential threat to the security of destination countries (Sow et al., 2016);(Telford, 2018), but there is little empirical evidence in peer-reviewed literature assessed for this chapter of climate migrants posing significant threats to security at state or international levels. There is also an inconsistency between framing in some policy discussions of undocumented migration (climate-related and other forms) as being "illegal'' and the objectives of the Global Compact on Safe, Orderly and Regular Migration and the Global Compact on Refugees (McLeman, 2019). Although the Global Compact on Refugees explicitly avoids the inclusion of climate-related migrants as refugees, terms such as 'climate refugees' are common in popular media and some policy discussions (Høeg and Tulloch, 2018);(Wiegel et al., 2019). The framing of migration policy discussions is relevant, for example, in discussing climate adaptation options for Pacific Island Countries, where there is considerable disagreement over policy discussions that range from a 'migration-with dignity' approach that would liberalize labour migration in the Pacific region, to those that see migration as a last resort option to be avoided as much as possible (McNamara, 2015);(Farbotko and McMichael, 2019);(Oakes, 2019);(Remling, 2020). A more beneficial policy framing in terms of ensuring that future migration contributes to climate resilience and sustainable development has been established since AR5 within the framework of the Global Compact for Safe, Orderly and Regular Migration (see 7.4.7.7).

Attitudes of residents in migrant-receiving areas with respect to climate-related migration warrant consideration when formulating adaptation policy (medium confidence). Existing research is modest and difficult to generalize with respect to the impacts of climate-related migration and displacement on social dynamics and stability in receiving destinations, with outcomes being tied to attitudes and social acceptance of receiving communities and efforts to integrate migrant arrivals into the community (Koubi and Nguyen, 2020). Research from Kenya and Vietnam shows that residents of receiving communities view environmental drivers as being legitimate reasons for people to move, and are unlikely to stigmatize such migrants (Spilker et al., 2020). In these examples, urban residents viewed environmental motivations as being comparable to economic reasons for migrating, and did not see climate-related migrants as posing any particular risks for receiving communities. However, more research is needed to determine whether such findings are generalizable. Case studies from India suggest that a lack of recognition by local authorities of climatic factors as being legitimate drivers of rural-urban migration may lead to discrimination against migrants in terms of access to housing and other social protections, thereby undermining household resilience (Chu and Michael, 2018).

7.4.4.4 Planned Relocation and Managed Retreats

There is high agreement among existing studies that immobile populations often have high vulnerability and/or high long term exposure to climate hazards, and that non-climatic political, economic and social factors within countries may strongly constrain mobility (Zickgraf, 2019);(Ayeb-Karlsson et al., 2020);(Cundill et al., 2021). Section 7.2.6.2 highlighted the particular vulnerability of immobile populations in the face of growing climatic risks. However, research suggests governments should be slow to label such populations as being 'trapped' or to actively promote relocations in the absence of local agreement that *in situ* adaptation options have been exhausted (Adams, 2016);(Farbotko and McMichael, 2019). In the case of Indigenous settlements, efforts made to incorporate traditional knowledge in decision making and planning increase the potential for longer term success {Manrique, 2018, Climate-related displacements of coastal communities in the Arctic: Engaging traditional knowledge in adaptation strategies and policies}. Considerable health implications can potentially emerge within populations that are relocated as part of planned retreat and represent an important consideration for planners that requires greater research (Dannenberg et al., 2019). Organized relocations are not inherently transformative in their outcomes but, depending on the circumstances under which they occur and on how issues of equity and respect for the rights of those affected, are implemented, relocation could potentially be made transformative in a positive sense (Siders et al., 2021).

Disruptive and expensive relocations of low-lying coastal settlements in many regions would become increasingly necessary in coming decades under high levels of warming (high confidence). Organized relocations require long-term innovation, planning and cooperation on the part of governments, institutions, affected populations, and civil society (Hauer, 2017; Hino et al., 2017);(Haasnoot et al., 2021);(Moss et al., 2021). Recent examples illustrate the substantial financial costs of organized relocations, ranging from US$10,000 per person in examples from Fiji, to US$100,000 per person in coastal Louisiana, USA (Hino et al., 2017). Organized relocations are politically and emotionally charged, will not necessarily be undertaken autonomously by exposed populations, and are most successful when approached proactive and strategically to avoid increasing the socio-economic vulnerability of those who are relocated (Jamero et al., 2017), (Wilmsen and Webber, 2015);(Chapin et al., 2016);(McNamara et al., 2018);(Hauer et al., 2019);(Bertana, 2020). Key considerations for protecting the rights and wellbeing of people who might need to be resettled include proactive communication with and participation of the affected communities, availability of compensation, livelihood protection, and ensuring there is permanence and security of tenure at the relocation destination (Tadgell et al., 2018). Availability of funds for resettlement, how to manage relocation from communally owned lands, how to value privately owned land to be abandoned, and the potential for loss and damage claims are just some of the many potential complications (Marino, 2018);(McNamara et al., 2018). As a proactive option, researchers in Bangladesh have suggested the creation of "migrant-friendly towns" to provide options for autonomous relocation from hazardous areas (Khan and Huq, 2021).

7.4.5 Adaptation Solutions for Reducing Conflict Risks

There has been increased activity within the international community to understand and address climate-conflict linkages since AR5, with high level actions including the UN Climate Security Mechanism, launched in 2018, tasked with providing integrated climate risk assessments to the UN Security Council and other UN bodies, in partnership with UN and external actors (DPPA et al., 2020). G7 governments initiated an integrated agenda for resilience (Rüttinger et al., 2015) and the Berlin Call for Action in 2019 sought foreign policy as a platform to address climate security concerns focusing on risk-informed planning, enhanced capacity for action within the UN and improvements to operational response to climate security risks (Federal Foreign Office 2019). The non-peer-reviewed literature that currently addresses these policy dimensions is generated by a small number of consultancies funded by governments from the Global North and can lack diverse perspectives and priorities.

7.4.5.1 Environmental Cooperation and Peacebuilding

The environment can form the basis for active peacebuilding and a sustainable natural environment is important for ongoing peace (high agreement, medium evidence). Environmental peacebuilding (EP) is a framework increasingly utilised to understand the diverse ways in which the natural environment supports peace and can be utilised in peace building: preserving the natural environment such that degradation does not contribute to violence, protecting natural resources during conflict and using natural resources in post-conflict economic recovery (Kron, 2019). EP frames natural resources as facilitating peace rather than driving conflict (Dresse et al., 2019) with emerging literature analysing what this means in practice(Kovach and Conca, 2016);(Krampe, 2017);(Ide, 2019);(Ide et al., 2021);(Johnson, 2021);(Kalilou, 2021). There is emergent evidence for the success of these pathways. For example, a natural resource sharing agreement on the Kenya-Uganda border was able to reconcile spatial, logistical and conceptual barriers to addressing climate risks in development contexts (Abrahams, 2020). However, the long-term impacts of EP approaches on sustaining peace are yet to be monitored and evaluated (Ide and Tubi, 2020). EP may be successful depending on the context and the element of peace being built (Johnson, 2021) or undermine processes when environmental arguments are co-opted for geopolitical purposes (Barquet, 2015) or depoliticise conflict (Ide, 2020).

Formal institutional arrangements for natural resource management can contribute to transnational cooperation (high confidence) (See also Chapter 4). Evidence from the transboundary water sharing agreements provides evidence for cooperation rather than conflict over resources (Timmerman et al., 2017);(Timmerman, 2020);(Dinar et al., 2015). Transboundary water agreements and river basin organizations help build robust institutions that facilitate trust and relationship building that have benefits in other domains (strong agreement, medium evidence) (Dombrowsky, 2010);(Krampe and Gignoux, 2018) ;(Barquet et al., 2014) (Ide and Detges 2018). However, outcomes can be mixed as combining issues can stall progress and the international and top down nature of these approaches limits transferability to intra-state conflict at the local level (Rigi and Warner, 2020);(Ide et al., 2021);(Krampe et al., 2021).

7.4.5.2 Adaptation in Fragile Settings

Climate-resilient peace building has the potential to limit the impact of future climate change on peace efforts (medium confidence). Practical guidance has been developed, driven by policy concerns on climate-conflict links. The United Nations Environment Programme, the European Union and Adelphi have developed a toolkit for addressing climate fragility risks in peacebuilding, adaptation and livelihoods support (Programme et al., 2019)). Crawford et al (2015) provide recommendations for climate-resilient peacebuilding consistent with the UN Secretary-General's five peacebuilding principles, including integrating ex-combatants through the construction of climate resilient infrastructure, using climate impacts as a platform to engage previously conflicting groups, developing national disaster risk reduction and management strategies, and climate-proofing economic development activities. The United States Agency for International Development, in a report prepared for the Adaptation Thought Leadership and Assessments (ATLAS) program (Adelphi and Inc, 2020) drawing on resilience and peacebuilding programs in the Horn of Africa, recommend two critical conditions to ensure activities address compound climate fragility risks. Firstly, conducting local analyses of the links between climate, conflict, and fragility to identify specific risks to target; and secondly, ensuring long term commitment with a focus on participation and flexibility.

Conflict-sensitive adaptation that focuses on institutional frameworks, conflict management, and governance mechanisms has the potential to address complex interacting risks and emergencies over the long term (medium agreement, limited evidence). (Scheffran et al., 2012);(Matthew, 2018) (Okpara et al., 2018). However, most adaptation activities are planned and implemented under development or climate finance funds without systematic integration of conflict sensitivity, and National Adaptation strategies rarely and only implicitly address conflict and potential changes to power relations (Tänzler et al., 2019). Practitioners and policy researchers have attempted to address this gap by developing guidance and delivering training (e.g. (Tänzler et al., 2019);(Bob and Bronkhorst, 2014). However, there are real challenges relating to discounting indirect impacts on conflict and maladaptation (Asplund and Hjerpe, 2020) and risks of unintended, perverse outcomes (Mirumachi et al., 2020). Crawford and Church (2020) highlight the synergies between adaptation planning under the UNFCCC's National Adaptation Plan process and conflict reduction. Discussing development more broadly, Abrahams (2020) suggests three barriers to development that incorporate conflict-climate risks: geographically disconnected impacts and outcomes, the discourse of climate as a threat multiplier (rather than underlying peace), and teleconnected risks occurring at different scales. Effective approaches rely on understanding local power dynamics and social relations (Sovacool 2018; Roth et al. 2019, Sapiains et al 2021) (*high agreement, medium evidence*).

7.4.5.3 Gender-based Approaches toPpeacebuilding

Gender-based approaches provide novel underutilised pathways to achieving sustainable peace (high confidence, high evidence). Security council resolutions have encouraged the incorporation of gender analysis into peacebuilding, and research has shown that taking into account the gendered nature of networks and dialogues opens new avenues for cooperation and are conflict-sensitive (Dunn and Matthew, 2015), creating potential for women's rights and advocacy groups to be drivers of peace (Céspedes-Báez, 2018). For example, women are working to reduce climate vulnerability security risks in urban settings by entering local politics and joining community based organised and civil society networks (Kellog, 2020). The gendered nature of vulnerability and access to natural resources [see 4.6.4, 4.7.5.3, 5.4.2.3, 5.5.2.6, 5.8.2.2, Cross-Chapter Box GENDER in Chapter 18] will influence the efficacy of interventions to prevent conflict or to build durable peace (Pearse, 2017);(Chandra et al., 2017);(Fröhlich et al., 2018). However, this understanding has not so far resulted in widespread employment of gender-led analyses (Fröhlich and Gioli, 2015). However, this understanding has not so far resulted in widespread employment of gender-led analyses (Fröhlich and Gioli, 2015). This represents a key opportunity for expansion of the solution space for climate-related conflict. Analysis of peace processes (not confined to climate drivers) demonstrates the benefits of women's participation in peace processes for devising strategies for building peace (Paffenholz, 2018);(Cárdenas and Olivius, 2021) and for the durability of that peace (Shair-Rosenfield and Wood, 2017);(Krause et al., 2018).

7.4.6 Climate Resilient Development Pathways

Climate resilient development is a set of trajectories that strengthen sustainable development and efforts to eradicate poverty and reduce inequalities, while promoting fair and equitable reductions of GHG emissions. Climate resilient development also serves to steer societies towards low-carbon, prosperous, and ecologically safer futures (WGII, Chapter 1). *All pathways to pursue climate resilient development will involve balancing complex synergies and trade-offs between development pathways and the options that underpin climate mitigation and adaptation (very high confidence; WGII, Chapter 18).* Pathways to climate resilient development can be pursued simultaneously with recovering from the COVID-19 pandemic (WHO Manifesto for a healthy recovery from COVID-19; Cross-Chapter Box COVID in Chapter 7, Ebi et al., 2021).

Meeting commitments against seven existing global priorities would facilitate climate resilient development pathways and transformational futures for health, wellbeing, conflict and migration (*high agreement, medium evidence*):

1. Fully implementing the World Health Organization (WHO) Operational Framework for building climate-resilient health systems (WHO, 2015b)
2. Achieving Universal Health Coverage (UHC) under SDG 3 (good health and wellbeing)
3. Achieving net zero GHG emissions from healthcare systems and services
4. Achieving the Sustainable Development Goals
5. Adopting mitigation policies and technologies that have significant health co-benefits (see Cross-Chapter Box, including energy systems, urban, infrastructure, societal)
6. Meeting the objectives of the Global Compact for Safe, Orderly, and Regular Migration
7. **7.** Inclusive and integrative approaches to climate resilient peace

These transformations map across all of the five system transitions identified in WGII Chapter 18 – energy systems; land, ocean, and ecosystems; urban and infrastructural systems; industrial systems, and societal systems.

7.4.7.1 Fully implementing the WHO Operational Framework

The WHO Operational Framework for building climate-resilient health systems was designed to increase the capacity of health systems and public health programming to protect health in an unstable and changing climate (WHO, 2015b). The guidance defines a climate resilient health system as *one that is capable to anticipate, respond to, cope with, recover from, and adapt to climate-related shocks and stress, so as to bring sustained improvements in population health, despite an unstable climate*. Full implementation of this framework has the potential to achieve transformational adaptation; the fundamental attributes of health system would change to anticipate and effectively manage the population health and healthcare risks of climate change. This includes having the knowledge, capacity, tools, and human and financial resources for health systems to extend beyond soft limits to adaptation.

The framework outlines 10 key components (Figure 7.15) that, when achieved, will:

- guide professionals working in health systems, and in health determining sectors (e.g. water and sanitation, food and agriculture, energy, urban planning) to understand and effectively prepare for the additional health risks posed by climate variability and change;
- identify the main health functions that need to be strengthened to build climate resilience, and to use these to develop comprehensive and practical plans (e.g., the health component of NAP (H-NAP)); and
- support health decision-makers to identify roles and responsibilities to implement this plan, for actors within and outside the formal health sector.

Achieving full implementation of the WHO Operational Framework requires determination and commitment – with associated funding – from the health community specifically, and health-determining sectors more generally. Identifying priority areas is an immediate step required to commence this implementation process, which will be different in different contexts. The active engagement with Communities of Practice to share lessons and experiences would be a useful approach to support national and sub-national efforts – many of these exist already (e.g., Climate Change Community of Practice in Canada, and the 'weADAPT' initiative under the auspices at Stockholm Environment Institute).

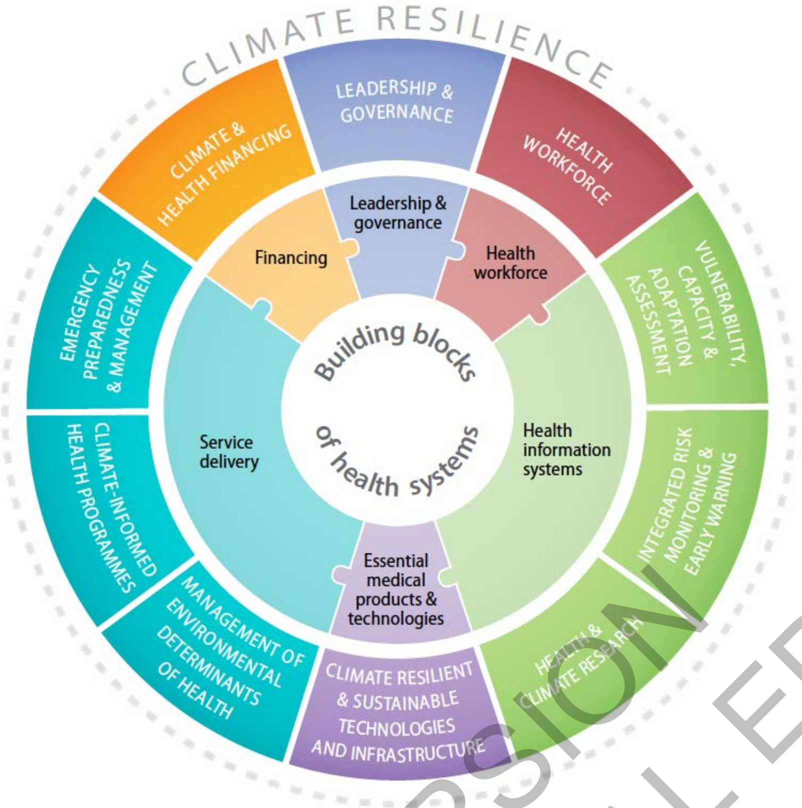

Figure 7.15: Ten components of the WHO operational framework for building climate resilient health systems, with links to the building blocks of health systems. Source (WHO, 2015b)

Table 7.9 summarizes selected characteristics of health systems under SSPs 1 (a world aiming to sustainable development), 2 (a world continuing current trends), and 3 (a world with high challenges to adaptation and mitigation). The table highlights the importance of investments that promote sustainable and resilient development, to decrease vulnerability no matter the magnitude and pattern of climate change. Adapting under SSP3 would be challenging even under pathways of limited additional climate change.

Table 7.9: Characteristics of health systems under SSPs 1, 2, and 3. Modified from Sellers and Ebi (2017) (Sellers and Ebi, 2017)

	SSP3	SSP2	SSP1
Basic characteristics	Reactive; failure to adapt; siloed information channels and national governance; limited partnerships	Incomplete planning; new information incorporated as convenient; occasional partnerships	Proactive; adaptively managed; frequent partnerships; interdisciplinary
Leadership and governance	Little focus at national and international levels on climate change and health; minimal planning conducted	Planning on climate change and health, but not comprehensive and often side-tracked on other issues	Strong climate change and health planning apparatus, including health components of national adaptation plans; regional / international partnerships
Health workforce	Climate change and health not rarely incorporated into training; few provisions for new training programs or funding for increase health worker positions in climate change-relevant specialties; health disparities not addressed	Climate change and health not systematically incorporated into training; new training programs insufficient to fill gaps in demand; limited attention to addressing health disparities	Systematic inclusion of climate change and health in worker training; expansion of funding and training; financing and incentive mechanisms to address health disparities

Health information systems	Assessments of vulnerability and adaptation rarely, if ever conducted; information not useful for planning; minimal risk monitoring or research	Vulnerability and adaptation assessments occasionally conducted, but generally of poor quality; early warnings incomplete; fiscal and political constraints on research	Vulnerability and adaptation assessments regularly conducted and used in planning; robust early warning networks; research agenda focused on vulnerable communities
Climate resilient and sustainable technologies and infrastructure	Facilities sited and constructed without climate consideration incorporated; medical supply chains no modified	Capital cost serves as key factor in siting and construction; increasing vulnerability of facilities to shocks	Health infrastructure designed to be robust to storms/floods, with redundant systems added to ensure continuity of care
Service delivery	Policies to manage environmental health hazards generally not followed; care practices not modified to accommodate climate information; few changes to emergency management procedures; health inequities worsen	Environmental health policies are not robust; marginal improvements in care practices; risk assessments and communication inadequate; no shift in health inequities	Policies to manage environmental health hazards regularly reviewed; practitioners review care practices and adjust as appropriate based on local climate and health conditions; robust communication tools developed; health service improvements reduce health inequities
Climate and health financing	Few funds devoted to climate change and health activities, particularly in low- and middle-income countries; few if any financing partnerships between high- and low- and middle-income countries; very weak regional and international coordinating bodies due to funding constraints	High-income countries generally form robust financing mechanisms; fiscal pressures in low- and middle-income countries constrain their financing abilities; financial partnerships formed across countries, but financing often not robust; regional and international coordinating bodies receive inadequate funds	Robust funding streams for climate change and health; climate change and health activities receive continuing financial support; effective financing partnerships; regional and international coordinating bodies effectively funded

Stress testing is an approach for evaluating the extent to which health systems are prepared for a future different from today (Ebi et al., 2018a). These desk-based exercises identify a desirable future outcome, such as successfully managing an extreme heatwave, flood, or storm with characteristics outside the range of recent experiences. The exercises move beyond identifying likely challenges from hazardous exposures to specifying policies and measures that could be successful under a different climate and development pathway. The exercises consider socioeconomic and political factors that can influence the extent of health system vulnerability and factors that can affect health system demands by impacting population health. Stress testing is designed to identify conditions under which it would be difficult for the health system to maintain its essential functions and to identify interventions that could maintain essential system functions despite climate-related shocks and stresses.

7.4.6.2 Achieving Universal Health Coverage Under SDG 3 (good health and wellbeing)

Universal Health Coverage (UHC) is when all people have access to the health services they need, when and where they need them, without financial hardship (WHO, 2021b). Achieving UHC is one of the targets in the SDGs. However, climate change is threatening to undermine the achievement of UHC through negative health outcomes and healthcare system disruptions (Salas and Jha, 2019);(Phillips et al., 2020);(Kadandale et al., 2020);(Roa et al., 2020). Climate change and UHC progress are closely linked to one another, as they both strive to improve health and achieve health equity (Salas and Jha, 2019). Supporting UHC is key to securing population health under a changing climate, as well as addressing structural inequalities (Roos et al., 2021);(Aleksandrova, 2020);(Phillips et al., 2020). Many regions of the world with the highest levels of vulnerability to the health impacts of climate change also have low levels of UHC; an integrated approach to

UHC planning that incorporates climate change will have great benefits particularly in improving health equity (Salas and Jha, 2019).

The COVID-19 pandemic has shown some countries taking positive steps to achieving UHC. For example, Ireland nationalized healthcare for the duration of the pandemic, and many countries including Australia have enhanced their telehealth services which has enabled specific groups to access health services, particularly those in rural and remote settings, and has allowed continuous care to the community (Monaghesh and Hajizadeh, 2020); see also Cross-Chapter Box COVID in Chapter 7).

7.4.6.3 Achieving Net Zero GHG Emissions from Healthcare Systems and Services

The health care system is a core component of UHC, supporting climate resilient and environmentally sustainable healthcare facilities (Corvalan et al., 2020). Health systems are large carbon polluters and have the potential to look beyond traditional 'green' initiatives towards more fundamental, longer-term redesign of current service models, with health practitioners participating actively in this process (Charlesworth and Jamieson, 2018). In the largest and most comprehensive accounting of national healthcare service emissions, the UK's National Health Service (NHS) quantified its health services' emissions and identified that 62% came from the supply chain, 24% from the direct delivery of case, 10% from staff commute and patient and visitor travel, and 4% from private health and care services commissioned by the NHS (Tennison et al., 2021).

The health sector has considerable opportunity to reduce its own carbon footprint, and by doing so would contribute to mitigation efforts, and help reduce health burdens associated with greenhouse gases emissions (Vidal et al., 2014);(Duane et al., 2019);(Charlesworth and Jamieson, 2019);(Charlesworth et al., 2018);(Guetter et al., 2018);(Bharara et al., 2018);(Frumkin, 2018)(high confidence). The UK's NHS National Health Service has committed to becoming the world's first net zero national healthcare system. Other examples of recent and ongoing initiatives include those undertaken by the Kaiser Permanente and the Gundersen Clinics in the US. Health Care without Harm, particularly across the Asia Pacific region; and the Green Hospital Initiative in New Delhi (Frumkin, 2018; Bharara et al, 2018).

7.4.6.4 Achieving the Sustainable Development Goals Would Increase Resilience in Health-determining Sectors and Contribute to Reducing the Risks of Involuntary Displacement and Conflict.

The Sustainable Development Goals (SDGs) are globally agreed objectives that integrate the economic, environmental, and social aspects of sustainable development, to end poverty, protect nature, and ensure that all people enjoy peace and prosperity. The SDGs were developed under the principle that the goals are integrated and indivisible, such that progress in one goal depends on progress in others (WHO, 2016a). Promoting health and wellbeing is not the sole responsibility of the health sector; it is also partially determined by strategies, policies, and options such as poverty reduction, promoting gender equality, ensuring all people enjoy peace and prosperity, eliminating nutritional insecurity, and ensuring availability and sustainable management of water and sanitation (Morton et al., 2019);(Bennett et al., 2020). Unique themes in the SDGs for health policy and systems research include social protection to protect and promote access to health services; stronger and more effective multisectoral collaborations beyond the health sector to address the upstream drivers of health and wellbeing; and participatory and accountable institutions to strengthen civic engagement and local accountability within health systems (Bennett et al. 2020).

For example, clean water, sanitation, and hygiene (WASH) are essential to human health and wellbeing. Unsafe water and sanitation and lack of hygiene caused an estimate 870,000 associated deaths in 2016 (WHO, 2021c). Only 71% of the global population have access to safely managed drinking water services; only 45% of the global population has access to safely managed sanitation services; and 60% had basic handwashing facilities in their home. About 25% of healthcare facilities lack basic water services, exposing workers and patients to higher infection risks. More than 80% of countries reported in 2018 that they lacked sufficient funding to meet national WASH targets. As detailed in 7.2.2.2, Box 7.3, 7.3.1.4, and 7.4.2.3, the burden of climate-sensitive waterborne diseases would be reduced if WASH targets were met.

The World Health Organization developed a Global Action Plan for Healthy Lives and Wellbeing for All that brings together multilateral health, development, and humanitarian agencies to support countries to accelerate progress towards the health-related SDGs (WHO, 2021c). Themes include sustainable financing to reduce unmet needs for services; community and civil society engagement to generate knowledge to inform policymaking and health responses; addressing the socio-environmental determinants of health; ensuring health and humanitarian services in fragile and vulnerable settings; research and development; and digital health. In 2020, enhanced collaboration through the Global Action Plan provided support for an equitable recovery from the COVID-19 pandemic in, for example, Lao People's Democratic Republic, Pakistan, Tajikistan, Somalia, South Sudan, Malawi, Nepal, and Columbia, highlighting the potential for multisectoral integration of economic, environmental, and social aspects of sustainable development to maintain essential health services and core public health functions during shocks and stresses (WHO, 2021a).

Meeting the SDGs also contributes toward reducing involuntary displacement and conflict, as assessed in sections 7.4.7.7 and 7.4.7.8.

7.4.6.6 Adopting Mitigation Policies and Technologies that have Significant Health Co-benefits)

Substantial benefits from climate action can result from investing in health, infrastructure, water and sanitation, clean energy, affordable healthy diets, low-carbon housing, clean public transport for all, improved air quality from transformative solutions across several economic sectors, and social protection. These benefits are in addition to the avoided health impacts associated with climate change. (see Cross-Chapter Box HEALTH in Chapter 7).

[START CROSS CHAPTER BOX HEALTH]

Cross-Chapter Box HEALTH: Co-benefits of Climate Actions for Human Health, Wellbeing and Equity

Authors: Cristina Tirado (Chapter 7 WGII); Robbert Biesbroek (Chapter 13); Mark Pelling (Chapter 6); Jeremy Hess (Chapter 7); Felix Creutzig (Chapter 5, WGIII); Rachel Bezner Kerr (Chapter 5); Siri Eriksen (Chapter 18); Diarmid Campbell-Lendrum (Chapter 7); Elisabeth Gilmore (Chapter 14); Maria Figueroa (Chapter 2, WGIII); Nathalie Hilmi (Chapter 18); Peter Newman (Chapter 10, WGIII); Sebastian Mirasgedis (Chapter 9, WGIII); Yamina Saheb (Chapter 9, WGIII); Gerardo Sanchez (Chapter 7); Pete Smith (Chapter 12, WGIII); Adrian Leip (Chapter 12, WGIII); Dhar Subash (Chapter 10, WGIII); Chris Tristos (Chapter 9); Mercedes Bustamante (Chapter 7; WGIII); Luisa Cabeza (Chapter 9, WGIII); Diana Urge-Vorsatz, (Chapter 8, WGIII),

Achieving the Paris Agreement and SDGs can result in low-carbon, healthy, resilient, and equitable societies with high-wellbeing for all (very high confidence). (Alfredsson et al., 2018);(O'Neill et al., 2018) {1.5 WGII} {5. WGIII}. Given the overlap in sources of GHGs and co-pollutants in energy systems, strategies that pursue GHG emission reductions and improvements in energy efficiency hold significant potential health co-benefits through air pollution emission reductions (*high confidence*) (Gao et al., 2018). Air quality improvements alone can substantially offset, or most likely exceed, mitigation costs at the societal level (Schucht et al., 2015);(Chang et al., 2017);(Markandya et al., 2018);(Vandyck et al., 2018);(Peng et al., 2017; Woodward et al., 2019; Sampedro et al., 2020);(Xie et al., 2018);{Fig.Ch5 WGIII[KE4] }). Pursuit of a mitigation pathway compatible with warming of +1.5 C, with associated cleaner air, avoided extreme events, and improved food security and nutrition, could result in 152 +/- 43 million fewer premature deaths worldwide between 2020 and 2100 compared with a business-as-usual scenario (Shindell et al., 2018)Reaching the Paris Agreement across nine major economies by 2040 could result in an annual reduction of 1.18 million air pollution-related deaths, 5.86 million diet-related deaths, and 1.15 million deaths due to physical inactivity (Hamilton et al., 2021). In Europe, a mitigation scenario compatible with RCP 2.6 could reduce total pollution costs, mostly from PM2.5, by 84%, with human health benefits equal to more than 1 € trillion over five years (Scasny et al., 2015). In the EU, ambitious climate mitigation policies could reduce years of lost life due to fine particulate matter from over 4.6 million in 2005 to 1 million in 2050, reduce ozone-related premature deaths from 48,000 to 7,000, and generate health benefits of 62 billion €/year in 2050 (Schucht et al., 2015).

However, there may be significant trade-offs between mitigation and other societal goals (Dong et al., 2019);(Gao et al., 2018). In some scenarios, mitigation policies consistent with the NDCs may slow poverty reduction efforts (Campagnolo and Davide, 2019) with implications for health. A framework of "co-impacts" that assumes neither a general beneficial nature of all implications from mitigation policy nor a hierarchy between climate and other types of benefits, may be more appropriate (Ürge-Vorsatz et al., 2014);(Cohen et al., 2017).

Transitioning to affordable clean energy sources for all presents opportunities for substantial wellbeing, health, and equity co-benefits (high confidence). (Gibon et al., 2017);(Lacey et al., 2017) (Peng et al., 2018);(Vandyck et al., 2018); (Williams et al., 2018);{18. WGII} {6.3. WGIII}. Residential solid fuel use affects health and degrades indoor air quality for up to 3.1 billion people in low and middle-income countries (WHO, 2016b); (Wang et al., 2017a). Adherence to planned emission reductions from the Paris Agreement related to renewables could subsequently improve air quality and prevent 71,000-99,000 premature deaths annually by 2030 (Vandyck et al., 2018). This effect increases with a 2°C pathway, with 0.7–1.5 million premature deaths avoided annually by 2050 (Vandyck et al., 2018). Co-benefits are also observed at national and regional levels. For instance, China could expect 55,000–69,000 averted deaths in 2030 if it transitioned to a half-decarbonized power supply for its residential and vehicle sectors (Peng et al., 2018).

Investing in universal basic infrastructure, including sanitation, clean drinking water, drainage, electricity, and land-rights, can transform development opportunities, increase adaptive capacity, and reduce vulnerability to climate-related risks (high agreement, high evidence). {6.1, 6.3 WGII}. Transformative approaches that reduce climate-related risks and deliver enhanced social inclusion and development opportunities for the urban poor are most likely where local governments act in partnership with local communities and other civil society actors (*high confidence*) {6.1, 6.3, 6.4 WGII}.

Rapid urbanization offers a time-limited opportunity to work at scale towards transformational adaptation and climate resilient development (medium evidence, high agreement). Multi-level leadership, institutional capacity, and financial resources to support inclusive adaptation, in the context of multiple pressures and interconnected risks, can help ensure that the additional 2.5 billion people projected to live in urban areas by 2050 are less exposed to climate-related hazards and contribute less to global warming (*high confidence*) {6.1, 6.3, 6.4 WG II}. Integrating low-carbon, inclusive adaptation into infrastructure investment driven by rapid urban population growth and COVID-19 recovery can accelerate co-benefits {Ch6, WGII, Urban X-WG Box}.

Urban planning that combines clean, affordable public transportation, shared clean vehicles, and accessible active modes can improve air quality and contribute to healthy, equitable societies and higher wellbeing for all. Stimulating active mobility (walking and bicycling) can bring physical and mental health benefits (high confidence). {6. WGII} {8.2 WG III} (Rojas-Rueda et al., 2016); (Avila-Palencia et al., 2018); (Gascon et al., 2019); (Hamilton et al., 2021). The health gains from active mobility outweigh traffic-related injuries, from a decreased incidence of chronic diseases(Ahmad et al., 2017);(Maizlish et al., 2017);(Tainio et al., 2017);(Woodcock et al., 2018).

Urban green and blue spaces contribute to climate change adaptation and mitigation and improve physical and mental health and wellbeing (high confidence). (Hansen 2017; EC, 2018; WHO, 2018; Rojas-Rueda et al. 2019). {13.7.3, WGII} {6. WGII} {8.4 WGIII). Urban green infrastructure including urban gardens, can bring benefits to social cohesion, mental health and wellbeing and reduce the health impacts of heatwaves by decreasing temperatures, thus reducing inequities in exposure to heat stress for low income, marginalized groups (Hoffman et al., 2020; Hoffmann et al., 2020){5.12.5;14.4.10.3 WGII} {7.4 WGII} {6. WGII} {13.7}. Trade-offs of increasing urban green and blue spaces include potential public health risks related to increased vectors or hosts for infectious diseases, toxic algal blooms, drowning, and aeroallergens (Choi et al., 2021);(Stewart-Sinclair et al., 2020); {6. WGII}

Climate adaptation and mitigation policies in the building sector offer multiple wellbeing and health co-benefits (high confidence). (Diaz-Mendez et al., 2018);(Macnaughton et al., 2018) {3.6.2, WGII} 9.8 WGIII}. Leadership in Energy and Environmental Design (LEED) certified buildings in the United States, Brazil, China, India, Germany, and Turkey saved $7.5 billion in energy costs and averted 33MT of CO2 from 2000-2016.(Macnaughton et al., 2018) These measures can increase health benefits through better indoor air quality, reduction of the heat island effect, improved social wellbeing through energy poverty alleviation, creation of new jobs, increased productive time and income, increased thermal comfort and lighting indoors, and reduced noise impact. (Smith et al., 2016); (McCollum et al., 2018);(Thema et al., 2017);(Mirasgedis et al., 2014);(Alawneh et al., 2019);(Diaz-Mendez et al., 2018);{9.8 WGIII}. The value of these multiple co-benefits associated with climate actions in buildings is equal or greater than the costs of energy savings (Ürge-Vorsatz et al., 2016);(Payne et al., 2015);{9.8 WGIII){14.4.5.3 WGII}.

Shifting to sustainable food systems that provide affordable diverse plant-rich diets with moderate quantities of GHG-intensive animal protein can bring health co-benefits and substantially reduce GHG emissions, especially in high income countries and where ill health related to overconsumption of animal-based products is prevalent (very high confidence). {5.12.6, WGII} {7.4, 13.5, WGII} {5.WGIII} (7.4 WGIII) (Springmann et al., 2018c);(SRCCL, 2019); (Clark and Tilman, 2017); (Poore and Nemecek, 2018); (Hayek et al., 2021). Transforming the food system by limiting the demand for GHG-intensive animal foods, reducing food over-consumption and transitioning to nutritious, plant-rich diets, can have significant co-benefits to health (*high confidence*) (Hedenus et al., 2014); (Ripple et al., 2014);(Tirado, 2017); (Springmann et al., 2018c); IPCC SR1.5, 2018). (SROC 2019).(SRCCL, 2019); (Nelson et al., 2016); (Willett et al., 2019);(Tilman and Clark, 2014);(Green et al., 2015);(Springmann et al., 2016b);(Springmann et al., 2018b);(Springmann et al., 2018a);(Springmann et al., 2018c); (Milner et al., 2015);(Milner et al., 2017);(Farchi et al., 2017);(Song et al., 2017); (Willett et al., 2019). Reduction of red meat consumption reduces the risk of cardiovascular disease and colorectal cancer; and the consumption of more fruits and vegetables can reduce the risk of cardiovascular disease, type II diabetes, cancer, and all causes of mortality (WHO, 2015c);(Tilman and Clark, 2014);(Sabate and Soret, 2014); (Willett et al., 2019). {7.4 WGIII} {5.12.5 WGII} {6.3 WGIII}. Globally, it is estimated that transitioning to more plant-based diets - in line with WHO recommendations on healthy eating - could reduce global mortality by 6–10% and food-related greenhouse gas emissions by 29–70% by 2050 (Springmann et al., 2016b). There are limitations in accessibility of affordable of healthy and diverse diets for all (Springmann et al., 2020) and trade-offs such as the potential increase of GHG emissions from producing healthy and diverse diets in low- and medium-income countries (Semba et al. 2020). Agroecological approaches have mitigation and adaptation potential, deliver ecosystem services, biodiversity, livelihoods and benefits to nutrition, health, and equity (Rosenstock et al., 2019);(Bezner Kerr et al., 2021);{5.4.4; 5.14.1 WGII} {13.5, 14.4.4 WGII}.

[END CROSS CHAPTER BOX HEALTH HERE]

7.4.6.7 International policy frameworks for migration that contribute to climate-resilient development

Climate-related migration, displacement and immobility in coming decades will coincide with global and regional demographic changes that will produce a widening distinction between high-income countries that have aging, slow-growing (or in some countries, shrinking) population numbers and low-income countries that have rapidly growing, youthful populations. Given this dynamic, coordinated national and international strategies that integrate migration and displacement considerations with wider adaptation and sustainable development policies may contribute to climate-resilient development. Since AR5, the international community has established a number of agreements and initiatives that, with continued pursuit and implementation, would create potential for climate-related migration to be a positive contribution toward adaptive capacity building and sustainable development more broadly (Warner, 2018).

The 2018 Global Compact for Safe, Orderly and Regular Migration provides an important opportunity for planning for and responding to future climate-related migration and displacement (Kälin, 2018). Among its 23 objectives, the Compact explicitly encourages the international community to implement migration policies that facilitate voluntary migration and actively prepare for involuntary displacements due to climate change, especially in low- and middle-income countries. The Compact's objectives include reducing barriers to legal and safe migration, facilitating the freer flow of remittances between sending and receiving communities, and by doing so aim to increase the potential for migration to make positive contributions to sustainable development and to adaptive capacity-building. It also contains specific provisions pertaining to climate- and disaster-related migration and displacement. Objective 2 of the Compact aims at reducing drivers of involuntary or low-agency migration, and recommends that states establish systems for sharing information on environmental migration, develop climate adaptation and resilience strategies harmonized at sub-regional and regional levels; and cooperate on disaster risk prevention and response. Other objectives in the Compact relevant to climate-related migration include Objective 5 (increasing pathways for regular migration) and Objective 19 (facilitating migrants' ability to contribute to sustainable development). Objective 18, which links migration with skills development, is consistent with the 'migration with dignity' approach to displacement risks (McNamara, 2015);(Kupferberg, 2021). The 2018 Global Compact on Refugees observes that climate hazards increasingly interact with the drivers of refugee movements. The guidelines this Compact provides to governments regarding options and actions for addressing the causes of refugee movements and considerations for assisting and supporting refugees are useful for governments seeking guidance for all forms of displacement more generally, including displacement linked to climate change.

Pursuant to the Paris Agreement, a task force was struck by the Warsaw International Mechanism to make recommendations to the Conference of the Parties to the UNFCCC on how to reduce the risks of climate-related displacement. Its 2018 report recommended that parties work toward development of national legislation, cooperate on research, strengthen preparedness, integrate mobility into wider adaptation plans, work toward safe and orderly migration, and provide assistance to people internally displaced for climate-related reasons. Such recommendations dovetail strongly with the objectives of the Compacts on Migration and Refugees, as well as the Sendai Framework for Disaster Risk Reduction and the 2030 Sustainable Development Goals (SDGs). The SDGs, which include multiple goals and targets in which migration plays an explicit role in fostering development (Nurse, 2019), may be seen as completing the international policy arrangements necessary for addressing future climate-related migration and displacement.

7.4.6.8 Inclusive and integrative approaches to climate resilient peace

Climate resilient development pathways to reduce conflict risk rely on a shift in perspective; from framings around resource scarcity and security to sustainable natural resource governance and peace (Brauch et al 2016, Barnett, 2018; Dresse et al 2018). (Day and Caus, 2020) Recognizing that conflict results from underlying vulnerabilities, development that reduces vulnerability offers the best win-win option for building sustainable, climate-resilient peace rather than specific security-focused interventions *(high confidenc*e). To this end, meeting the Sustainable Development Goals represents an unambiguous path to reducing conflict risk in a climate-changed world (Singh and Chudasama, 2021). There is growing acceptance in the development community, despite reservations about the securitization of climate, that instability and conflict exacerbated by climate change has the potential to undermine development gains (Casado-Asensio et al., 2020);(Day and Caus, 2020).

Core to achieving climate resilient peace are new ways of working, that involve cross-issue and cross-sectoral collaboration and integration as a default to policy and programming. The Security Council Resolution 1325 Women and peace and security (S/RES/1325 (2000)) and the Sustaining Peace Agenda (A/RES/70/262 (2016) are notable examples of this. The 2020 UNEP report on gender and security recommends integrating policy frameworks, better financing to strengthen women's roles in peacebuilding, integrated programme design and further research on gender, climate and security linkages. Inclusive approaches recognize that much of the vulnerability that drives conflict risk, is generated by existing inequality and marginalization of large proportions of the population – for example women and youth – and that peace cannot be achieved without their needs being taken into account, and their participation in peace processes (Mosello et al., 2021). Diverse and inclusive partnerships also require ways to better engage local level participation and improving understanding of how to build consensus, through human rights-based approaches that understand non-violent conflict and protest to be potentially positive and constructive elements of transformational approaches to building resilience (Nursey-Bray, 2017);(Ensor et al., 2018);(Schipper et al., 2021). There is an increasing focus on the role of environmental defenders in highlighting violations and gaps in state obligations through non-violent protest (Butt et al., 2019);(Scheidel et al., 2020). Addressing the lack of participation of researchers and experts from countries most at risk of conflict in many climate-related conflict and peacebuilding assessments and initiatives, would also support this objective.

Climate resilient development pathways for sustainable peace also require different ways of gathering intelligence and informing conflict risk. Dynamics that affect such risks exist across scales from the local to the regional and require response in a transboundary manner. There is increasing emphasis on engaging local stakeholders and diverse partnerships to inform context appropriate measures and better policy coordination (Bremberg et al., 2019);(Tshimanga et al., 2021);(Abrahams, 2020). The UN's Climate Security Mechanism, working across three UN departments, takes an integrated approach to analyze and support timely and appropriate responses to conflict risk focusing on risk assessments and early warning systems to aid conflict prevention, climate-informed peace and security activities and conflict-sensitive development, and promoting inter-sectoral cooperation, partnership, and information sharing (DPPA et al., 2020). There is already acknowledgement that adaptation needs to be effectively monitored and to help learning so that maladaptation can be avoided (Eriksen et al., 2021). Here the academic community, which until now has predominantly focused on understanding the causal relationship between conflict and climate, could contribute to advancing monitoring and evaluation of climate resilient peacebuilding initiatives (Mach et al., 2020);(Gilmore et al., 2018)..

[START FAQ7.1 HERE]

FAQ7.1: How will climate change affect physical and mental health and wellbeing?

Climate change will affect human health and wellbeing in a variety of direct and indirect ways, depending on exposure to hazards and vulnerabilities that are heterogeneous and vary within societies, influenced by social, economic and geographical factors as well as individual differences (see Figure FAQ7.1.1). Changes in the magnitude, frequency and intensity of extreme climate events (e.g. storms, floods, wildfires, heatwaves and dust storms) will expose people to increased risks of climate-sensitive illnesses and injuries, and, in worst cases, higher mortality rates. Increased risks for mental health and wellbeing are associated with changes caused by impacts of climate change on climate-sensitive health outcomes and systems (see Figure FAQ7.1.2). Higher temperatures and changing geographical and seasonal precipitation patterns will facilitate the spread of mosquito- and tick-borne diseases, such as Lyme disease and dengue fever, and water- and food-borne diseases. An increase in the frequency of extreme heat events will exacerbate health risks associated with cardiovascular disease, and affect access to fresh water in multiple regions, impairing agricultural productivity, increasing food insecurity, undernutrition, and poverty in low-income areas.

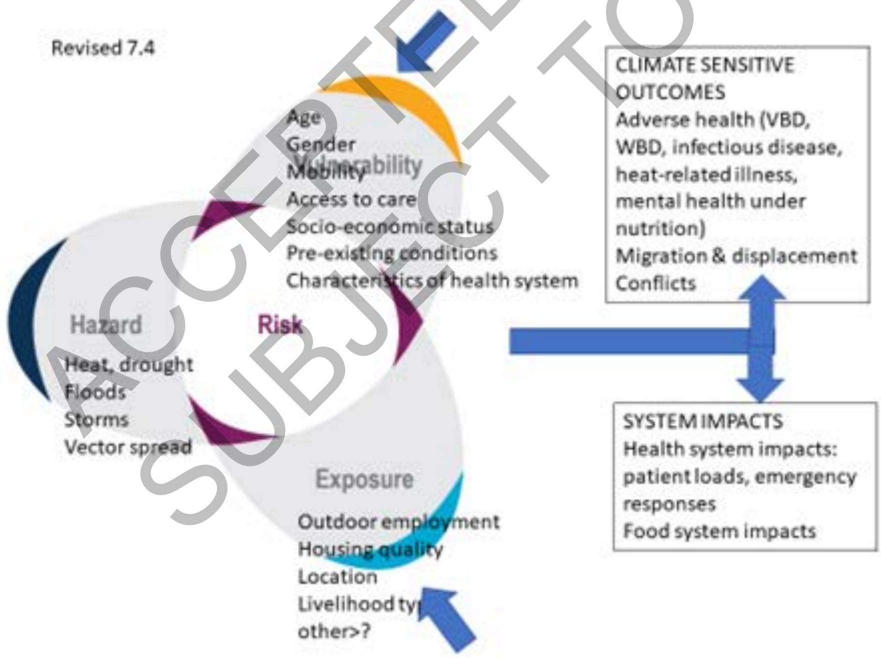

Figure FAQ7.1.1: Pathways from hazards, exposure and vulnerabilities to climate change impacts on health outcomes and health Systems

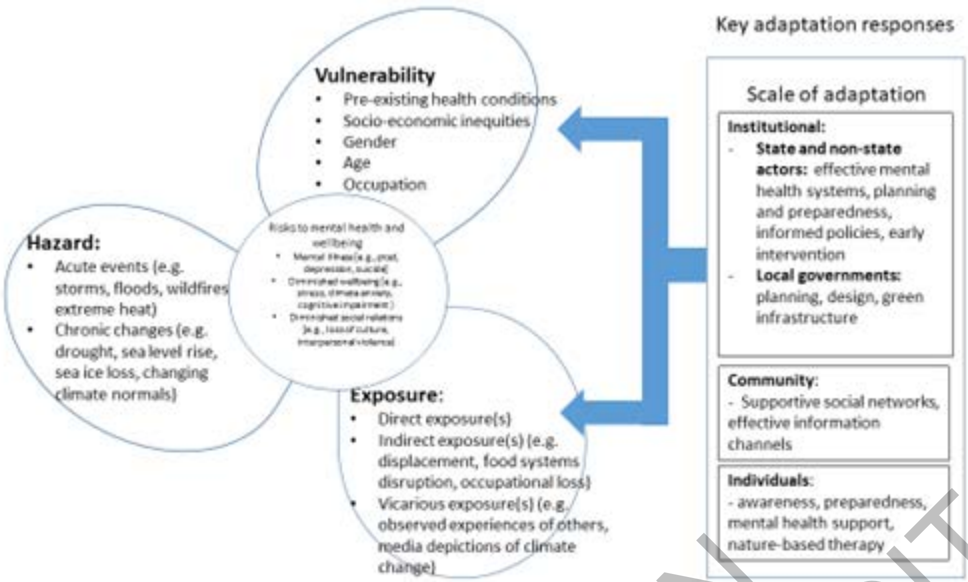

Figure FAQ7.12.: Climate change impacts on mental health and key adaptation responses

[END FAQ7.1 HERE]

[START FAQ7.2 HERE]

FAQ7.2: Will climate change lead to wide-scale forced migration and involuntary displacement?

Climate change will have impacts on future migration patterns that will vary by region and over time, depending on the types of climate risks people are exposed to, their vulnerability to those risks, and their capacity – and the capacity of their governments – to adapt and respond. Depending on the range of adaptation options available, households may use migration as a strategy to adapt to climate risks, often through labour migration. The most common drivers of involuntary climate-related displacement are extreme weather events, floods, and droughts, especially when these events cause severe damage to homes, livelihoods and food systems. Rising sea levels will present a new risk for communities situated in low-lying coastal areas and small island states. The greater the scale of future warming and extreme events, the greater the likely scale of future, involuntary climate-related migration; progress toward the sustainable development goals has the opposite effect.

[END FAQ7.2 HERE]

[START FAQ7.3 HERE]

FAQ7.3: Will climate change increase the potential for violent conflict?

Adverse impacts of climate change threaten to increase poverty and inequality, undermine progress in meetings sustainable development goals, and place strain on civil institutions – all of which are factors that contribute to the emergence or worsening of civil unrest and conflict. Climate change impacts on crop productivity and water availability can function as a 'risk multiplier' for conflict in areas that are already politically and/or socially fragile and depending on circumstances, could increase the length or the nature of an existing conflict. Institutional initiatives within or between states to protect the environment and manage natural resources can serve simultaneously as mechanisms for engaging rival groups and adversaries to cooperate in policymaking and peacebuilding.

[START FAQ7.4 HERE]

FAQ7.4: What solutions can effectively reduce climate change risks to health, wellbeing, forced migration and conflict?

The solution space includes policies, strategies and programmes that consider why, how, when, and who to sustainably adapt to climate change. Effectively preparing for and managing the health risks of climate change requires considering the multiple interacting sectors that affect population health and effective functioning of health systems. Considering the close interconnections between health, migration and conflict, interventions that address climate risks in one area often have synergistic benefits in others. For example, conflicts often result in large numbers of people being involuntarily displaced and facilitate the spread of climate-sensitive diseases; tackling the underlying causes of vulnerability and exposure that generate conflict reduces risks across all areas. A key starting point for health and wellbeing is strengthening public health systems so that they become more climate resilient, which also requires cooperation with other sectors (water, food, sanitation, transportation, etc) to ensure appropriate funding and progress on sustainable development goals. Interventions to enhance protection against specific climate-sensitive health could reduce morbidity and mortality and prevent many losses and damages (Figure FAQ7.4.1). These range from malaria net initiatives, vector control programs, health hazard (syndromic) surveillance and early warning systems, improving access to water, sanitation and hygiene, heat action plans, behavioral changes and integration with disaster risk reduction and response strategies. More importantly, climate-resilient development pathways (CRDP) are essential to improve overall health and wellbeing, reduce underlying causes of vulnerability, and provide a framework for prioritizing mitigation and adaptation options that support sustainable development. Transformative changes in key sectors including water, food, energy, transportation and built environments offer significant co-benefits for health.

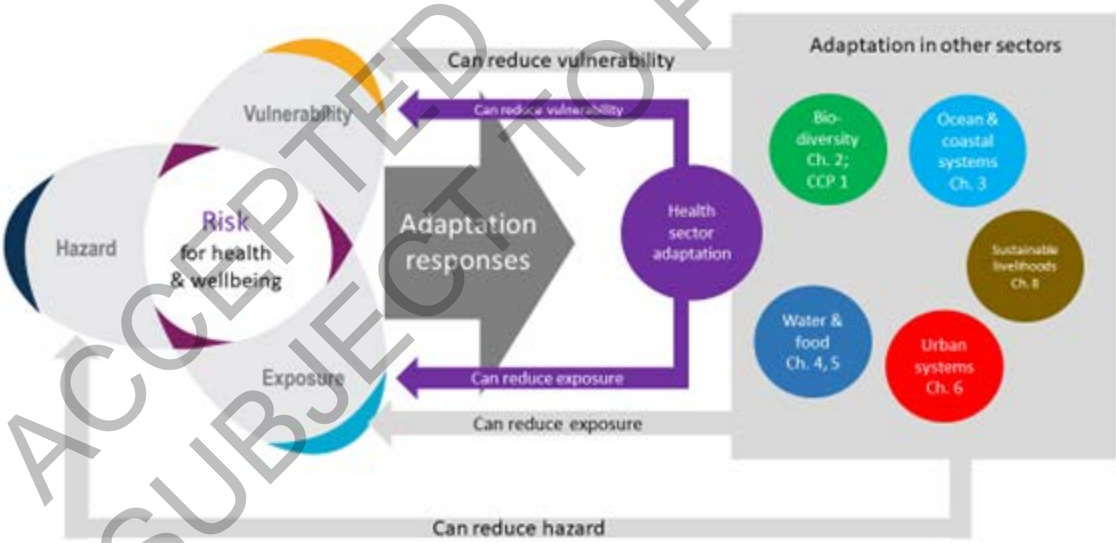

Figure FAQ7.4.1: Solution space for adaptation to climate change in health and other sectors.

[END FAQ7.4 HERE]

[START FAQ7.5 HERE]

FAQ 7.5: What are some specific examples of actions taken in other sectors that reduce climate change risks in the health sector?

Many of the greatest actions to face risks of climate change in other sectors lead to benefits for health and wellbeing. Adaptive urban design that provides greater access to green and natural spaces simultaneously enhances biodiversity, improves air quality, and moderates the hydrological cycle; it also helps reduce health risks associated with heat stress and respiratory illnesses, and mitigates mental health challenges associated with congested urban living. Transitioning away from internal-combustion vehicles and fossil fuel-powered generating stations to renewable energy mitigates GHG emissions, improves air quality and lowers risks of respiratory illnesses. Policies and designs that facilitate active urban transport (walking and bicycling) increase efficiency in that sector, reduce emissions, improve air quality, and generate physical and mental health benefits for residents. Improved building and urban design that foster energy efficiency improve indoor air quality reduce risks of heat stress and respiratory illness. Food systems that emphasize healthy, plant-centered diets reduce emissions in the agricultural sector while helping in the fight against malnutrition.

Chapter 8: Poverty, Livelihoods and Sustainable Development

Coordinating Lead Authors: Joern Birkmann (Germany), Emma Liwenga (Tanzania), Rajiv Pandey (India)

Lead Authors: Emily Boyd (Sweden), Riyanti Djalante (Indonesia), François Gemenne (Belgium), Walter Leal Filho (Germany), Patricia Fernanda Pinho (Brazil), Lindsay Stringer (United Kingdom), David Wrathall (USA)

Contributing Authors: Stavros Afionis (Greece), Liana Anderson (Brazil), Desalegn Ayal (Ethiopia), Connor Joseph Cavanagh (Norway), Jon Ensor (United Kingdom), Harald Heubaum (United Kingdom), Monirul Islam (Bangladesh), Rachel James (United Kingdom), Emma li Johansson (Sweden), Murukesan Krishnapillai (The Federated States of Micronesia), Joanna M. McMillan (Germany/Australia); Nicholas P. Simpson (South Africa), Jamon Van Den Hoek (USA), Emmanuel Raju (Denmark)

Review Editors: Taikan Oki (Japan), Marta G. Rivera-Ferre (Spain), Taha Zatari (Saudi Arabia)

Chapter Scientists: Ali Jamshed (Germany/Pakistan), Joanna M. McMillan (Germany/Australia), Mohammad Ravankhah (Germany/Iran)

Date of Draft: 1 October 2021

Notes: TSU Compiled Version

Table of Contents

Executive Summary

Adverse impacts of climate change, development deficits and inequality exacerbate each other. Existing vulnerabilities and inequalities intensify with adverse impacts of climate change (high confidence[1]). These impacts disproportionately affect marginalised groups, amplifying inequalities and undermining sustainable development across all regions (*high confidence*). Due to their socio-economic conditions and the broader development context, many poor communities, especially in regions with high levels of vulnerability and inequality, are less resilient to diverse climate impacts (*high confidence*) {8.2.1, 8.2.2, 8.3.2, 8.3.3}

Under all emissions scenarios, climate change reduces capacities for adaptive responses and limits choices and opportunities for sustainable development. Higher levels of global warming lead to greater constraints on societies. Climate change increases the threat of chronic and sudden onset development challenges, such as poverty traps and food insecurity (high confidence). Adaptation interventions and transformative solutions that prioritize inclusive and wide-ranging climate resilient development and the reduction of poverty and inequality are increasingly seen as necessary to minimize loss and damage from climate change (*high confidence*) {8.2.1, 8.2.2, 8.3.1, 8.3.2, 8.3.3}.

Observed societal impacts of climate change, such as mortality due to floods, droughts and storms, are much greater for regions with high vulnerability compared to regions with low vulnerability, which reveals the different starting points that regions have in their move towards climate resilient development (high confidence). Observed average mortality from floods, drought and storms is 15 times higher for countries ranked as very high vulnerable, such as Mozambique, Somalia, Nigeria, Afghanistan and Haiti compared to very low vulnerable countries, such as UK, Australia, Canada and Sweden in the last decade (*high confidence*). Over 3.3 billion people are living in countries classified as very highly or highly vulnerable, while 1.8 billion people live in countries with low or very low vulnerability. The population in most vulnerable countries is projected to increase significantly by 2050 and 2100, while the population in countries with low vulnerability is projected to decrease or grow only slightly. Vulnerability is a result of many interlinked issues concerning poverty, migration, inequality, access to basic services, education, institutions and governance capacities often made more complex by past developments, such as histories of colonialism (*high confidence*) {8.3.2, 8.3.3}.

A growing range of economic and non-economic losses have been detected and attributed to climate extremes and slow onset events under observed increases in global temperatures (medium evidence, high agreement). If future climate change under high emissions scenarios continues and increases risks, without strong adaptation measures, losses and damages will *likely*[2] be concentrated among the poorest vulnerable populations (*high confidence*). The intersection of inequality and poverty presents significant adaptation limits, resulting in residual risks for people/groups in vulnerable situations, including women, youth, elderly, ethnic and religious minorities, Indigenous People and refugees. Climate change is *likely* to force economic transitions among the poorest groups, accelerating the switch from agriculture to other forms of wage labour, with implications for labour migration and urbanization (medium evidence, high agreement). Under an inequality scenario (SSP4) the projected number of people living in extreme poverty may increase by 122 million by 2030 (*medium confidence*) {8.2, 8.3.4, 8.4.1, 8.4.5, Map 8.8, Box 8.5, 16.5.2.3.4}

Both climate change and vulnerability threaten the achievement of the UN Sustainable Development Goals (SDGs) (medium confidence). This undermines progress toward various goals such as no poverty

---

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

(SDG1), zero hunger (SDG2), gender equality (SDG5) and reducing inequality (SDG10), among others (*medium evidence, high agreement*). Gender inequality and discrimination are among the barriers to adaptation (*high confidence*) {8.2.1¸8.4.5}. Also maladaptation can lead to additional complex and compounding future risks and threaten sustainable development (*high confidence*) {8.4.5.5, 8.2.1.7}

Under higher emissions scenarios and increasing climate hazards, the potential for social tipping points increases (medium confidence). Even with moderate climate change[3] people in vulnerable regions will experience a further erosion of livelihood security that can interact with humanitarian crises, such as displacement and forced migration (*high confidence*) and violent conflict, and lead to social tipping points (*medium confidence*). Social tipping points can also be coupled with environmental tipping points {8.3, 8.4.4}.

Vulnerable population groups in most vulnerable regions have the most urgent need for adaptation (high confidence). The most vulnerable regions are particularly located in East, Central and West Africa, South Asia, Micronesia and Melanesia and in Central America (high confidence). These regions are characterized by compound challenges of high levels of poverty, a significant number of people without access to basic services, such as water and sanitation and wealth and gender inequalities as well as governance challenges. Areas of high human vulnerability are characterized by larger transboundary regional clusters (*high confidence*). Additional support and structures are needed to reduce the existing gaps between future adaptation needs and current capacities, and to support transitions from vulnerable livelihood with adequate integration of the Indigenous Knowledge and Local Knowledge systems. Greater investments are required under higher levels of global warming and of inequality (RCP 4.5; RCP8.5 and SSP4) (*high confidence*) {8.3, 8.4, Box 8.6}.

The direct and indirect consequences of the COVID-19 pandemic have worsened inequalities within societies, thereby increasing existing vulnerabilities to climate change and further limiting the ability of marginalized communities to adapt (medium confidence). The COVID-19 pandemic is expected to increase the adverse consequences of climate change since the financial consequences have led to a shift in priorities and constrain vulnerability reduction (*medium confidence*). Moreover, the COVID-19 pandemic is also influencing the capacities of governmental institutions in developing nations to support planned adaptation and poverty reduction of most vulnerable people/groups, since the crisis also means significant reductions in tax revenues (*high confidence*) {8.3, 8.4¸8.4.5.5}.

Those with climate-sensitive livelihoods and precarious livelihood conditions are often least able to adapt, afforded limited adaptation opportunities and have little influence on decision making (high confidence). Enabling environments that support sustainable development are essential for adaptation and climate resilient development (high confidence). Enabling and supportive environments for adaptation share common governance characteristics, including multiple actors and assets, and multiple centres of power at different levels and an effective vertical and horizontal integration between levels (*high confidence*). Enabling conditions can support livelihood strategies that do not undermine human wellbeing (*medium confidence*) {8.5.1, 8.5.2, 8.6.3, 5.13}.

Mitigation and adaptation responses to climate change influence inequalities, poverty and livelihood security and thereby aspects of climate justice (medium confidence). Improving coherence between adaptations of different social groups and sectors at different scales can reduce maladaptation, enable mitigation and advance progress towards climate resilience (medium confidence). The poor typically have low carbon footprints but are disproportionately affected by adverse consequences of climate change and also lack access to adaptation options. In many cases, the poor and most vulnerable people/groups are most adversely affected by maladaptation (*medium evidence, high agreement*). Climate justice and right based approaches are increasingly recognized as a key principle within mitigation and adaptation strategies and projects (*medium confidence*). Narrowing gender gaps can play a transformative role in pursuing climate justice (*medium confidence*). Climate resilient development is therefore closely coupled with issues of climate justice. Synergies between adaptation and mitigation exist and these can have benefits for the poor (*medium confidence*) {8.4, 8.4.5.5, 8.6}.

---

[3] meaning low or moderate emission scenarios

There is increasing evidence that nature-based solutions (e.g., urban green infrastructure, ecosystem-based management) can provide important livelihood options and reduce poverty while also supporting mitigation and adaptation (medium confidence). However, the trade-offs over time between nature-based solutions and their dynamics are insufficiently understood. Appropriate governance, including mainstreaming and policy coherence, supported by adaptation finance that targets the poor and marginalised, is essential for adaptation and climate compatible development (*medium confidence*) {8.5.2, 8.6.3, 5.14}.

8.1 Introduction

The impacts of climate change have already significantly affected the livelihoods and living conditions, especially of the poorest and most vulnerable, and will continue to undermine development during the coming century. This chapter assesses the societal consequences of climate change and related hazards in terms of adverse and irreversible consequences for the most vulnerable. To understand societal consequences of climate change we assess impacts through the perspective of vulnerability, poverty and livelihoods of people and identify why climate events trigger sudden and slow-onset disasters, and how the most severe, acute and chronic impacts cause and deepen human suffering. We also examine issues of climate justice. Understanding and engaging with climate justice requires a plural focus on the historical social and institutional relations and inequalities which produce climate change, cause people to be vulnerable to climate hazards, and shape responses to them (Newell et al., 2021). An assessment of observed impacts on the poorest and their strategies for adaptation carries important lessons for inclusive, broad-based solutions to climate change.

As a starting point, this chapter examines linkages between climate change, specific climate-related hazards and impacts on multidimensional poverty, vulnerability and livelihoods. Past assessments have identified the linkages between climate change, poverty, livelihoods and human vulnerability, and shown how climate change leads to differential consequences for different communities and populations. The IPCC Fifth Assessment Report (AR5) identified socially and geographically disadvantaged people exposed to persistent inequalities at the intersection of various dimensions of discrimination based on gender, age, ethnicity, class and caste (IPCC, 2014a). AR5 also showed evidence climate change is a universal driver and multiplier of risk that shapes dynamic interactions between these factors. Climate change is one stressor that shapes dynamic and differential livelihood trajectories. Also, the IPCC Special 1.5°C report underscored with very *high confidence* that global mean temperature, harm and human wellbeing losses are increasing substantially (Hoegh-Guldberg et al., 2018; Roy et al., 2018).

This chapter builds on this, examining equitable development, robust institutions and poverty reduction as essential inputs to societies' capacity for adaptation (i.e., closes the adaptation gap) in order to avoid losses and damages from climate change. It assesses quantitative spatio-temporal information on human vulnerability at a global scale and for specific sub-regions, livelihood groups and communities at the local level. The chapter assesses the newest literature on how multidimensional poverty and human vulnerability to climate change is measured and also examined the agreement of different index systems in terms of global hotspots of human vulnerability.

In addition, the chapter explores how climate change affects different livelihoods and livelihood assets and also examines factors that characterize vulnerability to climate change, focusing on different dimensions of human vulnerability and its sub-systems (e.g., access to infrastructure services). In this context the chapter also assesses quantitative data to map human vulnerability as well as economic and non-economic losses that are highly relevant for understanding adverse impacts of climate change.

The chapter assesses the newest scientific knowledge on how the most vulnerable and marginalized people are experiencing different climate influenced hazards and changes, how these groups prepare for and adapt to these changes. Hence, it examines how climate change intersects with broader processes of development. It also considers the various impacts of climate change on the livelihoods of the poorest, the capabilities, assets and activities required for a means of living. It examines the institutional conditions that promote livelihood resilience in the face of climate change. Quantitative analysis and qualitative data on observed adverse climate change impacts and future projections and trends in vulnerability show that societal impacts of climate change cannot solely be explained by looking at temperature changes or climatic hazards alone.

The chapter provides due consideration as how societal impacts of climate change are emerging as a result of climatic changes, development and vulnerability. In this regard, it also explores how past and present conditions of poverty, inequality and vulnerability determine observed and future societal impacts of climate change, including future adaptive capacities of societies exposed to climate change. It highlights new entry points to address climate risks and adaptation needs through the targeted reduction of poverty, inequity and vulnerability, linking particularly global quantitative information with local livelihood-oriented qualitative information.

The chapter also outlines new approaches for identifying social tipping points, meaning moments of rapid, destabilizing change across scales that can complement the discussion about physical tipping points in the climate system. It also addresses new perspectives on the baselines for assessing future vulnerabilities, and potential for irreversible losses, emphasizing not only economic but also non-economic losses, which are linked to past and present development trajectories. There is mounting evidence on non-economic losses, including the loss of land, livelihoods, social networks, cultural values and the irreversible degradation of ecosystem functions, as observed, for example, in parts of the Amazon. Non-economic losses are intertwined with economic losses to influence human health, nutrition, wellbeing and social stability, and therefore also influence present and future vulnerabilities and adaptive capacities. Non-economic losses from climate change disproportionately affect the poor. People in vulnerable situations are often disproportionally affected as they are less resilient and have less access to institutional support (including protection mechanisms) and coping strategies. This knowledge is key for informing integrated strategies for sustainable livelihood transitions and adaptation.

The chapter assesses newer literature about the synergies and trade-offs for the poorest and most vulnerable people/groups between adaptation mitigation, and sustainable development strategies, which societies must negotiate in order to pursue Climate Resilient Development. It explores synergies and mismatches in key development sectors that the poorest rely on, including agriculture, forestry and energy. It identifies the development strategies, elements of institutional design and financial mechanisms likely able to support risk reduction and adaptation. Our assessment reveals that successful adaptation is not solely a question of levels of funding, but depends on broader institutional design that determine societal development and enabling conditions for adaptation to and mitigation of climate change. An assessment of enabling conditions for adaptation supports the finding that more convergent, integrated and comprehensive approaches to adaptation are needed. The chapter concludes that climate justice requires consideration of the legal, institutional and governance frameworks that significantly determine whether adaptation is successful in addressing the needs of the poor.

Thus, intersections between climate hazards and socioeconomic development are assessed from the point of view of vulnerability, poverty, livelihoods and inequality (see Figure 8.1). Chapter 8 adopts this wider perspective to examine the differential nature of observed and future disproportionate vulnerabilities (i.e., who is most susceptible to climate hazards and events, where, at the core to understanding of what scale and why?) as well as the inequalities inherent in adaptation and mitigation solutions as part of a wider climate justice perspective adopted in Chapter 8, and challenges for climate resilient development.

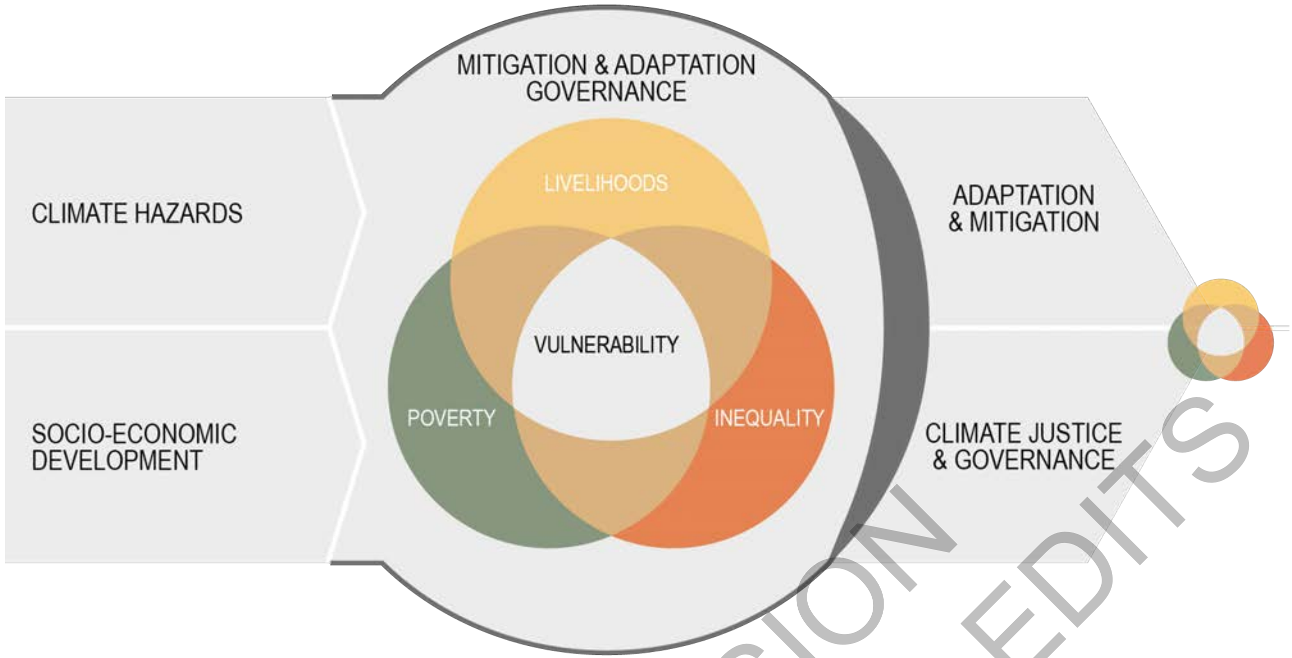

Figure 8.1: The lens of chapter 8 to better understand the human dimension of climate change at the nexus of climate change, climate hazards and socio-economic development.

Finally, our assessment points towards the fact that human vulnerability to climate change is a complex and multifaceted phenomenon that is often influenced by historic development processes, such as structures that originated with colonization. Also, recent global shocks not directly related to climate change, such as the COVID-19 pandemic and its socio-economic consequences, impact climate vulnerability and inequitable impacts occurring between countries and within countries. Recent studies show that COVID-19, and other social, economic and political crises, have worsened the circumstances of the poor and further marginalized them.

Overall, the chapter is a key in terms of understanding societal impacts of climate change and factors that determine the various differential adverse consequences of climate change on societies. The information presented and assessed in the chapter is fundamental for informing adaptation and risk reduction strategies, since climatic information alone cannot explain sufficiently why some regions, societies or groups are suffering significantly more under climate change compared to others. Concepts such as vulnerability, intersectionality and climate justice provide important insights on how societal impacts of climate change are influenced and determined by broader societal development contexts.

8.2 Detection and Attribution of Observed Impacts and Responses

8.2.1 Observed impacts of climate change with implications for poverty, livelihoods and sustainable development

This section reports on new evidence on the observed impacts of climate change to livelihoods and the poor since the previous assessment (IPCC, 2014a). New evidence provides additional insight into the interlinkages between climate change, poverty and livelihoods, and affords this assessment with greater confidence. New evidence has been evaluated according to climate change hazard categories developed for the AR6 (IPCC, 2021), and summarized in Figure 8.2.

8.2.1.1 Interactions between climate hazards and non-climatic stressors affecting livelihoods

New evidence highlights the potential for multi-hazard risks to push the poor into persistent traps of extreme poverty (Räsänen et al., 2016). Risk of extreme impoverishment increases for low-income people experiencing repeated and successive climatic events, whereby before they have recovered from one disaster, they face another impact (Forzieri et al., 2016). Cascading and compounding risks arise from multiple climate hazards producing 'overlaying impacts,' for example, in mountainous regions, where the combination of glacier recession and extreme rainfall result in landslides (Martha et al., 2015). There is *robust evidence* that this effect has been observed around slow- and rapid-onset climate events related to drought, i.e., rising temperatures, heatwaves, and rainfall scarcity, with devastating consequences for agriculture(Vogt et al., 2018; Bouwer, 2019). Particularly the urban and rural landless poor face difficulties rebuilding assets following one-off disasters or a series of shocks (Garcia-Aristizabal et al., 2015).

Climate change is one driver among many that challenges livelihoods of the rural poor, including economic transitions associated with industrialization and urbanization, and also governance failures such as unclear property rights and civil conflict (e.g., Nyantakyi-Frimpong and Bezner-Kerr, 2015). Recent research adds evidence about the ways that climate hazards impact non-climatic stressors with implications for poverty reduction (Nelson et al., 2016). The risk that climate hazards may push the poor into persistent extreme poverty intensify with stagnant wages, rising costs of living, mobility traps, and ethnic or religious discrimination (Cramer et al., 2014; Carter et al., 2016). Likewise in both urban and rural environments, non-climatic factors related to governance exacerbate the impacts of climate events among the poorest, including poor service provisioning (e.g., waste collection), poor urban planning (e.g., waste water drainage), and water management failures (Di Baldassarre et al., 2010; Leal Filho et al., 2018) as well as poor rangeland management, intensification of farming land uses (i.e. overgrazing, deforestation), degradation of wetlands, shortage of water and soil erosion in rural areas (Olsson et al., 2019).

A key risk for the poor is shocks to specific livelihood assets that may force low-income groups into persistent poverty traps (Figure 8.4; Chambers and Conway, 1992; Cinner et al., 2018) but evidence also suggests that climate change impacts are also driving transient forms of poverty, i.e. a modality of poverty which is recurring (Angelsen et al., 2014). Recurrent poverty is, for instance, seen in relation to crop losses and decreasing agricultural production when income losses worsen living conditions (Ward, 2016; Kihara et al., 2020). Recent research shows that climate change impacts may exacerbate poverty indirectly through increasing cost of food, housing and healthcare, among other rising costs borne by the poor (Islam et al., 2014; Ebi et al., 2017; Hallegatte et al., 2018) (*high confidence*). Severe adverse impacts of climate change at present and future risks may result from permanent, sudden, destabilizing changes accompanying climate events such as decreases in food security, large-scale migration, changes in labour capacity or conflict (Bentley et al., 2014). Overall, there is more evidence that even under medium warming pathways, climate change risks to poverty would become severe if vulnerability is high and adaptation is low (*limited evidence, high agreement*) (see Section 16.5.2.3.4)

Reliable and precise estimates of the impacts of climate change on persistent poverty are difficult to generate, e.g., due to data scarcity and data gaps (Hallegatte et al., 2015; Hallegatte et al., 2018; Kugler et al., 2019). However, progress has been made towards detection and attribution of climate change impacts on the poorest by linking standard climate observations in low-income countries with new non-traditional forms of data (including Indigenous Knowledge, historical archival data, satellite imagery, and data from digital devices) (Kuffer et al., 2016; Lu et al., 2016; Bennett and Smith, 2017; Steele et al., 2017).

8.2.1.2. Links between climate-related hazards, observed losses, poverty and inequality globally

There is *high confidence* that climate-related hazards, including both slow-onset shifts and extreme events, directly affect the poor through adverse impacts on livelihoods (see Figure 8.2), including reductions and losses of agricultural yields, impacts on human health and food security, destruction of homes, and loss of income (Hallegatte et al., 2015; Connolly-Boutin and Smit, 2016). One of the key factors that drives disproportionate impacts among poor households globally is lost agricultural income (*high confidence*) (Hallegatte et al., 2015; Islam and Winkel, 2017). Also of concern are the impacts of climate hazards to human health, which is a primary resource that the poor rely on (Figure 8.2). There are only few robust global estimates of observed income losses to the poor that comprehensively account for all climate hazards;

nevertheless, (Hallegatte and Rozenberg, 2017), estimating average impacts of climate change on incomes of the poor, found that across 92 developing countries, the poorest 40% of the population experienced losses that were 70% greater than the losses of people with average wealth.

c)

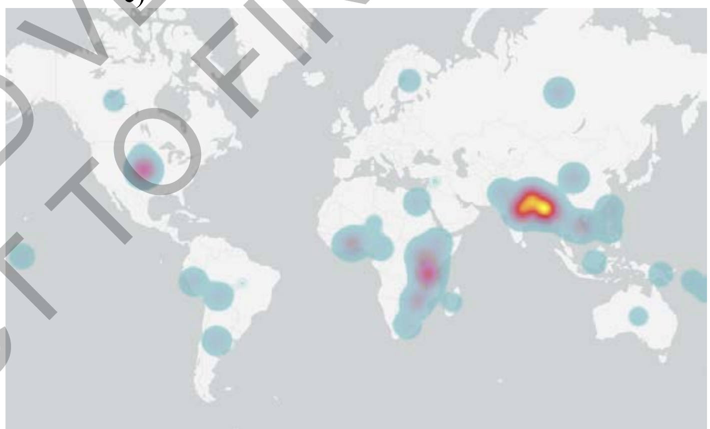

Figure 8.2: Summary of confidence on the observed impacts of 23 climate hazards on 9 key livelihood resources on which the poor depend most. Panel A displays 207 confidence statements on the total set of livelihood impacts. Based on a standardized assessment of available literature since the AR5 (2014), each impact category was assigned a confidence statement based on weight of evidence; *high confidence* is represented with HC, *medium confidence* with MC and *low confidence* with LC. An average numerical confidence score is assigned for impacts from each climate hazard, and for each livelihood resource category, representing total risk. Panel B depicts the "high risk" cluster of livelihood impacts, where confidence is highest. Panel C represents the spatial distribution of relative confidence. Hotspots represent highest confidence of observed livelihood impacts; however the absence of spatial information reflects not an absence of observed livelihood risk, but the relative weight of evidence sampled in this assessment exercise.

Overall, our assessment shows (see Figure 8.2) *high confidence* that two categories of climate hazards pose high risk to a broad range of livelihood resources that the poor rely on: warming trends and droughts (Figure 8.2b). Two key livelihood resource categories –life, bodily health and food security, and crop yield (representing agricultural productivity) are most at risk to a broad range of climate hazards (*high confidence,* Figure 8.2b). In addition to warming and drought, both pluvial and fluvial flooding, severe storms, and sea level rise represent a high-risk cluster for livelihood impacts (*high confidence,* Figure 8.2b).

Figure 8.2 reflects the fundamental threat that climate hazards pose to the survival of plants, livestock, fish as well as the human bodies on which livelihoods depend (*high confidence*) (see Horton et al., 2021). The dependence of livelihoods on biological, ecological and human survival depicted in Figure 8.2 is also treated in Chapter 5. Likewise, impacts to livelihood resources can be compared to impacts to other key assets (see AR6 WGI Chapter 12, Section 12.3 and Table 12.2).

It is revealed that warming trends and droughts pose greatest risks to the widest array of livelihood resources, and are particularly detrimental to crops and human health, a long-term requirement for livelihoods and wellbeing (*high confidence*) (see Figure 8.2b; Section 8.4.5.3; Section 16.5.2.3.4; Campbell et al., 2018). A wide range of hazards also threaten the survival of fish and livestock that livelihoods depend on (*high confidence,* Figure 8.2b), as well as other sources of income for the poor. Salinity is a secondary hazard related to droughts, coastal flooding and sea level rise, and poses a fundamental risk to agriculture (*high confidence*). There is also *robust evidence* for rainfall variability driving short-term impacts to agricultural productivity as well as permanent loss of agriculture (*high confidence*).

While severe storms, pluvial and riverine floods, and coastal floods primarily impact private livelihood resources, such as homes and income (*high confidence,* Figure 8.2b), warming and droughts also affect common pool resources, such as rangeland, fisheries and forests (*high confidence,* Figure 8.2b). Multiple hazards undermine ecosystems that Indigenous Peoples and poor communities depend on for food security and income and have sustainably managed over the long-term, such as forests, grazing land, and marine fisheries (Barange et al., 2014; Leichenko and Silva, 2014; Béné et al., 2016; Jantarasami et al., 2018).

Highest confidence for observed livelihood impacts is spatially concentrated in South Asia, Africa, North America, and to a lesser extent Small Island States (SIDS) (Figure 8.2c). The hazards most prevalent in all regions include warming trends, droughts and sea level rise (Figure 8.2c), and undermine crop productivity, crop varieties, and cropland in most regions (high confidence). Along coastlines, climate hazards threaten livelihoods particularly exposed to extreme weather, flooding, and sea level rise, and where poor populations are heavily dependent on agriculture and fisheries (*high confidence*). One third of total sampled evidence on livelihood impacts was observed in just three countries—Nepal, India and Bangladesh—indicating accumulating experience with livelihood impacts in South Asia (Figure 8.2c). However, this spatial representation of confidence does not mean that observed livelihood impacts are not occurring in other regions as well. Relative to South Asia, in Central Asia and the Caribbean, for example, the weight of evidence of livelihood impacts though lighter is still robust. Among industrialized nations, there is highest confidence that climate change has impacted livelihood resources in the United States.

8.2.1.3. Observed differential vulnerability to climate change, and loss and damage

The negative impacts of climate change on groups of vulnerable and/or marginalized communities generate so-called 'residual impacts' and residual risks that can remain a challenge in their lives (Warner and Van der Geest, 2013; James et al., 2014; Klein et al., 2014; Boyd et al., 2017). Such 'unacceptable' losses and damages include the loss of income sources, food insecurity, malnutrition, permanent impacts to health and labour productivity, loss of life, loss of homelands, among others (McNamara and Jackson, 2019; Schwerdtle et al., 2020). The literature on loss and damage provides evidence not only on economic dimensions of global losses and damages, but also experiences of non-economic losses from the impacts of climate change, (see detail in Section 8.3; Barnett et al., 2016; Roy et al., 2018; McNamara and Jackson, 2019). The extreme events that have occurred in recent years highlight the potential for loss and damage, including 2019's Cyclone Kenneth, the strongest in the recorded history of the African continent, which made landfall in northern Mozambique causing 45 deaths and destroying approximately 40,000 houses, leaving hundreds of thousands at risk of acquiring waterborne diseases such as cholera during a prolonged recovery period (Cambaza et al., 2019).

In parallel to evidence on loss and damage, the science of climate event attribution has evolved from a theoretical possibility into a subfield of climate science. As attribution science strengthens, with it the evidence base linking greenhouse gas emissions to extreme heat events, heavy rainfall and wind storms grows and becomes more robust (Otto et al., 2016; Stott et al., 2016; Otto et al., 2018a; Otto, 2020; Clarke et al., 2021; van Oldenborgh et al., 2021a; van Oldenborgh et al., 2021b; Verschuur et al., 2021).

Climate justice questions arise about the observed differential losses and damages due to climatic hazards to affected populations in close connection with their vulnerability (Wrathall et al., 2015). Individual extreme weather events attributable to climate change result in losses and damages in communities and societies, which allow a quantification of the differential impacts of such events on different groups (Hoegh-Guldberg et al., 2019a). Considering the disproportionate adverse impacts of climatic hazard on most vulnerable groups and regions and their relatively minor contribution to anthropogenic climate change (Mora et al., 2018; Robinson and Shine, 2018), it is evident that vulnerability reduction and adaptation to climate change have also to be seen as an issue of climate justice and climate just development (Byers et al., 2018).

Probabilistic attribution allows an assessment of people's future climate risks and estimates about the costs of successfully adapting to them (James et al., 2014; James et al., 2019). To answer questions about impacts on people, the vulnerable and poor in particular, requires attribution, vulnerability and adaptation science to move far beyond understanding physical events and incorporate information (including Indigenous Knowledge and Local Knowledge) on people's vulnerability and capacities, and exposure and losses resulting from discrete events (Bellprat et al., 2019). Attribution science is therefore highly compatible with risk management tools (i.e., risk reduction, risk transfer, insurance, risk pooling, recovery, rehabilitation, and compensation) suggested in policy (James et al., 2019).

New observations provide greater evidence on the role of extreme poverty and global inequality, most of the detrimental direct impacts of climate change (e.g., rising food insecurity) disproportionately affecting the Global South (Hasegawa et al., 2018; Mbow et al., 2019; Khan and Zhang, 2021) compared with the Global North. Poor populations in many countries are also disproportionately facing extreme losses and damage from heatwaves, flooding and tropical weather extremes (Gamble et al., 2016). New case studies, such as the European heatwave of 2018, illustrate significant negative impacts across crop production in the Global North (Beillouin et al., 2020), livestock value chain (FAO, 2018; Godde et al., 2021), and fishing (Plagányi, 2019). Heatwave-induced intense fires can cause property damage, physical injury and death, as well as health and psychological harm of the victims. Heatwaves also create ideal conditions for the prevalence of certain pathogens, increase the risk of temperature related health problems, and exacerbate many pre-existing diseases (Rossiello and Szema, 2019).

A focus in the chapter is on the intersections between climate hazards and differential vulnerability resulting in actual and potential economic and non-economic losses (Section 8.3, 8.4; Thomas et al., 2019). Increasingly intersections of age, gender, socio-economic class, ethnicity and race are recognised as important to the climate risks and differential impacts and losses experienced by vulnerable, marginal and poor in societies (*high confidence*).(Section 8.2,2.3; Cross-Chapter Box GENDER in Chapter 18; Nyantakyi-Frimpong and Bezner-Kerr, 2015). For example, linkages between wildfires and gendered norms and values are real-world examples (Walker et al., 2021). A broader climate agenda which considers social structures and power relations intersecting with climate change extremes is important (Versey, 2021), in order to understand disproportionate impacts of climate hazards, observed and future losses and vulnerability (see Figure 8.3).

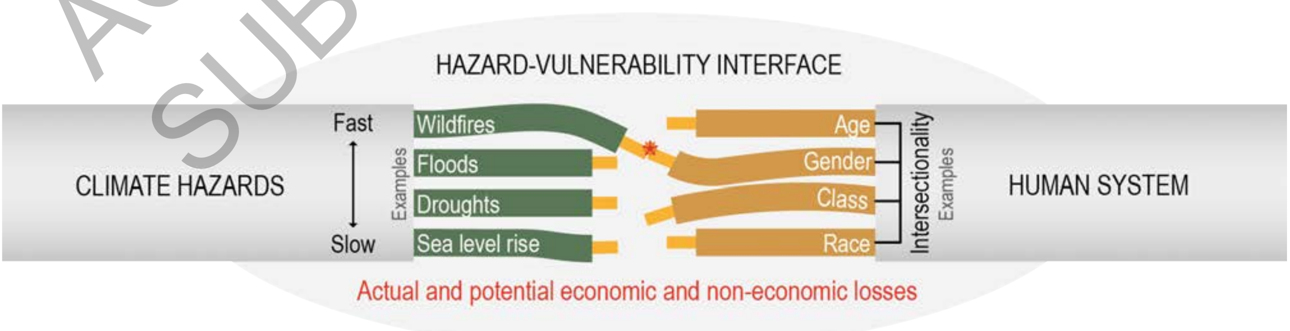

Figure 8.3: This is a schematic figure to illustrate the relationship between risk and impacts from climate change (including economic and non-economic losses and damages) and human systems lead to systemic vulnerability. We need to understand who is vulnerable, where, at what scale and why. We cannot just look at the climate hazard (e.g., wild fires, floods, droughts, sea-level rise, etc.) but must also look at who is being affected by these hazards and factors that make people/groups vulnerable (e.g., poverty, uneven power structures, disadvantage and discrimination due to, for

example, social location and the intersectionality or the overlapping and compounding risks from ethnicity or racial discrimination, gender, age, or disability, etc.) (see also Cross-Chapter Box GENDER in Chapter 18 and Section 5.12).

Extreme events (e.g., heatwaves, cold periods, icy conditions) occurring in the Global North illustrate that such events cause disproportionate impacts among aging populations, due to their immobility, isolation, infrastructure deficiencies and poor health assistance (Carter et al., 2016; Reckien et al., 2018). A well-known example is the heatwave in 2003 that killed thousands of elderly citizens across Europe (Poumadere et al., 2005; García-Herrera et al., 2010; Laaidi et al., 2011). More recently, in the Nordic region, elderly populations are experiencing distress associated with heatwaves and extreme cold events, with significant increases in morbidity and mortality due to cardiovascular and respiratory failure, showing that both age and underlying health issues intersect with climate change impacts (Carter et al., 2016; Li et al., 2016). The elderly also experience severe impacts from extreme winter seasons, such as in Finland, where of the from 3 000 deaths associated with extreme winter weather and 50 000 injuries associated with slippery from pavement conditions, the majority were people over 65 years old (Carter et al., 2016). Adaptation to extreme events including heatwaves, cold periods and icy conditions in the Global South and North will increase energy demand and the individuals' carbon footprint across all income levels (van Ruijven et al., 2019).

The 2018 US National Climate Assessment has identified the fact that south-eastern United States is already experiencing more frequent and longer summer heatwaves, and by 2050, rising global temperatures are expected to mean that cities in the south-eastern part of the United States of America may experience extreme heat (USGCRP, 2018). This includes disadvantaged African American communities who are more exposed and hence disproportionately experiencing the impacts of climate change (Shepherd and KC, 2015; Marsha et al., 2018). The historically discriminated Sami as an example of Indigenous People in Northern Sweden, and Maasai in Africa are examples of Indigenous People who also face climate risks and have limited resources, capacity or power to respond (Leal Filho et al., 2017; Persson et al., 2017)

8.2.1.4 Climate-related hazards, livelihood transitions and migration

Agricultural livelihoods of the rural poor, especially in Africa, Asia and Latin America, are already in transition due to the forces of industrialization, urbanization and economic globalization (De Brauw et al., 2014; Tacoli et al., 2015), and scientific evidence shows that climate change is accelerating livelihood transitions from rural agricultural production to urban wages (Cai et al., 2016; Cattaneo and Peri, 2016; Kaczan and Orgill-Meyer, 2020).

There is now *robust evidence* from virtually every region on earth showing that the livelihood impacts from a multitude of climate hazards are driving people to diversify rural income sources (Figure 8.2; Cross-Chapter Box MIGRATE in Chapter 7). Rural households frequently accomplish the goal of livelihood diversification with an increasing reliance on migration, urban wage labour and remittances (Marchiori et al., 2012; Bohra-Mishra et al., 2014; Gray and Wise, 2016; Nawrotzki and DeWaard, 2016; Banerjee et al., 2019a). What is different about rural-to-urban livelihood transitions under climate change impacts is that they accelerate both rural and urban stratification of wealth (Barrett and Santos, 2014; Thiede et al., 2016). On the one hand, climate change impacts on rural livelihoods increase the necessity of migration as in income strategy, accelerating migration (Cai et al., 2016) even while households that cannot select individuals for migration become more impoverished (Suckall et al., 2017; Nawrotzki and DeWaard, 2018).

On the other hand, climate change impacts widen the range of households willing or needing to engage in migration to include those less able to bear the costs of urban migration (Afifi et al., 2016; Hunter and Simon, 2017). The effect is also greater urban poverty, and a higher social burden of migrants seeking urban wages (Singh, 2019). Evidence suggests that poor households often move in desperation to make ends meet. In the context of climate hazards such as coastal inundation and salinity, economic necessity often drives working-age adults in poor households to seek outside earnings(Dasgupta et al., 2016). Labour migration in the context of climate change is also gendered, and as more men seek employment opportunities away from home, women are required to acquire new capacities to manage new challenges, including increasing vulnerability to climate change (Banerjee et al., 2019b).

Migration and displacement are directly induced by the impacts of climate change (*high confidence*, Cross-Chapter Box MIGRATE in Chapter 7), however, migration responses to climate change are differentiated across the spectrum of households' wealth. In well-off households, migration can be used as a way to support income diversification through remittances (Gemenne and Blocher, 2017). High levels of poverty mean that a large part of African populations do not have sufficient resources to be mobile (Borderon et al., 2019; Leal Filho et al., 2020b). The poorest households, conversely, will typically lack the resources that would allow them to migrate in ways that maintain an acceptable standard of living, and may find themselves unable or unwilling to move in the face of climate change impacts (Sam et al., 2021).

There is *high agreement* and *robust evidence* that climate change impacts also have a major influence on key enabling conditions for migration, such as sociodemographic, economic and political factors (Abel et al., 2019; Borderon et al., 2019), and that climate change impacts to development and governance may affect how people migrate (Wrathall et al., 2019; Cross-Chapter Box MIGRATE in Chapter 7). Mobility, which was considered as most viable climate change adaptation strategy to poor pastoralists, is restricted due to the political marginalization of pastoral groups, land privatization, governments' decentralisation policies, and plantation investment (Blench, 2001; Randall, 2015; Leal Filho et al., 2020b). While migration can be an adaptation response to climate change impacts (Black et al., 2011; Gemenne and Blocher, 2017), climate change impacts can also act as a direct driver of forced displacement (Marchiori et al., 2012). Societal groups that are forced to involuntarily migrate in response to climate change impacts may lack resources to invest in planned relocation mainly due to lack of good governance systems (Reckien et al., 2018). For people displaced by climate change impacts, policy interventions have a determining influence on migration outcomes, such as the numbers of migrants, the timing of migration and destinations (Gemenne and Blocher, 2017; Wrathall et al., 2019).The process of displacement and forced migration leaves people more exposed to climate change related extreme weather events, particularly in low income countries which often host the highest number of displaced people (Adger et al., 2018).

Climate change may be accelerating livelihood transitions and migration in ways that accelerate urbanization (Adger et al., 2020). Although a range of climate hazards are noted for accelerating rural-to-urban livelihood transitions (see Cross-Chapter Box MIGRATE in Chapter 7), a key theme to emerge across many case studies is the impact of rising temperatures on agricultural productivity (Mueller et al., 2014; Cattaneo and Peri, 2016; Call et al., 2017; Wrathall et al., 2018). In other words, when people cannot farm due to rising temperatures (and related stressors), they migrate. In this context, migration as a livelihood diversification strategy may evolve and take multiple forms over time (Bell et al., 2019), such as temporary migration (Mueller et al., 2020), seasonal migration (Gautam, 2017), or permanent migration (Nawrotzki et al., 2017), but generally conforms to existing patterns of migration (Curtis et al., 2015).

A key concern for the poor are climate change impacts that undermine livelihood diversification and resilience, narrowing the set of available livelihood alternatives (Tanner et al., 2015; Bailey and Buck, 2016; Perfecto et al., 2019).

8.2.1.5 The long-lasting effects of climate change on poverty and inequality

New studies document the long-term effects of climate change impacts on people's livelihoods that persist long after a hazard event. For example, in Mali, 30 years after 1982-1984, the period of most intense drought during the protracted late 20th century drying of the Sahel, the impact of drought on livelihoods and food security is still recognizable. The most food secure households associated with persistent drought induced famine were those that diversified livelihoods away from subsistence agriculture during and after the famine (Giannini et al., 2017). Meanwhile, a larger fraction of households with fewer livelihood activities, lower food security with higher reliance on detrimental nutrition-based coping strategies (such as reducing the quantity or quality of meals) were those unable to diversify livelihoods 30 years previously. Sufficient time has passed to consider the long-term outcomes for the poor in extreme cases featured in previous IPCC assessments, including Hurricane Katrina (2005) (e.g., Fussell, 2015; Raker et al., 2019) and Hurricane Mitch (1998) (e.g., Alaniz, 2017), forewarning that recovery is complex and requires significant sustained long-term investment in 'soft' aspects of development, including community organization and mental health (O'Neill et al., 2020; Fraser et al., 2021).

The IPCC Special Report on 1.5°C concluded that climate change has already increased the probability and intensity of individual extreme weather events occurring(Roy et al., 2018), and our new baseline consideration should be that serious climate change impacts are already being experienced by the most vulnerable, with long-term implications for development (Box 8.1; Roy et al., 2018). In both developing and developed countries the disproportionate impacts of the compounding effects of climate change on development are felt by the most disadvantaged. For example, the residual impacts of storms like Hurricane Maria (see Section 8.2.1.1) illustrate how rising temperatures, extreme weather events, coral bleaching, and sea level rise come together and create compounding hazard-cascades to leave long-lasting effects on the lives of the poor, as well as their food and water security, health, livelihoods and prospects for sustainable development—not only in developing countries (Adger et al., 2014; Olsson et al., 2014; Hoegh-Guldberg et al., 2018; Roy et al., 2018), but also in highly inequitable industrialized countries within the same region (Gamble et al., 2016). According to the US National Climate Assessment (USGCRP, 2018). damages caused to communities by Hurricanes Irma and Maria in 2017 sparked unprecedented humanitarian crises. Hurricane Maria, a category 5 hurricane, passed through Dominica, St Croix, and Puerto Rico and is considered the worst climate disaster in recorded history to affect those islands (Rodríguez-Díaz, 2018). Approximately 200,000 people migrated from Puerto Rico to the mainland US in the weeks following the storm (Alexander et al., 2019). Estimates for direct and indirect casualties in Puerto Rico point out a total of 4645 excess deaths, equivalent to a 62% increase in the mortality rate (Kishore et al., 2018). The example of Hurricane Maria and Puerto Rico illustrates that vulnerability is part of a long history of discrimination and colonial governance which led to greater impacts on the island (Moleti et al., 2020). In Puerto Rico, the economic costs of the collapse of the island's energy, water, transport, and communication infrastructures are estimated to range from $25 to $43 billion (USD in 2017), further indebting the island, and putting its long-term development at risk. Meanwhile the economic impacts of Hurricanes Irma and Maria on the Caribbean region are estimated between $27 and $48 billion, and have long-term implications for state budgets, infrastructure supporting development of the poorest.

New evidence provides little expectation of net positive impacts of climate change for the poor (Hallegatte et al., 2015). Nevertheless, some benefits of climate change adaptation include improved disaster preparedness, the accumulation of social assets, economic benefits of agricultural diversification, and benefits associated with migration, as well as the political benefits of collective action (Pelling et al., 2018). In contrast, wealthier tiers of society facing climate change impacts are more able to liquidate assets to avoid losses from climate change, to be formally compensated for losses (Fang et al., 2019), and employ social positions to leverage gains from adaptation (Nadiruzzaman and Wrathall, 2015).

The poor frequently suffer the direct and indirect impacts of climate change, including the cost of adopting adaptive measures (Atteridge and Remling, 2018; Bro et al., 2020). Costs to the poor may also include the secondary impacts of first order adaptation activities, including the livelihood consequences to people migrating due to climate change impacts. The poor frequently bear indirect impacts of adaptation interventions, such as flood protection barriers, which may displace flood waters away from high-income populations toward poorer communities (Mustafa and Wrathall, 2011). Adaptation programming may also indirectly affect the poor as public resources are drawn into risk reduction interventions, and away from spending on social welfare and safety nets (Eriksen et al., 2015). Measures to enhance social welfare and safety nets themselves help enhance the poor's resilience to climate impacts because they focus on non-climatic stressors affecting livelihoods, which interact with climate hazards. Therefore, diverting attention away from safety nets may in fact undermine adaptation efforts (Leichenko and O'Brien, 2019; Tenzing, 2020).

[START BOX 8.1 HERE]

Box 8.1: Climate Traps: A Focus on Refugees and Internally Displaced People

A population of concern, extremely vulnerable to climate change impacts with limited capacity to adapt, are those displaced and resettled in the course of conflict or disaster, either internally or across borders (Burrows and Kinney, 2016). The risk for refugees and internally displaced people (IDPs) is two-fold: on the one hand, refugee and IDP settlements are disproportionately concentrated in regions (e.g., Central Africa and the Near East) that are exposed to higher-than-average warming levels and specific climate hazards, including temperature extremes and drought. On the other, these populations frequently inhabit settlements and legal circumstances that are intended to be temporary but are protracted across generations, and at the same time, face legal and economic barriers on their ability to migrate away from climate impacts. (Adams, 2016; Devictor and Do, 2016). Large concentrations of these settlements are located in the Sahel, the Near East and Central Asia, where temperatures will rise higher than the global average, and extreme temperatures will exceed thresholds for safe habitation (Figure Box8.1.1). Already largely dependent on state and humanitarian intervention, these immobile populations will require interventions to safely maintain residence in areas exposed to climate hazards. Adaptation planning should prioritize immobile populations living in an already destabilized development context, on improving their capacities to deal with the further consequences of climate change.

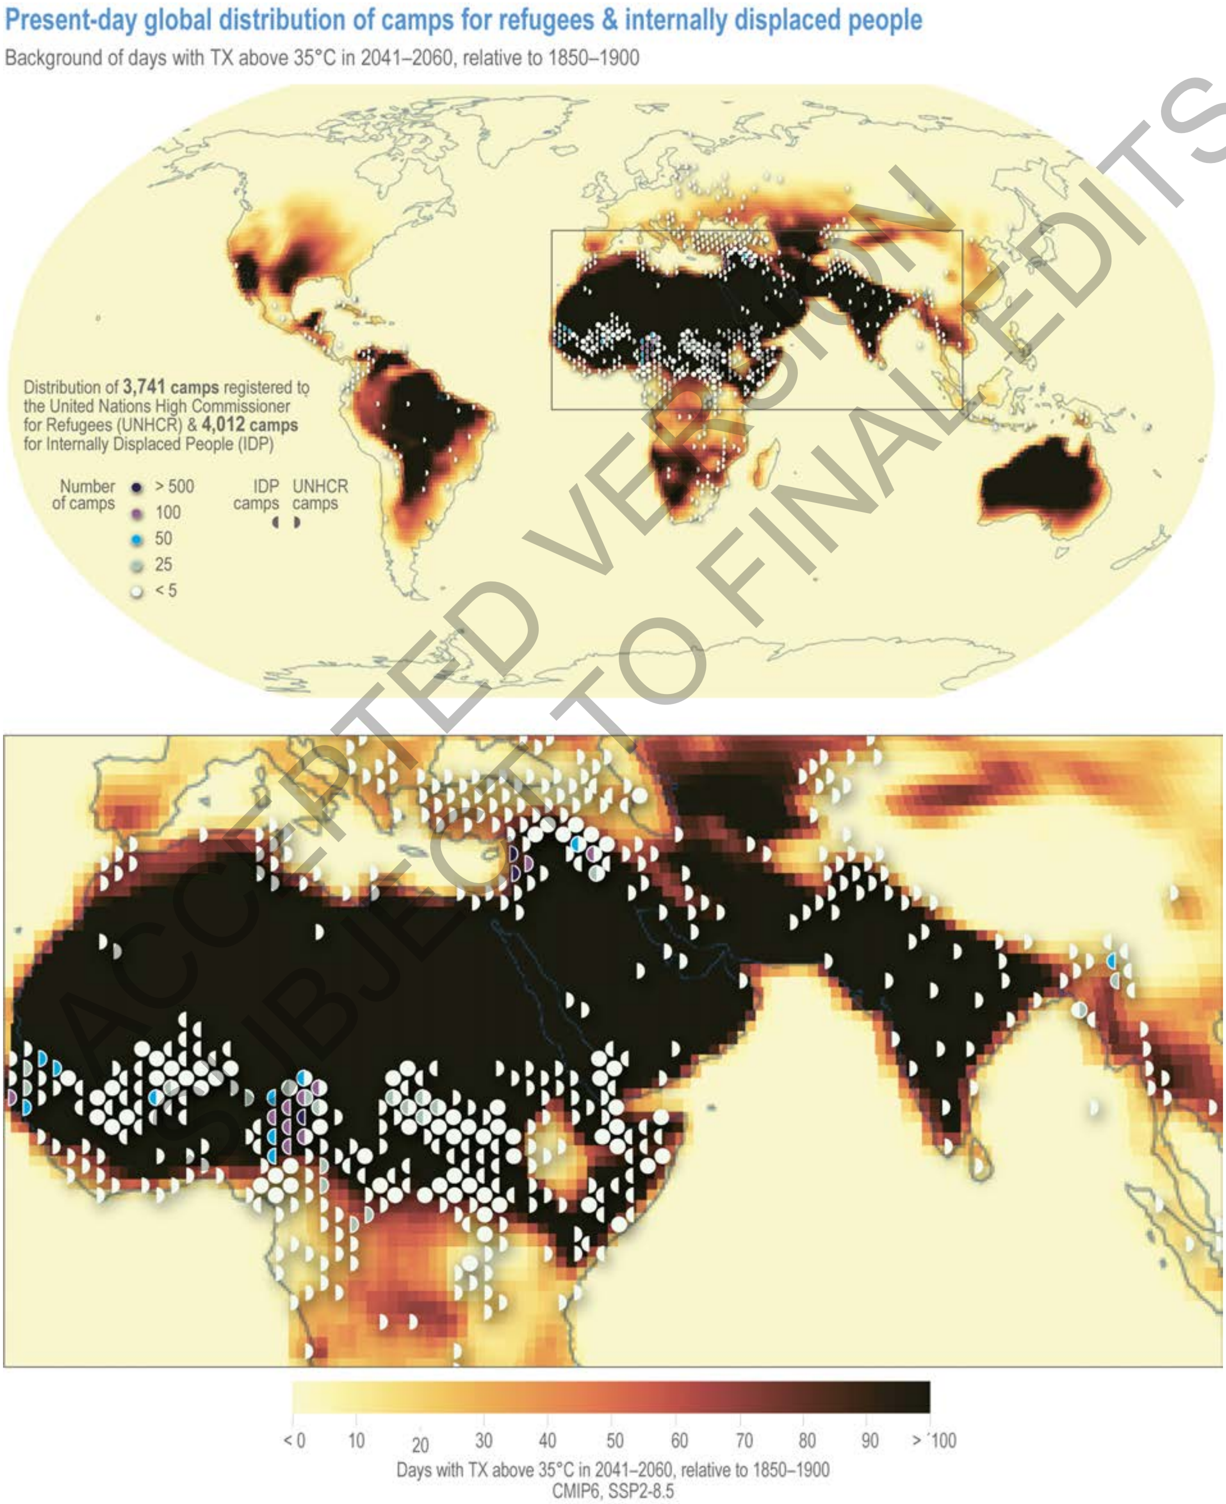

Figure Box 8.1.1: The global distribution of the United Nations High Commissioner for Refugees (UNHCR) refugee and internally displaced people (IDP) settlements (as of 2018) overlaid with annual mean near surface air temperature (°C) in 2040-2059 under RCP8.5.

Refugees and IDPs fit into a global category of extremely structurally vulnerable people that are missing from standard poverty assessments, officially uncounted or uncountable using traditional census and survey methods (Carr-Hill, 2013). These include highly mobile populations, internally displaced by war and environmental hazards (UNHCR, 2020; IDMC, 2021); itinerant labourers; urban poor in informal settlements (Lucci et al., 2018); unauthorized migrants living in countries where they do not hold citizenship (Passel, 2006); guest workers (Reichel and Morales, 2017); the homeless and institutionalized (Caton et al., 2007); rural nomadic, pastoralist or landless populations (Randall, 2015); Indigenous Peoples and forest dwelling communities (Galappaththi et al., 2020); among others. Frequently living without social safety nets, such as health care and formal education, these uncounted or 'missing millions' are vulnerable to problems associated with acute and chronic poverty, such as the spread of infectious disease and malnutrition (Ezeh et al., 2017). Because these 'missing' populations are not counted, they are frequently not a part of planning (Carr-Hill, 2013), including adaptation planning. In any particular national context, these missing populations may represent a small fraction of the population (about 5% in South Asian countries), however cumulatively hundreds of millions of people may be missing from official estimates (Carr-Hill, 2013). Over the last decade, techniques for estimating the locations, numbers and socioeconomic status of missing populations have moved beyond census and nationally representative household surveys, leveraging advances in satellite imagery (Kuffer et al., 2016; Bennett and Smith, 2017) and data from mobile digital devices (Jean et al., 2016; Xie et al., 2016; Steele et al., 2017).

[END BOX 8.1 HERE]

8.2.1.6 Interactions between climate hazards and social-ecological thresholds

Climate change threatens to rapidly transform unique and threatened ecosystems (RFC1), such as tropical rain forests, coral reefs, arctic and high-mountain ecosystems, as well as the Indigenous and forest-dwelling people whose livelihoods, cultures and identities are dependent on these ecosystems. In recent years, the case of Amazonia illustrates how such systems are transforming, with detrimental consequences for Indigenous Peoples, and the vital role that Indigenous Peoples serve in protecting vulnerable ecosystems (Ricketts et al., 2010; Box 8.6). Globally, Indigenous territories cover the greatest area of remaining tropical forest in comparison to other protected areas, and encompass the bulk of Earth's biodiversity, and are the locus for a number of key ecosystem services across spatial and temporal scales(Walker et al., 2020). Specifically, in 2014 Indigenous territories and other protected areas represented the equivalent of 58.5% of all the carbon stored in the Brazilian Amazon biome and had the lowest deforestation rate (2.1%) and fire incidences, evidencing the effectiveness in safeguarding important ecosystems services and wellbeing (Nogueira et al., 2018). It is estimated that Indigenous territories in the Brazilian Amazon contribute at least US$5 billion each year to the global economy through food and energy production, greenhouse emissions offsets, and climate regulation and stability (Siqueira-Gay et al., 2020). Given the high incidence of poverty of the Amazonian countries and high proportion of traditional and Indigenous Peoples, remoteness and neglected governance place these unique ecosystems and Indigenous populations as highly vulnerable to climate change impacts (Pinho et al., 2014; Brondízio et al., 2016; Mansur et al., 2016; Kasecker et al., 2018). Despite their importance, the survival of Indigenous Peoples in the Amazon is on the brink in the wake of increasing deforestation, land conflicts and invasions, cattle ranching, mining, fire incidence, health problems, and human rights violation (Ferrante and Fearnside, 2019). There is increasing evidence that both economic and non-economic losses and damages are currently and will be unevenly experienced by populations in vulnerable conditions, such as children, women, Indigenous Peoples and traditional communities (Pinho, 2016; Lapola et al., 2018; Roy et al., 2018; Eloy et al., 2019; Machado-Silva et al., 2020). Increasing wildfires inside protected areas, in particular, territories of Indigenous Peoples and traditional communities, is worrisome and presents challenges for the future of unique and threatened socio-ecological systems, and the ecosystem services they provide. The Amazonian Indigenous territories and protected areas can deliver protection of biodiversity and important ecosystem services if appropriate governance mechanisms are in place and their land tenure rights and livelihoods are secured (Steege et al., 2015). The role of enabling environments is discussed in Section 8.5.

8.2.1.7 Linkages between climate change impacts and sustainable development goals (SDGs)

Many of the observed outcomes of climate change, for example migration, are also outcomes of multidimensional poverty in low income countries (Burrows and Kinney, 2016). Future impacts may be better understood if the vulnerability and the capacity for adaptation is understood to be rooted in a sustainable development context (see Box 8.2). The UN Sustainable Development Goals (SDGs), which aim to reduce poverty and inequality, and identify options for achieving development progress, also provide insight on reducing climate vulnerability (United Nations, 2015). Firstly, climate change impacts may undermine progress toward various SDGs (medium confidence), primarily poverty reduction (SDG1), zero hunger (SDG2), gender equality (SDG5) and reducing inequality (SDG10), among others (*medium evidence, high agreement*). In both developing and high-income countries, climate change hazards in connection with other non-climatic drivers already accelerate trends of wealth inequality (SDG 1) (Leal-Filho et al., 2020). Climate impacts on SDGs illustrate the complex interrelations between development. For example, in regions encountering obstacles to SDGs, characterized by high levels of inequality and poverty, such as in Africa, Central Asia and Central America, climate change is likely to exacerbate water insecurity (SDG 6), which may then also drive food insecurity (SDG 2), impacting the poor directly (i.e. via crop failure), or indirectly (e.g. via rising food prices) (Conway et al., 2015; Hertel, 2015; Cheeseman, 2016; Rasul and Sharma, 2016). There is a pressing need to address poverty issues, since these may negatively influence the implementation of all SDGs (Leal Filho et al., 2021a).

At the same time, there is increasing evidence that successful adaptation depends on equitable development and climate justice; for example, gender inequality (SDG 5) and discrimination (SDG 16) are among the barriers to effective adaptation (*high confidence*) (Bryan et al., 2018; Onwutuebe, 2019; Garcia et al., 2020). Likewise, both climatic and non-climatic threats to development, such as conflict (SDG 16), may seriously undermine capacity to formulate and implement adaptation policies, and design planning pathways (Hinkel et al., 2018). The risk of conflict associated with climate change has great potential to undermine other development goals (Box 8.4). Where sustainable development lags and human vulnerability is high, there is also often also a severe adaptation gap (Figure 8.12; Birkmann et al., 2021a). The SDGs may provide important cues on how to close the adaptation gap: climate action needs to be prioritized where past and future climate change impacts threaten SDGs, and where investment in SDGs improve capacity for adaptation (see Section 8.6).

[START BOX 8.2 HERE]

Box 8.2: Livelihood Strategies of Internally Displaced Atoll Communities in Yap

On Yap Island in the Federated States of Micronesia, displaced atoll communities have been under considerable pressure due to climate change. This is because of the island's vulnerability, as a result of its weak economic status, and the little access it has to technologies that may support adaptation efforts. This trend is seen in many Small Island Developing States (SIDS) (see also Chapter 15). On small islands and remote atolls where resources are often limited, recognizing the starting point for action is critical to maximizing benefits from adaptation. They do not have uniform climate risk profiles, and not all adaptations are equally appropriate in all contexts (Nurse et al., 2014) (*high confidence)*.

The recurrences of natural hazards (e.g., El Nino driven tropical storms, associated coastal erosion and saltwater or seasonal droughts leading to water scarcity) and crises threaten food and nutrition security through impacts on traditional agriculture, leading to income losses and causing the forced migration of coastal communities to highlands in search of better living conditions. As many of the projected climate change impacts are unavoidable, implementing some degree of adaptation becomes crucial for enhancing food and nutrition security, strengthening livelihoods, preventing poverty traps, and increasing the resilience of coastal communities to future climate risks (Krishnapillai, 2018).

With support from the US Department of Agriculture and USAID, the Cooperative Research and Extension wing of the College of Micronesia- Federated States of Micronesia Yap Campus has been providing outreach, technical assistance and extension education to regain food and nutrition security and stability by improving the soil and cultivating community vegetable gardens as well as indigenous trees and traditional crops. This program implemented a three-pronged adaptation model to boost household and community resilience under harsh conditions on a degraded landscape, hence addressing poverty risks and promoting more sustainable livelihoods (Meyer and Jose, 2017).

The following three strategies- a) gender-focused capacity development on soil health management, b) good practices in Sustainable Land Management and c) income generation activities were employed to mitigate crop production losses and increase resilience to climate influenced hazard events within the 258 hectares of degraded lands in Gargey Village.

The project first focused on increasing the capacity development for 1,100 residents of Gargey Village, including women and youth, in order to create a base of community knowledge for soil health management. Training on soil health management including the following: use of cover crops and improved fallow, legumes, composting and agroforestry systems, mulching, minimum tillage, and contour farming, as well as altering production practices (planting time, spacing, pest and disease, harvesting time), alternative crop production methods (container gardening, raised bed gardening, small plot intensive farming), hands-on training on compost preparation, and seed germination.

Dissemination and use of good practices in Sustainable Land Management (SLM)

Following capacity building, the project trained villagers on the use of SLM practices to further soil resilience during ongoing and acute precipitation events. The SLM practices focused on volcanic soil management and compost preparation and use, along with the planting of native trees and crops. The protective soil cover was improved through cover crops, crop residues or mulch, and crop diversification through rotations. Local salt-tolerant crop varieties were introduced. Seed packets and seedlings were distributed to ensure a continuous supply of resilient traditional plants and to provide for sustainable post-disaster recovery.

Income generation activities

The project also included training to increase the incomes of households by training household members in the cultivation of vegetables using various alternative crop production methods. Households were then able to sell their vegetables in the local markets.

Less hunger and more cash from leafy vegetables is a concept adopted at the household level to not only reduce poverty, but also to empower displaced communities to address the dilemma of malnutrition. Practices include growing a variety of nutritious vegetables as part of a large crop portfolio and using alternative crop production methods, such as small-plot intensive farming using container gardening or raised-bed gardening (Krishnapillai and Gavenda, 2014). In addition, focusing efforts on increasing the sustainable production of staple crops confers significant nutritional benefits.

More households in the settlements are consuming vegetables since home gardeners started harvesting regularly and sharing their produce with extended families or selling them for income generation. The location-specific, community-based adaptation model improved food and nutrition security and livelihoods (Krishnapillai, 2017). People can access more nutritious and reliable food sources, and they are growing their own food and selling their surplus, creating new optimism about their future.

The climate-smart agriculture package increased land cover by more than 50% within Gargey village. This includes the planting of 42 varieties of native trees and crops. Current major crops that are being successfully grown at this location include coconut, breadfruit, mango, noni, chestnut, pineapple, sugarcane, land taro, tapioca, and sweet potato, among others. There have been additional benefits in terms of improvement in water availability. These activities directly benefited the resilience and food security of more than 1,000 residents in Gargey Village, and lessons learned from this project have helped to scale up similar projects at 3 locations in Yap that have experienced equivalent climate-damaging processes.

Overall, this case study illustrates the benefits of promoting resilient crop production in Gargey Village, as an example of displaced atoll communities. Innovative and sustainable CSA strategies offered broader insights and lessons for enhancing adaptive capacity and resilience, on a degraded landscape. The coherent strategies and methods employed strengthened livelihood opportunities by improving access to services, knowledge, and resources. By its concurrent focus on enhancing food security through traditional crops, coupled with nutrient-rich vegetables, promoting rainwater-harvesting systems and water conservation, and promoting resilient household livelihood opportunities, atoll communities brought together crucial elements needed to reduce vulnerabilities, and to better cope with disasters and climate extremes while embracing the traditional culture. The location-specific yet knowledge-intensive CSA methods deployed, offered opportunities for atoll communities to revitalize themselves, overcoming barriers while adjusting to new landscapes.

[END BOX 8.2 HERE]

8.2.2 Poverty-environment traps and observed responses to climate change with implications for poverty, livelihoods and sustainable development

Across all geographical regions, there is evidence that anthropogenic climate change is hindering poverty alleviation and thereby constraining responses to climate change in five main ways:

a) by worsening living conditions (Hallegatte et al., 2017; Hsiang et al., 2017),
b) by threatening food and nutrition security due to undernutrition and reduced opportunities for income generation (Burke et al., 2015),
c) by disrupting access to basic ecosystems services such as rainwater, soil moisture (reducing the productivity of agricultural land) or via the depletion of habitats (e.g., mangroves, fishing grounds) that particularly vulnerable and poor people are depending on (Malhi et al., 2020),
d) by creating favourable conditions for the spread of vector-transmitted diseases (Liang and Gong, 2017).
e) and by threatening underlying gender inequalities exacerbated by climate impacts such as access and control to productive inputs and reinforcing social-cultural norms that discriminate against gender, age groups, social classes and race (Singh et al., 2019b).

Responses to observed impacts such as glacier melt, sea level rise and increases in the frequency of extreme weather events such as droughts, hurricanes and floods need to take into account how they influence other policy issues and sectors, including poverty alleviation, human health and well-being (Orimoloye et al., 2019), water/energy and the built environment (Andrić et al., 2018), transportation and mobility (Markolf et al., 2019), agriculture (Hertel and Lobell, 2014) and biodiversity/ecosystems (Nogués-Bravo et al., 2019), only to mention a few. Recent literature provides evidence that impacts of climate change together with non-climatic drivers can create poverty-environment traps that may increase the probability of long-term and chronic poverty (Figure 8.4; Hallegatte et al., 2015; Djalante et al., 2020; Malhi et al., 2020; McCloskey et al., 2020) (*high confidence*) (see Figure 8.4).

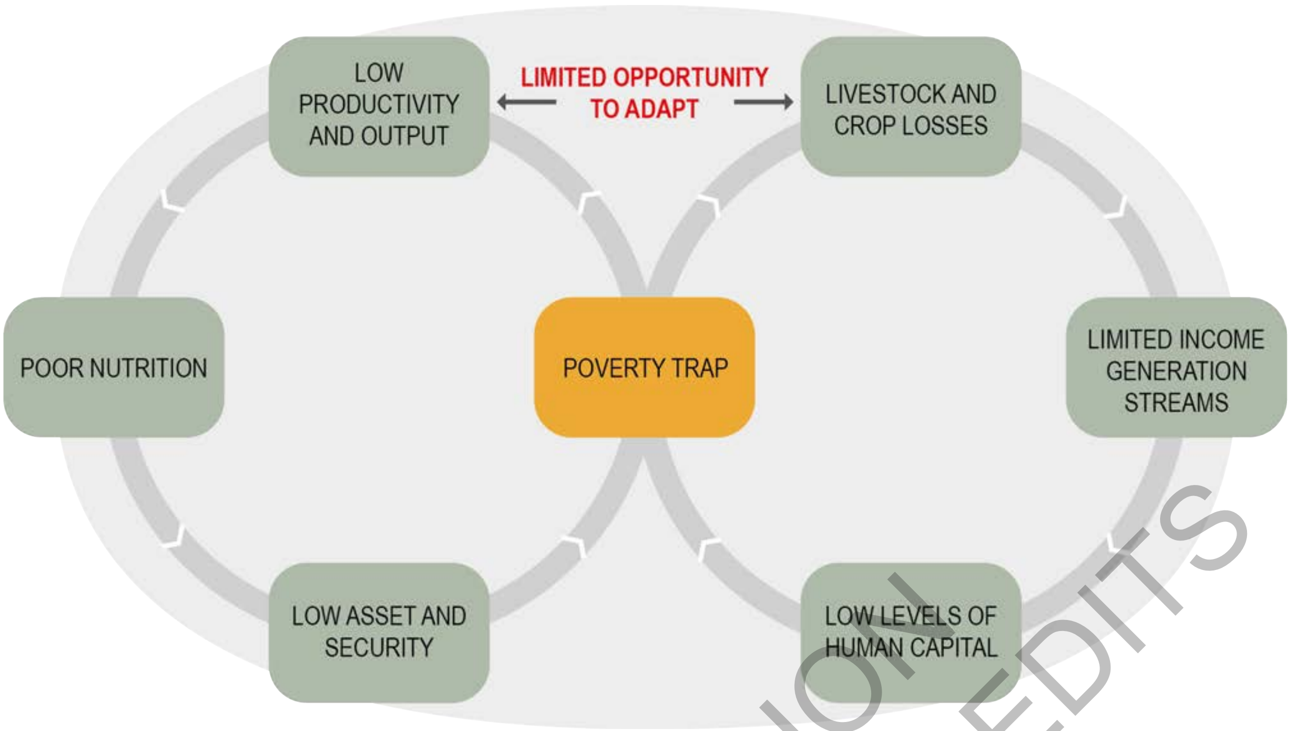

Figure 8.4: Schematic representation of a poverty-environment traps that can increase chronic poverty.

In addition, observed climate change responses, including autonomous and planned adaptation, can exacerbate poverty and vulnerability (Eriksen et al., 2021). There is *robust evidence* that planned responses to climate change, such as large scale adaptation projects, in some context can also increase vulnerability due to the reinforcement of inequalities and the effects of further marginalization (Fritzell et al., 2015; Eriksen et al., 2021). There is increasing *evidence* that also the responses to indirect impacts of climate change, such as to shifts in marine or terrestrial ecosystems due to climate change (Seddon et al., 2016) affect different groups differently and impact poverty and livelihood security. Apart from influences on agriculture trends (Reichstein et al., 2014) and changes in yields (Reyes-Fox et al., 2014; Craparo et al., 2015), climate change has significant (direct and indirect) impacts on livelihood assets and resources such as forests, livestock production and fisheries, which may undermine the livelihoods security in the medium- and long-run.

[START BOX 8.3 HERE]

Box 8.3: COVID-19 Pandemic

During the COVID-19 pandemic, countries such as India were affected by with hydro-meteorological hazards (Raju, 2020) making it extremely difficult to handle a public health crisis in the context of compounding risks and cascading hazards (Phillips et al., 2020). The COVID-19 pandemic can increase the adverse consequences of climate change, since it has the potential to delay some key adaptation actions. On the other hand, the pandemic also highlights the importance of better preparedness to the impacts of climate change (Djalante et al., 2020). Overall, the COVID-19 pandemic has worsened the economic situation within many countries and local communities particularly for already marginalized groups (Gupta et al., 2021). The accumulation of crises, such as the COVID-19 pandemic alongside climate change impacts, underscore the fact that stressors do not occur in isolation, but are interlinked, with clear implications for structural vulnerability and adaptation options available to the poorest (Sultana, 2021). Responses to COVID-19 has led to significant economic and social distress within and across societies and local communities, especially in poorer countries. The direct health and economic impacts of the lockdowns have further limited the ability of many people across the developing world to pursue income-generating activities, and sustain livelihoods that are already affected by climate hazards. In addition, poor or most vulnerable groups face further marginalization due to misinformation that these groups transmit the virus to other wealthier groups and areas. The pandemic has intensified inequalities in both developing countries (FAO, 2020) and in industrialised nations (Anderson et al., 2020; McCloskey et al., 2020) whereby vulnerable groups are especially affected (Raju et al., 2021). Whereas different models and scenarios contain different data and figures, an agreement exists that it is likely that socio-economic impacts are particularly severe within selected global regions and areas that are already characterized by a rather high level of human vulnerability (see also Section 8.3). This also implies that the capacity of people to prepare for present and future climate change impacts will further decrease within these countries and population groups under the direct and indirect consequences of the COVID-19 pandemic.

Moreover, the COVID-19 pandemic has not only influenced climate change research (Leal Filho et al., 2021b) but is also influencing the capacities of governmental institutions and nations to support planned adaptation and poverty reduction favouring the most vulnerable groups, since the crisis also means among other issues a significant reductions in tax revenues (Clemens and Veuger, 2020). COVID-19 may also force people to seek alternative sources of income that can lead to the further erosion of long term adaptive capacities. In many settings, the pandemic has had significant impact on businesses and SMEs (Schmid et al., 2021). The important role of governmental support for buffering crises and periods of income loss of individual households (e.g., unemployment) and private businesses (e.g., SMEs) has also been demonstrated during the COVID-19 pandemic in OECD countries (OECD, 2020b).

Livelihood disruptions and an increasing probability of higher levels of poverty and of structural vulnerability in various countries have already been observed (Laborde et al., 2020b). These vulnerabilities and the new layers created by the pandemic must be seen with an intersectional lens (Raju, 2019; Sultana, 2021).

In addition, the COVID-19 pandemic has also revealed the unequal access to vaccine and the importance of national state institutions to buffer negative impacts, for example of the lock downs or in terms of unemployment. The COVID-19 pandemic recovery also sets some basis for a stronger narrative towards a green recovery approach (Djalante et al., 2020; Forster et al., 2020).

[END OF BOX 8.3]

8.2.2.1 Characteristics of responses

Many of the observed responses to climate change aim to reduce exposure of people to climate-related hazards, such as flood defences, sea walls and embankments (Gralepois et al., 2016), rather than aimed at specifically addressing structural vulnerability to climate change, which means the root causes of vulnerability (e.g., Mikulewicz, 2020; McNamara et al., 2021a). Evidence emerges that responses to impacts of climate change should consider next to the physical climate event, also historical, institutional root causes that make people or systems vulnerable. However, addressing structural vulnerability must be balanced with the political context and the range of options available to people, communities or countries (see Section 8.3). Political frameworks need to consider both types of responses, to revive democratic debate and citizenship (Pepermans et al., 2016). In addition to reducing poverty and vulnerability, planned climate change responses must also be intersectoral, in order to increase their effectiveness. This requires higher levels of vertical and horizontal coordination and integration (GIZ, 2019). Horizontal coordination encompasses for example the integrated coordination of responses to climate change across different sectors, which requires suitable governance structures and processes that allow for such a coordination (Di Gregorio et al., 2017; Burch et al., 2019). Vertical integration is needed in order to ensure that effective responses also include different levels of governance and benefit from knowledge at different scales. The inclusion of local knowledge within national or provincial adaptation strategies requires such linkages and vertical coordination. Overall, there is an increasing body of literature that highlights the importance of improved integration and coordination also in order to promote a higher effectiveness of strategies and an improved consideration of social justice and climate justice when designing and implementing responses (Levy and Patz, 2015).

However, evaluating the effectiveness, social impacts and social justice of climate change responses is not uniform across locations, nations and regions for three principal reasons:

a) temporal dimensions of responses: effective and appropriate climate change responses require that strategies and responses are tested in a specific context and that ongoing learning and adaptive management is a necessary to avoid maladaptation or other unintended consequences (Eriksen et al., 2021),

b) goal of responses: responses may have distinct and locally specific goals, such as reducing vulnerability(Sarker et al., 2019), which is distinct from increasing resilience (Alam et al., 2018). Vulnerability reduction and the increase of resilience (i.e., raising the ability to cope) are two different goals and often involve different processes, and
c) level of responses: there is a need to ascertain the relevant level at which the responses are needed or expected (e.g., the individual level, community level, regional level). This analysis, however, also needs to consider the differential capacities of people, for example, the limited capacities of poor people or constrained capacities of most vulnerable countries (see also Section 8.3).

Effective responses to climate change impacts for one group could impose higher costs and negative consequences for other groups, in terms of shifts in exposure and vulnerability. This category of response is known as maladaptation. Maladaptation actions defined in the IPCC SR1.5°C (IPCC, 2018b) and in the Land Report (IPCC, 2019a) are the ones that usually have unintended consequence, and can lead to increased negative risk to poor population mostly in the global south to climate hazards by either increasing greenhouse gas (GHG) emissions and or by increasing the vulnerabilities to climate change with diminished welfare, now and in the near future (Roy et al., 2018). For example, migration to urban centres can represent a significant adaptation opportunity for the migrants themselves, but can also increase the vulnerability of their community of origin or destination (for example, through a depletion of the workforce or an addition pressure on environmental resources and infrastructure respectively) (Gemenne and Blocher, 2017). Some types of observed responses to climate change may not yield long-term benefits. For example, food imports during droughts or adverse climate conditions are not a fully adequate response, since they may alleviate a problem on the one hand (i.e., an imminent food shortage due to crop failure), but on the other, lead to no long-lasting improvements in physical conditions and create new dependencies that can increase vulnerability in the long-run (Zimmermann et al., 2018).

In the AR5, the maladaptation outcomes emerge when impacts of climate change impacts and risks are disproportionately born by the poorest populations (Olsson et al., 2014). Since then, most maladaptation evidence emerges as a consequence of failure to address root causes of vulnerabilities that emerge under high and multiple forms of inequalities. In fact, the literature shows that adaptation practices can indeed redistribute vulnerabilities and increase risks to already poor and marginalized people with risk to maladaptation outcomes mainly in the Global South countries (Atteridge and Remling, 2018).

The maladaptation outcomes also emerge when responses are not equitable at the policy level, and exacerbate the precarity of vulnerable populations by excluding them from benefits and support, while attending to the needs of people of the most enfranchised segments of society (Thomas and Warner, 2019); Asplund and Hjerpe 2020). In Tanzania, the political marginalization of pastoralist access to critical riparian wetlands and increasing expansion of agriculture may result in adaptation pathways that heighten risk for these groups while reducing risk for others (Smucker et al., 2015). Salim et al. (2019) found that adaptation to flooding in Jakarta privileges political economic elites, while poor infrastructure in poorest neighbourhoods exacerbates loss of assets, housing and displacements (Salim et al., 2019). In Bangladesh, intense and consecutive flooding led to that national and regional-level adaptation plans, that resulted in maladaptive trajectories as local poverty context and precarities of properties are not carefully considered and disconnected from local autonomous practice (Rahman and Hickey, 2019).

Overall, the assessment shows that understanding impacts of climate change should not be limited to the analysis of direct impacts or physical changes under different climatic conditions, but needs also account for the distributional effects that responses to climate change may imply. For example, responses implemented in order to benefit one sector or social group (e.g., farmers), should not undermine the wellbeing of others (e.g., pastoralists). Documented cases of maladaptation (see Eriksen et al., 2021), hint towards the fact that responses to climate change can exacerbate in some cases existing inequality and may discourage other types of responses (see also Section 8.5 and 8.6). Furthermore, responses to similar climate change impacts and hazards may be extremely differentiated according to various social contexts (see Section 8.3). In some cases responses to climate change (e.g., relocation programmes) can even trigger social tipping points when climate change responses lead to major social transformations, such as forced displacement (see Section 8.4).

Also the influence of new global phenomena, such as urbanization, issues of urban health (Schmid and Raju, 2020) and the consequences of the COVID-19 pandemic need to be considered when assessing actual and potential consequences of different responses to climate change. For example, inequalities, vulnerabilities and poverty pockets are expected to change and increase, particularly in urban areas in countries with rapid urbanization processes and high levels of poverty (Djalante et al., 2020), hence urban and urbanization trends need more attention. Urbanization processes add another level of complexity (Raju et al., 2021). This is particularly the case in rapidly growing medium-sized cities in Africa that at present do not have sufficient the resources to cope and adapt and to implement climate sensitive land-use planning (Birkmann et al., 2016).

[START BOX 8.4 HERE]

Box 8.4: Conflict and Governance

Climate change impacts carry the risk of amplifying or aggravating existing tensions within and between communities or countries (Sakaguchi et al., 2017). There is however little evidence for a universal direct causal linkage between climate change and violent conflicts (Mach et al., 2019). The triggering of conflicts related to climate impacts is strongly determined by contextual factors, such as the type of government or the level of development (Mach et al., 2019). A study of 156 countries (Abel et al., 2019) showed that an increase in periods of drought exacerbate the risk of conflict, especially in democratic countries. This influence was particularly marked during the period 2010-2012 in countries of Western Asia and Northern Africa which were undergoing political transformations such as the Arab Spring. Conflict can then represent people's discontent in governments' inefficient responses to climate impacts (Abel et al., 2019). Research has noted conditions under which climate change can increase risk of armed conflict, which include ethnic exclusion, agricultural dependence, large populations, insufficient infrastructure, dysfunctional local institutions, and low levels of development (von Uexkull et al., 2016; Ide et al., 2020).

Since the AR5, there is *robust evidence* of the socially-destabilizing measures and high-risk income alternatives that the world's poorest commonly take to cope with the impacts of climate change on livelihoods (Blattman and Annan, 2016). To avoid impoverishment, households often pursue risky livelihood alternatives, with high potential for return on investment (Sovacool et al., 2018), but which in some cases undermine environmental quality (Bolognesi et al., 2015), violate laws (Ahmed et al., 2019), contradict social norms (Hagerman and Satterfield, 2014), erode institutions (Sovacool et al., 2018), or affect intra- and inter-community cooperation (Nadiruzzaman and Wrathall, 2015). At the same time, a narrowing of livelihood options carries a strong potential for participation and association with violent non-state organizations and movements, either criminal or ideological (Nett and Rüttinger, 2016). In order to reduce the risk of instability and violence associated with climate change, a broadening of livelihood options among the most vulnerable people appears as an effective policy approach (Miguel et al., 2004).

The determinants of violence in the context of climate shocks are primarily poor institutional planning and response to impacts, such as the capacity of a government to respond to and manage environmental risk (Selby et al., 2017). In Latin America, for example, evidence on social conflicts related to disputes over access water use in the context of drought and decreasing water availability point to institutional failures, such as poor, inequitable or corrupt water governance (Poupeau et al., 2017). Such observation is not confined to low income countries. In industrialised countries, failure of governments to address climate change is *likely* to fuel discontent, a condition in which violent outcomes are possible (Ide et al., 2020).

In this regard, specific attention ought to be paid to how responses to climate change exacerbates inequalities within societies and create tensions between different groups—typically between those who are able to protect themselves from climate change impacts and those who do not have sufficient resources and/or are not prioritised in the responses to climate change. Frequently the possibility of migration from climate change is conflated with conflict outcomes from climate change; however there is *limited evidence* and *low agreement* that climate change and migration will result in increased conflict (Okpara et al., 2016b), while there is *robust evidence* and *medium agreement* that climate change can exacerbate existing tensions, which can in turn result in political violence and an increase in asylum-seeking (Marchiori et al., 2012). In the future, conflict in the context of climate change impacts may increase the number of migrants seeking asylum, although at present there is scant empirical evidence for this (Schutte et al., 2021). Recent evidence also provides support for social conflict around inequitable climate mitigation policy as well (e.g., fossil fuel subsidies and emissions reductions targets) (Rentschler, 2016).

In recent years, research on the climate-security nexus has developed considerably, and has highlighted risks pertaining to conflicts, geo-political rivalries, critical infrastructure, terrorism or human security (Gemenne et al., 2014). While different studies have identified have identified strong past correlations between climatic variations (of temperature and rainfall in particular) and the occurrence of violent conflicts (Hsiang et al., 2013), while others have stressed the need for stronger explanatory models or the risk of a selection bias (Benjaminsen et al., 2012; Solow, 2013; Buhaug et al., 2014).

While climate change may increase armed conflict risks in certain contexts (Mach et al., 2019), responses to climate change will be crucial to mitigate these risks. Poor institutional responses can directly drive violence, and there is *robust evidence* that inequitable responses further exacerbate marginalisation, exclusion or disenfranchisement of some populations, which are commonly recognized drivers of violent conflict.

As a ray of hope, *robust evidence* suggests environmental problems (related to climate change) can be dealt with cooperatively, hence leading to more positive and peaceful relations between groups (Wolf et al., 2003; Ide, 2019). To avert violent outcomes induced by climate change, stronger local and national climate adaptation institutions within vulnerable societies, and stronger cooperative resource governance mechanisms between vulnerable countries (such as transboundary water governance agreements) are needed.

[END BOX 8.4 HERE]

Table 8.1 and Table 8.2 present a summary of a set of common climate change responses observed, classified according to their main approach. All these responses demand a certain level of commitment, the support of adequate policies, and enough budget for their implementation (Archie et al., 2018). The observed climate change adaptation responses—differentiated along urban and rural settings—underscore the very different nature of various responses and the need for cross-sectoral approaches.

Table 8.1: Selected observed climate change adaptation responses in urban and rural areas commonly associated with positive implications for poverty, livelihoods and sustainable development

Modality of response	Impacts to urban communities	Impacts to rural communities (e.g., farmers, pastoralists)
Integrated natural resource management (e.g., van Noordwijk, 2019)	Better conservation of green areas and reduced exposure to floods	Conservation of natural resources e.g., water, soil, pasture, forest, wildlife, biodiversity, aquatic life.
Disaster Risk Management (e.g., Mall et al., 2019)	Pre-disaster risk management and post-disaster risk management measures reduce loss of life and damage to property	Disaster risk management may play an important role to avoid or limit the impacts of floods, droughts and other extreme events
Structural/physical improvements (e.g., Vallejo and Mullan, 2017)	Improving physical/structural measures to prevent property damages and foster ecosystems integrity	Flood defences may help to prevent property losses, planting of trees may stabilize slopes, reduce soil erosion and siltation, rainwater harvesting increases water availability, protection of biotopes supports biodiversity
Relocation of vulnerable communities (e.g., McNamara and Des Combes, 2015)	Moving vulnerable communities before and during climate-induced hazards may reduce loss of life	Reduces the exposure of vulnerable communities to climate change and extremes hazards e.g., floods and droughts, lessen their vulnerability, improve access to better resources and build their capacity to adjust to a new context

Education and Communication (e.g., Monroe et al., 2017)	Public education and awareness, improved communication may reduce the damages and losses from adverse impacts of climate change and from extreme events	Fosters awareness creation, reducing the degree of vulnerability to certain climate induced hazards and help build the capacity to adapt

While Table 8.1 shows selected adaptation responses, Table 8.2 shows selected mitigation responses that highlight that some mitigation responses (e.g., increasing energy efficiency) have a potential benefit also for the poor or more vulnerable groups for example through the reduction of costs for electricity. Both tables underscore that climate change mitigation and adaptation responses are strongly interlinked with broader development issues (industrial production, land-use planning, education, etc.) at different scales.

Table 8.2: Selected climate change mitigation responses

Modality of response	Impacts to urban communities	Impacts to rural communities (e.g., farmers pastoralists)
Land use planning (e.g., Frose and Schiling, 2019)	Helps to reduce greenhouse gas (GHG) emissions and support environmental conservation, preventing urban heat islands	Helps to reduce pressure on the natural resources (deforestation, land filling, damaging wetland) and promotes carbon sequestration
Improving industrial processes (e.g., van Vuuren et al., 2018)	Unlocks many opportunities for improvement, including the optimised use of energy, reuse of waste in the production, reducing GHG emissions, use of biomass and more efficient equipment	In rural settings, industrialization and technological innovation may directly assist vulnerable communities through provision of inputs e.g., water storage, drip irrigation, forecast information, or reuse of biowaste in agriculture or energy production, hence reducing costs and pollution levels
Renewable Energy (e.g., Cronin et al., 2018)	Reduction of GHG emissions and reduction of the cost of electricity	Some options (e.g., solar, wind) may help to reduce deforestation, reduce GHG emissions and promote healthier air within households
Energy efficiency (e.g., Abrahamse and Shwom, 2018)	Efficient end-user's energy utilization reduces energy wastage, reduces costs and lowers carbon emissions	Efficient end-user's energy utilization leads to natural resource conservation and a reduction of GHG emissions
Local/individual actions (e.g., Shaffril et al., 2018; Tvinnereim et al., 2018)	Can contribute to reduce carbon footprints	Fosters personal and community motivation to manage individually and communally owned resources. Helps to reduce GHG emission and foster resources conservation

8.2.2.2 Observed impacts and implications for structural inequalities, gender and access to resources

This section examines the mutual reinforcement of climate change impacts and structural inequalities. There is robust evidence that negative impacts and harm posed by climate change are also a result of social and political processes and existing structural inequalities (Sealey-Huggins, 2018). Climate change encompasses unevenly distributed impacts on women, youth, elderly, Indigenous Peoples, communities of colour, urban poor and socially excluded groups, exacerbated by unequal distribution of resources and poor access for some (Rufat et al., 2015; McNeeley, 2017; Sealey-Huggins, 2018). Structurally disadvantaged people, who are subject to social, economic and political inequalities resulting historically from discrimination, marginality or disenfranchisement because of gender, age, ethnicity, class, language, ability and/or sexual orientation, are disproportionately vulnerable to the negative impacts of climate change hazards (Kaijser and Kronsell, 2014; Otto et al., 2016). High levels of vulnerability at national scale (see Section 8.3) are often linked to complex histories, including long-term economic dependencies established and reinforced in the context of colonization.

Links between climate change, structural racism and development are less well established as an element of disproportionate impacts of climate change is relatively new (Sealey-Huggins, 2018). Discrimination is not restricted to structural racism and includes discrimination of all kinds including that of gender and caste because of which a considerable population is directly bound to suffer the harsh impacts of the climate change. The climate change and gender literature has come a long way demonstrating concrete examples of how structural inequalities operate. The political and micro-political aspects and how they interact with structural inequalities are also important to understand vulnerability. Henrique and Tschakert (2020) shows how the many adaptation efforts benefit powerful actors while further entrenching the poor and disadvantaged in cycles of dispossession. This critical analysis recommends acknowledging injustices, embracing deliberation, and nurturing responsibility for human and more-than-human others. Garcia et al. (2020) describes the socio-political drivers of gendered inequalities that produce discriminatory opportunities for adaptation. It utilises an intersectional subjectivities lens to examine how entrenched power dynamics and social norms related to gender create barriers to adaptation, such as lack of resources and agency. The analysis shows a pronounced dichotomy as women experience the brunt of these barriers and a persistent power imbalance that positions them as 'less able' to adapt than men.

Historical marginality and exclusion are context-specific conditions that shape vulnerability (Leichenko and Silva, 2014). There also exists *robust evidence* that on gender inequalities contribute to climate vulnerability, and that attention to gender is a key approach to climate justice (see Cross-Chapter Box GENDER in Chapter 18) and includes *robust evidence* on the differentiated impacts of climate change and climate-oriented policies on women (McOmber, 2020). For example, Friedman et al. (2019) show in Ghana that homogeneous representations of women farmers and technical focus of climate-orientated policy interventions may threaten to further marginalize the most vulnerable and exacerbate existing inequalities. Climate change impacts can also heighten existing gender inequalities (Jost et al., 2016; Glazebrook et al., 2020). On the one hand, climate change impacts can be gendered as a result of customary roles in society, such as triple workloads for women (i.e., economic labour, household and family labour as well as duties of community participation), and occupational hazards from gendered work indoors and outdoors (Murray et al., 2016). On the other, climate change hazards interact with changing gender roles in society, such as urban migration of both men and women in ways that break with tradition (Bhatta et al., 2016).

Gender influences the way that people also experience loss and process psychological and emotional distress of losses, such as mortality of children and other relatives in climate-related disasters (Chandra et al., 2017).Women's capacities are often constrained due to their roles in their household and society, institutional barriers and social norms. These constraints result in low adaptive capacity of women, which make them more vulnerable to hazards. As more men seek employment opportunities away from home, women are required to acquire new capacities to manage new challenges, including risks from climate change. Banerjee et al. (2019b) finds that capacity-building interventions for women staying behind, which aimed to strengthen autonomous adaptation measures (e.g. precautionary savings and flood preparedness), also positively influenced women to approach formal institutions. Besides, the intervention households were more likely to invest a part of the precautionary savings in flood preparedness measures than control households.

Next to the direct differential impacts of climate change on different social groups, the impacts of climate change can also exacerbate inequality due to the lower access and limited ability to benefit from services provided by ecosystems. The marginalised poor people often significantly depend on the access to surrounding environments, natural resources and ecosystem services for their livelihoods, for leisure or cultural practices. Thus shifts in such resources, for example, due to the bleaching of coral reefs or shifts in fish stock also cause severe challenges and risks to these communities (Leal Filho, 2018; Le, 2019), see also (UNTTSDCC, 2014).

Overall, the assessed literature highlights that climate change impacts are not emerging in isolation from development context and development pathways. Economic and social ramifications mean that they may exacerbate poverty and marginalization (Finkbeiner et al., 2018; Dogru et al., 2019). Choudhary et al. (2019) and Orimoloye et al. (2019) highlight how the effects of climate change can be even more prejudicial to poor countries, who in most cases already suffer from weak governance, high prevalence of informal settlements and lack of resources. Health, livelihood assets and economy are examples of aspects that will worsen as a result of the negative impacts of climate change and failure to provide opportunities for sustainable adaptation (United Nations, 2015). These facts highlight the importance of mitigation and adaptation measures especially in these regions characterized by high levels of vulnerability (see also Section 8.3).

8.2.3 Observed impacts and responses and their relevance for decision-making

Many countries base their adaptation strategies on National Adaptation Programmes of Action (NAPs), which often correlate different levels of decision-making and governance (Golrokhian et al., 2016). Whereas the involvement of national governments is needed for designing appropriate responses to climate change, recent studies underscore the need to also consider Local Knowledge and Indigenous Knowledge within adaptation and risk reduction strategies, thus fostering stronger linkages with local communities, leading to an improved vertical integration between different strategies, programs and different actors (Ford et al., 2016; Vij et al., 2017; Singh et al., 2020). The relevance of addressing the issue of vulnerability and poverty to reduce the climate change risks has been demonstrated within the assessed literature on the impact of climate change (Hallegatte et al., 2017). In this regard, it is noticeable that not many National Adaptation Programmes of Actions explicitly aim to reduce poverty, even though poverty reduction is associated with vulnerability reduction to climate change (Demski et al., 2017).

Next to issues of observed impacts and responses to climate change, it is important to assess observed barriers in implementing climate change responses. The discussion of barriers is complemented later in the chapter with an assessment of the enabling environments for adaptation (see Section 8.5.1). Some of the most common barriers outlined in the scientific literature are summarised in Table 8.3.

Table 8.3: Some common barriers in implementing climate change responses and their implications

Dimensions	Barriers in implementing effective climate change responses	Implications
Governance	Unfavourable political frameworks (Gupta, 2016).	Governance structures can undermine autonomous adaptation (Section 8.4 Table 8.6); Inability to include gender differentiated vulnerabilities in governance schemes (Bryan et al., 2017).
Social	Attitudes to risks and cultural values may hamper responses (Billi et al., 2019).	Social norms of reciprocity and cohesion may erode as a consequence of climate change responses (Volpato and King, 2019); Socio-cultural conditions as key barriers to gender differentiated support to impact reduction (Bryan et al., 2017).
Institutional	Limited availability coordination and prioritisation processes (Patterson and Huitema, 2019).	Lack of anticipatory risks undermining local's effort to cope with hazards (Singh et al., 2019a).
Behavioural	Psychological distress may cause insecurity and behaviour of some groups may increase vulnerability (Van Lange et al., 2018).	The psychological distress associated to loss of attachment to a place has also been observed among vulnerable communities in regions such as South Asia (Maharjan et al., 2020)
Financial	Limited financial resources to support adaptation projects (Khan et al., 2019).	The lack of financial resources and assets among urban poor increase their exposure and vulnerabilities to the increasing climate hazards (Salim et al., 2019)
Structural	Unsuitable infrastructure may increase exposure (Chinowsky et al., 2015; Vallejo and Mullan, 2017).	Structural Marginalization of Indigenous people and their local knowledge can exacerbate risks of maladaptation among SIDs countries (McNamara

		(McNamara and Prasad, 2014; Aipira et al., 2017; Granderson, 2017). Infrastructure projects to adapt to climate change impacts may increase the vulnerability of poor slum people
Technical	Lack of access to technologies which may support adaptation (e.g., climate services) (Bel and Joseph, 2018).	The highest level of illiteracy among women prevent their engagement to access technology and risk reductions in vulnerable communities (Balehey et al., 2018)

There are various characteristics of responses to climate change, which aim to protect livelihoods and prevent poverty expansion (i.e., an enlargement of the group of people already affected by poverty). Some of them are:

a) Timely: meaning that responses need to take place within a matter of weeks or months and not over years (Wise et al., 2014)
b) Targeted: with a focus on the affected communities and groups, to help alleviate the pressures they are under; (e.g., Aleksandrova, 2020)
c) Sustainable: with long-lasting results leading to self-sufficiency of the affected communities and their resource base, as opposed to short-term ones relying on external support (e.g., Caetano et al., 2020)
d) Integrated: the impact of climate change is multifaceted and far reaching and requires the engagement of various actors e.g., the vulnerable community, government agencies, local and international nongovernmental organisations, civil societies, media (Ayal et al., 2020)

Finally, responses as those outlined in Table 8.1 and Table 8.2, need to ensure the active participation of local stakeholders taking into account their diverse interests, so that they are grounded in reality. In addition, responses need to be complemented with operational procedures and timeframes so that they can be more systematically pursued and implemented (Alves et al., 2020).

8.3 Human Vulnerability, Spatial Hotspots, Observed Loss and Damage and Livelihood Challenges

This section assesses the literature on vulnerability—the assessment of vulnerability at global and national scales—and explores economic and non-economic losses of people and livelihoods exposed to and impacted by climate change. The section examines how climate change threatens livelihoods and juxtaposes global and local level assessments of vulnerability based on empirical data at different scales. The analysis of recent literature underscores that climate change impacts and adaptation needs cannot be understood by looking at climate change only. Vulnerability and livelihood security are seen as an important component to understand the human dimension of climate change (Rhiney et al., 2016; Cardona, 2017; Byers et al., 2018; Eriksen et al., 2020; Wisner, 2020; Birkmann et al., 2021a; Cole et al., 2021).

Linkages between global and individual vulnerability and livelihood security, including aspects of intersectionality are also assessed. Overall, the sub-chapter reveals that different countries, societies and specific groups within a society have very different starting points on their move towards climate resilience.

8.3.1 Assessments of risk and vulnerability

Conventional assessments of risks and the benefits of adaptation and risk reduction measures in the context of climate change primarily focus on the financial value of the avoided losses (in US Dollars) and the assets that are going to be protected from adverse consequences of climate change or extreme events due to specific measures (e.g., dyke construction). Even though these assessments fall short of measuring the real costs of addressing climate change impacts (see DeFries et al., 2019), they often support the definition of priorities in terms of protecting economic values and assets. However, these assessments do not sufficiently account for how climate change impacts and imposes risks on poor people, nor does it capture issues of climate justice and more complex societal impacts and future risks. For example, various observed losses in the context of climate change can not sufficiently be expressed in terms of an economic value (see Section 8.3.5), but these items or assets are highly relevant for various people with limited economic resources (Hallegatte et al., 2017). Consequently, the assessment of risks from climate change facing particularly poor people requires comprehensive assessments of human vulnerability, resilience and the impacts of climate change on human wellbeing going beyond a simple temperature societal-impact understanding. Knowledge about methods and approaches to assess human or human-environmental vulnerability and livelihood security, including aspects of intersectionality, is important in order to explore whether or not adaptation and development programmes are able to reduce vulnerability. The body of literature on these issues has grown significantly since the AR5 publication (IPCC, 2014a; Moser, 2014).

Literature since AR5 underscores that approaches to assess resilience, vulnerability, human wellbeing include global assessments that can inform strategies and priority settings for adaptation and risk reduction in the context of climate change (*high confidence*) (WHO, 2014b; Young et al., 2015; Feldmeyer et al., 2017; GIZ and BMZ, 2017; Hallegatte et al., 2017; Birkmann et al., 2021a; Garschagen et al., 2021; Toolkit, 2021).

These quantitative global assessments that emerged within the last decades have not sufficiently been assessed in former IPCC reports, for example in terms of the agreement on spatial hotspots or in terms of regional clusters of vulnerability and the linkages between past societal impacts and levels of vulnerability. The assessed literature show that conditions and phenomena that characterize systemic vulnerability (hazard independent vulnerability), such as high levels of poverty and gender inequality, limited access to basic infrastructure services or state fragility are highly relevant for understanding societal impacts of climatic hazards and future risks of climate change (e.g., Cutter et al., 2003; ADB, 2005; Cutter and Finch, 2008; World Bank, 2008; UNISDR, 2009; Crawford et al., 2015; Rufat et al., 2015; Carrao et al., 2016; Gupta, 2016; Rahman, 2018; Andrijevic et al., 2020; Jamshed et al., 2020a; Feldmeyer et al., 2021; Garschagen et al., 2021). These factors and context conditions also influence individual vulnerability at households or community level. Access to basic services, such as water and sanitation are linked to human rights and that if not granted increase the likelihood that people disproportionately suffer from climate induced hazards, due to their pre-existing lack of access to such services. In addition, increasing climate hazards further constrain the access to such services (United Nations, 2018; Kohlitz et al., 2019; Gupta et al., 2020).

There is an increasing evidence base that successful adaptation and risk reduction strategies need to acknowledge not only climate change and/or specific climate hazards (sea-level rise, flooding, droughts, etc.), but also human vulnerability and existing adaptation gaps and thereby the different starting points that societies or different groups have towards climate resilience (see UNEP, 2016; Birkmann et al., 2021a). Recent reports underscore that development and capacity indicators are useful to assess the broader adaptation challenges and adaptive capacities at global scale independent of a specific climatic hazard. Examples include the percentage of population with access to improved water sources and improved sanitation, the number of physicians per 1000 people or the dependency ratio (UNEP, 2018). These indicators are also part of more comprehensive vulnerability assessments, such as those assessed within this section namely the vulnerability components of the INFORM risk index (e.g., INFORM, 2019) and of the WorldRiskIndex (e.g., Birkmann and Welle, 2016; Birkmann et al., 2021a; Feldmeyer et al., 2021). Recent literature underscores that measuring vulnerability is seen as key for assessing factors that significantly determine actual and future adverse consequences of climate change and complex risks (Cutter and Finch, 2008; Cardona et al., 2012; de Sherbinin et al., 2019; Peters et al., 2019; Jamshed et al., 2020c; Visser et al., 2020; Feldmeyer et al., 2021). However, there is also important critique on indicator based assessments of vulnerability (see de Sherbinin et al., 2019; Rufat et al., 2019; Visser et al., 2020), particularly with regard to issues of validation and its use in decision-making processes. Nevertheless, we observe an emerging agreement in the literature that resilience building and adaptation to climate change has to be informed by climate and multidimensional assessment of the vulnerability of people, different groups and coupled human-environmental systems, including both quantitative and qualitative assessment approaches (IPCC, 2014b; UNEP, 2018; Singleton et al., 2021; Birkmann et al., 2022). Since, interdependencies between regional (supranational/sub-continental), national, community and individual vulnerability have often been overlooked, the chapter assesses both global and regional vulnerability as well as local livelihood vulnerabilities.

While past research regarding the nexus between climate change and poverty focused often on vulnerable groups in rural areas of low income countries (de Sherbinin, 2014; IPCC, 2014a; Barbier and Hochard, 2018), new global mega-trends, such as urbanization, underscore the need to assess both rural and urban communities and their vulnerability. In many rapidly growing cities in the global south, access to land and to housing is a challenge particularly for the poor and marginalized, contributing to a further increase in informal settlements that often emerge in highly hazard-exposed areas (Jeschonnek et al., 2014; Rana et al., 2021). In addition, migration from rural areas to urban centres, also due to increasing adverse impacts of climate change on rural livelihoods, can add another level of complexity (Flavell et al., 2020). Moreover, the context in which such urbanization processes take place is key. For example, rapidly growing medium-sized cities, for example in West-Africa, often do not have sufficient financial, technical and institutional resources to adapt urban structures to climate change (Birkmann and Welle, 2016; Birkmann et al., 2016; de Sherbinin et al., 2017). Hence, vulnerability in urban contexts is an emerging issue for international, national and local adaptation programmes. Rather than focusing on mega-cities and their exposure as primary hotspots, more attention has to be given to rapidly growing small- and medium-sized cities and their adaptation needs from the perspective of vulnerability reduction and poverty.

8.3.2 Global hotspots of human vulnerability to climate change

8.3.2.1 Hotspots and spatial patterns of multi-dimensional vulnerability

The assessment of literature published since the AR5 suggests that alongside already deteriorated specific conditions that determine individual vulnerability and livelihood security to climate change (see Section 8.2), high levels of poverty, lack of access to basic services (human rights to water and sanitation), poor governance, and conflicts are important factors that characterise vulnerability and systemic human vulnerability in particular (EC-DRMKC, 2020; Wisner, 2020; Feldmeyer et al., 2021; Garschagen et al., 2021; GIZ, 2021). These context conditions within a country or region limit the access to effective adaptation options particularly for the poor and marginalized groups.

Recent studies underscore that human vulnerability—thus the predisposition to be adversely affected—is largely determined by past and present development processes, rather than by the occurrence of individual events (Wisner, 2016; Cutter, 2018; Birkmann et al., 2020). Also the consequences of the COVID-19 pandemic will create newly poor particularly in countries that are already characterized by high levels of vulnerability (see Box 8.3; Laborde et al., 2020b; Lakner et al., 2020).

Quantitative studies and assessments published since AR5 provide additional insights about human vulnerability to climate change and resilience of societies at different scales using different indicator sets and approaches (Feldmeyer et al., 2017; Hallegatte et al., 2017; EC-DRMKC, 2020; Birkmann et al., 2021a; Feldmeyer et al., 2021; Garschagen et al., 2021).

While quantitative measures of vulnerability are widely used at different scales (Cutter et al., 2016; Garschagen et al., 2021), there are also studies that caution the use of such indices in policy making or risk reduction efforts (Rufat et al., 2019; Spielman et al., 2020). Such assessments of vulnerability have to be internally and externally validated and handled with care when applied in decision-making processes also in terms of their options and limits. At the same time, these assessments capture important conditions and structures that make people more susceptible to various climate hazards and climate change impacts and the relevance of these conditions is confirmed by quantitative impact assessments as well as many case study specific assessments (Welle and Birkmann, 2015; Feldmeyer et al., 2021; Birkmann et al., 2022). For example, the access to basic services (e.g., water and sanitation) (Bollin and Hidajat, 2013; Pandey et al., 2017b; UNEP, 2018; United Nations, 2018; Gupta et al., 2020; Jamshed et al., 2020a), and broader modes of engagement in governance and governance fragility (Crawford et al., 2015; Rahman, 2018; Andrijevic et al., 2020) significantly influence how climatic hazards translate into severe or non-severe losses and harm (see Section 8.5.2).

The lack of such support structures and resources can severely constrain opportunities of people to cope with and adapt to climate change, since it is not only the climate hazard, but also exposure and particularly the vulnerability of a society, a specific community or an individual household that determine adverse societal consequences of climatic hazards. International vulnerability and resilience assessments show that vulnerability varies across countries of similar wealth or income because multi-dimensional vulnerability, wellbeing and resilience depend on a larger set of factors (Birkmann and Welle, 2016; Hallegatte et al., 2017; INFORM, 2019). In this regard, vulnerability assessment is significantly different from climate exposure mapping.

The findings of these global assessments suggest, among other issues, that options to reduce vulnerability and enhance resilience do exist in various countries at different levels, in part irrespective of their income level (Feldmeyer et al., 2017; Hallegatte et al., 2017). Vulnerabilities at national and regional level influence community and individual vulnerability, particularly through structures that determine entitlements, the access to resources and processes of marginalization (Watts and Bohle, 1993; Thomas and Warner, 2019).

While different assessments use different sets of indicators, most of the global assessments with national scale resolution (Birkmann and Welle, 2016; Kreft et al., 2016; Feldmeyer et al., 2017; Hallegatte et al., 2017; Eckstein et al., 2019; INFORM, 2019; ND-GAIN, 2019; Garschagen et al., 2021), contain indicators that cover different aspects of economic poverty, inequality, access to basic infrastructure services, education and human capital (e.g., adult literacy rate) and some also include issues of gender inequality, specific vulnerable groups or insurance against extreme events. The assessments also differ, for example, in terms of their consideration of aspects of governance, such as corruption and conflict, or the consideration of social safety nets, such as insurance coverage, or the number of people affected by hazards(Feldmeyer et al., 2017; INFORM, 2019), as well as in terms of the consideration of losses experienced in the past or issues such as biodiversity as an aspect of adaptive capacity (Hallegatte et al., 2017; Birkmann et al., 2022). Moreover, the assessments differ in terms of the consideration of specific indicators and the inclusion or non-inclusion of specific hazard exposure (Welle and Birkmann, 2015; Hallegatte et al., 2017; INFORM, 2019; ND-GAIN, 2019; Birkmann et al., 2022).

Recent comparative studies of global assessments of vulnerability show *high agreement* on the spatial clusters that have very high or very low vulnerability to climate change, compared to larger differences in terms of exposure and risk (Birkmann and Welle, 2016; Hallegatte et al., 2017; INFORM, 2019; Feldmeyer et al., 2021; Garschagen et al., 2021; Schleussner et al., 2021). The comparison of the averaged ranking results at the scale of ’climate regions’ using the vulnerability components of the INFORM and the WorldRiskIndex—as two comprehensive global assessment approaches of systemic vulnerability (hazard independent vulnerability) (see Figure 8.5 and Figure 8.6)—also finds a *high agreement* in terms of most vulnerable regions and regions with low vulnerability (Figure 8.5; Feldmeyer et al., 2021). The assessment at this scale reveals that global hotspots of human vulnerability can be found in climate regions in East Africa, Central Africa and West-Africa. Followed by high vulnerability in Central America and South Asia and South East Asia, for example. Garschagen et al. (2021) in a comparison of further risk indices also found that there is high agreement on global assessments of vulnerability compared to exposure or overall risk.

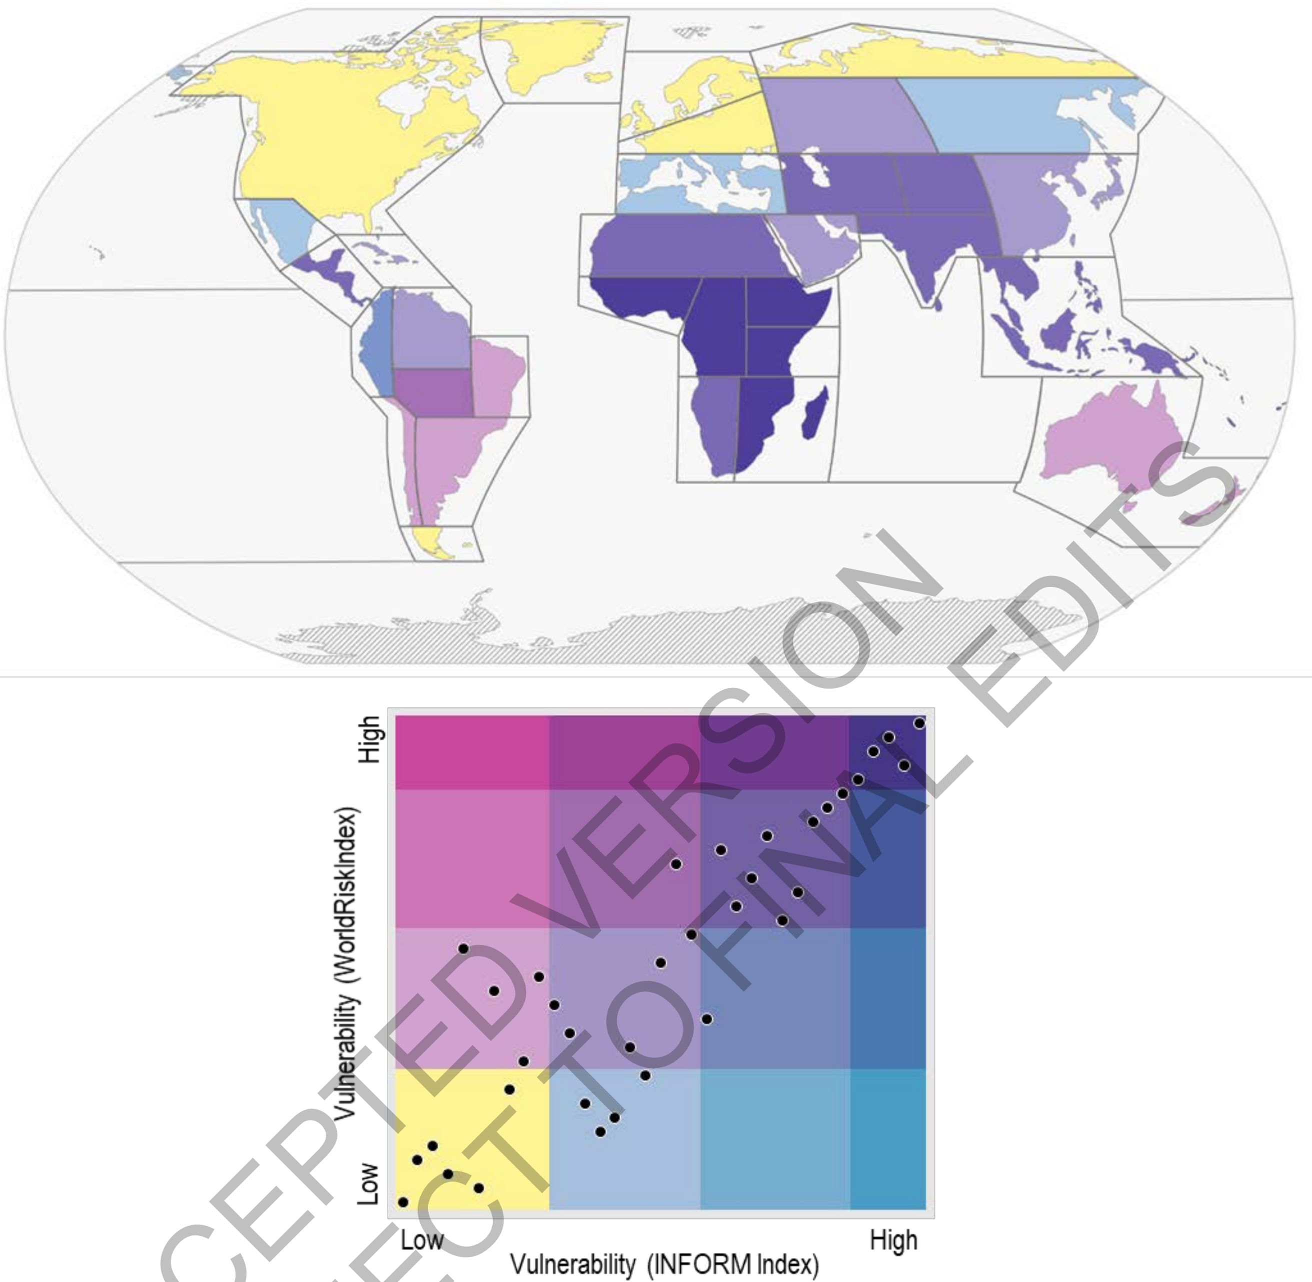

Figure 8.5: Aggregated vulnerability map at the scale of climate regions based on the averaged ranking of the INFORM Index's vulnerability component and the averaged ranking of the vulnerability component of the WorldRiskIndex. Based on the rankings of the INFORM index (INFORM, 2019) and the WorldRiskIndex (Birkmann and Welle, 2016; Feldmeyer et al., 2017). The map and diagram show the agreement between the two global vulnerability indices when ranking climate regions according to their vulnerability—darker colours show regions of higher vulnerability. The diagram shows how the 35 climate regions are ranked by each index and also serves as a legend for the map above.

The analysis of vulnerability assessment results of the INFORM Risk Index and WorldRiskIndex at the level of countries also coupled with population data confirms a *high agreement* on most vulnerable countries and it shows that global hotspots of human vulnerability are not just single countries, but often emerge within regional clusters, particularly in Africa, but also in Asia and Central America (see Figure 8.6 and Birkmann et al., 2021a). These regional clusters (Figure 8.6) are characterized by high levels of vulnerability in terms of socio-economic, demographic, environmental and governance conditions that make people more likely to face adverse consequences once a climate hazard occurs. The internal and external validation of these index systems shows its statistical validity and robustness (Welle and Birkmann, 2015; Marin-Ferrer et al., 2017; Birkmann et al., 2022). It also confirms a quantitative relationship between most vulnerable regions and fatalities and severely affected people due to climate influenced hazards (Birkmann et al., 2022). The vulnerability map in Figure 8.5 shows the vulnerability level (systemic societal vulnerability) linked to national scale and provides additional information about the population density within these countries. The background map does not show specific vulnerable populations within countries. Selected examples of sub-national human vulnerabilities have been added as additional information in terms of case studies based on information of other chapters within this report (see for example, Box 8.7, Chapter 14 Section 14.4.7, Chapter 13 Section 13.8.1, Chapter 10 Sections 10.3.3 and 10.5.1, Cross-Chapter Paper 6, Section 6.2.7, Chapter 5 Section 5.12 and Chapter 15 Section 15.3.4).

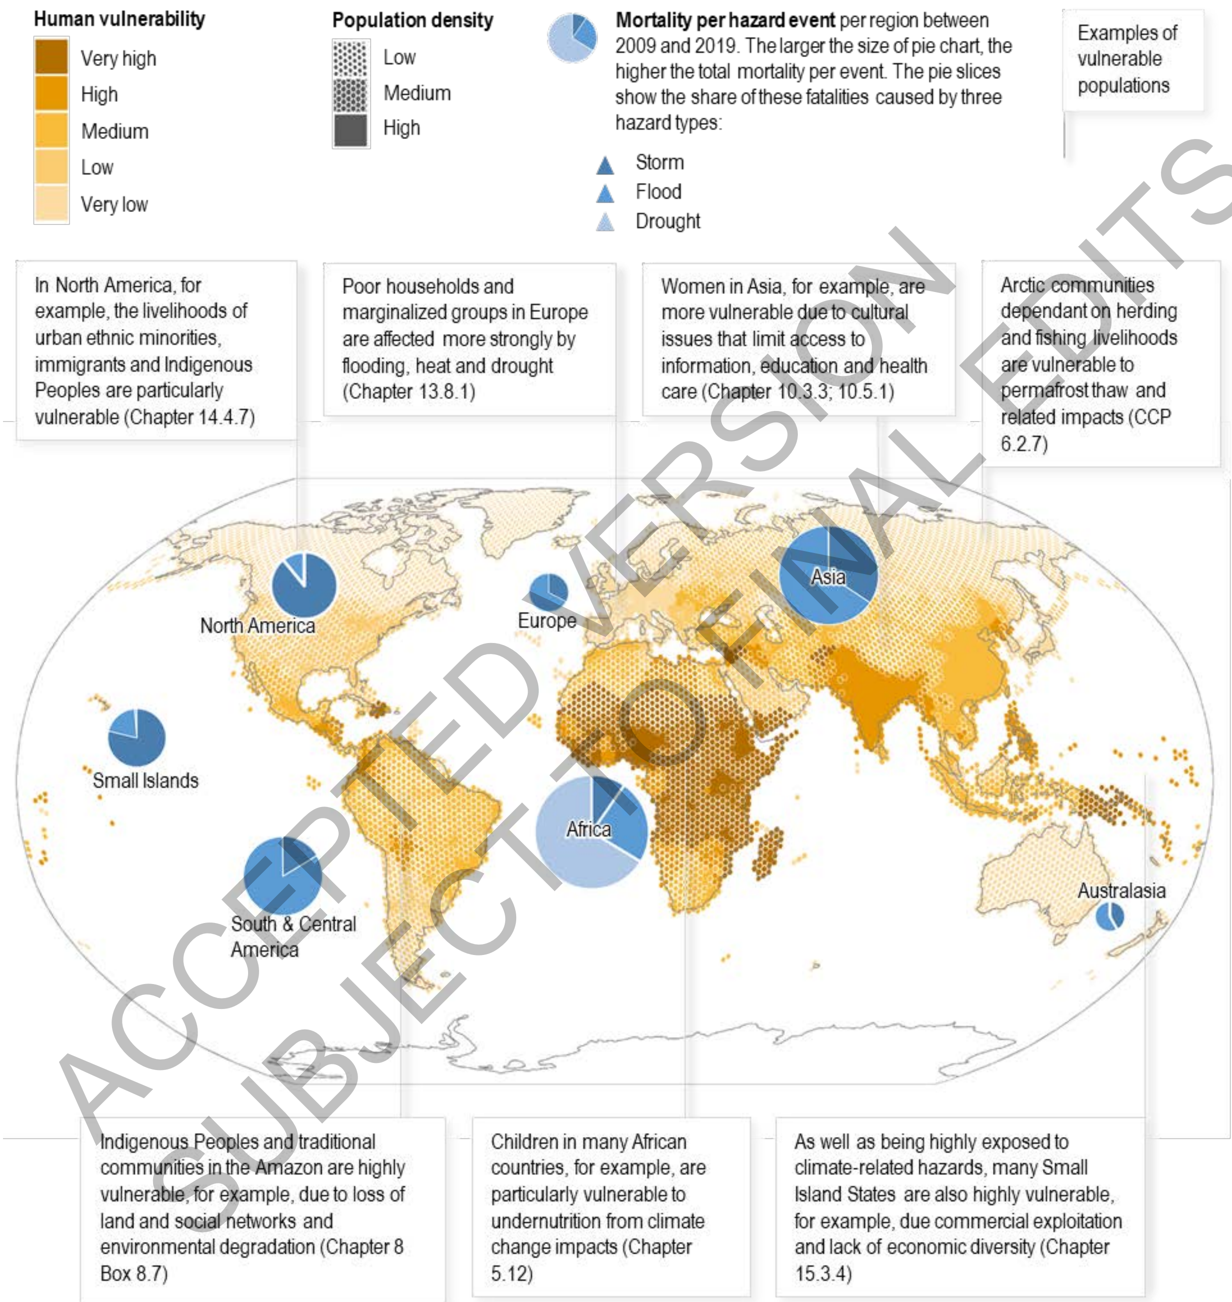

Figure 8.6: Global map of vulnerability. This map shows the relative level of average vulnerability as calculated by global indices (INFORM and WRI see details in 8.3.2). Areas shaded light yellow are on average the least vulnerable and those shaded darker brown are the most vulnerable. The map combines information about the level of vulnerability (independent of the population size) with the population density (see legend) to show where both high vulnerability and high population density coincide. The map reveals that there are densely populated areas of the world that are highly vulnerable, but also highly vulnerable populations in more sparsely populated areas. There are also highly vulnerable communities and populations in countries with overall low vulnerability as shown with sub-national case studies alongside the map. The map shows in the pie charts the number of deaths (mortality) per hazard (storm, flood, drought) event per continental region based on EM-DAT Data (CRED, 2020). This reveals that significantly more fatalities per

hazard (droughts, floods, storms) did occur in the past decade in more vulnerable regions. Over 3.3 billion people are living in countries classified as very highly and highly vulnerable, while approximately 2 billion people live in countries with low and very low vulnerability (Birkmann et al., 2022). These vulnerability values are based on the average of the vulnerability components of the INFORM Index (INFORM, 2019) and WorldRiskIndex (Birkmann and Welle, 2016; Feldmeyer et al., 2017) with updated data from 2019 classified into 5 classes using the quantile method. Other studies applied more vulnerability classes within their assessment and therefore provide slightly different numbers (Birkmann et al., 2021a). However, despite different calculation methods, the fact remains that there are significantly more people residing in countries with very high and highly vulnerability compared to those living in countries classified as having low or very low vulnerability.

Figure 8.7: Selected aspects of vulnerability. The diagram presents normalized indicator scores for a selection of aspects of human vulnerability aggregated to average values for each region. These indicator scores are based on the vulnerability indices mapped in Figure 8.6 (i.e., the INFORM Risk Index and WorldRiskIndex). This figure provides a more differentiated picture about the various dimensions of vulnerability that different regions and countries face and the severity of such challenges in each region. Such vulnerability challenges increase the risk of severe adverse impacts of climate change and related hazards (Birkmann et al., 2022).

Figure 8.7 provides an aggregated regional overview of selected indicators used within the vulnerability index mapped in Figure 8.6. The overview (Figure 8.7) shows that the many compounded challenges faced by African countries are starkly pronounced, but also on the other regions, especially Asia, Central and South America, and amongst the Small Island States there are several challenges such as inequality, governance issues and displacement which all increase the vulnerability and constrain adaptive capacities of these regions to climate change.

However, it is also important to note that vulnerability assessments do have their limitations (Heesen et al., 2014; Rufat et al., 2019). For example, also in high income countries specific groups can be highly vulnerable to climate change due to marginalization and discrimination due to ethnicity or gender. Gender inequality for example is also high in some countries classified in the literature as having low vulnerability (see Birkmann et al., 2021a; Birkmann et al., 2022). Nevertheless, these countries have in theory sufficient financial resources and governance capacities to deal with these challenges, while this is different for many country clusters classified as highly vulnerable.

Countries and regional clusters with low vulnerability (see Figure 8.5 and Figure 8.6), such as Australia and New Zealand or Iceland and North Europe, encompass population groups that are exposed and vulnerable to climate hazards, such as sea-level rise or droughts, but within these regions context conditions exist that allow the negative impacts and losses to be buffered (also for most vulnerable groups). These regions have higher financial and institutional capacities to support people at risk and planned adaptation at a different magnitude within their region, for example, as seen in compensation payments for drought exposed farmers (Hochrainer-Stigler and Hanger-Kopp, 2017; Australian-Government, 2021) or flood affected households in Germany in 2021. Also, the percentage of insured households against climate influenced hazards, such as floods or storms, is significantly higher in these regions (North America, Western Europe) compared to regions such as Western Africa or Micronesia (Welle and Birkmann, 2015; Feldmeyer et al., 2021; Birkmann et al., 2022).

While climate change differentially impacts people in vulnerable situations within countries including the poor, children, women, marginalized Indigenous or other ethnic minority people (Rhiney et al., 2016; Méndez et al., 2020), the global assessment results underscore that in most vulnerable regions and countries very limited resources and structures exist to support these groups when droughts, floods or storms occur and place an additional burden to these groups.

The assessments of human vulnerability also point towards important adaptation options that are not visible if one focuses on climatic hazards or temperature changes alone (Figure 8.9; Dückers et al., 2015; Cutter et al., 2016; Birkmann et al., 2021a). It is increasingly recognized as fundamental for vulnerability reduction and adaptation are social insurances and infrastructure programmes as well as legislation that improves the access of poor and marginalized groups towards basic infrastructure services and basic security. For example, the "free basic service programme" of the national government of South Africa (GovSA, 2021) is one example where a national government (Government of South Africa) has committed itself to provide a basic amount of free water, electricity and sanitation to low income households, particularly indigent people such as those living in informal settlements or remote rural areas. Coupled with incentives, for example in terms of a higher use of renewable energy e.g., solar home systems in rural areas (see GovSA, 2021) these investments can support vulnerability reduction and mitigation of greenhouse gas emissions. However, there is also critique of the programme design and implementation (see Nel and Rogerson, 2005; Muller, 2008) as is witnessed by ongoing service delivery protests (Mutyambizi et al., 2020). However, the example shows that current national programmes can—even if they are not classified as adaptation measures—provide important entry point to also reduce human vulnerability to climate change.

The relevance of human vulnerability has also been confirmed by recent assessments. Studies found that the average mortality[4] from floods, storms and droughts is 15 times higher in countries and regions ranked as very highly vulnerable (e.g., Mozambique, Somalia, Nigeria, Haiti, Afghanistan) compared to countries with very low vulnerability (e.g., UK, Sweden, Italy, Canada) (Birkmann et al., 2022). Even if one takes solely "high vulnerable countries" such as India, Pakistan and the Philippines (and not "very high" vulnerable countries), mortality is still nine times higher compared to very low vulnerable countries. Similarly, studies further revealed that average number of adversely affected people per hazard event (e.g., loss of the house) are 11 times higher in countries categorized as very high vulnerable compared to very low vulnerable (Birkmann et al., 2022). In addition to floods, droughts and storms, published EM-DAT data for wildfires and heat stress, confirmed higher suffering (higher average mortality) in more vulnerable regions compared to low vulnerable regions, particularly when excluding extreme outliers (CRED, 2020). These findings point towards the fact that in regions identified as highly vulnerable in the assessments even moderate future climate change and future climate hazards are likely to push people further into poverty and lead to significant destabilization processes in terms of livelihoods security (Wallemacq and House, 2018; Birkmann et al., 2022).

8.3.2.1.1 Historic roots of vulnerability in regions classified as highly vulnerable

While increasing attention is given to issues of human vulnerability, less attention has been given to the historical conditions that foster systemic vulnerability of societies. It is important to acknowledge that drivers and root causes of systemic human vulnerabilities and development challenges are not always new, and sometimes—for example in various countries in the Caribbean, Africa and Asia—can be linked to histories of imperialism, colonial structures (Grasham et al., 2019), and subsequent development and governance contexts (Southard, 2017; Zhukova, 2020). Thus, root causes of present structures of human and human-environmental vulnerability have in many cases historic dimensions, for example chronic poverty and structural inequality in Africa (Grasham et al., 2019) or the Caribbean are still influenced by the colonial power-relations outside of these countries making solutions for vulnerability reduction more difficult (see e.g., Douglass and Cooper, 2020). Also national borders, such as in many regions in Africa, sometimes cut through ethnic groups and therewith ignore important interrelations between communities on both sides of the border.

8.3.2.1.2 People residing in most vulnerable versus least vulnerable regions

[4] measured as death per hazard event and calculated by averaging the country values of mortality per event falling in different vulnerability categories

While global assessments often allow for country rankings, it is similarly important to better understand how many people are living in these different levels of vulnerability. The quantitative assessments underscore that a significantly higher amount of people is living in countries with very high and high vulnerability compared to the population living in countries classified as having low and very low vulnerability. An analysis that measured the vulnerability of countries according to the INFORM Risk Index and the WorldRiskIndex vulnerability-index components, differentiating vulnerability values into 7 vulnerability classes found that nearly twice as many people are living in most vulnerable countries compared to the number living in less vulnerable countries (Birkmann et al., 2021a). Another study that uses the same data and differentiates vulnerability into 5 classes (also considering the lack of coping capacity within the INFORM index, see (Marin-Ferrer et al., 2017)) concludes that about 3.3 billion people are living in countries classified as highly vulnerable, while approximately 2 billion people live in countries with low vulnerability (Birkmann et al., 2022). While these numbers are different, both results underscore that the absolute and relative number of people living in most vulnerable contexts is significantly higher compared to those that live in a country with a low vulnerability status (Birkmann et al., 2021a; Birkmann et al., 2022). These differences have also been observed in former years (Welle and Birkmann, 2015; Feldmeyer et al., 2017).

That means, even moderate changes in the global mean temperature, as identified in the recent IPCC report SR1.5°C (IPCC, 2018c) and in scientific literature (Hoegh-Guldberg et al., 2019a), can mean substantial increases in risks for more than 3 billion people due to high levels of vulnerability.

Overall, there is *robust evidence and high agreement* in the recent literature that countries and regions classified as highly vulnerable face multiple development challenges at once, in which high levels of poverty interact with limited access to water and sanitation or with high levels of forced migration and in some cases with state fragility making solutions difficult (Hallegatte et al., 2017; Marin-Ferrer et al., 2017; Feldmeyer et al., 2021; Garschagen et al., 2021; Birkmann et al., 2022). High levels of vulnerability within these regional clusters are the product of current development challenges, but are often caused by long and complex histories, including issues of colonization and marginalization, for example, in hotspots in Africa (Birkmann et al., 2021a).

8.3.2.2 Transboundary vulnerability and adaptation

Next to the identification of the level of agreement between different vulnerability assessments (Garschagen et al., 2021) and the spatial hotspots, global assessments of vulnerability and adaptation readiness also point towards the need of a transboundary perspective and the need for transboundary cooperation in terms of vulnerability reduction and adaptation (Tilleard and Ford, 2016; Birkmann et al., 2021a). Newer research points towards the fact that various phenomena of vulnerability particularly in highly vulnerable regions spill over national borders and emerge in rather regional clusters, such as forced migration and poverty in West and Central Africa as well as conflicts in the Near East or Asia (IDMC, 2020). That mean regional and transboundary challenges contribute to the formation of systemic human vulnerability, for example, forced migration that is occurring within countries, but also across international borders that is also influenced by climate change (Kaczan and Orgill-Meyer, 2020). In summary, these findings point towards the need for more transboundary approaches in vulnerability and risk reduction, adaptation and development. Recent literature and data presented in Figure 8.6 and (Birkmann and Welle, 2016; Feldmeyer et al., 2017; Hallegatte et al., 2017; INFORM, 2019; Birkmann et al., 2021a) demonstrate the need to strengthen approaches to monitor the regional dimensions of vulnerability and to develop strategies and programmes that allow for transboundary vulnerability and risk reduction and cooperation at different scales, for example, cooperation between national level institutions, but also transboundary networks of cities or communities (Tilleard and Ford, 2016; Benzie and Persson, 2019; Birkmann et al., 2021a). The transnational nature of climate change impacts means that addressing them requires concerted efforts among nations (IPCC, 2014b; Dzebo, 2019).

In addition, national response strategies for specific transboundary climate influenced hazards, such as river flooding, droughts or coastal flooding can also significantly influence neighbouring countries and can affect exposure and vulnerability of the respective country (Nadin and Roberts, 2018; Booth et al., 2020). Likewise, climate change may affect transboundary resources (e.g., underground water reserves) and transboundary ecosystems (e.g., in terms of the migration of species) (Vij et al., 2017) and thereby further reduces the capacity of vulnerable groups to cope and adapt. In addition, recent research indicates that social inequities are coupled with access to and quality of environmental resources, also in urban environments—meaning social and environmental justices are interconnected (see Schell et al., 2020).

Individual adaptation projects to specific climate hazards in regions classified as highly vulnerable are needed, however, recent studies underscore that deeper development challenges need to be addressed in order to make progress towards adaptation and vulnerability reduction and to avoid maladaptation (Eriksen et al., 2021). Adaptation and development projects, such as the construction of a dam as a response to water shortages in one country can significantly influence the exposure to water shortages and the response capacities of another country downstream. Often, transboundary challenges are a result of policy and resource management choices or uncertainty and addressing them requires a greater engagement between governing bodies, which may guide more suitable responses also in the context of climate change adaptation and vulnerability reduction (Earle et al., 2015; Tilleard and Ford, 2016; McLeman, 2018; Birkmann et al., 2021a).

Most of those countries and regional clusters identified as highly vulnerable have contributed little to the overall amount of greenhouse gas emissions and therefore support for (transboundary) adaptation from the international community is required in these places and for those living under these conditions also in order to support and achieve climate justice.

8.3.2.3 The effect of higher levels of global warming for most vulnerable regions and specific livelihoods

Evidence exists that threats to land-based livelihoods and risks of undernutrition increase significantly with higher levels of global warming (Hoegh-Guldberg et al., 2019a). With global warming of 1.5°C or less, impacts of climate change on livelihoods are still significant, for example, for West Africa and Sahel due to a reduction of area suitable for maize production of about 40%, however, the consequences of global warming of up to 3°C would mean a high risk of undernutrition for entire regions (see Hoegh-Guldberg et al., 2019a) that are already classified as most vulnerable (see Figure 8.6). That means the consequences of significant warming are a particular challenge for the regional hotspots of vulnerability, since already observed small changes in crop productivity due to increasing droughts or floods or changes in rainfall patterns could lead to severe health risks and undernutrition due to already existing precarious living conditions and due to the limited capacities that people and institutions have to build and enhance coping and adaptive capacities at the level of individual households, communities and even at the level of state institutions (see UNEP, 2018; Birkmann et al., 2021a). The risk of loss of life, displacement and adverse health consequences due to climate change in these most vulnerable regions (such as West Africa, Micronesia, South Asia—see Figure 8.5 and Figure 8.6) is higher compared to regions classified as having medium or low vulnerability (Birkmann et al., 2022). Nevertheless, also other regions and countries classified as less vulnerable, for example in Asia, are experiencing disasters and have a relative high share of the global fatalities or losses observed when considering also non-climatic natural hazards (CRED and UNDRR, 2020). In addition, changing climatic hazard and exposure patterns have to be considered, however, the agreement of major global index systems on exposure is significantly lower as compared to vulnerability (Garschagen et al., 2021).

Moreover, the assessment reveals that in most vulnerable regions a double burden of existing destabilized livelihood conditions and additional climatic hazards is already visible and largely influences societal impacts of climate change. For example, flooding along the White Nile in Uganda and South Sudan hit vulnerable communities that were displaced before because of conflicts and were thus up-rooted again by flooding (IDMC, 2020). Societal impacts and future risks of climate change to societies need to incorporate information about vulnerability and exposure—including capacities of people to cope and adapt (Wisner, 2016; Cardona et al., 2020). There is increasing evidence that individual and societal capacities to cope and adapt also depend on how governmental and national institutions can support people at risk (see Section 8.6). For example, climate information services depend on a functioning weather service, likewise, social safety nets as an adaptation strategy require financial resources, which are often absent for most people in highly vulnerable regions. In addition, examples of national programmes that target most vulnerable groups such as the free basic service programme in South Africa show that next to the adaptation to individual hazards, strategies exist that aim to reduce systemic human vulnerability (see GovSA, 2021).

At the same time, scientific evidence exists that more intense and frequent climate influenced hazards (e.g., storms, flooding, droughts, heat stress) can undermine decade-long poverty reduction efforts, particularly in most vulnerable regions (Mysiak et al., 2016; Formetta and Feyen, 2019; Laborde et al., 2020b; Lakner et al., 2020). There is agreement that with global warming of about 3°C such undermining of poverty reduction efforts will intensify and more regions will face development setbacks due to the spatial and temporal expansion of climate hazards, including the further erosion of capitals that enable people to develop adaptive capacities (*high confidence*) (see Section 8.5). Such trends can further exacerbate poverty traps (see Section 8.2.2). According to a World Bank report, between 32 and 132 million people could fall into extreme poverty in 2030 due to the impacts of climate change (Jafino et al., 2020). Models estimate that at 3°C warming and under an SSP1 there would be an additional 245 million people exposed to poverty. Under an SSP2 this number would increase to 904 million additional people exposed to poverty (SSP2) and under an SSP3 (with significant challenges for equity) about 1718 million additional people could be exposed to poverty (SSP3) in the year 2050 (Byers et al., 2018).

Overall, the assessments above underscores that adaptation and risk reduction require not only information about changing climatic conditions, but also assessments that capture the development contexts and structural inequality that determine and influence human vulnerability. Strategies that reduce poverty and inequality and that improve the access of people to basic services need to become a higher priority in adaptation and development planning in order to avoid that more than 3 billion people currently and even more in the future are exposed to severe adverse consequences of climate change. Reducing vulnerability to climate change is therefore indispensable for climate justice and just transitions (*high confidence*).

8.3.2.4 Compound challenges: vulnerability and state fragility

Literature in the area of climate change risk management and adaptation highlights the importance of overall governance systems and their functioning and inclusiveness in terms of vulnerability and risk reduction (Burch et al., 2019). Empirical evidence and scientific studies show linkages between issues of governance, conflicts and high levels of state fragility and systemic human vulnerability (see Figure 8.8; Section 8.5.2; Eklöw and Krampe, 2019; Peters et al., 2019; Mawejje and Finn, 2020)

The comparison of state fragility and vulnerability at the level of regions (UNSD regions) based on the vulnerability information of the INFORM and WRI index systems and information of the Failed State Index indicates clear linkages (see Figure 8.8), meaning that societal development and governance challenges often interact and in many cases are influenced by complex histories (see FFP, 2020; Birkmann et al., 2021a; Feldmeyer et al., 2021). Strategies to reduce systemic vulnerability and multi-dimensional poverty have to account for these broader governance challenges that hamper resilience building and the development of adaptive capacities to climate change at various levels.

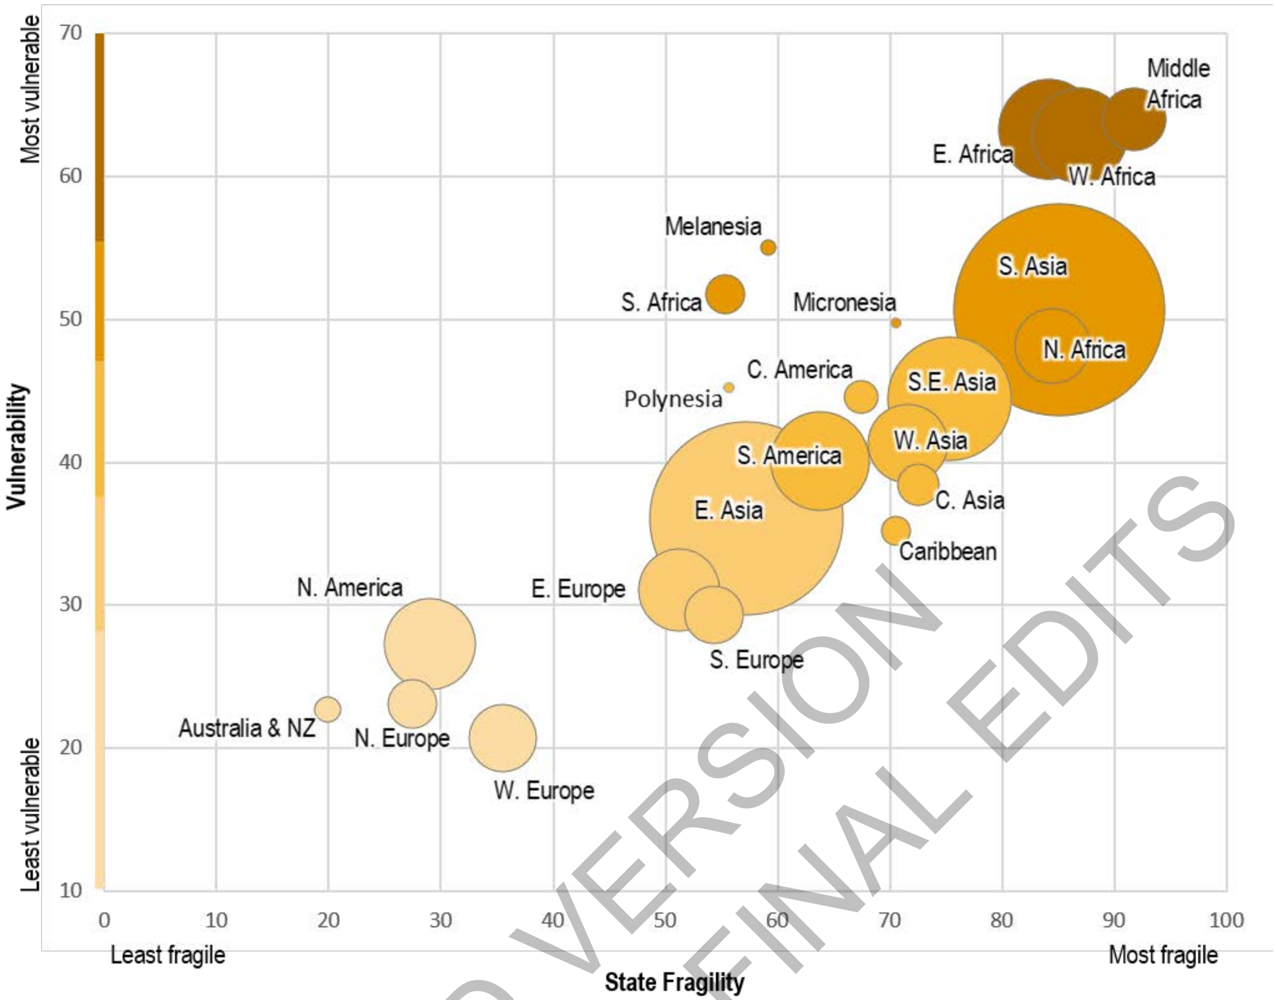

Figure 8.8: Comparison of the vulnerability and state fragility of global regions. The vulnerability values are the average of the vulnerability component of the WorldRiskIndex 2019 (Birkmann et al., 2021a; Feldmeyer et al., 2021) and the vulnerability and lack of coping capacity components of the INFORM Risk Index 2019 (Marin-Ferrer et al., 2017) classified into 5 classes using the equal count method(Birkmann et al., 2022). The state fragility values are based on the Fragile States Index 2019 (FFP, 2020), and regions are based on the intermediate and sub-regions of the United Nations Statistical Division. The size of each circle is proportional to the population (World Bank, 2019b) in the respective region.

Strategies to strengthen adaptation to climate change have therefore to acknowledge these interdependencies between climate change, vulnerability, development and governance (see Section 8.6.5). The results of different global vulnerability assessments and the role of governance conditions underscore that next to individual adaptation projects in specific sectors, integrated strategies and programmes are needed that reduce systemic vulnerability and support enabling conditions for adaptation for most vulnerable groups (see Section 8.6.5).

8.3.2.5 Trends in vulnerability and poverty in light of climate change and the COVID-19 pandemic

Literature that assesses trends of poverty and vulnerability as well as exposure to climate change reveals that geographic patterns of poverty and vulnerability are uneven and changing over time (Feldmeyer et al., 2017). However, a robust finding of different studies is that the population growth in most vulnerable country groups and regions “is” and very likely “will be” significantly higher in the future compared to population growth in countries classified as low vulnerable (see Section 8.4.5.2). In summary, a significant increase of population is expected in highly vulnerable countries in the future. In addition, global studies show that by 2030 it is expected that almost 50% of the world’s poor will be living in countries affected by state fragility, conflict and violence (UNISDR, 2009; Hallegatte et al., 2017).

Another important phenomena that modifies trends in vulnerability to climate change and poverty is the COVID-19 pandemic (see Box 8.3). It is *likely* that the COVID-19 pandemic with its global repercussions will continue to modify and, in many cases, intensify poverty and human vulnerability (Laborde et al., 2020a; Sumner et al., 2020). Recent studies that estimate the impact of COVID-19 on global poverty agree that a significant increase of poverty due to COVID-19 and the respective lockdown of countries is already observed or expected in the near future (Laborde et al., 2020b; Sumner et al., 2020). These studies underscore that 80% of those newly living in extreme poverty (living on under 1.9 USD per day) due to COVID-19 would be located in mainly two global regions: Sub-Saharan Africa and South Asia (Sumner et al., 2020). Consequently, the COVID-19 pandemic is likely to further increase inequality at different scales and increase the burden within regions already characterized by a significant adaptation gap in terms of high vulnerability (see also Figure 8.6). This implies that the capacity of people to prepare for present and future climate change impacts will further decrease within these countries and for specific vulnerable people/groups in these regions.

Recent scientific studies in the context of climate influenced hazards and disasters also underscore that various regions and countries classified as highly vulnerable are characterized by a high persistence of human vulnerability and chronic poverty (Feldmeyer et al., 2017; UN-DESA, 2020; World Bank, 2020). For example, various highly vulnerable regions in Central, West and East Africa, such as countries like Haiti, Afghanistan, Democratic Republic of Congo, but also Small Island Developing States (SIDS) in Melanesia and Micronesia have been characterized by high levels of poverty for decades (World Bank, 2020). Several of these highly vulnerable regions are also likely to experience a further increase in climate hazards such as sea-level rise in Melanesia and Micronesia and in coastal zones of West- and more severe droughts in Africa (IPCC, 2021).

There is evidence that in many world regions the exposure to climatic hazards is increasing with additional global warming (Chin-Yee, 2019; Hoegh-Guldberg et al., 2019a; IPCC, 2021). In addition, development patterns and practices such as urbanization and migration to exposed areas, for example, to coastal zones in West-Africa or South Asia is increasing exposure. While the spatial and temporal exposure to impacts from climate change and extreme events increases with higher levels of global warming (Hoegh-Guldberg et al., 2019a), in all global regions and various climate zones (IPCC, 2021), the burden is greater for the most vulnerable regions where people have limited support and capacities to build adaptive capacities for future impacts of climate change.

In this regard, vulnerability assessment results provide an important additional layer of information for decision making in terms of defining adaptation and risk reduction needs and priorities, as shown in Figure 8.9. The figure shows the published climatic information regarding observed changes in agricultural and ecological droughts (IPCC, 2021) combined with a background map of vulnerability. For example, the combined information reveals that even if the agreement on the type of changes in observed changes in droughts is low for North and South-East Africa, it is the high vulnerability in this region that requires urgent attention (see Figure 8.9).

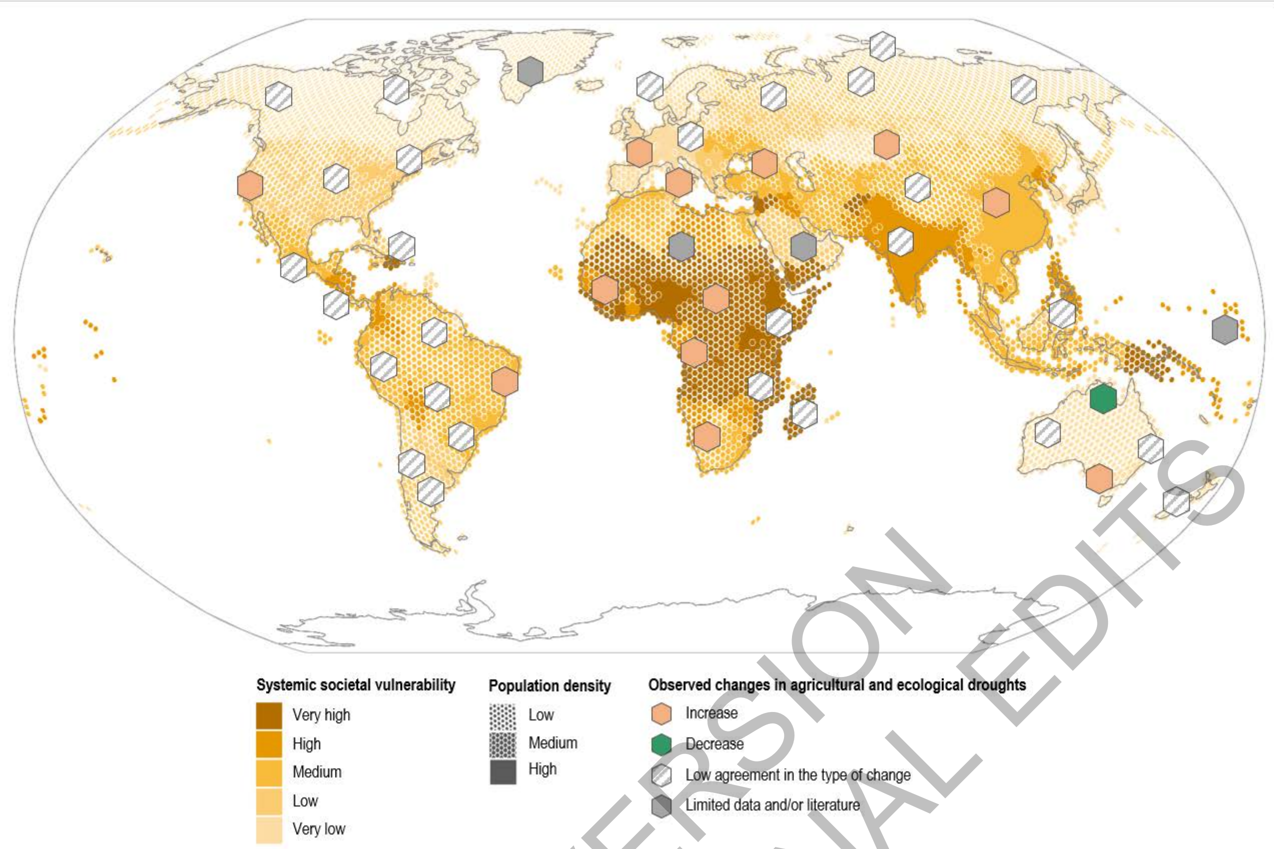

Figure 8.9: Map with observed changes in agricultural and ecological droughts (IPCC, 2021) overlaid over human vulnerability (see Figure 8.6) provides a more comprehensive overview for defining adaptation priorities.

Recent reports on extreme poverty and human rights (Alston, 2019) show that already millions face malnutrition due to devastating drought. In addition, the linkages between ecosystem vulnerability and human vulnerability and human well-being are important aspects that need more attention, since for example the degradation of marine ecosystems that support food systems for hundreds of millions of people will threaten food security (see for details Cross-Chapter Box Moving Plate chapter 5).

While the findings of the Alston report underscore the urgency to act in order to protect people's livelihoods, particularly in low income countries, it also shows that extreme poverty (Alston, 2019) and different dimensions of poverty are found in middle and high income countries.

A study of the World Bank (Hallegatte et al., 2017) estimates that losses in terms of wellbeing are significantly higher compared to actual asset losses experienced (Hallegatte et al., 2017). A higher proportion of the global absolute economic losses occurred in high income countries. About 56% of all disasters reported occurred in high-income countries, while the low-income countries account for 44% of the recorded disasters. However, low income countries account for about 68% of the total deaths reported, high income countries for about 32% (CRED, 2015; see also Section 8.3.2.1). In contrast, average absolute economic losses[5] were significantly lower in most vulnerable countries compared to low vulnerable countries (Birkmann et al., 2022). Economic loss trends from EMDAT database (CRED, 2020) must be interpreted with caution. Economic loss data is often incomplete and needs to be improved. However, these differences in terms of economic losses can also be explained in part with significant wealth differences and the monetary value of assets exposed. Consequently, there is a need to critically reflect the measures used to assess loss and damage from climate change. Interestingly, the number of people affected by droughts, floods and storms as a percentage of the total population and per hazard event again points to the disproportional suffering of most vulnerable countries (Birkmann et al., 2022).

[5] calculated by averaging the country values of economic losses per event falling in different vulnerability categories

Overall, there is *robust evidence* that at the global scale poor and most vulnerable people particularly in regions classified as highly vulnerable are disproportionately affected by wellbeing losses and loss of life in the context of climate change and climate influenced natural hazards (CRED, 2015; Hallegatte et al., 2017; Birkmann et al., 2022) (*high agreement*). In this context, also non-economic losses need to receive a higher attention (see Section 8.3.3.2). While there is an emerging understanding that inequality and multidimensional poverty are important determinants of systemic vulnerability to climate change (Dennig et al., 2015; Hallegatte and Rozenberg, 2017; Islam and Winkel, 2017) that affects more than 3 billion people today, only very few countries explicitly aim to reduce poverty and income inequality as an adaptation measure (see e.g., Brazil Ministry of Environment, 2016) *(high agreement)*. Reducing vulnerability is a prerequisite for climate justice and just transitions.

8.3.3 Livelihood impacts, shifting livelihoods and the challenges for equity and sustainability in the context of climate change

This section complements the global and regional assessment of vulnerability in the previous section with a more precise assessment of observed local conditions and livelihood impacts and shifts. Firstly, the section reviews linkages between vulnerability and livelihood impacts of climate change broadly. Secondly, it examines the range of observed disproportionate impacts according to economic (e.g., income) and non-economic (e.g., cultural) impacts of climate change. Thirdly, it examines current risks of adaptation limits and compounding effects across social groups and associated livelihood shifts.

8.3.3.1 The implications of vulnerability for past and present livelihood impacts of climate change

Climate change impacts add to livelihood challenges and can further increase inequality and poverty (see Section 8.2.1), whose root causes are social, institutional and governance-related. Various regional clusters of high vulnerability (see Figure 8.6) are also influenced by historical processes, such as colonialism and power-relations that made people and countries vulnerable (Schell et al., 2020). Thus, vulnerability to climate change is not primarily linked to the degree of exposure to climate change impacts, but determined by societal structures and development processes that shape context and individual vulnerability (see the above Section 8.3.2), and values and lived experiences of climate hazards (Djoudi et al., 2016; Walker et al., 2021). Intersectionality approaches are central to grasping differential vulnerability (Thomas et al., 2019) for past and present livelihood impacts of climate change (see Figure 8.3 and Section 8.2.2.2). Assessing observed local conditions and livelihood impacts and shifts requires us to consider reinforcing social phenomena such as age, gender, class, race and ethnicity which shape social inequalities and experiences of the world and also intersect with climate hazards and vulnerability (Walker et al., 2021).

This understanding helps to clarify how social structures, institutions and governance mechanisms matter to address social causes in addition to climate magnifiers while holding them accountable (see Section 8.5). For example, low-elevation coastal zones concentrate high levels of poverty in some specific areas: 90% of the world's rural poor are concentrated in the low-elevation coastal zones of just 15 countries, and this population keeps growing (Barbier, 2015). Yet studies on the economic impacts of climate change and also Integrated Assessment Models typically overlook the distributional effects of these impacts according to vulnerability and exposure and do not sufficiently account for agent and societal heterogeneity (Balint et al., 2017; Sovacool et al., 2021).

Since the AR5, *high confidence* is attributed to the fact that the, mostly detrimental, climate change impacts and risks are experienced mainly by the poorest people around the world (Olsson et al., 2014; Roy et al., 2018). There is *high confidence* that climate change impacts will put a disproportionate burden on low-income households and thus increase poverty levels (IPCC, 2014a; Hallegatte and Rozenberg, 2017).

There is *robust evidence* that economic development based on the exploitation of natural resources can significantly increase the vulnerability of communities at the local level. For example, there is a correlation between political arrangements and environmental degradation that brings about both disasters and an increase in disaster risk (Cannon and Müller-Mahn, 2010; Pereira et al., 2020) and while development is recognised by some as a key element for adaptation (Cannon and Müller-Mahn, 2010).

Maladaptation is an important thread given its relevance to assess ways that well intentioned development can exacerbate past and existing vulnerabilities and undermine livelihoods (see Section 8.2.2.1). Evidence shows that some local development projects can undermine resilience and increase the vulnerability of neighbouring communities, leading to maladaptation (Magnan et al., 2016; Schipper, 2020; Eriksen et al., 2021). Development projects can also negatively affect the vulnerability and create new ones of the very community where they are implemented (Burby, 2006; Magnan et al., 2016; Atteridge and Remling, 2018; Thomas and Warner, 2019; Work et al., 2019). Maladaptation has also received growing attention since AR5 as projected future climate risk for vulnerable social groups (see Section 8.4.5.5) and in the context of adaptation constraints and trade-offs in climate resilient development (see Section 8.5.1 and 8.6.1), Despite maladaptation, there is however *robust evidence* that inclusive and sustainable development at the local level, can reduce vulnerability (Cannon and Müller-Mahn, 2010; Patnaik et al., 2019).

8.3.3.2 Economic and non-economic losses and their relevance for poverty and livelihoods

Economic losses include income and physical assets and non-economic losses include mortality, mobility, mental wellbeing losses from climate change (see Section 8.3.4). The IPCC WGII AR5 primarily associated losses and damages with extreme weather events and economic impacts, and treated it primarily as a future risk. New evidence provides insights into present-day losses and damages from slow-onset impacts (e.g., sea level rise) (Adamo et al., 2021) and non-economic losses (e.g., cultural impacts, emotional and psychological distress) (McNamara et al., 2021b) which previously received much less attention. AR5 had more focus on losses and damages in high-income regions than in regions most at risk, such as Small Island Developing states and Least Developed Countries (LDCs) (van der Geest and Warner, 2020).

Impacts of climate change are affecting the economic and non-economic dimensions of people's lives, including subsistence practices of communities that are experiencing decreases in agriculture productivity and quality, water stress, increases in pests and diseases, disruption to culture, and emotional and psychological distress, just to cite a few (Savo et al., 2016). For example, the cumulative effects of slow-onset events threaten food security especially among the poor in Latin America and the Caribbean—regions which face the largest gender gap in terms of food security globally (Zuñiga et al., 2021). In general for Global South countries, the global average temperature warming (including the Paris target of 1.5°C) means substantially higher warming and including higher frequency and magnitude of extreme events, that will result in significant impacts on societal vulnerability (Aitsi-Selmi and Murray, 2016; Djalante, 2019).

Measuring losses from climate change impacts in terms of poverty and inequality can be difficult, and part of the lack of assessments of non-economic loss and damage can be attributed to the limited observational climate data on poor countries and population impacted, which are mostly concentrated in the Southern hemisphere (Roy et al., 2018).This is also due to the challenges posed by limited data available for assessing attribution (Cramer et al., 2014; Harrington and Otto, 2020; Otto et al., 2020a) and no comprehensive set of adaptation metrics (Otto et al., 2020b). Economic losses and damages from climate change are often assessed and reported after disasters or within crises, however, non-economic losses from climate change are often overlooked as is their relevance for poverty and livelihoods. For those who experience both economic and non-economic losses the impacts of climate change are very real and profound (Tschakert et al., 2017; Roy et al., 2018) Particularly in low-income and most vulnerable regions, it is not the absolute economic loss, but the combination of economic and especially non-economic losses that need to receive higher attention and need to inform adaptation strategies.

8.3.4 Observed disproportionate impacts according to economic and non-economic losses and damages due to climate change

Since AR5 a new discourse on Loss and Damage (L&D) has emerged with new typology and elaboration of a definition. L&D has a long and contentious history and is enshrined in the Paris Agreement (see Cross-Chapter Box LOSS in Chapter 17). Despite ambiguity about what constitutes L&D (Boyd et al., 2017), it focuses on how to avert, minimize, and address the negative impacts of climate change, including those that cannot be avoided through adaptation. It can also be thought of as the observed residual risk (and potentially irreversible losses) from climate change when adaptation limits are encountered and mitigation has failed (Boda et al., 2020). L&D is considered a policy mechanism (see Cross-Chapter Box LOSS in Chapter 17). It is also a burgeoning science for loss and damage (Mechler et al., 2019b) which advances the breakdown on compounding vulnerabilities and highlights the disproportionate effects of climate change on the vulnerable and marginal (see Box 8.5 for illustration of distributional effect of both the drought and responses in the Cape region in South Africa). New evidence provides additional insight into loss and damage from slow onset events related to climate change (sea level rise, drought) (see Anjum and Fraser, 2021; Lund, 2021) For example, (Singh et al., 2021) found growing evidence of urban droughts leading to economic losses (e.g., groundwater over-extraction, financial impacts) and non-economic losses (e.g., conflict, increased drudgery).

The literature is assessed according to this new L&D typology, which includes both extreme and slow onset events and has a strong emphasis on climate justice and disproportionate impacts of climate hazards (see Figure 8.3) with a new focus non-economic loss and damage.

8.3.4.1 Economic (e.g., income, assets) impacts of climate change and vulnerability

While extreme events are not new, the intensity and frequency of extreme events are stacking, leading to additional increase in poverty or vulnerability in some regions, exacerbated by Covid-19, and up against existing development pathways leading to significant impact on economic losses globally (*high confidence*). There is *robust evidence* that many African countries experience climate-related losses in terms of loss of crop yields, destroyed homes, food insecurity through increased food prices, and displacement (Box 8.5; Olsson et al., 2014). Attention has been focussed on low income groups, women and children, poor rural communities, and Indigenous Peoples such as the example of the Dupong, an Indigenous Peoples in Ghana using indigenous strategies to limit adverse impacts of climate change-induced water shortages (Opare, 2018). In Kenya economic loss and damage during droughts between 2009−11 drought incurred costs including trucking emergency water and food supplies as well as loss of livestock and livelihoods, particularly in areas cross-sectoral economic effects were estimated to reduce GDP by 2.8% per year (King-Okumu et al., 2021a). Past studies have similarly shown that in context of extreme events such as floods or droughts the most commonly sold assets are livestock and land. The sale of property particularly reduces the asset base and creates long-term vulnerabilities to future events and can trigger chronic poverty *(high confidence*). People may face food shortages in the future from lack of crop production (Opondo, 2013).The sale of cattle affects the household asset base, as well as the important access to animal traction power for farming.

In South Asia, there is *robust evidence* of economic impacts of climate change (Cao et al., 2021), for example in the Sundarbans (a transboundary ecosystem with components in both India and Bangladesh, with the problem of unproductive livelihoods being common across residents of both countries) observations show local livelihoods are rapidly becoming unproductive (loss of fish, and increasing salination making agriculture increasingly difficult) (Ghosh, 2018); conditions that are exacerbated by climate change impacts (*high confidence*). Cyclone and storm surges induced by climate change force saline water into agricultural lands along the coast, which damages crops not only in the year the cyclone hits, but for several years afterwards (Rabbani et al., 2013). They showed in Shyamnagar Upazilla in Satkhira district the proportion of salinity-free farmland has gone down over the past 20 years, from more than 60% to nil (Rabbani et al., 2013). Vietnam has also experienced effects of flooding and salinization in the Mekong delta coupled with rapid social development. Intensified floods and droughts have dramatically resulted in loss of livelihoods in agriculture and fisheries in some areas of the basin (Evers and Pathirana, 2018). In Vietnam the expected salinization increases livelihood shifts into areas that are more risky, such as shrimp farming. Furthermore, the Vietnamese Mekong Delta is characterized by strong migration processes towards cities, particularly Ho Chi Min, meaning that abrupt livelihood shifts are already happening. There are emerging examples of Indigenous Peoples affected by climate change in indigenous farming mountain communities of the Nepal Himalaya. (Sujakhu et al., 2019). The Philippines has experienced extreme events, such as typhoon Haiyan in 2013, which left more than 7353 reported people dead or missing, and damaged or swept away more than 1.1million houses and injured more than 27,000 people (McPherson et al., 2015). More than 4 million were displaced. The cost of damages has been estimated at US$864 million with US$435 million for infrastructure and US$440 million for agriculture in affected regions (McPherson et al., 2015).

Sea-level rise, coastal flooding and surge inundation is an increasingly pressing problem across the urban Pacific, including the urban and coastal population of Vanuatu (McDonnell, 2021). Pacific region islands such as Vanuatu (Handmer and Nalau, 2019) are particularly vulnerable to climate change. Kiribati and

Tuvalu are impacted by exceptionally high tides that affect the urban atolls of South Tarawa and Funafuti, and cyclonic activity causing extensive economic damage in Tuvalu (Curtain and Dornan, 2019). Limited migration opportunities for low-income households can result in forced immobility, and high tides, sea-level rise and cyclonic damages could result in relocation of significant groups of the population.

A pertinent example of economic losses is the example of the Torres Strait in Australia. This example shows evidence of communities living on remote islands Boigu, a low-lying mud island inundated by the sea during high tides and storm surges, and those most exposed and vulnerable to climate change have limited livelihood assets and face challenges to secure external support with government and others. Place-based values evoke a reluctance to relocate or retreat with economic losses such as community infrastructure, housing, and cultural sites (McNamara et al., 2017). In the Great Barrier Reef, Australia sea level rise and sea level global temperature warming affects fisheries productivity and tourism (Evans et al., 2016). Unprecedented burn area of wild forest fires in Australia between September 2019 and January 2020 (Boer et al., 2020) burnt almost 19 million hectares, destroyed over 3,000 houses, and killed 33 people (Filkov et al., 2020).

The 2018 European heatwave in Northern and Eastern Europe experienced multiple and simultaneous crop failures—among the highest observed in recent decades (*high agreement*). These yield losses were associated with extremely low rainfalls in combination with high temperatures between March and August 2018 (Beillouin et al., 2020). Across Europe, in 2018 people experienced one of the worst harvests in a generation. Northern and Eastern Europe experienced multiple and simultaneous crop failures—among the highest observed in recent decades. These yield losses were associated with extremely low rainfalls in combination with high temperatures between March and August 2018. This compounding of extreme conditions in 2018 led to one of the highest negative relative yield anomalies at the scale of Eastern and Northern Europe, across a large array of crop species(Beillouin et al., 2020).

Extreme climate events are disproportionately impacting economies of the most vulnerable everywhere (*medium evidence, high agreement*). In the United States, Central America and Caribbean, Hurricanes Katrina, Harvey, Irma, Maria and Michael are examples of extreme climate events that have displaced households, destroyed homes, and led to loss of income among the poor and marginalized (Klinenberg et al., 2020). Puerto Rico was devastated by Maria but received less support from the Federal Emergency Management Agency (FEMA) (García, 2021). Evidence is emerging on unequal governance response in the US versus Puerto Rico (Joseph et al., 2020). Floods, storms and heatwaves have impacted the poorer communities, and even wildfires in California, impact many wealthy groups, also impacted infrastructure used by all, for example, with lengthy electrical power blackouts, but particularly impacted vulnerable to disasters such as undocumented Latino/a and Indigenous immigrants in the case of the Thomas Fire in California's Ventura and Santa Barbara counties(Méndez et al., 2020) Hurricane Irma in 2017 hit Ragged Island in the Bahamas as a category 5 storm leaving the island in ruins and deemed 'unlivable' by its authorities, with most infrastructure left as rubble, no essential utilities remained, schools and health clinics were in ruins and the stench of dead animals was overwhelming. This storm resulted in significant economic loss and damage by the community through loss of their homes, churches, schools, agricultural land, and infrastructure (Thomas and Benjamin, 2020).

Across South America, groups of farmers, children, elderly, Indigenous Peoples and traditional communities are increasingly exposed to floods, droughts, wild forest fires, losses in crop yields, resulting in significant economic costs (*medium evidence, high agreement*) (see Box 8.6). Urban communities, in particular those living in informal settlements, are exposed to heatwaves. In Peru, analysis of water risks posed by climate change in the Vilcanota-Urubamba basin, Southern Peru, seasonal water scarcity and 'Glacial Lake Outburst Floods' (GLOF), pose a serious threat for highly exposed and vulnerable people. It showed that very high risk potentials of 134 current and another six out of 20 future glacier lakes as potentially highly susceptible to outburst floods. A total of eight existing and one possible future lakes indicate future river discharge could be reduced by some 2-11% (7-14%) until 2050 (2100). Farmers, in particular smallholders risk losses to growing irrigated agriculture and hydropower capacity with effects on water scarcity and food security (Drenkhan et al., 2019).

There are additional dimensions of economic losses that are of a more diffuse nature. In particular, climate change is also expected to negatively affect labour supply, particularly in temperature exposed industries (agriculture, mining, manufacturing, construction), due to increases in the number of extreme hot days (Graff Zivin and Neidell, 2014; Garg et al., 2020). Low-income countries have on average a large share of workers in such industries and will thus be especially hard hit. Aside from labour supply, a number of studies also document negative impacts to manufacturing productivity (Acharya et al., 2018; Pogacar et al., 2018; Somanathan et al., 2021). These findings provide a channel to explain macroeconomic consequences of climate change (Burke et al., 2015). However, there are also noneconomic costs in that extreme heat will cause increased discomfort to workers, such as psychological stress, disease and in extreme cases, death among the workforce in developing economies as well as tropical and sub-tropical countries (Ansah et al., 2021).

8.3.4.2 Non-economic (e.g., mobility, wellbeing)

Climate change loss and damage presents an existential threat to some (Boyd et al., 2017). For example the Pacific Island Countries have contributed least to total greenhouse gas emissions, the nations of the South Pacific are highly vulnerable to rising sea-levels, tropical cyclones and other climate-related risks (Nand and Bardsley, 2020). For example across Oceania there is significant risk that sea-level rise will lead to forced relocation. Pacific leaders underscore importance of losses including deep connections between their world views and their land, and that leaving their islands can only be considered an option of 'last resort' (McDonnell, 2021).

Non-economic loss and damage (NELD) is values based (subjective and intangible) and relates to norms, social values and highlights intersectional experiences and perspectives on climate risk. The discourse on loss and damage includes a framing of NELD as loss of human and non-human life and mental and physical health and are experienced widely across the world in vastly different ways associated with social values (Tschakert et al., 2019). There are respectable arguments for the case that all life has intrinsic value (Vetlesen, 2019). The NELD framing of climate impacts highlights that not all risks are measurable. While difficult to measure, there are a growing number of cases of non-economic loss and damage globally (*medium evidence, high agreement*). Illustrative examples of non-economic loss and damage from climate change include the Pacific (McNamara et al., 2021b) and Small Island Developing States (SIDS) in the Caribbean. (Martyr-Koller et al., 2021). For example, the hurricane season in 2017 was particularly extreme resulting in climate-induced displacement with direct implications for non-economic loss and damage, including threats to health and wellbeing and loss of culture and agency (Thomas and Benjamin, 2020).

In the context of the Pacific Islands NELDs are thought of as interconnected and span human mobility and territory, cultural heritage and Indigenous Knowledge, life and health, biodiversity and ecosystem services, and sense of place and social cohesion (Carmona et al., 2017; Ojwang et al., 2017; McNamara et al., 2021b). There are gaps in our understanding of NELD, much of the evidence is from the Global South and at smaller scales (*high agreement*), NELD is not explicitly linked to attribution science yet and evidence often lacks coverage on certain groups (Boyd et al., 2017; Carmona et al., 2017; Ojwang et al., 2017). Non-economic losses are often associated with displacements and migration in terms of climate change and human vulnerability (Section 8.2.1.4), studies show that the impacts of extreme flooding, droughts and/or hurricanes and cyclones that can lead to a sense of lost identity and place, and emotional distress, that are hardly assessed dimensions of impacts and risks (Adger et al., 2014; Barnett et al., 2016; Tschakert et al., 2017; Serdeczny et al., 2018). Non-economic losses are particularly relevant for understanding adverse consequences of climate change on the poor and most vulnerable population groups (*high confidence*). These NELD categories are still overlooked vulnerability assessments and adaptation planning. A novel way to consider NELD in assessments is to interconnect to a sustainable development perspective (Boyd et al., 2017; Boda et al., 2020).

In order to categorise the different types of non-economic loss and damage that exist (Serdeczny et al., 2016), based on their literature review, the authors come up with a set of systematic categories that capture what is usually thought about as having intrinsic value and according this framing of non-economic loss and damage this includes: human life, sense of place and mobility, cultural artefacts, biodiversity and ecosystems, communal and production sites and agency and identity (Serdeczny et al., 2016; Serdeczny, 2019). For example, there is emerging evidence on linkages between slow onset events and mobility decisions, trajectories and outcomes (Zickgraf, 2021). In addition, categories include psychosocial and emotional distress (van Der Geest and Schindler, 2016). For example, research shows potential increased risk of Intimate Partner Violence (IPV) following disasters, noting that societies that are vulnerable to climate change may need to prepare for the social disasters that can accompany disasters revealed by natural hazards (Malik and Stolove, 2017; Rai et al., 2021).

Geographical focus on non-economic losses in the literature is mainly on the Global South with studies mainly smaller in scale (*high agreement*). Many events studied include severe storms, floods and landslides. Key groups affected include low income groups, agropastoralists, women and girls, children and youth, Indigenous Peoples, ethnic and religious minorities. In Europe, the Samis who as a group face significant challenges to health as ecosystems deteriorate (Jaakkola et al., 2018). In Africa, In Zimbabwe storm Idai affected 270,000 people and subsequent flooding and landslides left 340 people dead and many others missing (Chanza et al., 2020). There is evidence of loss of cultural heritage sites where effects of sea-level rise and coastal erosion, the other considering climate change and variability (Brooks et al., 2020). Haile et al. (2013) show flood casualties in Ethiopia include children drowned while playing outside during the 2007 flood period although official data is hard to come by (p. 489). Moreover, loss of place was experienced when many of local houses in Itang built from wood, grasses and mud walls, which are easy to reconstruct building economics are not strong enough to withstand an extreme flood and 38% of the surveyed houses were severely damaged by the 2007 flood. These houses were constructed as an adaptation strategy but could not withstand the floods. In Kenya, Opondo (2013) shows loss of human life was the most severe impact of floods. For example, in the focus group discussion with men, 'it was reported that a boat capsized on River Nzoia at Siginga and ten people died'. (p. 457). In Mozambique, Brida et al. (2013) show loss of sense of place occurred after flooding in the central districts of Caia and Mopeia, flooding had a devastating impact on homes and livestock (Brida et al., 2013). Health impacts of the forest fire impacts in Amazon basin countries have disproportionately affected vulnerable people/social groups (see Box 8.6).

In the literature on non-economic loss and damage there are many examples of loss of life (*high agreement*), one such is in Nepal related to one of the deadliest deadliest landslides in Nepal history resulting in the death-toll of 156 people (van der Geest, 2018). Evidence from landslide Jure and consecutive rainfall in Sindhupalchok in Nepal also indicated that experience with impacts led to harmful mental stress such as fear of new landslides in about 68.4% of people interviewed (van Der Geest and Schindler, 2016). One study in Nepal has shown that almost a quarter (23%) of the households interviewed had sold property including homes, livestock, and heirloom possessions in response to flooding (Bauer, 2013). Human deaths are increasingly associated with losses and damages from tropical cyclones/typhoons Bangladesh, such as the Southern coastal districts of Bangladesh, in particular Khulna and Satkhira (Chiba et al., 2017). Chandra et al. (2017) A case study from Mindanao`, Philippines also reports physical injuries and loss of life in the Philippines from the most powerful typhoon for over a century until 2012, affecting more than six million people, killing at least 1000 people (Eugenio et al., 2016). Beckman and Nguyen (2016) identify the floods 2004 pulled away 24 houses in the commune, loss of families when their houses were flushed away.

An illustrative example is climate-induced loss of wellbeing and (im)mobility in Bhola Slum, an informal settlement in Dhaka, Bangladesh. Research revealed that Internally Displaced People from the southern coast experienced loss of belonging, identity, quality of life and social value produced in people a nostalgia and desire to return home (Ayeb-Karlsson et al., 2020). Another example is of urban climate change justice through the lens of migrants in the Indian cities of Bengaluru and Surat, where experiences of environmental marginality can be attributed to a lack of recognition of citizenship rights and informal livelihood strategies driven by broken social networks and a lack of political voice, as well as heightened exposure to emerging climate risks and economic precariousness. In this case migrants experience extreme forms of climate injustice in their invisibility to formal government and even are actively erased from cities through force or discriminatory development policies (Chu and Michael, 2019). Non-economic loss and damage also includes the loss of social networks that has lasting implications for psychological health as well as for coping with crises following disasters or challenges posed by adverse climate change impacts. For example, many households from Cyclone Aila-affected villages of Dacope and Koyra upazilas of Khulna District in Bangladesh migrated to other places permanently after the cyclone as these affected villages were subject to long-term flooding (e.g., two or three years) following the cyclone. They migrated as they were unable to restore their livelihoods and thus, were unable to secure necessary income for survival (Saha, 2017).

The examples show the multifaceted nature also of intangible and non-economic losses that people experience in the context of climate change and daily risks they are exposed to. Conventional vulnerability assessments cover some aspects that are linked to the likelihood to experience non-economic losses, such as aspects of health, governance, education and in some cases also forced migration and the role of social networks. Overall, both elements of this assessment here underscore that it is not just the climatic stressor, but rather the underlying context conditions that decide whether an extreme event translates into a disaster.

8.3.5 Economic and non-economic losses and damages due to climate change and their implications for livelihoods and livelihood shifts

This section examines the intersections between losses and damages and livelihood shifts. This requires an examination of the differentiated aspects of livelihoods. Understanding economic (e.g., loss of food crops, infrastructure, assets etc.) and non-economic losses (e.g., health, wellbeing, loss of place, agency) and their consequences for livelihoods is important that the intangible aspects clearly become visible and to receive greater attention in loss assessments and in designing adaptation strategies and programmes. Figure 8.10 provides a summary of examples of observed impacts of climate hazards on economic and non-economic capitals and the section assesses livelihood implications across regions. It shows examples of climate hazards attributed to climate change in studies since AR5, across a range of geographical sites for heatwaves, drought, hurricanes, and floods and non-economic losses and damages. The figure 8.10 reveals examples of climate hazards attributed to climate change in studies since AR5 across a range of geographical sites for extreme and slow onset events, such as heatwaves, drought, hurricanes and sea level rise. These are associated with non-economic losses and damages. These figure underscores that non-economic losses and damages lead to significant livelihood threats and livelihood changes. Also limits of adaptation become evident (Chapter 16).

Figure 8.10: Examples of non-economic loss and damage associated with climate hazards attributed to climate change with background on the global vulnerability and symbols with corresponding detail in the table showing examples where non-economic losses have been documented. It is important to note the following. 1. The figure is not exhaustive in terms of examples of extreme or slow onset events or losses. 2. It does not capture undocumented cases in the scientific literature. 3. It is an illustration of the relationship between unequivocal human induced climate change and intangible losses (Adapted from Boyd et al., 2021).

8.3.5.1 Livelihood shifts resulting from loss and damage from climate change

While there are limited studies that directly link economic and non-economic loss and damage from climate change to global-scale in livelihood transformations there is *robust evidence* on the granular linkages, at community, national and regional levels, between losses, coping strategies and livelihood shifts. Across Africa climate change is impacting crop yields, destroying homes and resulting in loss of infrastructure, and leading to non-economic losses associated with involuntary migration and displacement (Olsson et al., 2014), and loss of livestock and assets (see IPCC SR 1.5°C Chapter 3 (Hoegh-Guldberg et al., 2018)), resulting in long-term reduction in the capacity for agriculture and land management. For example, in March 2019 tropical cyclone Idai in Mozambique, Zimbabwe and Malawi led to substantial losses of agriculture, loss of infrastructure, and lack of access for aid and support, all of which contributed to significant displacement in each country (Fischel de Andrade and de Lima Madureira, 2021). Examples of livelihood impacts include livelihood shifts among Kenyan pastoralists to camel husbandry, resulting from household inequalities in assets and changes in relation to weakening of social norms of reciprocity and social cohesion (Volpato and King, 2019).

Extreme climatic events pose serious disruptions to local livelihoods and asset bases and requires them to reconstruct, transform and diversify livelihoods (Uddin et al., 2021). Examples of livelihoods shifts across Asia and Southeast Asia (e.g., India, Bangladesh, Vietnam, Philippines) include rural communities in coastal areas, urban settlements that are experiencing economic losses (high confidence) from for example crop failure and reduced access to fish, which contribute to non-economic losses associated with involuntary migration (Ghosh, 2018) and the malnutrition of children (Siddiqi et al., 2011). Chiba et al. (2017) shows in Bangladesh the connection between mental stress and impacts to the fundamental capacity to sustain livelihoods, such as food and a place to live, due to severe damage to houses, homesteads, properties, livestock and crops, loss of family members and relatives, and anxiousness about securing employment and income in the future. In Bangladesh coastal communities experienced losses in livelihood assets due to Cyclones Sidr and Aila (Uddin et al., 2021) and a significant number of cyclone victims were displaced from their homes by severe cyclones. People have had to change their occupations – both intra- and intersectorally – and confronted increased consumption and social costs. The study uncovered differences in impacts between occupations such as farming and fishing, and the latter was likely to change occupation post-disaster. They also show evidence that local people are learning to live with change and uncertainty by nurturing and combining various types of knowledge and social memory, generating diversified livelihood options, and self-organizing to enhance their resilience to future extreme weather events. In Bangladesh Ahmed et al. (2019) found cyclones, riverbank erosion, salinity intrusion, and floods negatively impacted people's lives by reducing their livelihood options. Their study found when there are limits to adaptation strategies many people turn to 'illegal livelihoods' included using fine mesh nets to collect shrimp fry in the rivers as well as logging in the Sundarbans. These people include the poorest and vulnerable, and law enforcement only exacerbate their vulnerability. Escarcha et al. (2020), studied impacts of typhoons, floods, and droughts on crop production and effects on livelihoods of cash crop focused rural villages in the Philippines. Their preliminary observations show a shift from crop to livestock production as a buffer activity to recover from crop losses. Farmers changed their farming activities as a multi-adaptive response driven by past experiences of climatic changes, farmers' social relations, household capacity, and resources available.

In Central Asia, the Sahel and South Asia, three global poverty hotspots, change impacts were shown to undermine traditional knowledge about livelihoods in ways that jeopardise future culture cohesion and sense of place (Tucker et al., 2015). Acosta et al. (2016) identified loss to productive sites in the Philippines with landslides destroying agriculture leaving many farmers without livelihoods. Similarly, Beckman and Nguyen (2016) in Vietnam identified an example where communal dams had been destroyed in floods leading to lack of irrigation for communal sites and local loss of farmland for farming communities. Chandra et al. (2017) identified the vicious cycle between declining agricultural production and conditions of soil erosion due to floods and droughts resulting in decreased crop fertility to productive sites with implications for decline in crop yields, loss of crops and of livelihood assets. Climate change related extreme weather events such as typhoons, floods, and droughts can have detrimental impacts on crop production (*high confidence*) and in the Philippines and Pakistan have significantly affected the livelihoods of cash crop focused rural villages (Escarcha et al., 2020; Jamshed et al., 2020b). There is an emerging shift from crop to livestock production as a buffer activity to recover from crop losses (Section 5.10.4; Jamshed et al., 2017; Escarcha et al., 2020). As with many examples of livelihood shifts, the viability of the shifts long-term under climate change have yet to be assessed further.

In Africa, many communities do already experience drought and flood-related disasters (high confidence) such as those that negatively impact livelihoods and assets the Muzarabani district of Zimbabwe (Mavhura, 2017). The Muzarabani community has revived and developed new livelihood strategies to manage risks, including local informal safety nets, local farming practices and the traditional flood-proofing structures. Food security and agriculture productivity are examples of livelihood resources most at risk to climate hazards (see Figure 8.2) (*high confidence*). An illustration of such risks to cocoa farmers in Ghana includes increased incidences of crop pests and diseases, wilting of cocoa leaves, high mortality of cocoa seedlings which affected expansion and farm rehabilitation, and wilting of cherelles resulting in losses of crop yield. An illustration of livelihood shifts resulting from losses is of farmers shifting to cereals due to the unpredictable climatic patterns and the shortened duration of rainfall. Yet, insecurity with storage, supply chains and low returns from cereal production, coupled with land scarcity in the Western Region, have resulted in a return to cocoa production (Asante et al., 2017).

Research from Australia shows complex linkages between the impacts of drought on livelihood income, health and cultural heritage, increasing risk of heat stroke, and possibly a link to suicide among male farmers (Alston, 2012; Hanigan et al., 2012; Marshall et al., 2019). The link between agricultural losses and suicides has also been noted in South Asia, including India (Carleton, 2017). Livelihoods are shifting with impacts to wellbeing, as noted by (Evans et al., 2016) showing connections between loss of fishery productivity and impact on tourism sector livelihoods in the Great Barrier Reef region. In Europe, losses to Indigenous Peoples are associated with loss of wellbeing of Sami communities and has forced livelihood shifts from reindeer herding due to loss of ecosystems to support the animals (Persson et al., 2017; Jaakkola et al., 2018). Traditional pastoralist systems are also greatly impacted by cumulative dual challenges of encroachments of other land users and by climate change. Traditional Sami reindeer herding strategies are still practiced, but that rapidly changing environmental circumstances are forcing herders into uncharted territories where traditional strategies and the transmission of knowledge between generations may be of limited use. For example, rotational grazing is no longer possible as all pastures are being used, and changes in climate result in unpredictable weather patterns unknown to earlier generations (Axelsson-Linkowski et al., 2020). These examples show that there are complex factors underpinning the linking loss and damage and shifting livelihoods. Moreover, there are significant challenges to undertake a shift and secure alternative livelihoods.

Linkages between losses, coping strategies and livelihood shifts in Small Islands (e.g., in the Pacific region Kiribati and Tuvalu, and in the Caribbean the Bahamas) shed light on impacted low-income households. For example, farmers have experienced extensive damage to homes and loss of infrastructure, and experience lack of migration opportunities (Curtain and Dornan, 2019). Evidence is growing that there is also significant loss of cultural heritage in resettlement (Barnett and O'neill, 2012), evidence from Small Islands displaced communities suggests that resettlement can have impacts on sense of place, identity and social fabric, a theme highly relevant to loss, coping and adapting livelihoods, and not only restricted to Small Islands (McNamara et al., 2021b). Roberts (2015) identified loss of communal sites in Kiribati and it is predicted that by 2050 up to 80% of the land on the island of Buariki and 50% of the land on Bikenibeu may be completely inundated and these effects will result in significant loss of livelihoods and displacement. Throughout the Caribbean evidence indicates that there will be an overall reduction in the area of land suitable for crop cultivation, as the region’s climate gets progressively warmer and as rainfall becomes more variable (Rhiney et al., 2016).

The multiple shocks of extreme events reduce crop yields, destroy homes, and lead to loss of infrastructure and displacement (high confidence) and are experienced in South and North America. For example in Peru glacial outbursts have led to loss of livelihoods (Drenkhan et al., 2019). People use a range of coping and adaptation strategies to deal with hazards where they live, such as shifting livelihood activities, inputs or production areas. However, traditional techniques are increasingly failing due to changing weather patterns. Across Peru, findings demonstrate that people use temporary and permanent migration among their many coping and adaptation strategies. Hazards related to water excess have been the key force in destroying homes and driving displacement in Peru. On the flipside, studies demonstrate that water scarcity also threatens livelihoods and thereby influences migration in Peru. While non-climatic reasons for moving dominate migrants’ motivations in many areas of Peru, water-related climatic drivers of migration are becoming increasingly relevant (Wrathall et al., 2014). Peru’s smallholder farmers and urban poor are not responsible for the climate crisis, yet their lives and cultural heritage are being increasingly jeopardized by its effects, making improvements in governance an imperative for Peru (Bergmann et al., 2021). Another area of significance is coffee production in Brazil where the majority of Brazilian coffee farms are operated by smallholders, producers with relatively small properties and mostly reliant on family labour (Koh et al., 2020). In the United States (e.g., New Orleans and Puerto Rico) people have lost livelihoods due to displaced households, destroyed homes, and led to loss of income as well as loss of social networks and family networks and loss of cultural heritage. For example, impacts of Hurricane Katrina have led to people being displaced from their employment, many evacuees had to relocate to new areas, which disrupted their social networks and placed them in unfamiliar labour markets, resulting in mental health challenges (Palinkas, 2020). There has also been a 'climate gentrification' in parts of New Orleans (Aune et al., 2020). Many of those who returned to their pre-Katrina areas had to deal with extensive damage to their homes and to public infrastructure.

In summary, across regions there are an increasing number of examples of observed economic and non-economic loss and damage from climate change. Adaptation measures need to better incorporate actions to tackle the burgeoning negative social, psychological and wellbeing impacts of climate change (Barnett et al., 2016; Box 8.5). At present, losses from climate change are potentially growing faster than adaptation measures across the globe. It is still uncertain how economic and non-economic losses trigger successful or viable new climate-related livelihood transitions for the poor and people/groups in vulnerable situations in the future (see Section 8.4.4, 8.4.5). In all likelihood, economic losses from climate hazards (e.g., drought) will be compounded by many factors including COVID-19 and other vulnerability drivers. For instance, globally small-scale coffee producers have been destabilised by COVID-19, but also because of history of recurrent (climate) shocks and structural inequalities, and may have to shift into alternative livelihoods (Guido et al., 2020). Coastal communities in Vanuatu have been impacted in the immediate period after COVID-19 showing changes in village populations, loss of cash income, difficulties in accessing food and experiencing shifting pressures on particular resources and habitats (Steenbergen et al., 2020). This trend poses real challenges to equity and sustainability.

[START BOX 8.5 HERE]

Box 8.5: Western Cape Region in South Africa: Drought Challenges to Equity and Sustainability

Nature of the drought

Between 2015 and 2017, the Western Cape region experienced an unprecedented three consecutive years of below average rainfall—leading to acute water shortages, most prominently in the city of Cape Town (Sousa et al., 2018). Anthropogenic climate change made the drought five to six times more likely (Pascale et al., 2020; see also AR6 WGI Chapter 10, Section 10.6.2). The severity of the drought presented new challenges to the existing management and governance capacity to ensure equitable and sustainable water service delivery. The city's water supply infrastructure and demand management practice were unprepared for the 'rare and severe' event of three consecutive years of below average rainfall (Wolski, 2018; Muller, 2019). Despite a potential total storage volume of about 900,000 ML of water (enough water for around a year and a half of normal usage, after taking evaporation into account), Cape Town's reservoirs fell from 97% in 2014 to less than 20% in May 2018 (Ouweneel et al., 2020; Cole et al., 2021). The drought saw residents queue for water as restrictions were imposed together with threats of closure of water provision to households (Sorensen, 2017; Scheba and Millington, 2018). Poor communication in the early stages of the drought (Hellberg, 2020), and a lack of trust in the administration, contributed to a near-panic situation at the threat of 'Day Zero' as dams almost ran dry in the first half of 2018 (Enqvist and Ziervogel, 2019; Simpson et al., 2020c). 'Day Zero' was avoided largely through public response, water demand management and the 2018 winter rains (Sorensen, 2017; Booysen et al., 2019a; Muller, 2019; Rodina, 2019b; Matikinca et al., 2020). At a household-level, responses to the drought saw everyday residents can display unprecedented degrees of resilience (Sorensen, 2017), including behavioural and attitudinal shifts and technological innovation across the full socio-economic spectrum (Ouweneel et al., 2020). But the private nature of some of these responses extended existing inequality in water access through privileged forms of 'gated adaptation' by elites which conventional water governance arrangements were unprepared for (Simpson et al., 2019b; Simpson et al., 2020a).

These 'climate gating' actions, such as drilling boreholes, secured water access for high-income households and companies, but excluded a large proportion of Cape Town's population who could not afford such private technologies (Simpson et al., 2019a; Simpson et al., 2020b). These responses were unanticipated by the city administration and compounded fiscal challenges faced by the municipality which could no longer use revenues from high-consumption households to cross-subsidise water for low-income households (Simpson et al., 2020a). This shift threatened to undermine the sustainability of the municipal fiscus and general water access (Box 9.8; Simpson et al., 2019a; Simpson et al., 2020a). In order to recover losses, municipal water tariffs for consumers were raised by 26% in 2018 (Muller, 2018; Simpson et al., 2019a). In addition to decline in tourism, median estimations of the overall economic impact of the drought indicate loss of 27.6 billion South African Rand (US$1.7 billion) translating into 64,810 job losses in the Western Cape, with Cape Town accounting for approximately half of those job losses (DEDAT, 2018). This had a disproportionate impact on unskilled and semi-skilled workers, particularly for those from low- and middle-income households (DEDAT, 2018). The drought also exacerbated the potential for sanitation health risks of the urban poor where tens of thousands of people lack access to safely managed sanitation facilities (Enqvist and Ziervogel, 2019).

The Day Zero Disaster Plan included prioritising and protecting the poor and most vulnerable communities where critical infrastructure and facilities and vulnerable and informal residential areas would remain connected while higher income residential areas would be cut off (Cole et al., 2021). Yet it is important to recognise that pre-existing deficiencies in service delivery meant water access for the urban poor did not change as significantly during the drought, particularly those in informal settlements who collect water from standpipes (Enqvist and Ziervogel, 2019; Matikinca et al., 2020). For these communities, the negative economic impact of the drought was compounded by the unintended consequences of demand management regulation emanating from the drought response. South Africa ostensibly ensures a constitutional right to water, regardless of ability to pay (Rodina, 2016), 58). Since 2018 however, as a consequence of new water tariffs instituted during the drought, Cape Town residents now have had to 'prove their poverty' in order to register as indigent households and access their water right (Scheba and Millington, 2018). Further, since 2007 and with increasing effect during the drought, the municipality has installed approximately 250,000 water management devices as a credit control and, during the drought, also a consumption control measure. As these have been largely installed in low-income homes, this control measure disproportionately affected poor households (Scheba and Millington, 2018; Enqvist and Ziervogel, 2019).

Lessons from the drought

The effect of communication at different stages in the drought highlights how critical information needs to be provided in a format and language that empowers people to act appropriately and collaboratively (Muller, 2019; Rodina, 2019b; Rodina, 2019a). Getting political decisions made in a timely fashion and with public support is a long-standing challenge for managers of urban water supplies (Muller, 2017; Muller, 2019). In Cape Town this was further challenged by dependence on a malfunctioning national department for water supply planning, poor coordination between the spheres of government—city, provincial and national governments—and poor collaboration between political representatives, technical experts, and strategic managers (Madonsela et al., 2019; Nhamo and Agyepong, 2019; Rodina, 2019a; Ziervogel, 2019b). This highlights the need to strengthen partnerships and collaboration across sectors and scales of governance (Ziervogel, 2019a) including the adoption of a 'whole-of-society' approach that recognises the contributions of non-state actors as adopted in the Cape Town Resilience Strategy (CoCT, 2019; Simpson et al., 2020a). Experienced yet inflexible water management initially operated at a distance from politicians and their citizens here was limited knowledge and capacity in how various municipal departments thought about risk, exposure and vulnerability of Cape Town's highly-differentiated population(Mukheibir and Ziervogel, 2007; Pasquini et al., 2015; Madonsela et al., 2019). In the later stages of the drought, Cape Town's water management department was able to work collaboratively across different departments and with politicians to implement responses.

The Cape Town case highlights how disaster planning for slow-onset city-wide shocks will be become increasingly important to safeguard equity and sustainability across African cities (Cole et al., 2021). It demonstrates the importance of integrating state and non-state responses to climate change in municipal adaptation and disaster planning (Booysen et al., 2019a; Booysen et al., 2019b; Simpson et al., 2020a), particularly for responses with unintended consequences. Further, water tariff models need to be flexible enough and have built-in redundancies in order to prioritize the needs of the urban poor and ensure climate responses do not disproportionately affect low-income groups and deepen existing inequalities (Scheba and Millington, 2018; Enqvist and Ziervogel, 2019; Simpson et al., 2019b). Systems and relationships of mutual accountability can also build more effective water management between spheres of government and enhance horizontal collaboration between municipal departments and non-state entities (Ziervogel, 2019b; Ziervogel, 2019a).

[END BOX 8.5 HERE]

In summary, this section has moved beyond the IPCC WGII AR5 in laying out structural elements of vulnerability and climate related vulnerability hotspots globally such as poverty, lack of access to basic services, gender inequality and undernourishment. The assessment provides new quantitative evidence about the global spatial distribution of systemic human vulnerability and therewith underscores that various hotspots of countries classified as very high or high vulnerable emerge in regional clusters. In addition, the number of people living in very high and high vulnerable country contexts is significantly higher in some assessments even twice as many as the number of people living in countries classified as low and very low vulnerable. The evidence suggest that statistically relevant differences in fatalities per hazard events are not just a produce of the hazard event, but strongly linked also with the level of vulnerability of a region or community exposed. The assessment of non-economic losses has also received only little attention in past IPCC Assessment Reports, therefore this sub-chapter provides new insights on how (next to measurable economic losses) non-economic losses and intangible losses emerge. These non-economic losses represent an important dimension of societal impacts of climate change that has not sufficiently captured so far within standard damage or post disaster assessments. Finally, the section provides evidence about the existing adaptation gap in terms of differential vulnerabilities and various non-economic losses already experienced.

8.4 Future Vulnerabilities, Risks and Livelihood Challenges and Consequences for Equity and Sustainability

Future climate vulnerability and risks to livelihood security are significantly influenced by present and past development trends, equity and sustainability. Consequently, observed impacts covered in previous sections provide essential insight for enhancing future adaptation and risk reduction. Since the AR5, new research approaches incorporate past lessons to project and assess climate change vulnerability and socio-economic conditions into the future. Scenario tools and methods are a powerful approach for integrated assessments of emissions pathways, associated warming and development contexts, helpful in guiding analysis of adaptation policy and planning (Berkhout et al., 2014; Birkmann et al., 2021a). Both quantitative and qualitative scenario approaches that assess future vulnerability and risks as well as livelihood challenges at global, national and local scales allow experts, planners, decision-makers and affected people to articulate and visualize development futures. These approaches can complement emissions pathway scenarios.

8.4.1 Future exposure, climate change vulnerability and poverty at the global scale

The Shared Socioeconomic Pathways (SSPs) scenarios orient climate models around possible development pathways that produce future exposure patterns, risk probabilities and vulnerability for future populations (O'Neill et al., 2014; O'Neill et al., 2017a). While the likelihood of any given scenario actually occurring is highly uncertain, they have the advantage of pairing with computational models to generate robust projections about risk profiles in possible futures, and therefore assess the relative influence of different drivers of change. In this way, scenario tools generate pictures of future vulnerability and adaptation pathways, and often have both an analytic and normative function. The decision-making context will determine which specific scenario approach is most appropriate (Rozenberg et al., 2014). Scenarios are limited by stakeholders' imaginations, and as such, new emergent challenges, such as the COVID-19 pandemic, are difficult to anticipate in scenario planning. Nevertheless, recent studies and forecasts of the impact of COVID-19 on poverty conclude that in the near and medium-term future major portions of the newly poor will emerge in Sub-Saharan Africa and South Asia (Laborde et al., 2020b; Sumner et al., 2020). Since these countries are already characterized by high levels of absolute poverty and vulnerability to climate change, it is likely that these regions will face more severe challenges in overcoming vulnerability and will be confronted with a growing adaptation gap. Thus, the implication for scenario planning is that single crises or events, such as the COVID-19 pandemic, might not significantly alter existing vulnerabilities, but rather reinforce them.

8.4.1.1 Exposure and vulnerability under different scenarios and alternative development pathways

At the international and national level, the Shared Socio-economic Pathways (SSPs) (O'Neill et al., 2017a) have been developed to outline various development pathways, associated emissions and levels of warming, but also different possible development profiles (i.e., levels of economic growth, poverty, inequality, demographic change, etc.) that are highly relevant for adaptation.

Studies using the SSPs to understand multidimensional poverty are few but growing, and underscore the impacts of climate change on poverty are extremely sensitive to different levels of warming (Byers et al., 2018). Multi-sector risks approximately double between 1.5ºC and 2ºC GMT change, and double again in a +3°C world. Comparing a +1.5°C world pursuing sustainable development (SSP1) to a high-poverty and high-inequality +3°C world (SSP3), Byers et al. (2018) project substantial increases in populations exposed to drought, water stress, heat stress and habitat degradation (see in detail Byers et al., 2018). While in a +1.5°C world exposed populations increase by 7-17%, the increase within a +3°C plus world is 27-51% (Byers et al., 2018; Frame et al., 2018). Populations in Asia and Africa account for more than 80% of the global population exposed to these phenomena, and within South Asia and the Sahel, up to 90% of populations are exposed. Scenario tools help us to understand the burden of increasing multidimensional poverty, and potential for poverty traps, if mitigation and adaptation measures are not taken rapidly and effectively implemented.

At the national and sub-national levels, studies on development and risk scenarios capture specific challenges, for example, urban growth, demographic change, human health and aging (e.g., Dong et al., 2015; Chapman et al., 2019). In this regard, local scenarios of human vulnerability can inform future strategies for adapting to hazards such as heatwaves in cities under different socio-economic development strategies. These scenario approaches allow to focus on changes in climatic and societal conditions as well as urban transformations. This provides a more comprehensive basis for defining adaptation goals (see Fekete, 2019; Birkmann et al., 2021b). Also costs and benefits of different adaptation measures can be assessed against different future scenarios of climatic and societal change.

Contrasting with 'top-down' SSP scenarios, (Berkhout et al., 2014) outline how mesoscale and 'bottom-up' scenarios have been developed to inform spatial planning, for example, in the Netherlands. Increasing computational power has opened possibilities for large-scale 'bottom-up' simulations of people's livelihoods in the context of evolving climate change impacts, such as the migration decisions of farmers facing drought in Mexico over the coming century (Bell et al., 2019) and livelihood decisions of people facing coastal flooding in Bangladesh to the year 2100 (Bell et al., 2021). Such 'bottom-up' scenarios can generate projections about future outcomes, inform mapping and assess future vulnerability, with special emphasis on livelihoods of the poor. Researchers conclude that results of respective scenarios that aim to inform adaptation and risk reduction policies in the context of climate change have to match the frames of the stakeholder (Berkhout et al., 2014; Conway et al., 2019). Scenarios that assess potential future vulnerabilities and future capacities for adaptation require more attention, since many approaches for projecting future climate risk still largely overlook non-climatic drivers that determine future vulnerability and exposure (Windfeld et al., 2019).

8.4.2 The influence of future climate change impacts on future response capacities

The influence of climate change also impacts the future response capacities of people and nations to deal with future climate change and climate hazards. Recent studies (Mysiak et al., 2016) conclude that climate change can increase the severity and intensity of crises or even trigger disasters, particularly floods, storms, forest and wildfires, and droughts, have undermined decade-long poverty reduction efforts, particularly in low income and at-risk countries (Djalante, 2019). Climate influenced (disaster) risks are getting more complex and systemic (UNDRR, 2019). The magnitude of global annual average economic losses from natural and climate induced hazards to the built environment alone are estimated in the United Nations Office for Disaster Risk Reduction (UNDRR) Global Assessment Report (2019) comparable with the gross domestic product (GDP) of the 36th largest economy in the world - the Philippines at that time (in 2015) (UNISDR, 2015; Mysiak et al., 2016). In addition, a World Bank study concludes that losses of human-wellbeing are higher than the overserved economic losses from natural hazards (Hallegatte et al., 2017). In this regard, it is *likely* that future impacts of climate change, particularly under increasing levels of global warming (above 1.5°C) will also increase non-economic losses (see Section 8.3.2.3) and losses of human-wellbeing that are particularly relevant to most vulnerable groups and the poor.

Furthermore, the expected future increase in the number of exposed people to climate hazards, such as sea-level rise and coastal flooding is not only determined by changing hazard patterns, but also by regional processes of migration and urbanization for example in Asia and Africa, including an increasing number of urban poor living in low-elevation coastal zones (United Nations, 2018). This can increase again the probability that more people require assistance and support for buffering these effects of climate related hazards, for example in coastal zones. Historical urbanization processes, in coastal cities in Asia (e.g., in China, Vietnam, etc.) and Africa (e.g., in Nigeria) have increased the exposure of people to climate hazards, such as sea-level rise, which by 2100 under RCP8.5 will globally threaten 630 million people, largely in coastal cities (Kulp and Strauss, 2019).

In addition, Smirnov et al. (2016) conclude that worldwide the number of people exposed to extreme droughts will increase under both the RCP4.5 and the RCP8.5 particularly at the end of the century. The authors assess that under RCP4.5 the average monthly global population exposed to drought will increase between the periods 2008-2017 and 2081-2100 from the mean of 80 million to 212 million, and under RCP8.5 from about 90 million to approximately 472 million people. The research findings underscore that there is a high probability that exposure increases to extreme droughts particularly in regions and countries classified already today as high vulnerable (e.g., Sudan, Nigeria, etc.) (Smirnov et al., 2016). Extreme droughts are expected to further erode coping and adaptive capacities of those already characterized by high levels of vulnerability (see Section 8.3.1). Building adaptive capacities for most vulnerable groups in the future in these areas will be a challenge, since high levels of livelihood insecurity are coupled with high levels of structural vulnerability at national and regional scale (poverty, state fragility, etc.) making planned adaptation support very complex and difficult. Therefore, increasing adaptation gaps at different scales are anticipated in the future.

Increasing population exposure (e.g., due to urbanization of coastal zones, etc.), coupled with higher frequencies and intensities of specific climate hazards are *likely* in connection with the existing adaptation gap (e.g., high levels of vulnerability) to compromise development and human security. Recent studies, such as by Harrington (2018), conclude that the actual exposure and the physical individual recognition of some climate hazards, will be higher in low-income countries. The study of Harrington (2018) underscores that changes in extreme heat, for example, will be felt by the average citizen of a low-income country after 1.5ºC of global warming and will not be felt by about 40% of people living in high-income nations until well after double the amount of global warming is reached (3°C increase). In this context, it is important to note that even if a city or place is exposed to heat stress, people experience it quite differently due to different levels of vulnerability and adaptive capacities, such as the ability to afford air conditioning (Barreca et al., 2016). That means well-off populations are better insulated from effects of global warming than poorer or more vulnerable groups, even if they are geographically living in the same exposure zone. These findings underscore that issues of climate justice need to be considered within the problem definition and not solely at the end when designing adaptation strategies. Impacts of future climate hazards (heat stress, flooding, etc.) differ not only due to changes in frequency and intensity of the hazard itself, but also significantly in terms of the opportunities people have to respond and prepare for these hazards and climatic changes at present and in the future. However, it is also important to note the extreme heat stress has also caused significant fatalities in countries classified as low vulnerable, such as seen within the heat wave in Europe in 2003.

8.4.3 The influence of climate change responses on projected development pathways

Responses to climate change can have dual effects on development pathways. On the one hand, mitigation and adaptation processes can create significant development opportunities. The potential of mitigation policies for jobs creation, in particular, has been highlighted (Healy and Barry, 2017). However, responses to climate change can also have detrimental effects on future development: mitigation policies such as the building of hydro-electrical dams or the culture of biofuels can lead to communities' dislocation and populations' resettlement, particularly of disadvantaged groups within a society (de Sherbinin et al., 2011; Eriksen et al., 2021). Adaptation policies can also hinder some development processes: for example, the promotion of migration as an adaptation strategy can lead to communities being deprived of their workforce, and resenting the departure of some of their members (Gemenne and Blocher, 2017), even though they may offer new livelihood opportunities. However, the migration consequences in the context of climate change are often more nuanced and different trade-offs and benefits occur (see Porst and Sakdapolrak, 2020). For example, remittances support family members, at the same time in some cases these can also create imbalances in local markets (Melde et al., 2017). Evidence exists that some climate responses such as small-scale agricultural livelihood adaptation strategies have improved the ability of people to sustain their livelihood and to reduce poverty (Osbahr et al., 2010).

8.4.4 Social tipping points in the context of future climate change

Climate change has the potential to trigger major, sudden social transformations, yet there are no clear linear relationships between the magnitude of climate change impacts and the social changes they induce(Steffen et al., 2018). Evidence shows that major destabilizing social transformations (e.g., forced migration) can occur in response to limited climate change impacts, even while major climate change impacts can be mitigated through the resilience of social, political and economic systems and thus yield only minor social impacts.

In the context of climate change, 'tipping points' have been identified as critical thresholds at which a tiny perturbation can qualitatively alter the state or development of a system (Lenton et al., 2008; Lenton et al., 2019). The concept of tipping points is usually associated with large-scale components of the climate system that could be pushed past an irretrievable threshold as a result of human-induced climate change (Lenton et al., 2008), such as the deterioration of Antarctic ice sheets (Pattyn and Morlighem, 2020). Social tipping points refer to similar mechanisms of destabilization resulting from impacts of climate change on human societies at multiple scales and the societal context conditions in which these impacts occur. They are reached when climate change impacts force destabilizing social transformations from one state to another (Lenton et al., 2019): from sporadic losses due to climate change to chronic losses and impoverishment, from peace to violence, from a democracy to an authoritarian regime, from adequate food provisioning to famine, or into forced migration. For example, small variations in the rainfall or temperature can jeopardise livelihoods that are dependent upon subsistence agriculture, which can lead to migration and/or tensions around resources (see Figure 8.11). Social tipping points can also occur when intangible elements that ensure the survival of individuals and communities are eroded or removed. This is the case, for example, when the social fabric of a community falls apart. The Millennium drought in Australia led to higher rates of male suicide, especially among farmers, and droughts in Ghana led to similar outcome when people were forced to drink from the same water source as their animals, which they perceived as robbing them off their human dignity (Bryant and Garnham, 2015; Tschakert et al., 2019).

In socio-ecological systems, tipping points occur when a (small quantitative) change inevitably triggers a non-linear change in the corresponding social component of the socio-ecological systems, driven by a self-reinforcing positive feedback mechanisms, that inevitably and often irreversibly lead to a qualitatively different state of the social system' (Milkoreit et al., 2018).

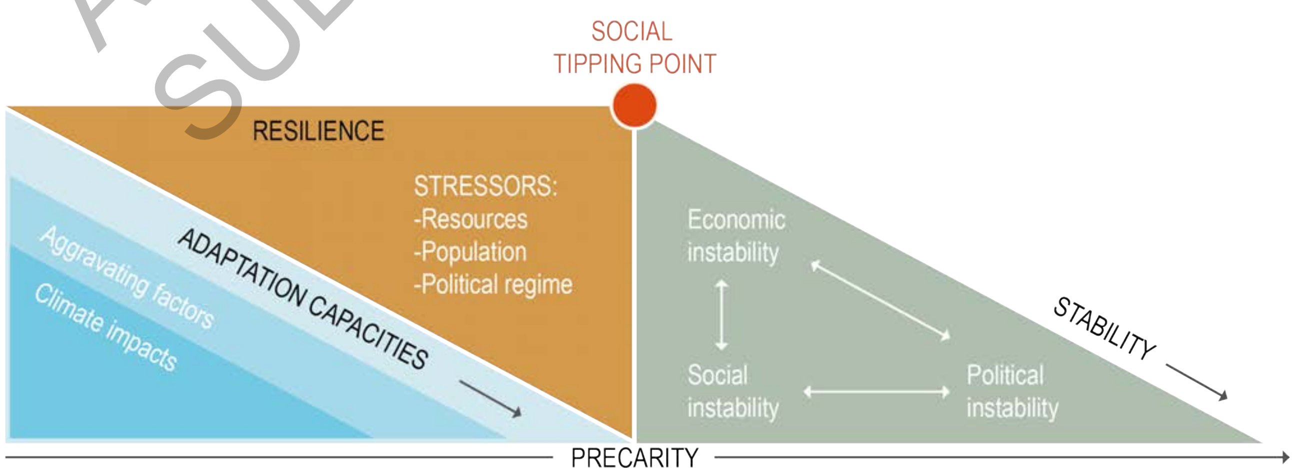

Figure 8.11: A social tipping point is reached when climate impacts push a society towards a state of instability. Those climate impacts are typically aggravated by economic, social and political stressors that reduce adaptive capacity and overwhelm its resilience. Once a social tipping point is reached, a society may experience mutually reinforcing states of economic, social and political instability, leading to cascading disruptions such as livelihoods insecurity, migration and displacement, food insecurity, impoverishment, civil and political conflict, and change of political regimes.

In recent years, significant research efforts have been made to identify early warning signals for social tipping points (Barrett and Dannenberg, 2014; Bentley et al., 2014; Lenton et al., 2019). While some identify early warning signals through time series (Scheffer et al., 2012), others see them in interaction networks and individual thresholds (Barrett and Dannenberg, 2014; McLeman, 2018). Empirical research conducted in a transboundary contentious region—the Jordan river valley—showed that there were significant local and regional differences in the identification of social tipping points (Rodriguez Lopez et al., 2019).

Empirical evidence shows that social tipping points can be triggered long before climate tipping points are reached. For example, recent research in West Africa shows that migration decisions are often based on the perceptions of environmental changes by local populations rather than on the actual observed changes (De Longueville et al., 2020). The migration of some members of a community can also trigger the migration of the whole group, as the migration of some members can have a strong impact on the community (Gemenne and Blocher, 2017). In other contexts, the expectation of a climate impact can trigger social or political shifts: for example, the expectation of lower snow cover levers can reduce or stop investments in ski resorts. Some planned relocations of populations are already underway in anticipation of future climate impacts (de Sherbinin et al., 2011), while the government of Indonesia decided in 2019 to move its capital city, Jakarta, in anticipation of future floods.

Shifting livelihoods is a typical adaptation strategy but can also reflect a social tipping point if this shift affects the community as a whole. Therefore, social tipping points should not be confused with the carrying capacity of a community. Whilst the carrying capacity of a community is a fixed, predetermined limit, social tipping points are dynamic, and constantly evolving under the influence of different social and political factors—such as solidarity networks or governance mechanisms. The carrying capacity of a community can evolve over time, but remains a static concept, unlike social tipping points. Social tipping points have also been applied to adaptation, through the concept of adaptation tipping points, which indicate how much pressure a socio-environmental system is able to absorb (Ahmed et al., 2018). Beyond the adaptation tipping point, the efficiency of adaptation responses will be limited, and can even transform into maladaptive options.

8.4.5 Projected risks for livelihoods and consequences for equity and sustainability

8.4.5.1 Projected risks for livelihoods

There is *robust evidence with high agreement* that future climate change impacts will have severe consequences for poor households, particularly those situated in areas highly exposed to actual or future climate hazards, such as low lying coastal communities (see also Cross-Chapter Paper 1 COASTS), drylands (see also Cross-Chapter Paper 3 DRYLANDS) or remote mountain (see also Cross-Chapter Paper 5 MOUNTAINS) settlements with low levels of connectivity to markets, poor infrastructure and high dependence upon poor quality natural capital (Barbier and Hochard, 2018; Gioli et al., 2019). While livelihoods operate in a dynamic context characterised by multiple interacting structures and processes, climate change can act as a risk multiplier. When current livelihood activities become untenable as a result of both long trends and short-term shocks and climate hazards (e.g., droughts, floods), shifting livelihoods is a common response and in many cases can be unavoidable due to the negative consequences of these climate hazards on specific livelihood capitals (see Section 8.5). Such shifts can involve a change in livelihood activities (e.g., continuing in agriculture but growing different kinds of crops), or a change to broader livelihood strategies (e.g., diversifying into handicrafts or paid employment, specialising in one particular activity, or migrating, seasonally or permanently in search of other livelihood opportunities) or even an entire change of the livelihood activity, for example, abandoning agriculture altogether (McLeman and Smit, 2006; Black et al., 2011). Shifting livelihoods can therefore involve mobility or take place in situ. Some of these shifts also lead to social tipping points.

8.4.5.1.1. Proactive and reactive livelihood shifts and their relevance for future risks due to climate change

Livelihood shifts may also take place proactively as new opportunities emerge and reduce climate impacts by providing buffers of financial capital. For example, (Hirons, 2014) assesses artisanal and small-scale mining as an emerging livelihood opportunity in Ghana. Evidence challenges the popular assertion around the idea of wealth seeking for short term profit and reveals an alternative scenario whereby artisanal and small-scale mining can be a poverty-driven activity, particularly in areas in which agricultural employment has not delivered sufficient income or where crops are highly exposed and sensitive to climate change impacts. Income from new livelihood activities can support recovery following specific events (major flooding or drought) linked to climate hazards and climate change. Livelihood shifts therefore take place in a highly dynamic and heterogeneous context. Another example comes from (Okpara et al., 2016a) the Small Lake Chad, Republic of Chad. Fluctuating water levels linked to seasonal flood pulses and droughts were shown to link closely to livelihood dynamics. Lake drying led to new adaptive behaviours based on seasonality (e.g., migration of herders to different areas of the lake shore to access water resources, in line with more predictable seasonal changes) as well as linking to opportunism supported by climate change impacts. For example, during times of lake flooding, new opportunities for fishing opened for people that were otherwise operating primarily as pastoral or agricultural households. However, these kinds of livelihood shifts remain largely reactive and can bring negative as well as positive impacts. In the Lake Chad case, it resulted in social clashes between different groups, while in other examples from Tanzania, livelihood shifts towards extensification of farming led to deforestation (Suckall et al., 2014), which could constitute a maladaptive shift. Such findings have important implications for the types of government and institutional support that can enable livelihood shifts and highlight the need to consider trade-offs for climate change mitigation, as well as with other adaptation options (see Section 8.6).

8.4.5.2 Future risks, vulnerabilities, differentiated inequalities and livelihood shifts

Overall, there is *high agreement* that future climate change impacts are going to worsening poverty and exacerbating inequalities within and between nations with projections that by 2030 these will increase significantly (Olsson et al., 2014; Hallegatte and Rozenberg, 2017; Roy et al., 2018). In addition, the COVID-19 pandemic and consequences linked to measures to reduce the spreading of the virus are *likely* to increase poverty, particularly in regions already facing high levels of vulnerability and poverty (Laborde et al., 2020b; Sumner et al., 2020).

Key risks due to future climate change, exposure and vulnerability are difficult to assess and are based on evidence from the past and *likely* future vulnerabilities and livelihood challenges. The assessment of Representative Key Risks (see Section 16.5.2.3.4) underscores that risks to living standards are potentially severe as measured by the magnitude of impacts in comparison to historical events or as inferred from the number of people currently vulnerable (see in detail Chapter 16). Table 8.4 provides an overview of what is known in the literature assessed about future risks, inequalities and particularly future vulnerabilities, including potential challenges for climate justice and adaptation barriers. For example, barriers for gender, ethnicity and class have been addressed for a long time yet need substantive intervention. Gender, along with many other structural inequalities (Table 8.4) that are deeply rooted, pose future threats to people/groups in vulnerable situations from, for example, the loss of land/assets, exposure to extreme events and so on. These people will also *likely* be highly exposed to future climate risks unless there are significant and new avenues for action on climate change now. For example, recent studies suggest that the total population of all countries classified as most highly vulnerable is projected to grow significantly. A study using 5 vulnerability categories globally concludes that the total population of all countries with very high vulnerability (see Figure 8.6) is projected to increase from 2019 numbers approximately by 102% by 2050 (i.e., roughly double) and 257% by 2100, while the population of all countries with very low vulnerability is projected to decrease by 9% by 2050 and 17% by 2100 (based on UN medium probabilistic projections). Another study estimates that the total population of all countries classified at most vulnerable (top 2 categories; using 7 vulnerability categories globally) is predicted to increase by 82% by 2050 and 192% by 2100. In contrast the population of all countries classified as least vulnerable (bottom 2 categories) is projected to only increase by 9% by 2050 and 1% by 2100 (see in detail UN-DESA, 2019; Birkmann et al., 2021a; Birkmann et al., 2022).

That means that, based on current population growth estimates and if vulnerability levels are not reduced significantly, more people will be living in more vulnerable context conditions in the future compared to those living in less vulnerable contexts. This is independent of the development of climatic hazard exposure. If significant reductions of vulnerability are achieved, this projection will change. However, the vulnerability and poverty of some regions and countries has proved over decades to be persistent, such as Haiti or Afghanistan. Consequently, the estimated future population growth is another factor that points towards the urgent need to reduce vulnerability and to narrow the adaptation gap.

While future adaptation options can also encompass measures or tools that emerge in future, most of the future adaptation options and their relevance for reducing vulnerability, poverty and inequality are known. Evidence exists that the importance of social networks that organise social protection and leverage resources in terms of reducing risks to climate change is increasing, particularly for most vulnerable people/groups in countries that have limited social security measures in place.

Table 8.4: Summary of interlocking categories differentiation future risks, vulnerabilities, inequality and adaptation

Future risks	Inequalities	Future vulnerabilities, future livelihood, future exposure (examples)	References
Increasing risk of displacement and damages to women and girls in floods	Gender inequality leaves women and girls hidden, forgotten, exposed, resulting in displacement impacts and limited resources, including social capital and increasing risk of human trafficking	Increasing future vulnerability of Women and girls due to high hazard exposure; gender differentiated vulnerability to urban flood in India); Increasing risk of human trafficking associated with exposure to future extreme events	(Singh, 2020; Cross-Chapter Box GENDER in Chapter 18)
Increasing risks of exacerbating inequalities and tensions	Differentiation based on Ethnicity and race leads to groups in society less visible, less rights, in particularly livelihoods that expose them to extremes. Unequal access to adaptation opportunities and benefits.	Increasing future vulnerability of Indigenous Peoples due to exposure to extreme events. Communities of colour are *likely* to be exposed to increased climate change impacts, e.g., differentiated health impacts on black and hispanic communities heat-related mortality rates and poverty for neighborhoods in New York City.	(Hsu et al., 2021; Section 8.3)
Increasing risk of loss of homes and assets in the case of floods	Class differences in exposure and awareness of flood risks. Lower caste disproportionately impacted by climate change	Increasing differentiated exposure among classes to events such as flooding.	(Jones and Boyd, 2011; Fielding, 2018)
Risks to loss of lives in cases where there is no agency	Religious and beliefs impact experience of climate change	Increasing vulnerability to climate change among different religious groups.	(Schuman et al., 2018)
Risk of premature mortality, risk of loss of livelihoods in employment	Age and aging populations. Elderly and young are disproportionately impacted by climate change, e.g., heatwave in France 2003 and Japan 2018. Youth	Increasing future vulnerability among elderly, underage youth and children vulnerable to increasing risks of health	(Hsu et al., 2021; Section 8.3)

	underemployed or in vulnerable livelihoods could be vulnerable to climate related risks which adversely affects the economy.	impacts of pollutants or floods, heatwaves	
Risks to mobility in a climate extreme	People with disabilities, for instance shows evidence emerging in the disaster risk reduction and humanitarian sector.	Increasing risks to people with disabilities disadvantaged exposed to extreme events. .	(King et al., 2019)
Risks of isolation for communities remote from centres of power	Geographical exposure. The location of people and societies within a particular territory is a determinant of inequality e.g., disruptions to food supplies to the Caribbean when there are climate extreme events.	Increasing risk and exposure among communities remote from urban centres far from resources and exposed to climate impacts	(Section 8.3; Cross-Chapter Box GENDER in Chapter 18)
Risks of food insecurity	Differentiation of asset / ownership / access among groups where unclear status.	Increasing risks to tenurial landless. If tenurial status is unclear, groups may experience loss of land and displacement.	(Section 8.2; Cross-Chapter Box GENDER in Chapter 18).

8.4.5.3 Future limits to adaptation

Local perceptions of losses from adverse effects of climate variability and change can help to assess the magnitude of impacts that individuals and communities have not been able to cope with or adapt to (James et al., 2014; Barnett et al., 2016; McNamara and Jackson, 2019 McNamara et al. 2021, Mecheler et al. 2020).

The IPCC Special Report on a 1.5°C warming world shows with *high confidence* that for the Arctic systems, if average temperature increase exceeds 1.5°C by the end of the century, compromising people's livelihoods and will exceed limits to adaptation and residual impacts can be expected (Ford et al., 2015; O'Neill et al., 2017b; Roy et al., 2018; Hoegh-Guldberg et al., 2019a). The loss and degradation of the Amazon forest concerning global warming temperatures (beyond 1.5°C) is another clear example of irreversible loss, with significant impact to people's livelihoods today and in the future (Hoegh-Guldberg et al., 2018; Roy et al., 2018). Moreover, the losses and damage from climate change impacts are also felt heavily by women, children and elderly given the intersectionality with socio-economic and gender inequalities (Li et al., 2016; Roy et al., 2018). For instance, gender and wealth inequality offers challenges to scale up the Maasai pastoralist community autonomous adaptive practices (Wangui and Smucker, 2018). These authors found that most female-headed and poorest households couldn't access the land, water for irrigation, and financial assets required to access adaptive practices that are available in the wider community. Consequently, future impacts of climate change are *likely* to increase rather than decrease inequality based on already observed impacts on adaptive capacities that constrain also future adaptation options particularly for the poor (Roy et al., 2018).

8.4.5.4 Future livelihood challenges in the context of risks and adaptation limits

The climate change risks in this section are addressed through the lens of livelihoods, human, food, water, and ecosystem security, building on key impacts and risks since AR5 (Oppenheimer et al., 2014), and key findings from SR1.5°C (Hoegh-Guldberg et al., 2018; Roy et al., 2018), SROCC (IPCC, 2019b), and SRCCL (IPCC, 2019a). The AR5 WGII risk tables (IPCC, 2014b), updated in SR1.5°C (Roy et al., 2018) offer an interesting entry point as it shows high confidence on key observed impacts and limits to the adaptation of natural and social systems that are compounded by the effects of poverty and inequality on water scarcity, ecosystems alteration and degradation, coastal cities in relation to sea-level rise, cyclones and coastal erosion, food systems and human health (Hoegh-Guldberg et al., 2018; Roy et al., 2018). As a consequence, the climate change risks substantially pose negative impacts on climate-sensitive livelihoods of smallholder farmers, fisheries communities, urban poor, Indigenous Peoples, informal settlements, with limits to adaptation evidenced on the loss income, ecosystems, health, and increasing migration (Roy et al., 2018). The compounded effects of socio-economic development patterns and climate change impacts are worse experienced among climate-sensitive ecosystems in the Arctic and Small Island Developing States (SIDS) (Roy et al., 2018). The future risks to these climate-sensitive ecosystems and livelihoods are potentially severe given their current high exposure to climate hazards, and high number of vulnerable of people exposed for example in the SIDS (see also Chapter 16 Living Standard; (Ahmadalipour et al., 2019); Liu and Chen 2021). Residual losses then may be unavoidable for some ecosystems and livelihoods affecting the vulnerable groups of people and countries as consequences of structural poverty, socio-economic, gender, and ethnics inequalities, that marginalize and exclude and limit the development of adaptive capacity for future changes (Olsson et al., 2014; Roy et al., 2018).

In Small Islands States (SDIS) key risks are represented by losses of livelihoods of coastal settlements, ecosystem services, infrastructure, and economic stability, exhibiting limits to adaptation in face of local's coping strategies capacity (Hoegh-Guldberg et al., 2019a). There is *high confidence* that sea-level rise in SIDS combined with extreme flooding events will threaten the future livelihoods of coastal communities (Hoegh-Guldberg et al., 2018; Roy et al., 2018).

In the global south, the increasing heat associated with warming of global temperature represents an important risks due to losses of labour productivity, crop failures and livelihood security, involving economic losses, and health effects as well as increasing deaths that are anticipated to have significant implications for poverty, inequality and equity (Carleton, 2017; Roy et al., 2018). The increasing temperature, droughts, and excessive rain lead to successive crop failures and lack of productivity that are affecting children's growth and health in developing countries (Hanna and Oliva, 2016). Likewise, the expected global temperature increase by the end of the century will have devastating health consequences for children, associated with sea-level rise, heatwaves, and incidence of malaria and dengue, and malnutrition, especially in Asia (Ghosh et al., 2018) and African countries as Chad, Somalia, Niger and Mali (Hanna and Oliva, 2016; Ghosh et al., 2018; Clark et al., 2020).

The incidence of floods also increases the occurrence of diseases (e.g., diarrhoea and respiratory infections) and undernutrition in children living in informal settlements and slums in Asia (Ghosh, 2018) and Africa (Clark et al., 2020). Women and children are currently bearing the worst impacts from climate hazards, and are unable to move due to assigned gender roles to avoid flooding risks in highly vulnerable slums in Bangladesh, causing them emotional distress and poor living conditions (Ayeb-Karlsson et al., 2020). In this region, the experienced severe floods associated with death, injury, infectious disease, mental and emotional stress and cultural disruptions—dimensions of noneconomic losses are often not accounted for in the disaster relief policies (Chiba et al., 2017) and these severely influence the ability to build adaptive capacities for future hazards (Roy et al., 2018). In the same way, risks to female-headed households with insecurity in tenure rights is greater, as these group were the most affected by flooding in 2018 in Dar es Salaam, Tanzania, that cost 3-4% of the country's gross domestic product (GDP) and affecting 4.5 million people (Erman et al., 2019).

In the Himalayas mountain range (part of the Hindu-Kush Himalaya, HKH) temperature warming is expected to increase up to 2°C by 2050 (*high confidence*), increasing flooding and bringing larger risks to food and water security on mountain communities that are already highly vulnerable given limited livelihood options and supporting infrastructure in these regions (Mishra et al., 2017). In Nepal, agriculture-oriented livelihoods are reported to be negatively affected by an increase in landslide frequency (92.6%) and intensity (97.3%) over a 20 years period (1996-2016) (van Der Geest and Schindler, 2016). The catastrophic landslide in 2014, the material losses experienced by poor households were 14 times greater than their annual gains associated with loss of crops and land; The NELD losses were emotional distress and fear of new event occurrence, showing that most poor households may not fully recover in their lifetime post an extreme event. This example is indicative of the representative future climate risks to these populations; Albeit livelihood diversification is commonly adopted by the poor households to reduce the impacts of extreme rainfall and landslides smallholders in Nepal, there are limits to these strategies given poor household infrastructure that challenge risk reduction and as so it is expected that migration to neighbouring countries as Bhutan or India will increase (van Der Geest and Schindler, 2016).

Expected future risks to vulnerable communities and Indigenous Peoples includes losses across a range of impacts. A larger household comparative analysis across countries in Southeast Asia, Africa, and Asia Mountain regions shows that more than 60% of the population reported losses from residual impacts concerning droughts, floods, cyclones, sea-level rise, glacier retreat, and desertification, despite autonomous adaptation involving changing food consumption, and relying on formal aid from government support (Warner and Van der Geest, 2013). Among Indigenous Peoples across the Global South as in the Brazilian Amazon, Australia and Botswana, locally autonomous adaptive measures, were not sufficient to avoid significant losses (some irreversible in case of lost habitats). The barriers and insufficient adaptive capacities are also intrinsically linked to historical marginalization and vulnerability of the population in these countries (Maru et al., 2014).

In the Arctic, temperature warming, and sea level rising constitute a key risk to the loss of identity and culture of Indigenous People, associated to migration and or relocation due to livelihoods deterioration from coastal erosion, permafrost thaw, and reduced fisheries productivity (Roberts and Andrei, 2015; Roy et al., 2018). These risks and losses often encompass various non-economic losses, such as the loss of identity that cannot be replaced or economically compensated (see also Section 8.3.5).

Likewise, in the Amazon basin, climate change hazards of severe droughts and floods (*high confidence*) (Cox et al., 2004; IPCC, 2019a), are exhibiting limits to adaptation among the majority of riverine communities, and smallholders farmers with residual impacts associated with losses of income, fisheries, and agriculture productivity as well as affecting non-economic livelihood dimensions, such as the ability to attend school and losses of place and identity through forced migration (Maru et al., 2014; Pinho et al., 2015; Lapola et al., 2018). Furthermore, the expansion of the agricultural frontier and construction of large dams to supply energy needs in the Amazon basin are amplifying the vulnerabilities and reducing future adaptive capacities, of smallholders, and the fisheries communities to climate risk (Bro et al., 2018; Castro-Diaz et al., 2018). It is expected that the global temperature warming level of 2ºC by 2050 in the Amazon will lead to a significant reduction of major rivers' water flow and leading to further food and water insecurity (Betts et al., 2018) likely to affect forest and river dependent livelihoods in the Region (Box 8.6; Lapola et al., 2018).

The glacier retreat associated with the increase in global warming temperature has also shown losses that are permanent and related to a sense of belonging and cultural heritage for the Glacier countries but with the most negative livelihood impacts experienced among poor households in the Peruvian Andes and Himalayas (Jurt et al., 2015). The risks for the glacier smallholder's livelihoods are expected to increase in the future once the shrinking glaciers are expected to increase water competition, crop failure, and extreme flooding (Kraaijenbrink et al., 2017). For example, in Bhutan adaptive measures such as changing crops, developing irrigation channels, and sharing water among the community members still insufficient to avoid loss and damage associated with the dramatically reduced water availability (Kusters and Wangdi, 2013; Warner and Van der Geest, 2013). In high Mountain Regions, the intersections of agro-pastoralists marginalization, difficult in access, and ecological sensitivity contribute to residual impacts associated with extreme climate hazards which can lead to irreversible losses and challenge poverty reduction efforts (Mishra et al., 2019).

In semi-arid West Africa, poor households have in place longer term local adaptation to deal with severe droughts that involves reducing household and cattle water consumption, planting drought-tolerant crops, and adopting integrated crop-livestock for efficiency, with migration either seasonal and or permanent mostly effective (van der Geest et al., 2019). Likewise, Senegal, Ethiopia, and Northern Kenya adaptation have advanced with external government and non-government organisation (NGO) support (Schäfer et al., 2019), including technological innovations and insurance to households (Schäfer et al., 2019) but not enough in preventing losses to already impoverished households (Schäfer et al., 2019).

There is *robust evidence* that future risks to climate-sensitive livelihoods as agriculture, livestock and fisheries are amplified by gender, age, and wealth inequalities (Wangui and Smucker, 2018), ethical background and geography (Piggott-McKellar et al., 2020; Thomas and Benjamin, 2020) as well as by ecological thresholds that challenge autonomous adaptation among vulnerable disadvantaged communities mostly in the Global South (Roy et al., 2018; Mechler et al., 2020).

The assessment also points towards the fact that there exist strong linkages between national level vulnerability (see e.g., Figure 8.6) and individual vulnerability at household or livelihood scale. Various disadvantaged and marginalized groups or communities within a society are significantly constrained in terms of the ability to build adaptive capacities for future climate change threats due to limited access to resources or government support for planned adaptation. Consequently, these linkages between regional, national and local vulnerability need more attention in research and practical adaptation strategies (vertical integration).

The next section discusses how risks emerge as a result of the failure in adaptation or when it is not implemented, with particular attention to risks that are impossible to adapt to and lead to inevitable loss and damage among the poor households, livelihoods and countries.

[START BOX 8.6 HERE]

Box 8.6: Social dimensions of the Amazonia Forest Fires and Future Risks

The Amazon ecosystem, together with the Arctic, is listed as the first out of five IPCC Reasons for Concern (RFCs) due to climate change, given the *high confidence* level that different temperature warming and greenhouse emissions will offer significant risks that threaten these unique ecosystems (O'Neill et al., 2017b; Roy et al., 2018). In addition to the scientific evidence, a resurgence of cross-national collective expressions about the fate of the Amazon forest, Indigenous Peoples and traditional communities, in the context of an unprecedented climate crisis and sustainable future, have gained pronounced importance. On 19 August 2019, the skies of Sao Paulo State were dark by 3pm due to the formation of a 'smoke corridor' associated with the extensive burning of the Amazon forest (Seymour and Harris, 2019). The fire outbreaks were a consequence of multiple factors related to political, social, economic and environmental scenarios concomitant with the weakening of environmental governance such as control and monitoring of deforestation and fire incidences programs (Escobar, 2019; Seymour and Harris, 2019). The deforestation rate and incidences of fire are both increasing in the Amazon of Brazil, Colombia and Peru (Seymour and Harris, 2019). Accordingly, 2019 registered an increase of 60% on the number of cumulative fire count in Brazil, Bolivia and Peru in comparison with the same period in 2018, and a 12% increase in comparison with the same period in an extremely dry year in 2016 (GFED, 2019). In this context, looking at this case study through the lenses of poverty, inequality and the Sustainable Development Goals (SDGs) addresses the compound effect of climate and land-use change in the Amazon forest fires and its cascading impacts and risks on the social domain in the region. There is evidence that both climate and land-use change impacts and risks are disproportionately borne by poor and vulnerable ethnical groups, remote rural communities and poor urban households in the Amazon(Pinho et al., 2015; Brondízio et al., 2016; Mansur et al., 2016; Pinho, 2016).

Fires are not a natural phenomenon in the Amazon region (Bush et al., 2004; McMichael et al., 2012) albeit used for food security, hunting and religious rituals among Indigenous Peoples and traditional communities (Hecht, 2006; Carmenta et al., 2019; da Cunha, 2020), and also as a widespread technique for land clearing for small and large-scale farms for agriculture (Morello et al., 2019). The dramatically increased forest burning observed in the Amazon recently are the results of illegal land grabbing, the small and large-scale cattle ranching sector and agribusiness practices coupled with loosening land tenure policies and decision making neglect of deforestation and burning monitoring data (Nobre et al., 2016; Lovejoy and Nobre, 2018; Leal Filho et al., 2020a). The fire outbreaks intensified substantially to the point that in August 2019 there were approximately 3500 fires in 148 Indigenous territories (DETER and INPE, 2019; ISA, 2019). Although most of the burning in the Legal Amazon in Brazil occurred on private land of medium and larger sizes (about 67%), around 33% was observed within Indigenous territories and protected areas called conservation units (UCs) (DETER and INPE, 2019; ISA, 2019). In 2019, 40% of the deforestation occurred in public forests, which encompasses undesignated forest lands, Indigenous territories and conservation units (UCs). This deforestation came accompanied by fires: 18% of the 2019 fires occurred on undesignated lands, 7% on Indigenous territories and 6% on UCs, where many traditional populations live (Alencar et al., 2020). It is also important to note that during 2019, 46% of the deforestation and 52% of the fires occurred on private rural properties and settlements, respectively, where the legal accountability of these crimes is possible. The 2020 deforestation rate presented an increase of 47% and 9.5% compared to 2018 and 2019, respectively, and was the highest in the decade (Silveira et al., 2020). The clear-cut inside indigenous territories more than doubled from 2018 to 2019 (Brasilis, 2021) and despite it decreasing from the 2019 rate, during 2020 it was the highest since 2008. It has been demonstrated that on average, at least 50% of yearly active fires being up to 5 km from deforested areas in the same year, reaching 74% during 2019 (Silveira et al., 2020). This means, that fires and deforestation have an increased threat to indigenous population (Oliveira et al., 2020), particularly during the year 2020 and currently in 2021 since, COVID-19 and air pollution from agricultural burnings greatly impacts respiratory health in the Amazon (Morello, 2021).

Health impacts, economic and non-economic losses

The health impacts and economic losses estimates are not homogeneously gathered for the entire Amazon basin countries, but some recent evidence associated with this knowledge gap shows the magnitude of the forest fire impacts, as well as where they spatially occur and who are the most affected by it. Fires associated with deforestation in the Amazon have been related to 1065-4714 deaths annually in South America (Reddington et al., 2015). The recent fires in the Amazon basin are directly affecting 24 million Amazonians with the worst impacts felt by children, and the elderly (Machado-Silva et al., 2020). Indigenous Peoples and traditional communities (Fellows et al., 2020). Children under five years old and the elderly in rural areas are respectively 11 and 22 times more affected by the smoke from fire outbreaks and temperature increase in the Amazon (Machado-Silva et al., 2020).

In the Acre State, the fire incidence coupled with extreme droughts in 2005 and 2010 led to an increase—from 1.2% to 27%—in hospitalizations of children (under 5 years) due to respiratory diseases (Smith et al., 2015). The same evidence was found among the rapidly deforested areas known as ‘Arc of Deforestation’ that have dramatically led to a higher number of respiratory diseases mainly in children under 5 years (do Carmo et al., 2013). There is also evidence for interlinked dynamics between deforestation, urbanization and incidence of fire episodes providing an appropriate environment for *Anopheles darlingi* vector propagation and the increased incidence of malaria in the region (Hahn et al., 2014). In the 2005 drought, burning in Acre alone recorded 400,000 people affected and the loss of 300,000 hectares of forest with direct costs of US$50 million (Brown et al., 2006). In 2010, the fires during the drought were approximately 16 times larger than that in the meteorologically normal years (Campanharo et al., 2019). The estimated total economic loss in 2010 was about US$243.36 ± 85.05 million, representing 9.07 ± 2.46% of Acre's gross domestic product (GDP) (Campanharo et al., 2019). The economic and non-economic losses associated with the impacts of climate change and future risks of fires outbreaks on native food crops (açai, guaraná), livelihoods, tourism, medicinal and spiritual sites, culture, migration patterns, place-based attachments, emotional and mental distress among the most affected and vulnerable population as Indigenous Peoples and traditional communities are still to be fully estimated for the region (Pinho et al., 2015; Brondízio et al., 2016). Also relevant is a trend of Amazonian forest fires spreading from the southern Brazilian Amazon to Bolivia and Peru, indicating that transboundary burning increases are systemic and will lead to extensive economic losses of wildcrops, infrastructure and livelihoods, and requiring a landscape level approach for deforestation and fire management and control (Kalamandeen et al., 2018).

Future vulnerabilities and risks for Indigenous Peoples and traditional communities

In the future, it is expected that by 2030 the incidence of extreme droughts in the Amazon will increase the costs of the health sector associated with treatment costs of respiratory diseases (20%-50%) and malaria incidence (5%-10%) incurring a high social cost as people will be impaired to carry out their livelihoods (Lapola et al., 2018). It is also expected that extreme droughts in the Amazon by 2030 will accelerate and intensify rural (traditional communities and Indigenous Peoples) migration to urban centres where their living standards are expected to decrease once they will occupy marginal areas within larger urban centres (Lapola et al., 2018).

In terms of adaptation and risk reduction, priority should be given to strengthening multi-scale governance and partnerships among different private and public actors. Also policies at national and sub-national levels are needed, such as control strategies to reduce deforestation and fire incidence, demarcating new Indigenous territories, payment for ecosystem services (REDD+) and investment in traceability for commodities productive chain market are needed (Morello et al., 2017; Scarano, 2017; Carmenta et al., 2019; Seymour and Harris, 2019). The increase in global temperature level up to 2°C will exacerbate food and water insecurity in the Amazon (Betts et al., 2018; Hoegh-Guldberg et al., 2018) (*medium confidence*). Thus, curbing fire incidence and deforestation rate will make it easier for the Indigenous Peoples and traditional and vulnerable population to reach the Sustainable Development Goals (SDGs), especially in terms of reducing poverty (SDG1), food security (SDG2), wellbeing and health (SDG3) and protecting terrestrial ecosystem (SDG15) (Roy et al., 2018).

[END BOX 8.6 HERE]

8.4.5.5 Maladaptation as a projected future risk particularly for the poor and marginalized

There is increasing evidence that maladaptation can lead to future risks to socio-ecological security when adaptation measures focusing on short -term action that may lead to adverse longer-term impacts to livelihoods and failures to address transboundary scales to avoid negative consequences for social and ecological systems (Warner and Van der Geest, 2013; Roy et al., 2018; Mechler et al., 2019a; see also Section 5.13.3). Hence, maladaptation can intensify and even accelerate future risks as a result from climate change mitigation and adaptation policies when responses to climate change hazards are embedded within 'business as usual' development approaches (Work et al., 2019). For instance, in Cambodia, the conventional development strategies intertwined with climate change mitigation and adaptation initiatives are increasing the probability of maladaptive outcomes in a context of high informality, and conflicts among poor farmers exposed and vulnerable to flooding (Work et al., 2019). The potential for maladaptation emerges from the vulnerability of precarious living conditions of poor farmers in informality, not accounted for in climate mitigation and adaptation strategies for irrigation, protected areas management and reforestation projects funded by multilateral donors (Work et al., 2019). (Work et al., 2019). As a consequence, losses emerge despite actions to prevent adverse impacts and maladaptation instead became a vector of increased vulnerability for poor and vulnerable communities (Mechler et al., 2019a).

The maladaptation outcome also emerges as a failure of adaptation. In Ghana, poor farmers in face of crop yield failure during severe droughts further exacerbate water use for irrigation and livelihood diversification, including selling firewood for charcoal production, forms of maladaptation as it can furthering increasing their vulnerability to climate risks, compromising food production, income generation, and sustainability (Antwi-Agyei et al., 2018b). In Cambodia, governmental adaptation strategies focusing on reforestation and conservation measures are eroding the local biodiversity, and the crop irrigation strategies are compromising scarce water resources and also excluding poor farmers susceptible to flooding from decision-making and benefits (Work et al., 2019). Likewise, in Ethiopia, efforts of adaptation programs to droughts contribute to current unsustainable development trajectories among pastoralist communities, resulting in charcoal production, overgrazing, migration and conflict with other groups and marginalization of livelihood (Magnan et al., 2016). In the Sudan, maladaptation outcomes to the poor population are linked to a dependency on war economy and post- conflict power dynamics that are and will affect sustainability and equity in the context of drought incidence (Young and Ismail, 2019).

In Bangladesh, a highly expensive Coastal Climate-Resilient Infrastructure Project can potentially increase the vulnerability of urban poor as they will remain in areas that are highly susceptible to flooding brought by sea level rise (Magnan et al., 2016). In Central America, the lack of assessments of future climate variability on crop yield scenarios coupled with lack of policy makers to incorporate autonomous local adaptation practices could lead to an unsustainable trajectory to local communities and risk of maladaptation (Beveridge et al., 2018). In Bhutan, small-scale rice farmers have adopted water -sharing measures to avoid the impacts of reduced and uncertain precipitation levels associated with monsoons, but these measures led to disruptions in social cohesion as conflicts over water sharing escalated (Mathew and Akter, 2015). In the same region, local governments prioritize the glacier retreat as a perceived risk to flooding on dams but overlook the slow and gradual impact of the deficit in precipitation affecting negatively the rice productivity (Mathew and Akter, 2015). In Burkina Faso, a region highly impacted by severe droughts, local communities have become less able to cope with droughts given a decline in cultural pastoralism and increased dependence on crops (van der Geest et al., 2019).

As seen, maladaptive responses to droughts, sea-level rise and flooding are negatively affecting poor farmers, pastoralists, and rural and urban informal workers, increasing loss of crops, infrastructure, income, conflict and migration. Given the high risks of maladaptation to poor people this agenda should be given priority among the development sector and planning (Magnan et al., 2016). The categories in Table 8.5 also represent important future compounding and complex risks that can emerge due to maladaptation (high confidence).

Table 8.5: Categories of Maladaptation as future risk and examples of outcomes and world regions based on literature assessment evidence. Confidence Level ** Medium (5-9 papers).

Categories of Risks to Maladaptation	Examples of Outcomes
Uncertainty (climate events)	Lack of knowledge of future climate extreme events hinder adaptation actions for the poor.
Inequalities	The exclusion of rights and access and benefits of adaptation
Sustainability	Further ecological degradation and biodiversity loss.
Informality	Reinforces vulnerabilities to the poor and marginalized population.
Poverty	It increase vulnerabilities and risks of maladaptation.
Scales (Temporal and Spatial)	There is negative trade-offs across short and longer term decisions as well as transboundary issues that increase likelihood of maladaptation.
Regions Evidence	South Asia and Southeast Asia (Bangladesh, India, Nepal, Maldives, Indonesia and Thailand) (6) **
	Africa (Ethiopia, Gahna, Malawaii) (3)
	Central America (1)
	Global South (2)
	Global (1)

8.4.5.6 Future challenges for vulnerability and livelihood security due to adaptation-limits of people and ecosystems

The risks and future losses of communities and livelihoods with higher exposure to the risks posed by climate change and with lower adaptive capacity will experience a higher burden of loss and damage in comparison to others (Tschakert et al., 2017). In Asia (Indonesia) and Arctic region, a decline of marine fisheries by approximately 3 million metric tons per degree of warming is expected to have severe negative regional impacts, especially on Indigenous People (Cheung et al., 2016).

It is projected that climate change impacts on incidence of disasters will push 122 million additional people into extreme poverty with global temperatures increase by 2030 (Hallegatte and Rozenberg, 2017; Hoegh-Guldberg et al., 2018; Jafino et al., 2020). It is also expected that around 330-396 million people will be exposed to lower agricultural yields at warming beyond 1.5°C (Hoegh-Guldberg et al., 2018), most of them in South Asia and Sub-Saharan Africa (Chapter 16; Roy et al., 2018; World Bank, 2019a). There is also *medium evidence* that tens to hundreds of millions of people that are dependent upon climate-sensitive livelihoods could out-migrate as a consequence of global temperature increasing, mostly in Africa, Asia and Latin America—posing additional risks to unsustainable urbanization and/or group conflict (Chapter 16; Hoegh-Guldberg et al., 2018; Roy et al., 2018).

The multi-intersectionality of inequalities (socioeconomic, caste, ethnicity, among others) and marginalization, in most of the cases exhibit adaptation limits, emerge through differential capacity to avoid risks that amongst the world's poor and vulnerable communities are highly deficient and at the brick of falling into poverty traps affecting future generations (Hallegatte and Rozenberg, 2017; Roy et al., 2018; Tschakert et al., 2019). For instance, the poorest communities in the Global South, whose livelihoods are dependent upon thriving ecosystems for health, food, water, energy, are disproportionately more exposed to temperature extremes, and droughts compromising the food and water security (Byers et al., 2018). There are also inequalities associated with the opportunities to adapt to risks that are unevenly distributed among global regions, with richer and more equal societies in the Global North presenting superior capacities than

Global South communities, sectors, ecological systems, and species where the most detrimental climate change impacts are experienced (Hoegh-Guldberg et al., 2018; Roy et al., 2018). The climate-sensitive livelihoods of poor and vulnerable communities in the global south, and the unprecedented ecosystems losses are examples of multiple limits of adaptation that emerge simultaneously also linked to the differential access to assets and resources, such as physical (propriety, income), social (health, age, education) , cultural (shared community values and norms, ethnicity), ecological (linked to land use change and productivity) and institutional (market, policies and governance) (Roy et al., 2018; Hoegh-Guldberg et al., 2019a; Olsson et al., 2019). The adaptation limits emerges mostly in the Global South countries, and disproportionately affect specific groups, with high poverty incidence, that are constrained by inadequate financial resources and institutional instruments (Tian and Lemos, 2018; Volpato and King, 2019), including lack of understanding and preparedness of the risks posed by climate change (Ayeb-Karlsson et al., 2016; Maharjan et al., 2020).

In other situations, adaptation limits to household's livelihoods emerge from ecological thresholds associated with global warming temperatures, such as deterioration of land and water resources, extinction of species and biodiversity that can lead to systemic crop failures, declined fisheries productivity and water availability and substantial risks to households' livelihoods (Roy et al., 2018). However, it is also important to note that limits are associated with development, technology, and cultural norms and values that can change over time to enhance or reduce the capacity of systems to avoid limits (Adger et al., 2014; Roy et al., 2018). It could also include aspects of maintaining security of air or water quality; as well as equity, cultural cohesion, and preservation of livelihoods (Adger et al., 2014; Tschakert et al., 2019). For soft limits, however, adaptation options could become available in the future owing to changing attitudes or values or as a result of innovation or other resources becoming available to most vulnerable and poor actors, households and countries. However, when compounded with lack of finance, and high costs associated with disasters and poverty and environmental degradation, soft limits might become hard ones in the future (see Figure 8.5; Gracia et al., 2018).

Table 8.6, built from SR1.5°C (Roy et al., 2018), illustrates how ecological thresholds and socio-economic determinants are linked to soft and hard adaptation limits and what are the potential and magnitude of livelihoods risks in the future. For instance, in the SR1.5°C (IPCC, 2018b) and SROCC (IPCC, 2019b), hard limits are expected with global warming beyond 1.5°C associated with the losses of coral reefs, that will lead to substantial loss of income and livelihoods for coastal communities (Roy et al., 2018; Mechler et al., 2019b; Oppenheimer et al., 2019). The loss of coral reefs in remote islands of Boigu in Australia are affecting low-lying communities facing financial, institutional (Evans et al., 2016) and cultural place-based attachment adaptation limits (McNamara et al., 2017). Another hard limit to adaptation and implications for income, and culture-and place-based livelihoods is related to the sensitivity of global fish to global temperature increase with losses of fish reproduction expected to 10% (SSP1–1.9) to about 60% (SSP5–8.5) potentially cascading into severe risks for fisheries livelihoods (Dahlke et al., 2020). In West African fisheries, the loss of coastal ecosystems and productivity are estimated to require 5–10% of countries' gross domestic product (GDP) in adaptation costs (Zougmoré et al., 2016), incurring financial limits in the poor countries to avoid socio-economic risks. The SROCC (IPCC, 2019b) showed that scientific knowledge limitations can constrain management of coastlines, mainly in the context of lack of data with affect most of the vulnerable and poor communities in the global south (Perkins et al., 2015; Sutton-Grier et al., 2015; Wigand et al., 2017; Romañach et al., 2018). The hard and soft adaptation limits are challenging to be defined, given the rate and intensity of climate change hazards and the mitigation and adaptation options available, but also the level and rate of non-climatic stresses increasing vulnerabilities and undermining adaptive capacity of poorest members of society and sensitive ecosystems (*medium evidence, high agreement*) (Klein et al., 2014; Roy et al., 2018).

The recent evidence show that adaptation limits can also be associated to financial and institutional mechanisms, and related to structural poverty and inequalities among rural farmers in India (Singh et al., 2019a) and among low-income countries (Tenzing, 2020), agro -pastoralists communities (Volpato and King, 2019), women (Balehey et al., 2018), slum informal settlements in Latin America (Núñez Collado and Wang, 2020), and informal workers in Southeast Asia (Balehey et al., 2018). For SIDS countries, multiple adaptation limits also emerge as a combination of political-institutional, and cultural aspects (Robinson and Wren, 2020) such as preserving national identity and sovereignty in the context of migration in the Marshall Islands (Bordnera et al., 2020). The widespread narrative that migration in the SIDS countries given sea level rise and global temperature increase by 2050 is inevitable, desirable and economically necessary, many more people will be exposed to migration and affected by multiple physiological and emotional distress (Bordnera et al., 2020). In the same way, the Mohawk community of Kanesatake, Canada, is faced with institutional and socio-political adaptation limits such as lack of land ownership rights, insurance and social institutions, to name only a few (Fayazi et al., 2020).

New emerging considerations to ecological limits to adaptation associated with severe glacier retreat in the Peruvian Andes, is expected to reduce lake discharge by 2-11% (7-14%) until 2050 (2100) affecting smallholders farmers, through crops yield failures and severely reduced hydropower capacity (Drenkhan et al., 2019). Also, the study showed very high risk of glacier lakes affected by Glacial Lake Outburst Floods (GLOF) in RCP8.5, posing serious threat to rural people's livelihoods (Drenkhan et al., 2019).

Table 8.6 represents different types of adaptation limits (Soft and/or Hard) that emerge over time and sometimes concomitantly and are leading to severe risks to livelihoods in a high poverty, unequal and hotter future, especially among the poor and vulnerable population in that, the Indigenous People, women, and children (see Section 16.5.2.3.4). The confidence statements is assessed through the evidence on papers as High (≥ 10 papers), Medium (5-9 papers), Low (≤ 4 papers) to ensure traceability on what are the nature of livelihoods barriers and ecological thresholds associated to 'soft" and or "hard" limits to adaption under a warming global world. The determinants of livelihood barriers are linked to: *Gender-based inequality or discrimination, poverty and inequality, Indigeneity and cultural place attachment, Artic Hunting and fishing, Urban Slum and Informal Settlements* incurring in soft and hard limits to adaptation. The Ecological thresholds assessed are associated to *Glacier Retreat, Loss of Coral Reefs, Biodiversity Loss, Ocean Acidification and warming, Sea Level Rise (SLR)* and *Heat Stress* incurring into hard limits to adaptation severe risks to people's livelihoods; The severity of risks to livelihoods is assessed by presenting a magnitude indicator either through the current number of people exposure and vulnerable to climate-sensitive livelihoods. The supporting literature has been provided in the Table SM8.1.

Table 8.6: Synthesis of hard and soft limits to adaptation and risks to livelihoods, equity and sustainability adapted from Chapter 5 of SR1.5°C (Roy et al., 2018).

Determinant	Nature of barrier to livelihood adaptation	Magnitude + Indicator	Soft Limit	Hard Limit	Confidence Level Based on Number of Papers
Socioeconomic and human-geographical determinants					
Gender-based inequality or discrimination	Gender-based inequalities constrain women's access to resources, thus limiting ability to invest in adaptive capacity and heightening vulnerability	World Bank: 62.151% [Employment in agriculture, female (% of female employment) (modelled ILO estimate) - Low income, 2020]; 25.409% [Employment in agriculture, female (% of female employment) (modelled ILO estimate)],	X		***High (≥ 10 papers)
Poverty and socioeconomic inequality	Poverty and lack of financial resources constrain ability to invest in livelihood diversification, resilience or adaptive capacity	World Bank: 10% [Poverty headcount ratio at $1.90 a day (2011 PPP) (% of population)]; 26.498% [Employment in agriculture (% of total employment) (modeled ILO estimate)]; 58.783% [Employment in agriculture (% of total employment) (modeled ILO estimate) - Low income], Low income countries, 2020	X		***High (≥ 10 papers)
Indigeneity and other cultural place-based attachments	Indigenous and other populations with strong cultural or economic attachments to place face barriers to adaptation due to noneconomic losses associated with migration,	SIDS total population of ca. 65 million(UN-OHRLLS, 2015); 476 million indigenous people worldwide (World Bank, 2016)		X	***High (≥ 10 papers)

	urbanisation, and some forms of livelihood transformation				
Arctic hunting and fishing communities	Residents of Arctic regions dependent on hunting and fishing livelihoods interrelated cultural and economic vulnerability due to risk crossing Arctic ecosystem thresholds and tipping points	Global arctic population, ca. 4 million (Larsen, 2015)	X	X	***High (≥ 10 papers)
Urban slum and informal settlement populations	Residents of slums and informal urban settlements are particularly vulnerable due to limited infrastructure and limited employment opportunities	33.331% [Population living in slums (% of urban population)], World, 2009; It is estimated that 50–57 million urban Africans (47% (44–50%) of the urban population analysed) were living in unimproved housing in 2015 mostly in the sub-Saharan Africa (Tusting et al., 2019)	X		***High (≥ 10 papers)
Ecological determinants					
Glacier Retreat	Seasonal water scarcity and/or Glacial Lake Outburst Floods (GLOF) pose a serious threat for highly exposed and vulnerable smallholders in the Peruvian Andes (Drenkhan et al., 2019). Tibetan Plateau region will reach peak water between 2030 and 2050 (Yao et al., 2020)	The flow decrease of the Tibetan Plateau region would affect water availability for 1.7 billion people with a gross domestic product (GDP) of US$ 12.7 trillion (Yao et al. 2019).In 2050, the number of people that will be living in water scarce regions will increase to 2.7 to 3.2 billion people (Luterbacher et al., 2020). As for 2010, 27% of global population (˜1.9 billion people) lived in severely water-scarce areas (Luterbacher et al., 2020).	X	X	***High (≥ 10 papers)
Loss of Coral reefs	Loss of 70-90% of tropical coral reefs by mid-century under 1.5°C scenario (total loss under 2°C scenario) (see SR1.5°C in Chapter 3, Sections 3.4.4 and 3.5.2.1, Box 3.4 (Hoegh-Guldberg et al., 2018), (Magnan et al., 2019).; Chapter 5, Section 5.2 (Roy et al., 2018)).	The Coral reef fisheries-dependent and coastal livelihoods, sustain 6 million direct fishing jobs and more than $6 billion in revenues globally (Teh et al., 2013), often among disadvantaged populations (Hoegh-Guldberg et al., 2018). In tropical regions, there are 1.3 billion people living by coast and depending upon fisheries for food and livelihoods (Sale et al., 2014). In Africa and Asia over 400 million people are dependent upon protein intake from fisheries (Hoegh-Guldberg et al., 2019b). Approximately 850 million people live within 100 kilometres of reefs and more than 275 million reside within 30 kilometres, many of whom are likely to be highly dependent on coral reefs, especially those who look to these marine ecosystems for food and livelihoods (Burke et al., 2011).		X	***High (≥ 10 papers)

Biodiversity Loss	Terrestrial species on average lose 20-27% of their range at 1.5°C (significantly higher range losses projected for some species at 2°C) (see IPCC SR 1.5°C Chapter 3, Section 3.4.3.2 (Hoegh-Guldberg et al., 2018); Chapter 4, Section 4.3.2 (de Coninck et al., 2018)). Tropical forests (vegetation shifts due mainly to drying), and high latitude and altitude ecosystems and Mediterranean-climate ecosystems (high vulnerability	The forest dependent livelihoods of 1.6 billion rural people (in 2012) is likely to be affected to risks of terrestrial forest and biodiversity loss (Newton et al., 2020).		X	**Medium (5-9 papers)
Ocean acidification and warming	Large-scale changes in oceanic systems (temperature, acidification) inflict damage and losses to livelihoods, income, cultural identity and health for island and coastal-dependent communities at 1.5°C (potential for higher losses increases from 1.5- 2°C and above) (see Chapter 3, Section 3.4.4.2.4 (Hoegh-Guldberg et al., 2018); Chapter 4, Section 4.3.5 (de Coninck et al., 2018); Section 5.2.2 (Roy et al., 2018).	500 million people who derive food, income, coastal protection, and a range of other services from coral reefs (Hoegh-Guldberg et al., 2017)	X	X	**Medium (5-9 papers)
Sea level rise (SLR)	Sea level rise and increased wave run up combined with increased aridity and decreased freshwater availability at 1.5°C warming potentially leaving several atoll islands uninhabitable (see IPCC SR. 1.5°C; Chapter 3, Box 3.5 (Hoegh-Guldberg et al., 2018); Chapter 4, Cross-chapter Box 4.1 (de Coninck et al., 2018)); The projected SLR is projected to affect human health and wellbeing, cultural and natural heritage, freshwater, biodiversity, agriculture, and fisheries (IPCC, 2018b; WHO, 2018; IDMC, 2019; McMichael et al., 2020).	It is projected that ~316–411 million people in 2060 will be living in areas to be affected by SLR, with most of them in South and Southeast Asia and in Africa (Neumann et al., 2015; Oppenheimer et al., 2019).The number of people at risk of floods will increase from its current level of 1.2 billion to 1.6 billion by 2050 (Luterbacher et al., 2020). It is estimated that 6–8% of Latin America and the Caribbean's population, face high risk associated with coastal hazards (Oppenheimer et al., 2019).		X	***High (≥ 10 papers)
Heat Stress	It is expected that by 2070 over 30% of global poor population will be living outside the human thermal comfort, beyond adaptive capacity, and affecting crop	It is projected that by 2100, human mortality from heat will affect increase and affect 1/4 of the population (-1/448% under drastic mitigation scenario) and to almost 1/5 in a higher emission scenario (-1/474% under a		X	**Medium (5-9 papers)

	and livestock productivity (Xu et al., 2020)	scenario of growing emissions) (Mora et al., 2017). Heat Stress contributes to deaths and health problems among the elderly and children. Specifically, heat stress is currently responsible for 38,000 annual deaths mostly among the elderly, and 48,000 from diarrhoea, 60,000 from malaria, and 95,000 from childhood undernutrition (WHO, 2014a; Roy et al., 2018).

8.4.5.7 Compounding future risks on equity and sustainability

The compounding future effects on equity and sustainability emerge when multiple stressors linked to environmental and/or climate change, together with underlying structural poverty, exclusion, marginalization, and conflicts creating risks that need to be addressed simultaneously. Compounding risks of climate change received attention in AR5 (Oppenheimer et al., 2014) including risks associated with compound hazards (O'Neill et al., 2017b), and their implications for future risk when repeated impacts erode human and ecosystem capacity, including through transboundary effects. In SRCCL (IPCC, 2019a), land degradation and climate change compounded to highly expose the livelihoods of the poor to climate hazards and caused food insecurity (*high confidence*), migration, conflict and loss of cultural heritage (*low confidence*) (Olsson et al., 2019).

The evidence of compounded risks emerge from specific climate and environmental hazards as in relation to heatwaves, droughts, altered precipitation regimes, and increasing aridity, cyclones, floods, hurricanes and wildfires (Table 8.7). Other evidence shows that the structural poverty and socio-economic inequalities (Lusseau and Mancini, 2019), disability (Sun et al., 2017), corruption (Markkanen, 2019) and isolation (Reyer et al., 2017) (Table 8.7) compound to amplify climate risks among rural and urban poor, smallholder farms, coastal settlements, with health impacts in children's development (Perera, 2017) and urban elderly (Sun et al., 2017). In Tanzania, a greater exposure of households to climate change impacts and risks is associated with increasing land value and variable tenure, compounded with declining farm yields, accelerating the negative effects among the population (Röschel et al., 2018). In India, extreme droughts and heatwaves compound extreme poverty, and high dependence on agriculture for income and food production will affect crop productivity, income and increase of food price among smallholder farms (Singh and Leua, 2017). Soil degradation and fertility compounded with incidence of droughts increase the vulnerability of already poor smallholders in Mozambique that lack access to technological advances for crop yield management and drought resistance crops (Kidane et al., 2019).

Table 8.7: Effects of compounded risks on the poor. Climate hazards: flooding, hurricanes, drought, heatwave. Confidence level: *** High (≥ 10 papers); ** Medium (5-9 papers); * Low (≤ 4 papers); NE (No evidence)

In the context of urbanization, in fast growing cities in Asia, Africa and Latin America that are highly socially and economically unequal, the climate change impacts from events such as flooding, and droughts, are amplified on water crisis mostly among the poor and marginalized population, and challenging governance for risk reduction (Gore, 2015; Dodman et al., 2017; Jiang and O'Neill, 2017; Pelling et al., 2018; Solecki et al., 2018). In the Global South, over 880 million people are living in precarious and informal conditions without access to water and sanitation mostly in sub-Saharan Africa and South Asia (see Chapter 6; Rosenzweig et al., 2018; Satterthwaite et al., 2018; Tusting et al., 2019). In rapid urbanization sub Saharan African countries, around 53 (50–57) million urban inhabitants (50% of urban population) and 595 (585–607) million rural inhabitants (82% of the rural population) are still living in unimproved housing in 2015 (Tusting et al., 2019).

Experienced losses and damage from climate extremes, such as fatalities or economic losses due to droughts or floods (see also Fig. 8.6), also matter for future vulnerability and risk, since the poorest segments of society take longer to recover after shocks (Gupta and Sharma, 2006; van der Geest, 2018). In some cases, poor households might never be able to fully recover from post disaster, especially in the context of increasing global temperature increase (van der Geest, 2018). Another example of compounding effects of climate change to equity and sustainability is migration, which is underpinned by the underlying socio-economic and political context of vulnerability (see Section 8.2).

In Latin America, compounding effects of climate change impacts (disasters) and armed conflict has contributed to increase forced migration to the point that in 2018 alone, 1.7 million people migrated due to extremes events, four times as high as the number of people leaving their homeland due to armed conflict (Serraglio and Schraven, 2019). In South America, migration within and between countries can stem from climate extremes primarily felt by the poorest and marginalized (by gender, age, ethnicity) populations that might not be able to adapt to the fast pace and scale of changes at the local level (Maru et al., 2014; Pinho et al., 2015; Serraglio and Schraven, 2019). In Mountain Regions, intersections of people's marginalization, difficulty in access, and environmental sensitivity in the context of incidence of climate extremes have combined to reduce the ability of mountain agro-pastoralists to cope with climate extremes (Mishra et al., 2019). Mountain ecosystems are also highly susceptible to disasters and disturbances, which can lead to irreversible loss, and challenge poverty reduction efforts (Mishra et al., 2019) Some risks associated with the degradation and loss of habitats and ecosystem services associated with land use changes and commodities in many countries have compounding impacts on equity and sustainability, associated with permanent losses to the livelihood of poor and marginalized groups such as Indigenous Peoples and traditional communities around the world (Roy et al., 2018). For instance, high deforestation rates and increased forest burning in many of the Amazonian countries are further exposing vulnerable Indigenous Peoples and Traditional populations to health problems, crop failures and shortages of freshwater supply, especially in the context of extreme droughts and non-supportive governance (Leal Filho et al., 2020a; Walker et al., 2020).

Overall, there is increasing evidence that the compounding effects of climate hazards intertwined with dimensions of poverty, environmental degradation, and inequalities, represent a key risk to equity and sustainability among poor and vulnerable populations (*medium evidence and high agreement*). Compounding risks - compared to compounding hazards - can also be significantly influenced by societal tipping points and by different factors of human vulnerability that determine underlying destabilization processes of societies and communities exposed to climate change, including issues of governance.

8.5 Adaptation Options and Enabling Environments for Adaptation with a Particular Focus on the Poor, Different Livelihood Capitals and Vulnerable Groups

This section focuses on adaptation at household and community scales, including options, capacity and enabling environment, which include actions required towards building resilience. The emphasis is on the decision-making space and governance including the role of the state, private sector and other actors. Successful adaptation requires not only identifying adaptation options and assessing their costs and benefits, but also exploiting available mechanisms for expanding the adaptive capacity of human and natural systems (Klein et al., 2014). At the same time, developing suitable responses to hazards for communities and users of climate services is important in ensuring the success of adaptation measures. But despite this, knowledge about adaptation options, including possible actions that can be implemented to improve adaptation and reduce the impacts of climate change hazards, is still limited.

8.5.1 Adaptation options to climate change hazards focusing on vulnerable groups

In light of the severe adverse consequences of climate change for the poorest populations whose livelihoods are frequently dependent on vulnerable ecosystems, it is essential to enhance knowledge about sustainable and appropriate adaptation strategies and measures, as well as recognise and respond to limits to adaptation as reported in AR5 (Somorin, 2010; Noble et al., 2014; Connolly-Boutin and Smit, 2016). There is increasing evidence on the adaptation options that enhance the ability of different socio-ecological systems to become resilient in the long-term in ways that do not exacerbate poverty and inequality, and which adaptations may have little or no impact, or even adverse effects (maladaptation). Analysis of climate hazards can provide an indication of required adaptation strategies, however, most importantly is the focus on exposure, vulnerability, however the novelty of the AR6 is assessing existing response capacities to cope and adapt to climate changes and associated hazards. There is increasing knowledge about the differential adaptation options within and across social groups and the influence of (enabling) conditions that enhance or limit these options.

From the analysis in the IPCC AR5, there is *high agreement* that engineered and technological adaptation options are still the most common adaptation responses, although there is increased recognition of the value of ecosystem-based, institutional and social measures, including the provision of climate-linked safety nets for those who are most vulnerable (IPCC, 2014a). It is important to note that climate adaptation measures are increasingly integrated within wider policy, development strategies and spatial planning frameworks. Such integration streamlines the adaptation planning and decision-making process and embeds climate-sensitive thinking in existing and new institutions and organizations across scales and levels.

In the past decades a number of categories of adaptation options have been identified and are also discussed in Section 8.5. Adaptation options are categorized in various ways, such as in terms of grey and green adaptation or hard and soft measures (Depietri et al., 2013; Chambwera et al., 2014; Grimm et al., 2015). Grey measures refer for example to technological and engineering solutions to improve adaptation of infrastructures or to protect a specific land use or city from adverse consequences of climate hazards (OECD, 2018). It is accordingly explained that ecosystem-based approaches, including natural infrastructure, can provide an effective complement or substitute for traditional built (or "grey") infrastructure. For example, watershed restoration can protect sources of drinking water and reduce the need for subsequent treatment. Green measures are often encompassing ecosystem-based (or nature-based) approaches. These make use of the multiple services provided by ecosystems to improve resilience and adaptive capacity or to reduce risk. Soft adaptation measures include policy, legal, social, management and financial measures that can alter human behaviour and support adaptive governance, contributing to improved adaptation capacity, increased awareness and change in values and actions on climate change issues.

Adaptation actions frequently include deliberate, coordinated, proactive policy decisions based on the awareness that conditions have changed or will change and that action is required to avert impacts or return to, maintain, or achieve a desired state (Carter et al., 1994). Noteworthy, governance provides an important contextual framing, particularly in contexts where it is weak or contested (e.g., some of the Sahel zone). In these cases, it can mean that adaptation options stem largely from the local level. Adaptation processes can be categorised as individual, collective, proactive, reactive, autonomous, coordinated, and natural (Chambwera et al., 2014). Apart from governments, other actors, organizations and institutions (including non-state agencies and private industry actors) also play an important part in adaptation processes, consequently also the discussion of enabling environments for sustainable or successful adaptation has to deal and consider these different scales and actors. For example, while autonomous adaptations are mainly undertaken by private actors, triggered by climate change induced market or welfare changes, planned adaptations can be carried out by both private and public actors. Natural adaptations appear within ecosystems as a reaction to climate change as well as other factors and incorporate innumerable possible actions that are context specific, ranging from managerial approaches, technological innovations, and ecosystem based approaches (Huq et al., 2004). Sanchez et al. (2017) draws attention to preconceived ideas about some adaptation measures that are either considered good or bad without proper evaluation. It is argued that the association ‘hard-bad’ and ‘soft-good’ is not necessarily true; the impacts of adaptation can only be established through a case-by-case assessment. The decision to select a more or less intensive adaptation measure should integrate all approaches, social, environmental, technical and economic, in a multi-criteria analysis. This analysis should value, inter alia, social and environmental sensitivity, benefits and drawbacks or trade-offs with climate, including all the adaptation options, among them the ‘no action’ alternative.

Adaptation frequently responds to an observed or anticipated ‘trigger’ for response, such as the looming loss of land to sea level rise (Barnett et al., 2014). Identifying adaptation needs stemming from climate risks and vulnerabilities provides a foundation for selecting a sequence of adaptation options that connect through time, a long-term adaptation pathway (Wise et al., 2014; Turnheim et al., 2015). National, sectoral, or local adaptation plans are *likely* to include a number of measures that are implemented jointly from across various categories including structural, institutional, and social options. While structural or physical adaptation encompasses measures for the engineered built environment it also can encompass nature based solutions, which include ecosystem based protection measures, for example to buffer risks and hazard exposure to extreme weather events. The category of ‘soft’ adaptation measures—changes in societal values or practices—are often linked to issues of education, information and behavioural changes to support communities within specific adaptation processes to climate change and climate hazards. Institutional adaptation deals with adaptation actions and measures introduced through new legal frameworks, laws and regulations for new institutions or policies for risk reduction and adaptation. This category can also encompass the development of new organizations that have the mandate to support adaptation (Noble et al., 2014). The appropriateness and accessibility of adaptation options under these categories for supporting the poor and most vulnerable groups differs. In many cases large scale structural measures are not affordable for many poor communities. Despite this important potential of Indigenous Knowledge for disaster risk reduction of the communities, it is often shunned by practitioners (Dube and Munsaka, 2018). It is further argued by practitioners that Indigenous Knowledge lacks documentation, it is not found in all generational classes, it is contextualised to particular communities and the knowledge cannot be scientifically validated. However, there is also evidence that both local communities and disaster risk reduction practitioners can benefit from the Indigenous Knowledge of communities (Dube and Munsaka, 2018).

In practice, adaptation refers to initiatives such as a policy, plan, project or decision that are designed to change and/or respond to something in the context of existing risks and hazards. For example, a farmer might adapt to drought by deciding to harvest their crop earlier; a municipality can decide to build a sea wall to adapt to increased flood risk.

The increasing complexity of adaptation practice means that institutional learning is an important component of effective adaptation (Noble et al., 2014). It is paramount that approaches to selecting adaptation options continue to emphasize incremental change to reduce impacts while achieving co-benefits. There is increasing evidence that transformative changes may be necessary in order to prepare for climate change impacts and adaptation options in the context of climate hazards (Noble et al., 2014). Transformation for some actors at some levels may equate with incremental change and transitions for other actors and scales. While attention to flexibility and safety margins is becoming more common in selecting adaptation options, many see the need for more urgent and transformative changes in our perception and paradigms about the nature of climate change, adaptation and their relationship to other natural and human systems.

In this context, there are many potential adaptation options available for marginal change of existing agricultural and other livelihood systems, often variations of existing climate risk management. According to Howden et al. (2007) implementation of these options is *likely* to have substantial benefits under moderate climate change for some existing cropping systems. Apparently, there are limits to their effectiveness under more severe climate changes. Hence, more systemic changes in resource allocation need to be considered, such as targeted diversification of production systems and livelihoods. Howden et al. (2007) further argue that achieving increased adaptation action will necessitate integration of climate change-related issues with other risk factors, which implies integrating non-climatic factors, such as climate variability and market risk, and with other policy domains, such as sustainable development. Noteworthy, an increasing number of research programs seek to support adaptation to climate change through the engagement of large-scale transdisciplinary networks that span countries and continents (Cundill et al., 2019).

Based on analysis of different adaptation options, there is *high agreement* that the many barriers to effective adaptation will require a comprehensive and dynamic policy approach covering a range of geographical scales and multiple actors across scales, taking into consideration both climatic and non-climatic stress factors (Eriksen et al., 2015). For instance, from the agricultural perspective this could imply the understanding by farmers of change in risk profiles to the establishment of efficient markets that facilitate response strategies. It is also important to note that Science, too, has to adapt employing a range of approaches, based on the fact that multidisciplinary problems require multidisciplinary solutions. Towards enhancing resilience, a focus on integrated rather than disciplinary science alone could be of utmost importance as well as strengthening of the interface with key stakeholders, ranging from decision makers, practitioners, policymakers, and scientists.

8.5.2 Enabling environments for adaptation in different socio-economic contexts

8.5.2.1 Factors that support enabling environments for adaptation

This section assesses the literature on components of the enabling environment for adaptation. The point of departure considers findings in both the SR1.5°C report, which note that adaptation becomes increasingly difficult (and expensive) at temperatures more than 1.5ºC warmer (IPCC, 2018a), and noting also that (IPCC, 2014a) underscores that there is no one-size-fits-all approach to adaptation for all contexts, and that mitigation and adaptation must be pursued in tandem.

Climate change affects people inequitably, and everyone does not contribute equally to climate change. A range of economic and non-economic impacts can be experienced. This has led some researchers to call for a more central role for rights-based approaches to adaptation, to help secure space for those marginalised from adaptation decision making and to prioritise access to resources and information for those most vulnerable to, or affected by, the social, cultural or economic consequences of climate change (Bee et al., 2013; Da Costa, 2014; Toussaint and Martinez Blanco, 2020; Box 8.7; Section 5.12). In terms of international law, the human rights obligations of states have been subject to multiple recommendations relating to climate change by UN treaty bodies in the reporting period. More broadly, rights-based approaches rely on the normative framework of human rights, requiring adaptation to be non-discriminatory, participatory, transparent and accountable in both formal (e.g., legal and regulatory) and informal (e.g., social or cultural norms) settings and at international, national and sub-national scales (Ensor et al., 2015; Arts, 2017). Sovacool et al. (2015) note that unless critical competing interests are addressed during planning, adaptations may fail to achieve the desired outcomes. This is increasingly seen at a political level within efforts to implement the Paris Agreement, in relation to the principle of 'Common but Differentiated Responsibilities and Respective Capacities' (CBDR-RC) (Box 8.7).

[START BOX 8.7 HERE]

Box 8.7: Addressing Inequalities in National Capabilities: Common but Differentiated Responsibilities and Respective Capabilities Relating to Adaptation and the Paris Agreement

Common but differentiated responsibilities and respective capabilities (CBDR-RC) is a key principle within the UNFCCC, and attempts to acknowledge countries' diverse development situations. The Convention and its Kyoto Protocol operationalized the principle by committing developed (Annex I) countries to absolute emission reduction or limitation targets and exempting developing countries from any binding reductions in emissions (Huggins and Karim, 2016; Pauw et al., 2019). In contrast, the Paris Agreement distinguishes between 'developed' and 'developing' countries instead of Annex I and non-Annex I countries and acknowledges significant asymmetries and inequalities not only between developed and developing countries, but also between developed and developing countries themselves, both in terms of vulnerability to climate change impacts, and capacity to mitigate the problem. The literature contains extensive analyses of CBDR-RC in relation to equity in mitigation efforts in the post-2020 regime (e.g., Michaelowa and

Michaelowa, 2015; du Pont et al., 2017; Liu et al., 2017; Holz et al., 2018; Sælen et al., 2019), but little in relation to adaptation, particularly relating to how it plays out in the Paris Agreement.

The somewhat static interpretation of CBDR-RC prior to the Paris COP was overcome through the introduction of a qualification to the CBDR-RC principle: the phrase ‘in the light of different national circumstances’. Without changing the original principle, the qualifier adds a dynamic element (Rajamani, 2016). Common but differentiated responsibilities and respective capabilities of Parties are therefore recognised not to be ‘tied to the annexes’, but instead evolve alongside national circumstances (Maljean-Dubois, 2016; Voigt and Ferreira, 2016 p.301). The Paris Agreement also recognises context, considering differentiation in relation to each of the Durban pillars, i.e., mitigation, adaptation, finance, technology, capacity building and transparency (Rajamani and Guérin, 2017).

Article 7 of the Paris Agreement acknowledges adaptation as a ‘global challenge faced by all’, recognising, for the first time, a global aspiration of ‘enhancing adaptive capacity, strengthening resilience and reducing vulnerability to climate change’. It calls for a balance between mitigation and adaptation funding and emphasises the need to provide developing country Parties, especially the most vulnerable, with ‘[c]ontinuous and enhanced international support’ for adaptation. The basis for differentiation under Article 7 therefore relies mostly on diverse national circumstances, capabilities and vulnerabilities. Least Developed Countries (LDCs), as well as Small Island Developing States (SIDS), are assumed by the literature, to be part of this category (Maljean-Dubois, 2016).

The literature offers two main perspectives when evaluating the effectiveness of these provisions on adaptation in the context of the post-Paris climate change regime. One argument follows that the Paris Agreement gives priority attention to the most vulnerable Parties and, unlike previous international agreements in the climate change regime, places adaptation on equal footing to mitigation (Magnan and Ribera, 2016; Pérez and Kallhauge, 2017; Morgan, 2018). Article 7 is interpreted here as a breakthrough, containing unprecedented provisions that give adaptation prominence and which elevate the importance of undertaking adequate action to cope with current and future climate change impacts. A second view argues that the Article 7 marks little departure from previous efforts to support adaptation efforts in developing countries (Doelle, 2016) or that it could have included stronger provisions, such as a quantitative goal with respect to adaptation needs and costs (Bodansky, 2016).

The literature nevertheless shows *high agreement* that other parts of the Paris Agreement do contain consequential provisions on adaptation and the operationalization of the CBDR-RC principle. Those provisions covering financial support are arguably the most pertinent, as they replace the dichotomy between developing countries and developed countries with a trichotomy which also includes ‘other Parties’ (Maljean-Dubois, 2016). While provision of support from developed Parties continues to be mandatory, these ‘other Parties’, apparently developing country Parties, are ‘encouraged to provide or continue to provide such support voluntarily’ (Article 9.2). Parties themselves determine whether they belong to this category. So far, several developing countries have made contributions to the Green Climate Fund, ranging from Indonesia and Mexico to Mongolia and Panama (Green Climate Fund, 2017). Expanding the donor base to these ‘other parties’ and breaking down the wall between donor and recipient countries marks a departure from previous practice, under which developing countries had no formal role in climate finance and support (Bodansky, 2016; Voigt and Ferreira, 2016).

[END BOX 8.7 HERE]

The scale of analysis, baseline conditions prior to adaptation and scale of action matter too when assessing the key components of an enabling environment for adaptation. At a national scale, it is well established that low income countries are less well positioned to manage climate change impacts, being variously attributed to a lack of institutional, economic or financial capacity to adapt effectively (Tol and Yohe, 2007; Barr et al., 2010). It can be particularly difficult to adapt to drought, for example, when it occurs in the pre-conditions of poor water supplies and sanitation (see Box 8.5 and Section 8.3.2), and in a context of corruption, governance failure and a lack of accountability. Adaptation productivity in higher income countries is further supported by better infrastructure and stronger institutions—low adaptation efficiency is linked to lower government spending, higher inequalities in income distribution and poor governance (Fankhauser and

McDermott, 2014). At smaller scales, even within a single socio-economic setting, different groups require different kinds of adaptation support and exhibit different vulnerabilities to climate change impacts. Huynh and Stringer (2018) found that households vulnerable to climate change impacts linked to sea-level rise and flooding in Da Nang City and Ngu Hanh Son District, Vietnam, had limited access to human, natural, physical, financial and social assets and lacked a diversified livelihood portfolio. An enabling environment for household level adaptation would need to address these factors in this context. However, the same authors found that at District scale, different challenges persisted, including obstacles to multidirectional flows of climate information, poor vertical interplay both upward and downward, and a lack of citizen participation in the governance of climate change.

Acknowledging that context and scale matter, it is nevertheless possible to set out the core components of a generic enabling environment (Figure 8.12), linking them to the literature on climate change and recognising how they can support adaptation in different socio-economic and environmental settings in which different emphases are required. This broad set of enablers requires different emphases according to the specific context, yet the interdependence between them is universally applicable.

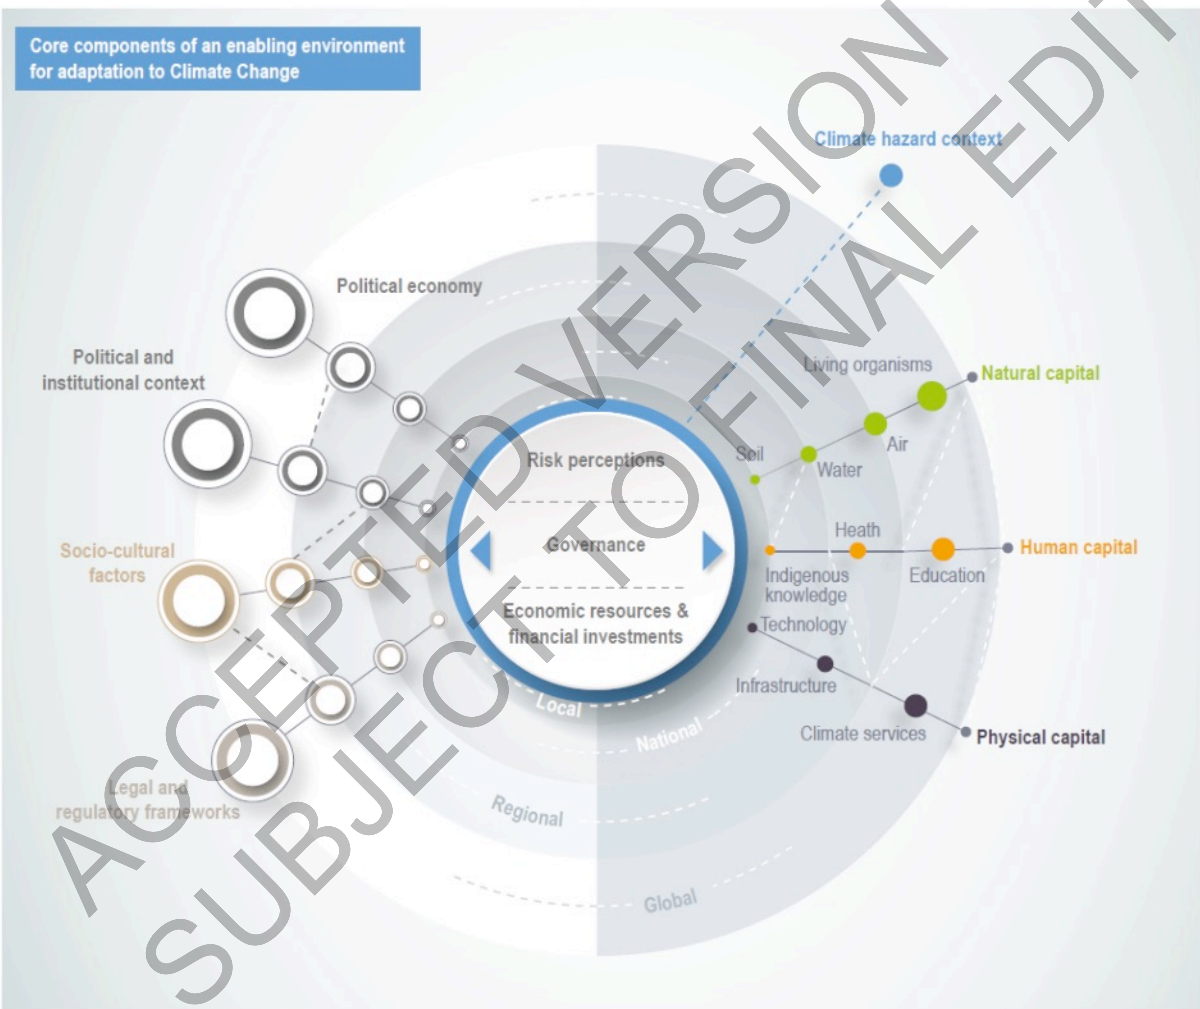

Figure 8.12: Core components of the enabling environment for adaptation to climate change (key interactions are illustrated but it should be noted that there are overlaps, interactions and feedbacks both within and between each item; and that different countries have different capacities and starting points in addressing these enablers and the interlinkages between them).

The specific political economy of each country and its underpinning philosophies shape the national political context in which public policy supporting adaptation is developed and implemented. It further shapes the context for private adaptation. Public policy targeting climate change seeks to address market failures, amend policy distortions and offer incentives for private adaptation, as well as provide climate-resilient public goods, climate services and safety nets for the poor and vulnerable (Fankhauser, 2017). In some countries that have a more stable institutional context, such policies are more straightforward to develop and implement; while in countries with weaker institutions (e.g., those emerging from conflict) a larger role may be needed for regional economic commissions and transnational networks to support the governance of 'borderless climate risks' (Benzie and Persson, 2019) particularly where these countries also are most vulnerable to climate change (see also Figure 8.6). To support enabling conditions in highly vulnerable countries that are also characterized by state fragility (see Figure 8.8), funding and projects designed to support adaptation may need to be modified to effectively promote regional cooperation and transboundary adaptation. Nevertheless, such interventions can also reinforce particularly powerful agendas and fail to assist and empower those with the greatest need to adapt(Biermann et al., 2010; Burch et al., 2019) neglecting community voices and sovereignty (Schlosberg and Collins, 2014). It is therefore important that the relevance of people and community empowerment to effectively achieve vulnerability reduction and climate change adaptation is recognised.

It is also insufficient to consider countries as stand-alone entities, due to links such as those provided by international trade. Taking Europe as an example, the continent has strong links to major trade partners such as India, Indonesia, Nigeria and Vietnam, so failure to assist adaptation in other locations opens up important vulnerabilities through supply chains (Lung et al., 2017). Policies seeking to protect national interests alone (e.g., in terms of food security) are seen as causes of negative impacts at a global scale (Puma et al., 2015; Challinor et al., 2017), with those nations and individuals least able to adapt to evolving climate changes experiencing exacerbation of existing imbalances (Elbehri et al., 2015). Least developed countries are projected to suffer greater import losses in more connected networks (Puma et al., 2015). In the food sector, poorer net food buyers are anticipated to experience the worst impacts of climate change (Gitz et al., 2015).

Behind each policy are decisions about the magnitude of financial resource investments in specific adaptation actions, and their allocation between different sectors and groups in society, both spatially and temporally. The IPCC has estimated that limiting the rise in global average surface temperatures to 1.5°C would require between $1.6 trillion to $3.8 trillion of annual investment in supply-side energy systems (those that generate energy) between 2016 and 2050 (IPCC, 2018b). Resource allocations however, are shaped by perceptions of the risks of climate change and the urgency of actions, as well as other motivational factors such as descriptive norms and perceived self-efficacy (van Valkengoed and Steg, 2019) and the underlying approaches taken to valuing human wellbeing (e.g., see work from Bhutan on Gross National Happiness and climate change actions (Kamei et al., 2021)).

An increase in finance mobilised, however, does not automatically equate to adaptation interventions on the ground, nor does guarantee the effectiveness of those adaptations deployed (Berrang-Ford et al., 2021). Unintended negative consequences may arise due to lack of understanding of the drivers of vulnerability (such as gender inequality or inequitable access to natural resources), non-involvement of marginalised local groups, retrofitting adaptation into existing development agendas, and insufficiently defining adaptation success (Eriksen et al., 2021). A 2017 study estimated that less than 10 percent of climate finance committed from international, regional and national climate funds to developing countries between 2003 and 2016 went to locally focused projects, suggesting a need to rethink approaches if the most affected groups are to build sufficient resilience to the impacts of climate change (Soanes et al., 2017).

The literature shows with *high confidence* that the poorest groups in society often lose out, and require greater planned adaptation support, having less capacity to adapt than better off groups with easy access to assets (Barbier and Hochard, 2018; Ziervogel, 2019b; Box 8.5). Developing countries such as Burkina Faso, Mali and Zambia are not only among the most vulnerable to climate change, they are also the least able to mobilise the finance needed to adapt to its impacts (ND-GAIN, 2019). Women and girls are often most heavily burdened. When building adaptive capacity these groups can require different support such that their knowledge, capacities and skills can be harnessed, in such a way that does not feminise responsibility and add to their burdens (Clissold et al., 2020; McNamara et al., 2021a).

There is broad support for the notion, enshrined in the Paris Agreement, that adaptation finance flowing to developing countries of the Global South should primarily benefit the most climate-vulnerable among them due to their limited technical capacity and financial capabilities, yet such countries are often insufficiently considered in funding decisions. There are nevertheless concerns regarding institutional fit: that foreign funding regimes may not map onto more recently developed administrative traditions, leading to dominance of governance models emanating from donors (Vink and Schouten, 2018). Research has found multilateral donors do not prioritise vulnerable developing countries at the project selection stage and they have received smaller allocations of adaptation finance from bilateral donors than less vulnerable countries (Saunders, 2019), leaving the poor vulnerable to climate impacts. The lack of climate finance flowing to LDCs and SIDs (currently 14 and two percent of the total, respectively) is compounded by access issues due to the inability of domestic institutions to meet specific fiduciary standards and other access requirements, insufficient human resource support and the inflexibility of current approaches which are biased in favour of governments and against non-traditional actors such as local enterprise and grassroots organisations (Shakya et al., 2021). Further, vulnerable developing countries shoulder additional financial burden, embodied in higher interest payments to service public and private debt, due to the increased cost of capital brought about by greater exposure to climate risks (Buhr et al., 2018). This has been further exacerbated by the recession and debt distress accompanying the Covid-19 pandemic (Kose et al., 2021). A range of reforms, including comprehensive debt relief by public creditors, green recovery bonds, debt-for-climate swaps and new SDG-aligned debt instruments may address unsustainable debt burdens, freeing up investment in climate adaptation and a green economic recovery (Volz et al., 2020; see Section 8.6.3.1)..

Greater investment is also needed in the developed countries of the Global North. For example, both the 2018 forest fires in Sweden, the 2019-2020 Australian bushfire season and the 2020 forest fire season along the US West Coast were unusually long and severe, resulting in unprecedented damage to natural habitats and human livelihoods and, relatedly, significant economic cost, particularly given interlinkages with other stressors such as Covid-19. While a range of drivers underpin annual fire seasons, including greater water withdrawal and years of fire suppression, early research indicates that climate change increases their likelihood due to long-term warming trends (van Oldenborgh et al., 2021a).

However, investing in poverty reduction does not necessarily lead to climate change adaptation and where adaptation does result, it does not always reduce vulnerability of the most marginalised, such as documented in case studies from Northeast Brazil (Nelson et al., 2016). Poverty also affects private adaptation options. For example, research from Portugal highlights the importance of private financial assets in helping older adults to adapt to extreme temperatures (Nunes, 2018).

Policies and investments that are adopted are embedded within the relevant legal and regulatory frameworks, which extend beyond national jurisdictions upward to the regional scale (such as the Southern Africa Development Community's Southern Africa Regional Framework of Climate Change Programmes, (2010)) and international scale, for example, UNFCCC, the 2015 Paris Agreement, the Sendai Framework for Disaster Risk Reduction, the New Urban Agenda and the SDGs. Legal and regulatory concerns also extend downward to shape local- and city-scale adaptation efforts (e.g., Sao Paulo's municipal policy and new master plan). Nevertheless, only a minority of countries have dedicated legal frameworks supporting adaptation (Lesnikowski et al., 2017) and these often lack in both precision and obligation—largely because adaptation is a contested global public good but also because adaptation is commonly bundled in with mitigation commitments (Hall and Persson, 2018). Coherence, horizontally and vertically in both policy and law is often lacking. At the same time, bottom-up, private, autonomous adaptation efforts are being better tracked, with different actors motivated by growing experiences of local climate change impacts (Berrang-Ford et al., 2014).While the emergent polycentricity of adaptation governance is beginning to take shape, wherein both state and non-state actors share a common adaptation goal and interact coherently, yet often independently, to advance progress towards it (Morrison et al., 2019), understandings of how various centres of decision making with different degrees of autonomy support an enabling environment for adaptation, remain at a nascent stage . Multiple scales and forms of adaptation occur, with attributes such as self-organisation, appreciation of site-specific conditions, and the need for learning and experimentation, alongside building of trust, increasingly shown to be vital (Dorsch and Flachsland, 2017). Literature indicates that professional and learning networks are important groups supporting adaptation in cities and can help harness resources (Woodruff, 2018); while (Hauge et al., 2019) research in Norway underscores the importance of working across multiple disciplines and the inclusion of actors from different levels of authority in multilevel municipal networks. They found that these factors can help to identify specific adaptation actions as well support knowledge sharing within participating organisations, which in turn helps garner commitment to adaptation and its implementation. They also found that it is important to involve local leaders in polycentric adaptation networks.

Among the many institutions, actors and roles associated with successful adaptation, two play an increasingly important role: local governments and the private sector (Noble et al., 2014). These groups often define the flows of information and finance from the top down, as well as supporting the scaling up of community and household adaptation. In some countries, for example, in South America (Argentina, Brazil, Paraguay) vocational agricultural schools, often in remote rural locations, play a key part in knowledge sharing activities that support adaptation. Similar valuable contributions are made by universities through their outreach activities, particularly those offering programs in environmental and agricultural fields. Many actors face a lack of resources and capacity, particularly at the local level. Local institutions, including local governments, non-government organizations (NGOs) and civil society organizations, are hampered by ongoing challenges in gaining support from higher governance levels—from national government or the international community, particularly in developing countries. At the same time, private sector actors, from individual farmers and small/medium enterprises (SMEs) as well as large multinational businesses, will seek to protect and enhance their production systems, supply chains and markets by pursuing adaptation-related opportunities. Yet, while these goals will help expand adaptation activities, they may not align with government or community objectives and priorities without coordination and incentives, and in the process, can reinforce existing capacities, inequalities and power relations (Sovacool et al., 2015). Similarly, an enabling environment for businesses' adaptation is highly differentiated and often requires structural deficits (such as limited market access, finance and transport and communications infrastructure) to be tackled (Gannon et al., 2020).

The challenges of climate change have driven governments around the world to emphasise climate services as a route to enhance decision-making and reduce climate-related risks, as well as inform adaptation, supporting calls for the right to information (Tall and Njinga, 2013). While there have been some efforts to evaluate the economic impact of climate services alongside other impacts (e.g, Tall et al., 2018), little is known about the institutional contexts in which investments in climate services have taken place, nor those groups that are most vulnerable or marginalised in relation to specific climate risks. Vincent et al. (2017) offer preliminary insights from Malawi, identifying that barriers to improved integration of climate services in national policy planning include factors relating to spatial and temporal scale, accessibility and timing of information provision, credibility and mismatches in time-frames between planning cycles and climate projections. An understanding of the factors that enable climate service investment is important for the development of climate services at local, national and international levels (Vaughan et al., 2017) but this area of literature is not yet well developed.

Overall, adaptation entails financial (and non-financial) costs not just in implementing adaptation actions, but also in designing, facilitating and preparing for actions—costs to create and maintain an enabling environment (see also Section 8.2.2.3, Cross-Chapter Box LOSS in Chapter 17). Financial and economic investments target the whole range of other types of asset (natural capital, physical capital, human capital, social capital). AR5 reports that aggregate economic losses accelerate with increasing temperatures (IPCC, 2014a). Costs may be borne when gaining information (e.g., investments in climate services), while adjustment costs are incurred as adaptations take place. Nevertheless, to enable adaptation, investment is needed in various natural, human, physical and social assets, as considered below. The importance of investment in each of these different types of asset varies according to the scale and livelihood system in need of adaptation and the ways in which livelihood resilience is framed and power is distributed, within each specific setting (Carr, 2020).

8.5.2.2 Natural capital

It is well established that climate change compounds the impacts of pressures that humans place on the environment (*high confidence*) and that environmental degradation can undermine options for adaptation and an enabling environment, with poor and natural resource dependent groups most acutely affected (see e.g., CCP3 for insights from deserts and semi-arid areas). Sustainable management of natural capital contributes to building resilience and the natural ability of ecosystems to adapt to climate change (IPCC, 2014a) and see also IPCC SROCC Chapter 5, Section 5.3.2 (Bindoff et al., 2019). Some systems like mangroves (found in 123 countries, many of which are in the developing world) offer a broad range of vital ecosystem services(Hamza et al., 2020). Mangroves provide regulating services by acting as a natural defence against sea level rise and storm surges; and by sequestering carbon in both the trees and sediments they capture. Provisioning services (e.g., fish, crabs, timber and fuelwood) from mangroves support livelihoods and livelihood adaptation options especially for those with few other livelihood opportunities, while these systems also provide important habitat (breeding, spawning and nursery grounds for fish) and biodiversity, and offer cultural services in the forms of education, recreation and spiritual benefits (Quinn et al., 2017). As the frequency of events such as hurricanes, storms and typhoons rises with climate change, natural capital assets like mangroves become increasingly important in protecting coastlines and supporting adaptation. While not reducing the hazard itself, the mangroves reduce exposure and in some cases also vulnerability. The literature shows with *high confidence* that environmental assets support both climate change mitigation (at a large scale) and adaptation (at a smaller scale), particularly for the poorest groups in society who directly depend upon natural capital for their subsistence (e.g., Angelsen et al., 2014). In turn, the legal and regulatory context and institutional set up determines who has access rights to different aspects of the natural resource base. This shows how different aspects of the enabling environment work in tandem to constitute one another.

In a market economy, human activities tend to exacerbate degradation of natural capital, despite its role in buffering climate change impacts, supporting mitigation and providing adaptation options. Economic agents base their decisions on market prices, even though market prices do not incorporate the costs of deteriorating natural capital because of externalities and other market failures, i.e., environmental degradation is not internalised (Bowen et al., 2012). At the same time, expanding populations, capitalism and consumption choices affect the condition of natural capital, alongside short-termism stemming from poverty, linked to the need for survival. All these factors therefore interact, with the aggregate effect of worsening the impacts of climate change, while also undermining future adaptation options, particularly for the poor. Adaptation policies should, but do not always, compensate for the prevalent market failures. For example, in Melanesia, sea walls have been built out of coral by local people in an attempt to reduce the impacts of rising sea levels, leading to outright destruction of some of the world's most productive and biodiverse coral reefs (Martin and Watson, 2016). Similarly, in the Congo Basin, farmers are adapting to increasingly variable rainfall by expanding their cropping activities into forested areas, releasing carbon into the atmosphere through forest clearance activities and threatening biodiversity. Agricultural land is also being degraded globally (see the IPCC's SRCCL (IPCC, 2019a)), and this too closes down adaptation and livelihood options for the poorest, natural resource dependent populations, while jeopardising food security, biodiversity and human health at wider scales. An enabling environment for adaptation therefore demands investment in sustaining natural capital at multiple scales, internalising the costs of degradation, as well as establishing the necessary legal and regulatory frameworks (and associated enforcement) to reduce its degradation(IPBES, 2018).

The literature increasingly shows that approaches such as nature-based solutions (NBS) and ecosystem-based adaptation (see Chapter 2 and Chapter 6) can offer value for money in tackling climate change from both a mitigation and adaptation standpoint (Seddon et al., 2020). According to the Global Commission on Adaptation, a global investment of $1.8 trillion between 2020 and 2030 into adaptation measures such as early warning systems, climate-resilient infrastructure, improved dryland agriculture, mangrove protection, and resilient water resources can yield $7.1 trillion in total net benefits (Global Commission on Adaptation, 2019). NBS operate by harnessing natural processes, sometimes in combination with technological or engineered solutions. Examples encompass green public spaces and parks (Sahakian and Anantharaman, 2020), green infrastructure, such as urban forests and street trees (Richards and Edwards, 2017) which create shade and reduce urban heat island effects whereby urban areas are warmer than their surroundings (Depietri et al., 2013), and support human health and wellbeing by keeping people in cities more closely linked with nature (Gulsrud et al., 2018). NBS also encompasses blue infrastructure including constructed wetlands, bioswales, rain gardens etc., which can reduce flood risks (Haase, 2015). While the literature is generally positive about the ability of NBS to support climate risk reduction and deliver multiple other benefits (Connop et al., 2016) such as green job opportunities, improved provision of recreational space, cleaner air, habitat provision and increased property values (Emmanuel and Loconsole, 2015), more research is required to specifically assess and evaluate the conditions and contexts in which these kinds of potential benefits are realised and how they can be mainstreamed into policy (Frantzeskaki et al., 2019). Similarly, there is *limited evidence* on unintended consequences (e.g., methane production, creation of habitat for disease vectors, increased human-wildlife conflict) and how these can be avoided (Wolch et al., 2014).

8.5.2.3 Human capital

Successful adaptation requires support to be directed towards human capital and socio-economic capabilities and competences, in terms of education, knowledge, experience, health and wellbeing, and migration, enabling people to contribute meaningfully towards development (Bowen et al., 2012). At the same time, strong human capital and investment in actions that build human capacities to deal with climate change, can further enhance adaptation activities linked to other capitals, and contribute positively to overall disaster risk reduction.

Analyses of educational attainment distributions with datasets reaching back as far as 1970 show that improving educational attainment in people of working age has been the most consistent and significant driver of economic growth globally (Lutz et al., 2008), showing the importance of the right to education. Education has further supported sustainable development by fostering empowerment, yielding access to information (including on climate change) and has clear links to other aspects of human capital, including health and mortality (Samir and Lutz, 2017). There is *medium evidence and high agreement* that education reduces vulnerability and enhances adaptive capacity (Frankenberg et al., 2013; Sharma et al., 2013), with *high agreement* that climate change impacts can have negative effects on existing levels of human capital, with some development pathways affected more than others (Samir and Lutz, 2017). Education can help to shape people's risk perception and assessment, as well as affecting knowledge sharing and the development of problem-solving abilities (Striessnig et al., 2013).

At the same time, Indigenous Knowledge and Local Knowledge can inform adaptation actions (Apgar et al., 2018), but is poorly integrated into formal educational systems and in some cases is insufficient to adapt to new hazards that are emerging as a consequence of climate change. Education further feeds into livelihood options, with close relationships between people's earning capacities, the livelihood choices they can make and their levels of financial capital. It also supports food security (Lutz et al., 2004). There is *medium evidence* that climate change can undermine human capital and education. For example, studies have shown that higher temperatures reduce exam educational performance (Park, 2020), while extreme weather events such as snow storms disrupt learning, yielding long lasting and multidimensional effects (Maccini and Yang, 2009; Cho, 2017; Graff Zivin et al., 2018).

As well as studies examining formal education, a large body of research has focused on social learning and its role in building adaptive capacity through joint knowledge production and reflexivity. Foregrounding the need for continuous changes in response to emerging conditions, this literature identifies the potential of shared learning for co-constructing policy and practice responses to complex, multi-stakeholder environmental problems, and highlights both the necessity and challenge of including non-dominant values, knowledge and expertise in adaptation decision making, considering the role of power dynamics therein (Collins and Ison, 2009; Ensor and Harvey, 2015; Phuong et al., 2017; Apgar et al., 2018; Brymer et al., 2018; Fisher and Dodman, 2019). A growing body of evidence also links to on organisational learning and adaptation. It was found that organisations' adaptive behaviours, like those of households and individuals, do not operate in a vacuum, with organisations' behaviours shaped by policy and market conditions amongst other factors. Mudombi et al. (2017) highlight further barriers in their study in South Africa, linked to inadequate resourcing, political interference, governance shortcomings and knowledge/expertise gaps within organisations, alongside short timeframes for implementing projects.

Adaptations that support human health and wellbeing require investments in physical assets and infrastructure linked to water and sanitation (see Chapter 4), particularly in rapidly urbanizing areas in the Global South, alongside specific pro-poor investment strategies given disproportionate climate change impacts on women (See Cross-Chapter Box GENDER in Chapter 18), other marginalized groups and low income households who lack access to healthcare. Climate change facilitates the spread of vector borne diseases such as malaria, as well as illnesses such as meningitis (Rocklöv and Dubrow, 2020). Impacts on health are also experienced, through food insecurity resulting from climate change, including malnutrition, as well as through loss of livelihoods, making it more difficult to afford and to access health services. Health aspects are considered in-depth in chapter 7 but we underscore the importance of a rights based lens on adaptation in supporting the right to health and food in the context of inequality.

A key dimension of human capital is local understanding of climate risk, which includes knowledge systems outside western scientific approaches. For millennia, local communities have relied heavily upon culturally accumulated Indigenous Knowledge participating in landscapes as stewards of their environment, engaged in profoundly detailed livelihood strategies that deal with natural hazards (Ajayi and Mafongoya, 2017). Indigenous Knowledge systems as they are embedded in culture, and are passed from generation to generation in various ways: livelihoods, traditions, spiritual practices and oral tradition, cultural identity, and historical memory. Indigenous Knowledge is known or learnt from experience, or acquired through observation and practice, and handed down from generation to generation. It is acknowledged that Indigenous Peoples communities, particularly those in hazard-prone areas, have developed a profound understanding and knowledge of disaster prevention and mitigation, early warning, preparedness and response, and post disaster recovery. While Indigenous Knowledge systems, themselves, are an indispensable dimension of capacity for adaptation, and where threatened represent a major risk to Indigenous Peoples communities. While still robust among Indigenous Peoples in many parts of Africa, Asia and Latin America, Indigenous Knowledge is not well reflected or incorporated in assessments such as this, and stands in danger of being lost as its custodians are passing away.

Indigenous Knowledge about natural hazards enables communities at risk to take steps to reduce climate risk. Indigenous Knowledge systems are locally indispensable resources for adaptation to climate change, yet are often misunderstood and undervalued. Generally, Indigenous Peoples and other local groups hold relevant local-scale knowledge about environmental change, the impacts of those changes on ecosystems and livelihoods at local scales, and possible locally effective adaptive responses. However, it is important that Indigenous Knowledge and Local Knowledge is situated within knowledge from other scales in order to assess its broader relevance and applicability (Ahlborg and Nightingale, 2012). Some authors suggest including Indigenous Knowledge in the IPCC assessment process should be of high priority, as it is becoming increasingly relevant for climate services (*high confidence*) (Strauss and Orlove, 2003; Crate and Nuttall, 2009; Crate, 2011). Their knowledge can draw attention to climate baselines and change, and identify adaptation priorities, such as plant and animal species that should be protected given local contextual environmental considerations. For example, using Indigenous Knowledge in weather and climate prediction, local communities in different parts of Tanzania have been coping with and adapting to increased climate variability normally manifested in the form of increased frequency and magnitude of various exigencies including droughts and floods, and outbreak of pests and diseases (Kijazi et al., 2013). Prediction of impending hazards has been an integral part of Indigenous Peoples' adaptation strategies. Various environmental and astronomical indicators are used to predict rainfall, including plant phenology, behaviour and movement of birds, animal and insects are widely used in many parts of Tanzania (Kijazi et al., 2013).

There are efforts in developing adaptation plans that utilize local knowledge. Local knowledge-based adaptation is focused primarily on the use of traditional knowledge to increase adaptive capacity at the community level and less on integration (Mimura et al., 2014). Hence, there is need to increase effectiveness of policy processes that work towards integration of local and scientific knowledge (Nakashima et al., 2013; IPCC, 2014a).

8.5.2.4 Physical capital

Ensuring sufficient investment in physical capital is vital to support development pathways at the national level, but for the poorest and most marginalised in society, physical capital represents an invaluable source of adaptation options (Hallegatte et al., 2019). Physical capital constitutes assets such as land, roads and other infrastructure (e.g., water supplies, electricity, mobile phone connectivity), housing and other buildings, as well as the materials and tools needed to make a living (e.g., farming, forestry and fishing equipment, transportation vehicles, technology). It can also help to foster a sense of place, and can support wellbeing. Climate change impacts on physical capital are often widespread, as well as economically and emotionally costly, particularly when communities afflicted by hardship (inadequate levels of sustainable human development through access to essential public goods and services and access to income opportunities (Abbott and Pollard, 2004).

Given the massive scale of investments required to build and sustain physical capital at the state level, it is imperative to ensure physical capital decisions take into account climate resilience; not least because retrofitting and replacing are both highly costly. The World Bank estimates that adapting over the period 2010-2050 to a world that is 2 °C warmer by 2050 will cost $70 billion to $100 billion per annum, with the infrastructure sector accounting for the largest share of costs (World Bank, 2010). At the same time, every $1 invested in preventive measures can save $5 of repairs (PRIF, 2013). While adequate financing and technical expertise are required, as well as foresight in planning and design and climate risk screening, successful adaptation relating to physical capital also demands legal and institutional enablers (e.g., development and enforcement of building codes and regulations; roll out of insurance options; planning restrictions to reduce construction in locations that are highly exposed to climate hazards etc). In some situations, these are lacking. For example, low-lying least developed countries such as Bangladesh, as well as small island nations, regularly suffer from climate events such as floods, typhoons, cyclones, hurricanes and saline intrusion (see chapter 15 on small islands). Hazards such as typhoons cause substantial damage and destruction, impede mobility, reduce connectivity, disrupt communications, food, water and energy supplies and render people homeless and without the assets they rely on to make a living. In the absence of adequate legal and institutional enablers, as well as livelihood assets, it makes the maintenance of physical capital far more challenging, as the case of Cyclone Aila in Box 8.8 demonstrates.

[START BOX 8.8 HERE]

Box 8.8: Cyclone Aila in Bangladesh: Impact, Adaptation and Way Forward

Historically, southern coastal Bangladesh, where the 1970 Bhola Cyclone killed 500,000 people, has been considered among the most climate vulnerable environments on Earth. However in recent decades, extreme weather events, like Cyclone Aila, though still destructive and destabilizing, have resulted in lower death tolls thanks to a concerted investment in flood mitigation infrastructure, a dense network of cyclone shelters and a robust early warning system (Chowdhury et al., 1993; Paul, 2009). Cyclone Aila struck the south-west coast of Bangladesh on 25 May 2009 with a wind speed of 120km/hour (Islam and Hasan, 2016). With tidal surges of up to 6.5 m, occurring over dry pre-monsoon soils, 11 coastal districts and more than 3.9 million people were affected (United Nations, 2010), 190 people died, and 7,100 people suffered injuries (Saha, 2017).

Aila greatly damaged the region's physical capital, including 6000 km of roads and 17,000 km of embankments. The cyclone polluted and damaged sources of drinking water and destroyed 243,000 houses and thousands of schools (Mallick et al., 2017; Paul and Chatterjee, 2019). In Satkhira and Khulna districts alone, 165,000 houses were destroyed and households were forced to live on damaged embankments in makeshift shanties(UNDP, 2015). Many people had to live in these temporary shelters for years (Saha, 2017). Aila occurred during a high tide and the surge of saline water inundated not only the roads, embankments and houses but also vast areas of agricultural field and shrimp farms (Paul and Chatterjee, 2019) leaving many areas waterlogged for months (Abdullah et al., 2016; Mallick et al., 2017). The effect of saline water logging inside embankments caused further harm to houses, roads, and culverts, adding more barriers to the post-disaster reconstruction activities (Roy, 2020). In the same area, tube-wells were damaged. Women had to travel up to 2 km every day to collect safe water, spending 30–90 minutes on this activity daily (Alam and Rahman, 2019). The distribution of costs across different socio-economic groups was not always as expected. A study in Aila affected Koyra sub-district of Khulna found that households with higher incomes were more vulnerable to Aila in both relative and absolute terms compared to middle- and low-income groups mainly due to damage to shrimp farming which underpinned their livelihoods (Abdullah et al., 2016). This highlights how specialised livelihoods can leave people more vulnerable as they have fewer options. However, the same study found that the damage to physical capital such as fishing nets and boats was statistically significantly greater for middle- and low-income groups. Damage to houses was statistically significantly more among poorer households followed by middle and higher-income groups.

A range of coping and adaptation actions were enacted in response to losses of and damage to physical capital (Table Box8.8.1). Actions varied across the different affected areas and were taken by the households themselves, by the Government, and NGOs.

Table Box 8.8.1: Coping and adaptation actions enacted in the cyclone Aila affected area in response to losses of and damage to physical capital

Coping and adaptation actions	Action group	References

Human migration—mostly forced due to loss of houses as well as other resources and livelihood activities	Households	(Abdullah et al., 2016; Mallick et al., 2017; Paul and Chatterjee, 2019)
Alternative livelihood activities such as crafts, and honey and wood collection from the Sundarbans, due to irreparable damage to fishing gear	Households	(Alam et al., 2015)
Saving money for house repairs or construction	Households	(Alam et al., 2015)
Underground storage of emergency items such as foods, matchbox, cooker and cooking fuel	Households	(Alam et al., 2015)
Selection of high land to build shelter along both sides of the embankments	Households	(Alam et al., 2015)
Tree plantation in the homestead periphery to protect the house from gusty winds and to use as a source of wood for house repair/construction	Households	(Alam et al., 2015)
Increasing height of the house plinth	Households	(Alam et al., 2015)
Changing of house roofing material from thatched to corrugated iron sheet or asbestos	Households	(Alam et al., 2015)
Informally allowing people to harvest Sundarbans forest wood without any charge so they could make makeshift houses	Forest Department	(Abdullah et al., 2016)
Rainwater harvesting using plastic or clay pots and artificial aquifer tube-wells for securing drinking water.	NGOs and Households	(Sultana and Mallick, 2015)
Replacement of mud walls of houses with wood or bamboo sticks to enhance durability	NGOs and households	(Sultana and Mallick, 2015)
Making thick shelterbelts along coastal embankments	NGOs and households	(Rahman and Rahman, 2015)

The impacts of some of these adaptations, particularly engagement in new livelihood activities after Aila, were varied, with income of the affected households increasing in some cases and decreasing in others. In Koyra, the income of the poorest and middle-income households increased by 16 % and 4% respectively, while the income of richer households (many of whom lost physical capital assets that they use to pursue their livelihoods) decreased by 50% (Abdullah et al., 2016).

Research into adaptation projects led by various actors has shown that adaptations taken by the households and community themselves are effective only to address typical challenges (such as seasonal shifts in temperature or rainfall) but are less effective in addressing extreme events that have long-lasting impacts. This is mainly due to lack of adequate resources and institutional support (Alam et al., 2015). At the same time, some coping mechanisms are harmful in the longer term, for example, harvesting Sundarbans forest wood after Aila for reconstruction could have negative impacts on the forest.

As of 2017, many of the affected areas had not yet been able to recover from the effects of Aila (Paul and Chatterjee, 2019). A transformative approach needs to be taken not only to help them recover in livelihoods terms, but also to support people’s wellbeing. Suggestions of physical interventions that are needed include higher and stronger dykes, cyclone-resistant housing, active maintenance and strict policing of embankment use and good governance (Abdullah et al., 2016). Enabling formal institutions could help, for instance, by improving the climate-resilience of physical capital (e.g., by developing and enforcing building codes for houses). Other institutional mechanisms could help to improve access to low interest credit, prevent maladaptation, improve enforcement of laws, and provide insurance. However, such institutional reforms need to be co-developed with local people and incorporate local cultural mechanisms (Islam and Nursey-Bray, 2017). Future adaptation strategies also need to take into account the limits to autonomous adaptation (i.e. that without external intervention) and differential level of impacts and adaptive capacities among different groups of households in the Aila affected areas. This example illustrates the importance of a more comprehensive approach to resilience building, and the need to better understand the interlinkages between the core components of an enabling environment for adaptation (see Figure 8.12).

[END BOX 8.8 HERE]

Physical capital in the form of technology is increasingly supporting climate change adaptation, despite that innovations can be rolled out under high uncertainty, opening up new risks (e.g., hacking). Moreover, deployment of technology is closely tied to other forms of capital, especially human capital, and innovations cannot just be rolled out in the absence of suitable institutional and technical support and training. Similarly, access to finance is vital. Some technological adaptations require a pre-existing level of infrastructure and literacy, raising important questions about inequality (Taylor, 2018). Rotz et al. (2019) warn of automation impacts on rural labour, especially in places with high youth unemployment, while Taylor (2018) notes that social classes and gender are impacted differently by technological change, and failure to address underlying inequalities will shape who becomes vulnerable. Adequate testing of technologies in terms of their applicability to different contexts is also required, ensuring they do not become maladaptive when applied at scale.

Similarly, technology must always be grounded in an appreciation of the cultural context. Research in the European Arctic with the Indigenous Sami Peoples found that use of GPS technology on reindeer, together with supplementary feeding, offer useful adaptations for some herders. However, there are fears such technologies may, over time, reduce the skills, cultural knowledge and Indigenous adaptations of the Sami (Andersson and Keskitalo, 2017), as, for example, reindeer become more tame through supplementary feeding, affecting their range selection. Overall, technology and other adaptations should seek not to erode Sami culture's adaptive capacity (Vuojala-Magga et al., 2011; Risvoll and Hovelsrud, 2016), particularly because reindeer grazing as a land management practice can play a useful climate change mitigation role too. Reindeer grazing protects tundra from tree line and bush encroachment, while summer grazing increases surface albedo by delaying snowmelt (Jaakkola et al., 2018).

8.5.2.4.1 Socio-cultural factors

Social and cultural factors are closely linked to values, beliefs and identities (Heimann and Mallick, 2016) and mediate the ways in which people respond to climate variability and change (Adger et al., 2013). There is *limited evidence* but medium agreement about the importance and role of social and cultural factors in shaping adaptation, in terms of both the need to adapt and the way it is presented and communicated, although evidence is somewhat mixed in terms of how experiences of weather affect opinions and perceptions of climate change (Howe et al., 2019). Research also highlights the importance of context in understanding relations between perceptions of risks and behaviour, arguing that power relations and other obstacles and opportunities play a vital role in shaping actions (Rufat et al., 2020). In general, nonetheless, adaptation is spurred when people perceive that there is an action they can take to make a difference (Kuruppu and Liverman, 2011; Mayer and Smith, 2019), although it cannot be assumed that action will be taken if the socio-cultural setting is not amenable and it contravenes the values underlying people's perceptions (Kwon et al., 2019). Research testing for the effect of beliefs on behavioural change from 48 countries highlighted the need for policy leaders to present climate change as solvable yet challenging, if fatalistic beliefs that act as barriers to adaptation were to be reduced (Mayer and Smith, 2019). This demonstrates how beliefs do not always reinforce actions, even when risks are perceived. Similarly, research from Burkina Faso working with the Fulbe ethnic group found that cultural norms restricted engagement in four of the most successful livelihood strategies that support adaptation to climate change (labour migration, working for development projects, gardening and female engagement in economic activities) (Nielsen and Reenberg, 2010). Cultural factors therefore play an important but under-researched role in adaptation.

Social factors in the context of adaptation, by contrast, are more widely studied. The literature on adaptation and the role of social capital as an enabler is diverse. There is *high confidence* that during disasters, social capital plays an important role in linking those who are affected to external supports and resources, while on small islands social networks can be dense and support adaptation (Petzold and Ratter, 2015), with traditional knowledge and societal cohesion helping small island communities to have self-belief and build resilience even in the absence of external interventions (Nunn and Kumar, 2018). Even the development of weak ties (e.g., one-way information transfer) can lead to establishment of mutual collaboration relations that can be more easily draw on in times of climate change related shocks and stresses (Ingold, 2017), while collective shared disaster experiences can cause new social groups to emerge and spur action, linked to a perceived common fate (Ntontis et al., 2020). However, this can exacerbate inequalities and create new ones, with those who are more connected having enhanced access to, for example, shelters following storm evacuations or earthquakes (Rahill et al., 2014). In adapting to more incremental changes, social capital has been shown to increase shared Local Knowledge and awareness, support participatory processes and strengthen ties to corporate and political institutions, increasing their responsiveness to local concerns, as shown by examples from Aldrich et al. (2016). They describe how in Houma, Louisiana, located west of New Orleans, rising sea levels and hurricane risks have drawn on and built social capital at the community level. Having what was perceived locally as insufficient federal government support, residents, church groups and town council members collaborated to spur adaptation. Community mobilisation led to construction of self-funded levees and water projects to protect 200,000 residents from storm surges. Projects include marshland restoration, the elevation of existing housing, improved pumping systems and canal drainage, as well as buyouts and relocations of businesses and housing that has been repetitively damaged. Funds were raised from households through donations via a self-imposed sales tax. While this example paints a positive picture of the role of social capital and collective action in adaptation activities, it also raises questions about the coherence of actions across levels, again, highlighting a role for polycentric governance if risks of maladaptation are to be reduced. The danger in the example presented here is that should federal plans in future conflict with the community level work, local efforts may have been in vain if installations have to be removed. This highlights the importance of careful evaluation of all adaptation options on an ongoing basis.

Further warnings about social capital as an adaptation enabler come from Acosta et al. (2016) who recognise that it may be detrimental to private adaptation in some cases. Their research in rural Ethiopia found that qualitative measures of trust predict contributions to public goods, supporting theories about collective action, but that the effects of social capital are not homogenous: it can be helpful in some contexts, but unhelpful, or even detrimental in others. This led them to highlight the need for policymakers to consider these potentially different outcomes. Other research, also from Ethiopia, suggested that households with more social capital are more specialised in their livelihood strategies. This could leave them more vulnerable to climate change impacts (as per the cyclone Aila example where shrimp farmers were specialised and hit hardest by the cyclone's impacts), though social capital acts as a kind of informal insurance (Wuepper et al., 2018).

8.6 Climate Resilient Development for the Poor and Pro-poor Adaptation Finance: Ensuring Climate Justice and Sustainable Development

This section evaluates climate-resilient development (CRD) focussing on potential synergies between adaptation and mitigation in different sectors, decision making approaches and adaptation finance especially for the poor. It examines whether climate change response options, meaning mitigation and adaptation, in different development sectors, create development synergies or trade-offs for low-income households and people living in poverty.

The link between development and climate change was not evaluated comprehensively until the first decades of the twenty first century (Figure 8.13; Klein et al., 2005; Tol, 2005). Until recently mitigation and adaptation, the two primary approaches to climate action, have been dealt with separately in climate change science and policy (Landauer et al., 2015). Nevertheless, synergistic "co-benefits" between mitigation and adaptation may be enhanced, and trade-offs reduced, through the holistic empirical evaluation of actions for climate change response (Runhaar et al., 2018). The synergetic effect of mitigation and adaptation has been documented for a few interventions across the globe, however, evidence-based quantification of the synergies and trade-offs are rare.

Where co-benefits have emphasized identifying mitigation-adaptation synergies, a key turn has been evaluating Climate Compatible Development (CCD), 'development that minimises the harm caused by climate change impacts, while maximising the many human development opportunities presented by a low emission, more resilient future' (Mitchell and Maxwell, 2010). CCD calls for triple wins, resulting in synergies between mitigation-adaptation-development through single interventions (Figure 8.13; Ellis and Tschakert, 2019). Climate compatible development offers specific entry points for identifying ways on how to strengthen synergies between mitigation and adaptation particularly within the context of low income countries. Effective integration of emission reductions and accommodation actions for mitigation and adaptation can be win-win strategies and may be cost-efficient (Runhaar et al., 2018) and have the potential to create opportunities to foster sustainable development (Denton et al., 2014).

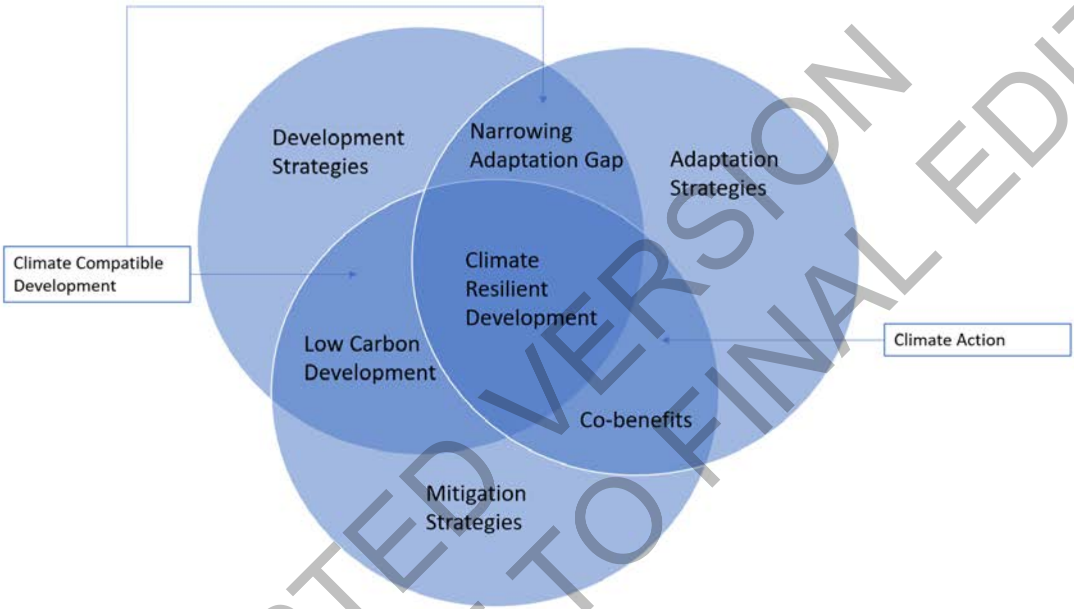

Figure 8.13: Climate Resilient Development (CRD). Actions and strategies consider both Climate Compatible Development and Climate Action.

This assessment identifies and evaluates approaches to Climate Resilient Development (CRD) "that deliberately adopt mitigation and adaptation measures to secure a safe climate, meet basic needs, eliminate poverty and enable equitable, just and sustainable development". The body of literature on the synergies and trade-offs between adaptation, mitigation, poverty, equity and sustainable development has grown steadily since the AR5 (IPCC, 2014a). The IPCC Special Report on the impacts of global warming of 1.5°C (IPCC, 2018c), suggests that 'Limiting warming to 1.5°C can be achieved synergistically with poverty alleviation and improved energy security and can provide large public health benefits through improved air quality, preventing millions of premature deaths'.

Implementing the integrative concept of CRD will likely produce transformative benefits affecting the poorest populations primarily (Roy et al., 2018; Leal Filho et al., 2019). The risks of transformative actions to the poor are diminished when undertaken in the context of good governance at multiple levels, within existing top-down and bottom-up processes, and making use of available levers of policy, technology, education and financial/economic systems (Stringer et al., 2020).

8.6.1 Synergies and trade-offs between adaptation and mitigation in different sectors with implications for poverty, livelihoods and sustainable development

8.6.1.1 Climate Resilient Development

Climate Resilient Development relies on identifying synergies between different strategies and actions in the field of climate change, primarily between mitigation actions with adaptation benefits (Locatelli et al., 2015), adaptation actions with mitigation benefits (Denton et al., 2014; Sánchez and Izzo, 2017), processes that promote both mitigation and adaptation measures, and policies and strategies that promote integrated mitigation and adaptation measures (Zhao et al., 2018). At the same time, adaptation and mitigation actions can be evaluated in terms of their co-benefits, the social, economic or other benefits of actions in addition to avoiding climate change impacts (Karlsson et al., 2020). The clearest co-benefits of mitigation are associated with economic development through low-carbon industrialization (IPCC, 2014c; Jakob et al., 2014; Lu, 2017). Co-benefits can include contributing to economic growth, reducing competition for resources, improved integration of scientific input to policy development and implementation, or improving political participation and social licensing in large-scale projects (e.g., hydropower) (Hennessey et al., 2017). Adaptation can support mitigation and contribute to co-benefits in various ways: ensuring development-based natural resource management (Denton et al., 2014; Suckall et al., 2015; Reang et al., 2021) , integrating water resources management (Liang et al., 2016; Sharifi, 2021), practicing sustainable agriculture (Bustamante et al., 2014; Duguma et al., 2014a; Di Gregorio et al., 2017; Reang et al., 2021), ensuring the protection of ecosystem services (Pandey et al., 2017a; Baumber et al., 2019), conserving biodiversity (Di Gregorio et al., 2017; Loboguerrero et al., 2019; Smith et al., 2019) and managing bioenergy resource (Dovie, 2019).

The key challenge for CRD is addressing climate change from the perspective of development: addressing the fundamental development obstacles that limit capacity for adaptation. Where development is not sustainable, especially if it is not equitable, capacity for adapting is greatly reduced—a phenomenon known as the adaptation gap (Figure 8.14; Birkmann et al., 2021a; UNEP, 2021). Figure 8.14 depicts the effect of development trajectories (as described in the Shared Socioeconomic Pathways framework) on capacity for adaptation, a key determinant of eventual outcomes. Achieving CRD through coupling adaptation with equitable sustainable development under and low emissions profiles that limit warming to 1.5°C (i.e., sustainability scenario) is necessary to close the adaptation gap. Even if emissions are kept low and 1.5°C emissions targets are achieved, if poverty and inequality remain high, then impacts are likely to remain high and may overwhelm capacity for adaptation. High poverty and high inequality in a society (i.e., inequality scenario) reduce the likelihood that countries are able to manage risk and avoid residual impacts, such as also documented in the assessment above (see Sections 8.2, 8.3, 8.4). Unsustainable development trajectories reduce capacity for adaptation and may result in highly unequally distributed residual impacts from climate change. Even despite rapid, equitable development and modest emissions reductions efforts necessary to limit warming to 2°C (i.e. the middle of the road scenario), there is still risk of unequal distribution of impacts. Under all high emissions scenarios (>3°C warming), universal residual impacts are unavoidable.

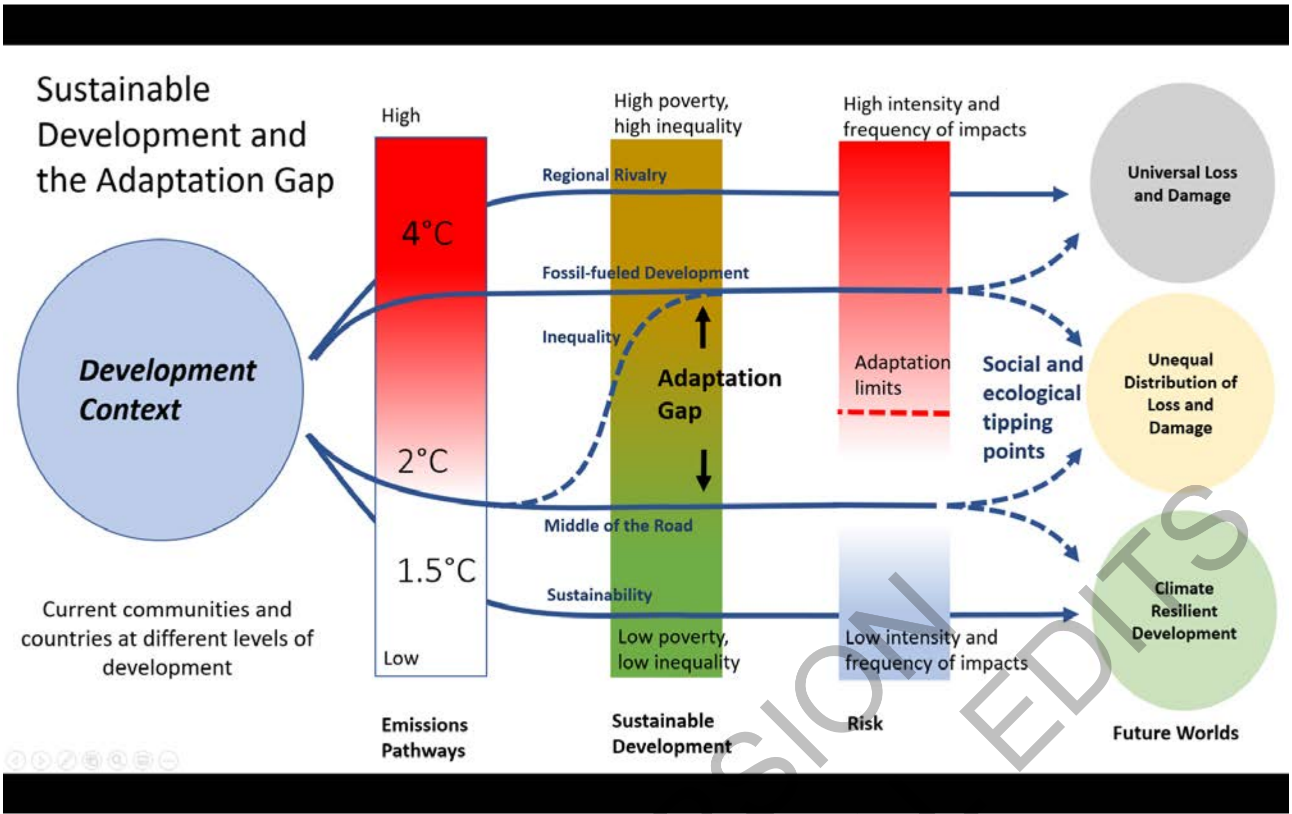

Figure 8.14: Conceptual figure illustrating the link between sustainable development and the adaptation gap. Even if emissions are kept low, if poverty and inequality remain high, then impacts are likely to remain high and may overwhelm capacity for adaptation.

Mitigation planning has not sufficiently considered poverty reduction policies, the basis for narrowing the adaptation gap (see also Figure 8.14). Many synergies between climate change mitigation and poverty reduction have been identified, although sometimes with *limited evidence*. The mitigation measures that have been most evaluated include clean development mechanisms (CDM), programs aimed at reduction of emissions from deforestation and forest degradation (REDD+), voluntary carbon offsets and biofuel production. However, while these mitigation programs stimulate economic growth, they may contribute to processes that trade-off against equitable development and threaten to further impoverish forest communities, such as large-scale land acquisitions (Carter et al., 2017; Schaafsma et al., 2021) and fortress conservation (see IPCC SR 1.5°C Chapter 5 (Roy et al., 2018) and see also Chapter 6 of this report).

The IPCC Special Report on Climate Change and Land (IPCC, 2019a) states that agriculture, food production and deforestation are major drivers of climate change and calls for coordinated action to tackle climate change that can simultaneously improve land, food security and nutrition, and help to end hunger. There are five land challenges identified including climate change mitigation, adaptation, desertification, land degradation and food security. This report identified three major categories of climate response options that show promise for achieving mitigation and increasing capacity for adaptation while addressing poverty: sustainable land management options, value chain management and risk management options (IPCC, 2019a). For example, programs supporting no-till agriculture and residue retention allows small-scale farmers to participate in mitigation and adaptation activities, with long-term benefits to soil health and food, energy and water security (Wright et al., 2014). Likewise, the installation of a solar powered drip irrigation system simultaneously reduces emission, improves water security and increases farmers' income; (Locatelli et al., 2015). Response options in terms of sustainable land management options, and value chain and risk management involves interlinkages between land-based climate strategies, synergies and trade-offs (see Chapter 6). On the other hand, a key trade-off for consideration CRD is the potential for maladaptation, where one adaptation intervention at one time, location or sector could increase the vulnerability at another time, location or sector, or increase the vulnerability of the target group to future climate change (*medium evidence, high agreement*) (Eriksen et al., 2011). A cause of increasing concern to adaptation planners, the understanding of maladaptation has changed subtly to recognize that it arises inadvertently, from poorly planned adaptation actions, but also from carefully deliberated decisions where wider considerations place greater emphasis on singular or short-term outcomes ahead of broader, longer-term threats, or that discount, or fail to consider, the full range of interactions arising from the planned actions across scales (Eriksen et al., 2021). Research identifies the challenge of avoiding maladaptation as one of reducing long-term structural vulnerability. Accordingly, one can consider that CCD and maladaptation as two sides of the same coin. Scholars of 'sustainable adaptation' define it as adaptation that contributes to socially and environmentally sustainable development pathways, which takes into account both social justice and environmental integrity (Eriksen et al., 2011). The parallels in maladaptation include the underlying drivers of vulnerability, namely socio-environmental processes such as conflict, marginalization, economic restructuring, exploitation, institutional fragility, etc (Antwi-Agyei et al., 2018b; Neef et al., 2018).

Harnessing opportunities for mitigation, adaptation and development in an effective manner may lead to 'triple-wins' under CRD, though empirical evidence is extremely rare for such 'triple-wins' strategies that address mitigation, adaptation and development in an effective manner (Tompkins et al., 2013). Integration of mitigation, adaptation and development is being initiated and operationalised through projects by several developing countries for achieving main national development priorities, such as poverty reduction, increased employment opportunities, energy security, transportation (Denton et al., 2014; Stringer et al., 2014). Important follow-on questions from that are pressing social questions about how trade-offs are deliberated, who wins and losses and who decides (see Section 8.4 and Ellis and Tschakert, 2019). Likewise, the efficiency, effectiveness and feasibility trade-offs of climate policies must be considered (i.e., can programs in developing countries be economically efficient and provide opportunities to achieve sustainable development targets for developing countries?) (Dang et al., 2003). Moreover, questions about co-benefits must consider the benefit-cost ratio of mitigative versus adaptive action for assets saved from destruction by climate impacts, for example (Stadelmann et al., 2014). Implementing a mitigation or adaptation option may affect positively or negatively, directly or indirectly, the feasibility and effectiveness of other options such as soil management leads to soil organic carbon (Locatelli et al., 2015; de Coninck et al., 2018). Farmers and local people are often also being encouraged to undertake mitigation and adaptation activities leading to long term benefits such as cultivation of no-till wheat with residue retention leading to low emission along with energy and water saving (Wright et al., 2014).

Moreover, regulatory structure for evaluation of mitigation and adaptation actions is required for understanding the co-benefits of these two actions such as choice of adaptation actions can be made according to their effectiveness per unit of money invested such as economic assets saved from destruction of climate change impacts and benefits can be evaluated in terms of economies, people, and the environment such as human lives and health protected contrary to the emission reduction by mitigation strategies (Stadelmann et al., 2014).

8.6.1.2. Climate Resilient Development Synergies and Trade-offs by Sector

Some sectors—such as agriculture, forestry, energy—are found to have more potential for CRD synergies than others, although trade-offs are also identified. Climate-smart agriculture, carbon-forestry programmes and the water-energy-climate nexus show trade-offs across levels and sectors with identified winners and losers (*high confidence*) (IPCC, 2018a). Mitigation can be designed to provide opportunities for enhanced adaptation with comparable co-benefits, even while adaptation portfolios can maximize co-benefits around sustainable resource management that reduce emissions (Dovie, 2019). Climate policy integration can be considered as the integration of multiple policy objectives, governance arrangements and policy processes of climate change mitigation and adaptation along with other policy domains (Di Gregorio et al., 2017) as well as sector policies integrating climate change adaptation and mitigation (England et al., 2018). Integrating climate policies may require balancing multiple sectoral goals, such as REDD+ projects, climate smart agriculture, water sector strategies, national policies on climate change and national conservation plans (Duguma et al., 2014a). Within the scientific discourse increasing attention is given to the question of the synergies and mismatches between mitigation and adaptation policies.

The assessed literature underscores that for synergies to be realized, mitigation and adaptation policies must be institutionally supported within a multi-level governance architecture (national to sub-national to municipal levels) with other priorities, and identify sustainable financing mechanisms within the country or via the international community (Dovie and Lwasa, 2017). Integrating and mainstreaming adaptation and mitigation across agencies within countries can bridge the divide between climate policy and sustainable development (Venema and Rehman, 2007).

The Paris Agreement recognized that the agreement will reflect equity and common but differentiated responsibilities (CBDR-RC) of national circumstances, (Voigt and Ferreira, 2016). The Paris Climate Agreement should be broadened to include mitigation co-benefits (Dovie, 2019). Integrating adaptation with mitigation may possibly contribute to amend or reduce the discursive rift between climate policy and sustainable development (Venema and Rehman, 2007).

Integrated climate change actions or responses can be inefficient and infeasible in the absence of enabling conditions, including the policy conditions that reinforce unified climate action, and sustainable financial mechanism for implementation of the programs and policies (Duguma et al., 2014b). In the absence of strong coordination, integrating mitigation and adaptation may undermine the overall or individual objectives of either climate response (Kongsager, 2018). A lack of coordination in mitigation and adaptation may also exacerbate the threats of climate change to sustainable development (Ayers and Huq, 2009; Kongsager, 2018). Therefore, for successful integration of CRD, it is necessary to move beyond considering either adaptation or mitigation towards better understanding the linkages between adaptation and mitigation projects and policies at multiple levels of governance, to identify potential trade-offs in projects and policies (Suckall et al., 2015) and to identify the enabling conditions for designing and implementing action leading to synergies (Denton et al., 2014; Kongsager, 2018).

Despite the potential effectiveness and efficiency of integrating mitigation and adaptation under a common CRD framework, gaps persist in our knowledge about the enabling conditions for synergies, due to the limited number of examples and even fewer evaluations. Potential benefits may be achieved by pursuing multi-level governance approaches, that means integrating decision-making at the local level with coordination at other levels, by actors and agencies simultaneously pursuing multiple other priorities (see Section 8.5.2 Shaw et al., 2014). For example, pursuing climate-resilient land-use pathways integrating climate policy within the land use sector requires a governance policy environment that combines multiple policy aims, including urban growth, soil conservation and water management alongside mitigation and adaptation. Facilitating climate resilient land use pathways combining the aims of climate change adaptation, mitigation and sustainable development requires a governance environment requires: i) internal climate policy coherence between mitigation and adaptation objectives and policies; ii) external climate policy coherence between climate change and development objectives; iii) vertical policy integration that to mainstreams climate change into sectoral policies; and; iv) overarching governance structures that facilitate horizontal policy integration cross-sectoral coordination by overarching governance structures for cross-sectoral coordination (Di Gregorio et al., 2017) as well as sector policies integrating climate change adaptation and mitigation (England et al., 2018).

Within sector policies and economic sectors (such as land-use, transportation, and technology) mitigation and adaptation have many positive, negative, direct and indirect linkages within and beyond the sector (Locatelli et al., 2015). The land-use sector, for example, includes agriculture and forestry and encompasses the management of a mosaic of interacting urban environments and ecosystems with a diversity of cultural and institutional attributes (Locatelli et al., 2015). The land-use sector is key to climate adaptation, where policy coordination can enhance food production, regulate urban microclimates, affect water security, and, in the case of mangroves, buffer the impacts of extreme climate events in coastal areas (Locatelli et al., 2015). City-level actions can also be pivotal for reduction in emissions and improvement in resilience (UCLG, 2015) such as zoning and planning that promotes green development and green and efficient energy use. Urban planning and transport policies are crucial to support a transition towards a low-carbon and resilient future (Ford et al., 2018) such as means of transportation as public and private transport facilities are crucial for emission reduction.

CRD may require multi-sectoral coordination, including public-private partnerships (Campbell et al., 2018). In the food system, for example, under a CRD framework transformative actions may require (1) incentives for expanded private sector activities and/or public-private partnerships; (2) publicly-backed credit and/or insurance; (3) public institutional support for strong local organisations and networking; (4) climate-informed weather advisories and early warning systems; (5) digital investments in technological transformation for agriculture (e.g., “digital agriculture” and virtual markets); (6) investments in climate-resilient and low-emission practices and technologies (Duguma et al., 2014b); (7) prioritisation and pathways of change; (8) capacity and enabling policy and institutions are crucial with careful consideration of trade-offs between adaptation and mitigation, and amongst other SDGs for achieving SDG13 'urgent action to combat climate change and its impacts' (Campbell et al., 2018). Moreover, the risks of transformative actions to the farmers is addressed by strong good governance at multiple levels, combining top-down and bottom-up processes along with by a mix of levers that combine policy, technology, education and awareness-raising, dietary shifts and financial/economic mechanisms, attending to multiple time dimensions (Stringer et al., 2020).

8.6.1.2.1 Agriculture and food production

Integrated CRD approaches in agriculture, such as climate smart agriculture (CSA), can reduce trade-offs and exploit synergies with biodiversity and food security to reduce the risk of climate change (Di Gregorio et al., 2017; Loboguerrero et al., 2019). There are many technologies and approaches in agriculture that leverage synergies relevant for CRD, including agroecology (Pandey et al., 2017a; Saj et al., 2017), climate smart agriculture (CSA), climate smart landscapes, organic agriculture mitigating climate change, conservation agriculture, ecological intensification and sustainable intensifications, which in many cases aim to address both adaptation and mitigation to climate change simultaneously (Kongsager, 2018). From these approaches, a number of scalable agriculture technologies have emerged that simultaneously achieve mitigation and adaptation goals, such as reducing water consumption while maintaining grain yield, including alternate wetting and drying (AWD) irrigation technology (Liang et al., 2016) and aerobic rice production (Wichelns, 2016). Likewise, a number of these approaches have been supported within international and national institutional frameworks (e.g., through incentives) to harness synergies (Kongsager et al., 2016).

Climate-smart agriculture (CSA) is discussed in the scientific literature as an approach that could transform agricultural production systems and food value chains in line with sustainable development and food security under climate change. However, concerns and critique have been raised, such as the insufficient consideration of the access to entitlements within CSA and the question who wins and loses when applying CSA in different country contexts (see Karlsson et al., 2017; Sain et al., 2017). CSA has three main objectives: sustainably increase agricultural productivity and incomes; adapt and build resilience to climate change and reduce and/or remove greenhouse gas emissions (FAO, 2017). Various CSA technologies are capable of improving crop yields, increasing net income, increasing input use efficiencies and reducing emissions (Khatri-Chhetri et al., 2017). However, up-take and adoption of CSA by local farmers in poor developing countries remains a challenge (Palanisami et al., 2015) due to the difficulty of identifying and prioritising of technologies suiting local climate risks and accommodating the farming practices of locals (Dougill et al., 2017; Khatri-Chhetri et al., 2017). An analysis of CSA implementation in Mali, for example, identified major challenges to policy makers' efforts to adopt CSA, including difficulties identifying CSA options and portfolios, valuing them, and prioritizing investments (Andrieu et al., 2017).

Potential opportunities from CSA may also result from Integration of "technological packages" (Totin et al., 2018), which include new market structures; knowledge infrastructure and agriculture extension services; and capacity building programs (Dougill et al., 2017; Totin et al., 2018); institutional support for key enabling programs, such as crop insurance, agro-advisories and rainwater harvesting (Khatri-Chhetri et al., 2017). CSA is able—if carefully designed—to achieve transformative "triple wins" for climate and development when it is accompanied by new governance architectures that are socially inclusive and respectful of traditions and livelihoods, and accommodate traditional institutions that underpin the bargaining power of the poorest and most vulnerable groups (Karlsson et al., 2017).

Conservation Agriculture (CA), another framework for achieving CRD, is based on three synergistic principles: a) soil management to reduce soil physical disturbance and reduce its degradation; b) crop management such as residue management to protect the soil top layers; and c) genetic management to increase agricultural systems' biodiversity and in consequences their resilience (DeLonge and Basche, 2017). In the cereal systems of the Indo-Gangetic Plains, India, Conservation Agriculture has increased crop yields, returns from crop cultivation, input-use efficiency, in spite of heat stress even while reducing GHGs emissions (Sapkota et al., 2015). However, also challenges with CA are documented in the scientific literature. For example, an evaluation of CA in Malawi noted that adoption of CA was challenged by weak integration of CA in agricultural policies; lack of institutional arrangements of promoters; and farmers' experiences (Chinseu et al., 2019).

Locally appropriate agroecological practices have clear potential to increase the resilience of livelihoods and enhance adaptation to climate change at field and farm levels across a wide range of contexts, often with significant mitigation co-benefits (Sinclair et al., 2019). Relatedly, agroforestry systems are the intentional integration of trees and shrubs into crop and animal production systems to solve societal challenges including climate change (Raymond et al., 2017). For example, in the tropics, such systems offer viable opportunities to mitigate and adapt to climate change for farmers through transforming into resilient farming systems and improving farm economy while securing environmental benefits to local and global communities (Swamy and Tewari, 2017). In Western Africa, the high plant functional diversity of agroforestry systems with a mix of trees and crops having different roles, such as shade provision, soil fertilization, fruit production, or timber value, maximises benefits and allows alternative adaptation strategies (Tschora and Cherubini, 2020). In spite of various benefits of agroforestry, the expansion of existing areas of agroforestry and the establishment of new agroforestry systems has remained limited (Martineau et al., 2016), mainly due to a lack of institutional supports, a lack of expert support to ensure adequate management, weak capacity for monitoring and regulation, and a lack of financial support (Hernández-Morcillo et al., 2018).

The enabling conditions for the expansion of agroforestry include training and expert support programmes for managers and sharing of best practices (Ashraf et al., 2015; Hernández-Morcillo et al., 2018; Tschora and Cherubini, 2020). Other scalable frameworks integrating food and agriculture within CRD include Sustainable Intensification (SI), which emphasizes sustainable practices to safeguard sustainable use of natural resources, and meet the growing demand for agricultural production, even while building resilience (Thierfelder et al., 2018). Integrated Agricultural Systems (IAS) aim to increase farm diversity and lower reliance on external inputs, enhancing nutrient cycling and increasing natural resource use efficiency (Smith et al., 2017), and may have the potential to enhance resilience against climate change impacts and risks (Gil et al., 2017). Policy frameworks that aim to integrate any of these approaches climate actions must account for the costs associated throughout the up-take and adoption process (Gil et al., 2017).

8.6.1.2.2 Livestock

As the consumption of animal protein and products rises along with global standards of living, CRD will require transformations in livestock-centred livelihoods. Livestock are a key contributor to global food security especially in marginal lands where animal products are a unique source of energy, protein and micronutrients (FAO, 2017; IPCC, 2019a), but also contribute disproportionately to the total annual anthropogenic GHG emissions globally and influence climate through land use change, processing and transport by emitting CO2; animal production by increasing methane emissions; and feed production, manure by emitting CO2, nitrous oxide, and methane, (Rojas-Downing et al., 2017). Mitigation of livestock emissions can be achieved by implementation of various technologies and practices such as improving diets to reduce enteric fermentation, improving manure management, improvement in animal nutrition and genetics (Rojas-Downing et al., 2017); altering land use for grazing and feed production, feeding practices, manure treatment and herd size reduction (Zhang et al., 2017). Adaptation strategies in the livestock sector include changes in animal feeding, genetic manipulation, alterations in species and/or breeds (Zhang et al., 2017); shifting to mixed crop-livestock systems (Rojas-Downing et al., 2017), production and management system modifications, breeding strategies, institutional and policy changes, science and technology advances, and changing farmers' perception and adaptive capacity (USDA, 2013).

Policies supporting sustainable rangeland management and the livelihood strategies of rangeland users have an outsized influence on both development and climate action (Gharibvand et al., 2015). Climate change adaptation, mitigation practices and livestock production can be supported by policies that encourage diversification of livestock animals (within species), support sustainable foraging and feed varieties (Rivera-Ferre et al., 2016), strengthen institutions such as agricultural support programs, markets and intra- and inter-regional trade (Zhang et al., 2017). For example, sustainable pastoralism can contribute to mitigation both by increasing carbon sequestration through improved soil management and by reducing methane emissions through changing the mix and distribution of the herd. Likewise sustainable pastoralism can also contribute to adaptation by changing grazing management, introducing alternative livestock breeds, pest management, and modified production structures (Joyce et al., 2013). Another example of rangeland adaptation is diversifying the use of rangelands such as supplementing with payments for ecosystem services, carbon sequestration, tourism or supplementary assistance for all land based activities (Gharibvand et al., 2015). However, challenges for climate smart livestock production systems remain due to a lack of information, limited access to technology and insufficient capital (FAO, 2017). Small-holders in cropping and livestock systems in Saharan Africa and South Asia, for example, face obstacles obtaining climate change mitigation and adaptation synergies due to poor access to markets and relevant knowledge, land tenure insecurity and the common property status of most grazing resources (Descheemaeker et al., 2016). Consequently, the appropriateness of these strategies and measures need to be further evaluated, particularly in terms of their usefulness for the poor and most vulnerable.

Different farming and pastoral systems can achieve reductions in the emissions intensity of livestock products. Depending on the farming and pastoral systems and level of development, reductions in the emissions intensity of livestock products may lead to absolute reductions in GHG emissions (IPCC, 2019a) (*medium confidence*). Significant synergies exist between adaptation and mitigation, for example, through sustainable land management approaches (*high confidence*). {4.8, 5.3.3, 5.5.1, 5.6}.

8.6.1.2.3 Forestry

Forests can support CRD in rural communities and households: they support consumption of energy, food and fibre; provide a safety net in cases of shocks; fill gaps during seasonal shortfalls; and are a means to accumulate assets and provide support to emerge out of poverty (Angelsen et al., 2014; Adams et al., 2020). Forest ecosystems are an essential element of climate change mitigation and adaptation, with the potential for synergy and conflict between the two climate action objectives (Morecroft et al., 2019). However, there are varied perspectives on the role of the forests, with some treating conservation and forest management practices as a barrier to livelihood resilience (Few et al., 2017) despite the broader role of forest management in climate mitigation (Houghton, 2012).

Forestry mitigation projects such as forest conservation, reduced deforestation, protected area management and sustainable forest management, can promote adaptation and can also have consequences for the development objectives of other sectors (for example, expansion of farmland) (Smith et al., 2014). REDD+ (reducing emissions from deforestation and forest degradation and fostering conservation, sustainable management of forest and enhancement of carbon stocks) is a payment programmes and may provide adaptation benefits by enhancing households' economic resilience (Sills et al., 2014; Duchelle et al., 2018) and also produce positive livelihood impacts through the employment benefits of supporting conservation and sustainable management of forests (Caplow et al., 2011). Furthermore, the management of ecosystem services may contribute to both mitigation and adaptation. For example, REDD+ projects, such as mangrove conservation and restoration simultaneously contribute to carbon storage and diversification of incomes and economic activities. At the same time, mangroves protect coastal areas against flooding and hydrological variations, improving capacity for adaptation in local livelihoods (Locatelli et al., 2016).

However, while studies of existing REDD+ programs noted the moderately encouraging impacts for mitigation and small or insignificant impacts for adaptation options (especially well-being), they underscored the potentially damaging impacts to local livelihoods (Milne et al., 2019; Skutsch and Turnhout, 2020) and suggested improved engagement with local communities, increased funding to strengthen the interventions on the ground, and more attention to both mitigation and adaptation outcomes in implementation for achieving the benefits of REDD+ program (Duchelle et al., 2018). Moreover, to effectively counter local threats to forests and biodiversity and attain positive biodiversity and development outcomes, REDD+ programs must be focused on better institutional support for governance, coordinating interventions and monitoring of plans, as well as making explicit linkages between REDD+ activities and national biodiversity conservation efforts (Panfil and Harvey, 2016) and assuring a fair distribution of benefits to local communities (Myers et al., 2018). An analysis of country-specific REDD+ programs in Cameroon for synergistic approaches to REDD+ with other national goals such as poverty reduction identifies two principal modes of strategic interaction management among actors. The first prioritizes relates to specific structures for designing REDD+ giving high priority to social safeguards, and the second relates to programming that builds trust, communication and confidence of participants creating an environment for enabling management through commitment and behavioural interaction by creating an overarching institutional framework and unilateral management (Somorin et al., 2016).

To achieve CRD, forestry conservation strategies need to be driven by climate action and forest management policies that benefit both ecological and human systems, and above all, involve forest communities in program and project implementation (Cordeiro-Beduschi, 2020). Synergies between mitigation and adaptation of the forestry sector can be enhanced by considering on-the-ground contexts of constraints and social trade-offs that may undermine implemented actions (Few et al., 2017). However, the lack of knowledge about trade-offs and synergies at the local level and between local and global scales makes this challenging.

Despite these constraints, forestry can serve as a foundation for CRD when adaptation and mitigation activities are effectively integrated from the stage of policy formulation with consideration of specific institutional structures and procedures that can assist to facilitate such integration (Locatelli et al., 2015). Effectively integrated adaptation and mitigation activities can be achieved by encouraging collaboration between the two activities, promoting research on the impacts of the integrated activities, their cost-effectiveness and their synergies within the complex setting of risks and uncertainty concerning the magnitude of climate change impacts (Bakkegaard et al., 2016), along with facilitating participation of communities in the two activities and defining forest policies (Ngum et al., 2019). Moreover, international donors and funds are also critical to guide countries to identify adaptation-mitigation synergies, through consultation processes, dialogue and awareness raising (Locatelli et al., 2016). Moreover, in order to be effective, nature-based climate solutions such as mixed species plantation, forest expansion and REDD+, must be people-centric and respond to the needs of the rural and Indigenous Peoples who manage ecosystems for their livelihoods while supporting at the same time the biodiversity of the ecosystems (Temperton et al., 2019; Fleischman et al., 2020).

8.6.1.2.4 Energy

The continued dependence on fossil energy sources for economic development is the primary source of increasing GHGs (Hansen et al., 2017). There is an emerging agreement in terms of the importance of the bioenergy sector for climate change mitigation (Jackson et al., 2016; Hansen et al., 2017), however, the options and limitations in terms of transforming the energy systems to support both mitigation and adaptation are still contested.

About 1 billion people globally (12.5% of the world's population) do not have access to electricity (World Bank, 2021), and yet access to electricity is required for basic adaptation strategies, such as the use of air conditioning and fans in homes and working spaces to mitigate heat stress and enable healthier lives, daytime activities, and night-time sleep quality. Electrification enables farmers to mechanically pump water from the underground to boost agricultural productivity, stabilise yields and make food security less reliant on erratic rainfall patterns and less vulnerable to dry spells. Access to electricity enables the spread of valuable information through television, radio, computers, and smartphones, including weather forecasts and disasters prevention and response (Dagnachew et al., 2018). The increasing access to electricity facilitates the SDG 7 coupled with other SDGs and societal goals, including mitigation of climate change (van Vuuren et al., 2018) through reducing energy consumption by the use of efficient technology and appliances. Electricity access can be an important enabler of adaptation action for different purposes in different sectors (Mastrucci et al., 2019).

Low-carbon development strategies can also be compatible with ecological sustainability, as proponents of bioenergy have claimed. Bioenergy can contribute to reducing emissions and energy inefficiencies in agricultural food and bioenergy sectors, even while safeguarding food and energy security. However, recent literature also points towards significant tensions and mismatches between increasing bioenergy on agricultural land and local livelihoods and food security (Yildiz, 2019). A growing list of studies have documented the detrimental trade-offs between small-holder food systems and large-scale biofuel production, which include dispossession and impoverishment of small-holder farmers, food insecurity, food shortages, and social instability (Hunsberger et al., 2017). Nevertheless, synergies between bioenergy and food security can be promoted by integrated resource management designed to improve both food and water security and access to bioenergy; investments in technology, rural extension, promotion of stable prices to incentivize local production; use of double cropping and flex crops that provide food and energy (Souza et al., 2017).

Trade-offs of bioenergy can be minimised by replacing land-intensive first generation biofuels (e.g., oil palm) with second and subsequent generations (e.g., microalgae). However, there are costs of relying on 'sustainable biofuels' as most of the agricultural and non-agricultural land would be needed for cultivation of biofuels along with reduction in pattern of energy consumption as well as attainment to a significant reduction in population (Gomiero, 2015). Contrasting impacts on environmental, economic and social sustainability are reported for production and use of biofuels (Azapagic and Perdan, 2011) ranging from positive impacts such as reduction in GHG emissions, energy security and rural development and negative impacts such as risk of increase of food prices, the risk of increase in GHG emissions through direct and indirect land-use change from production of biofuel feedstocks, as well as the risks of degradation of land, forests, water resources and ecosystems (UNEP, 2009). Biofuel production may cause loss of biodiversity (Jeswani et al., 2020) and may also impact on various ecosystem services, such as land, water and food, however biofuel production and use may pollute air, water and soil (Scovronick and Wilkinson, 2014). The collective benefits of biofuels may be realized by developing future policies based on integrated systems view with clear understanding about the interactions across sectors and land uses by analysing complete value chains (Jeswani et al., 2020).

Clean sources of energy such as solar and wind can facilitate both mitigation and adaptation. For example, in South Africa, clean sources of energy provide energy security with huge water savings along with creation of employment, proximity to point-of-use and, in many cases, less reliance on concentrated sources of energy (Mpandeli et al., 2018). Overall, the increased use of thermal solar panels contributes to reducing GHG emissions and improves air quality as well as providing benefits to the community and the environment. The differential adoption of solar panels can be managed by simultaneous investment in other technologies that utilize renewable energy along with investment in solar panels (Kaya et al., 2019). Development of a smart electricity grid connected to a renewable energy source reduces GHG emissions and decreases vulnerability to climate change by enhancing response to changing conditions and providing more reliable service to the population (Hennessey et al., 2017). Moreover, in the policy development for a low-carbon and climate resilient power system, a local nexus between mitigation and adaptation can be explored (Handayani et al., 2020). For example, use of efficient fuel in urban areas facilitates air pollution reduction and also provides health benefits for urban populations (Ramaswami et al., 2017). Green buildings substantially reduce energy consumption and also improve indoor environmental quality and thus contribute to mitigation and provide societal value in terms of health (MacNaughton et al., 2018). Besides, green roofed building contributes to keeping local temperatures cooler during the hot days and thereby reducing energy use for air-conditioning and thus contributing to both mitigation and adaptation (Sharma et al., 2016).

Positive synergies between adaptation and mitigation in the energy sector can include changes in production technologies and utilization of technologies by various industries, change in consumer or corporate behaviour, and the development of policies that alter the energy sector activities sufficiently to achieve a combination of reduced GHGs emissions and increased benefits for communities (Morand et al., 2015). However, the policy perspective must be based on the country circumstances, especially urbanization, economic growth and energy consumption matching with the income level of the country (Wang et al., 2018).

8.6.2 Decision making approaches for Climate Resilient Development

A range of different traditional economic decision support tools can be used to help guide resource allocation in relation to climate change adaptation (e.g., cost benefit analysis, cost-effectiveness analysis, multi criteria analysis) (Watkiss et al., 2016), with a strong focus on monetary values and the present and near-term. There are also tools to assess uncertainty (e.g., iterative risk management) and to guide decision making under uncertainty over longer time frames (through e.g., real options analysis, robust decision making involving substantial numbers of scenarios, portfolio analysis and rule based decision support for uncertainty where maximum regrets are minimised). Use of these tools nevertheless requires human capital and skills and more commonly they are applied to public rather than private (individual/ household) adaptation decision processes. Tools grounded in economics can lack sufficient consideration of which groups in society might gain and lose out from particular options (Sovacool et al., 2015; Stringer et al., 2019), neglecting to appreciate non-monetary factors (like wellbeing) which are non-economic, less tangible and harder to put a value on (see Section 8.3).

This section lists several groups of the strategies, ranging from mainstreaming and coherence, to dealing with the complexities through broader and innovative governance and scale, to provision of funding and the associated cost and benefit analysis, through focussing on the community and addressing underlying equity through transformational adaptation.

8.6.2.1 Policy coherence, policy integration and broader governance approaches

Mainstreaming and policy coherence is one of the most proposed strategies in dealing with adaptation and mitigation as a coherent approach, in the context of good governance. Politics, power and interests influence the prospects of achieving integrated climate policy and development goals in practice (Naess et al., 2015). Institutional incoherence has led to inefficiency and ineffectiveness (Di Gregorio et al., 2017). To achieve more coherent institutions and synergies, four major enabling conditions have been identified: (1) planned and/or existing national laws, policies and strategies; (2) existing and planned financial means and measures; (3) institutional arrangements in the country with specific reference to climate change issues; and (4) planned and/or existing plans, programmes and initiatives in the country (Kabisch et al., 2016). Another strategy offered is to develop a 'dual track approach' at local/municipality/city level through having a local climate plan and/or mainstreaming plan (Duguma et al., 2014b). This can lead to effective implementation of climate actions and diffusion of climate issues into local sector policies (Reckien et al., 2019). Effective climate policy integration (CPI) calls for four ways of coherence (Di Gregorio et al., 2017), namely between internal coherence (mitigation and adaptation policies objectives and policies), external coherence (climate change and development objectives), vertical integration (mainstream climate change into sectoral policies) and horizontal integration (overarching governance structures for cross-sectoral coordination).

Progress of policy integration varies from the global to local level. Progress in mainstreaming and coherence is emerging globally and has slowly made it down to the national level (Di Gregorio et al., 2017). Adaptation and mitigation should be mainstreamed into planning and implementation on food security programmes, and cross-cutting oversights are required to integrate land restoration, climate policy, food security and disaster risk management into a coherent policy framework (Woolf et al., 2015).

There has been an increase in the literature examining adaptation and mitigation synergy in the Nationally Determined Contributions (NDCs) submitted by countries to the UNFCCC. Agriculture and energy are the two priority sectors for which there have been significant pledges and commitments from countries, with, to some extent, good alignment between adaptation and mitigation. This alignment can provide good opportunities to integrate both into national sectoral policies (Antwi-Agyei et al., 2018a). This suggests that inclusive and sustainable economic and social development can be achieved if national governments focus on developing coherent, cross-sector approaches that deliver potential triple wins of mitigation, adaptation and development.

Different governance approaches such as polycentric governance, adaptive governance, multi-level governance, collaborative governance, or network governance are increasingly utilised to understand the processes of transitioning towards CRD. The potential of polycentric governance approaches for promoting both climate mitigation and adaptation is well established (Cole, 2015; Abbott, 2017; Morrison et al., 2017a; Warner et al., 2018). Polycentric governance deals with active steering of local, regional, national, and international actors and instigates learning from experience across multiple actors, levels of decision-making, and temporal scales (Ostrom, 2010). It is the source of power to achieve collective goals. Polycentric actors have the framing power, power by design and pragmatic power (Morrison et al., 2017b). It offers new opportunities for climate action through more opportunities for communication, trust-building, policy experimentation and learning (Cole, 2015). Adaptive governance is understood as various interactions between actors, networks, organizations, and institutions toward achieving a desired state of social-ecological systems (Chaffin et al., 2014). It requires a structure of nested institutions, diversity at different levels, connected by formal and informal social networks (Dietz et al., 2003). As Brunner and Lynch (2010) observe, the emergence of community-based initiatives in addressing climate change marks the emergence of adaptive governance.

8.6.2.2 The water-energy-food-nexus approach

Increasing demands for water, energy, food and materials are putting pressure on resource supply, and hence the nexus approach can inform transition pathways for interlinked resource systems (Johnson et al., 2019). Nexus approach, especially the water-energy-food nexus, is used to examine synergies and trade-offs between adaptation and mitigation (Howells and Rogner, 2014). As reviewed by (Wiegleb and Bruns, 2018), early use of the concept was by the World Economic Forum in 2008 where it was emphasised that issues of economic growth need to be considered within water, energy and food resource systems. This was later published as Water Security: The Water-Food-Energy-Climate Nexus. Another key activity was the Bonn2011 Nexus conference. Then in 2015, The Nexus Dialogue Programme was held by the UN and EU Commissions as an approach to implement the SDGs. UN Water underscores the water-food-energy nexus as central to development (Newell et al., 2019). It notes that demand for water, food and energy are rising due to a growing population, rapid urbanisation, changing diets and economic growth, and in most cases, the lack of knowledge on water-food-energy nexus has often led to mismatches in prioritization and decision-making which hinders sustainable development (Mitra et al., 2020). It is important to note, however, benefits of nexus approach are not always easily quantified and often accrue to local communities over time (Amjath-Babu et al., 2019).

A well-coordinated and integrated nexus approach offers opportunities to build resilient systems while harmonising interventions, mitigating trade-offs and hence improving sustainability (Biggs et al., 2015). This can be achieved through greater resource mobilisation and coordination, policy convergence across sectors, and targeting nexus points in the broader landscape (Mpandeli et al., 2018). Studies utilizing the nexus approach to climate change in different places show considerably different results. In the Southern African Region, climate change is already affecting water-energy-food resources and exerting further pressure on already scarce resources. It is proposed that adaptation can be achieved through cross-sectoral management of resources, by adopting water management practices, by aiming to produce more food and energy with less water resources, and through the adoption of cleaner and renewable sources of energy resulting in saving water and ensuring energy security in a region that depends on hydro and coal energy sources (Mpandeli et al., 2018). A study in developing Asian countries (Bangladesh, India and Vietnam), found following factors inhibit ability to govern the nexus consideration (i) absence of institutional coordination; (ii) influence of political priorities on decisions rather than use of scientific knowledge to shape the decisions; (iii) lack of capacity to understand interlinkages between sectors; (iv) lack of multi-stakeholder engagement in planning and decision-making processes; and (v) lack of incentive mechanisms and adequate finance to support the approach` (Bao et al., 2018). Applying the nexus approach on the Hindu-Kush Himalayan region identified three challenges: increasing population and declining agricultural land, stagnating or declining food production, and increasingly water and energy intensive food production despite water and energy scarcity (Rasul and Sharma, 2016). Nexus smart adaptation policies need to be complemented with system-wide adaptation, policy coherence and sectoral coordination, and targeting poverty and vulnerability linkages (Rasul and Sharma, 2016).

8.6.2.3 Community-based approach

Another important strategy to better determine impacts of adaptation and mitigation and promote inclusivity, ensure transparency and accountability is a community based approach. This approach also supports adaptation and mitigation indirectly through the strengthening of capacity and social capital. For example, in Bangkalan, Indonesia, the presence of high social capacity and readily available free agricultural inputs are the two decisive factors for effective climate change mitigation and adaptation as well as enhancing community livelihood (Sunkar and Santosa, 2018). The calls for considering Indigenous Knowledge and Indigenous People to support integrated strategies in adaptation and mitigation are increasing (Ford et al., 2016; Altieri and Nicholls, 2017; Brugnach et al., 2017). Detailed knowledge of local socio-ecological contexts may offer transformational processes to harness synergies (Thornton and Comberti, 2017). A study in the Ukraine on cooperatives shows that it offers a well-established livelihood strategy and means to support agriculture small holders. Moreover, social capital fulfils key roles in the process of capacity building and implementation of sustainable measures (Kopytko, 2018). In Indonesia, a well-known program focussing on community-led adaptation and mitigation activities is Proklim. It empowers communities to learn about climate change impacts, record data and plan actions for climate change (Muttaqin and Yulianti, 2019). Multi-stakeholder, participatory planning processes are beneficial to help farmers to screen and prioritise rural livelihood strategies in Indonesia. The necessity of CRD is reflected in standard development interventions: water management, intensification and diversification of agriculture and aquaculture, education, health, food security and skill building for farmers (Wise et al., 2016).

8.6.3. Future adaptation finance and social and economic changes within the context of poverty, livelihoods, equity, equality and justice

8.6.3.1 Coverage of adaptation finance

There is still some debate on what qualifies as adaptation finance and how such finance should be measured (UNFCCC, 2016). According to the Climate Policy Initiative, adaptation finance is 'finance with the aim of improving preparation and reducing climate-related risk and damage, for both human and natural systems, as short-term climate impacts will continue to exact economic, social, and environmental costs even if appropriate mitigation actions are taken.' (CPI, 2019). According to UNEP, the annual costs of adaptation in developing countries could range from $140 billion to $300 billion by 2030. Globally, adaptation costs are estimated to be even greater, with up to $500 billion per year by 2050 under a business-as-usual scenario (UNEP, 2021). While global climate finance flows reached $579 billion on average over the 2017/18 period, there has been a continued heavy imbalance in favour of mitigation finance, with adaptation finance totalling around $30 billion (compared to $532 billion for mitigation), or five percent of tracked climate finance. The World Bank has however, committed itself to increase direct adaptation finance to $50 billion over the 2020-25 period, putting the Bank's adaptation finance in developing countries on par with its mitigation investments (World Bank, 2019a). Adaptation finance is also growing alongside finance for actions with both mitigation and adaptation benefits, for example in forestry or agriculture, which rose to just over $12 billion (CPI, 2019), as well as increasing focus on adaptation and cross-sectoral projects. Looking only at climate finance flows from developed to developing countries, the OECD estimates a total of $78.9 billion mobilised in 2018, with mitigation accounting for 70 percent ($55 billion) of the total, adaptation 21 percent ($16.8 billion) and cross-cutting finance making up the remainder(OECD, 2020a).

Adaptation finance funds actions to adapt to the impacts of climate change, yet such actions are heavily context-, scale- and time-specific. Many mitigation actions in the energy sector can be easily quantified and employed across different jurisdictions. For example, solar photovoltaic (PV) presents an established way across a multitude of countries to produce low-carbon energy at a profit and reduce global GHG emissions. Adaptation needs, however, vary greatly from location to location and short-term solutions, for example investments in irrigation technologies to improve water availability for specific crops in a growing season, may differ from longer-term solutions, for example switching to different crops altogether. Benefits are not always easily quantified and often accrue to local communities over time rather than to investors looking for the kind of returns realised in mitigation actions.

Development finance institutions (DFIs) mainly draw on market-rate loans and, to a lesser extent, concessional lending and grants to finance adaptation actions. There are regional differences in the choice of instruments, too, owing to the degree of economic development: while most of the adaptation finance flowing to the Asia-Pacific is market-rate debt, the vast majority of adaptation finance flowing to sub-Saharan Africa is in the form of concessional debt or grants (Richmond et al., 2020).

Globally, the main sectors benefiting from adaptation finance to date include water and waste water management; agriculture, forestry, land use, and natural resource management; disaster risk management; and infrastructure, energy, and other built environment (Oliver et al., 2018). In recent years, this finance has moved away from a concentration on water and wastewater management to spread out more evenly across the sectors. Between 2015/16 and 2017/18, investment in water and wastewater management dropped from $11 billion to $9 billion, while investment in agriculture, forestry, land use and natural resource management grew from $5 billion to $7 billion, and investment in disaster risk management more than doubled from $3 billion to $7 billion (CPI, 2019). In addition, while mitigation actions are more easily delineated, for example wind farms in the energy sector, adaptation measures often need to be mainstreamed across a number of sectors and investment decisions.

There are strong interconnections between nature-based solutions, climate adaptation and mitigation actions. Ecosystem-based adaptation is a nature-based solution that uses ecosystem services to help communities adapt to climate change. Examples of such approaches were covered in Section 8.5.2.2. For example, mangrove restoration provides both climate mitigation (as carbon sinks) and adaptation to climate change (increasing the resilience of coastal communities) while also supporting the implementation of a range of other SDGs (for example through increased food security). Research has found that without mangroves, global flood damage costs would increase by more than $65 billion a year (Menéndez et al., 2020). There is, therefore, an urgent need to invest in a range of nature-based solutions.

[START BOX 8.9 HERE]

Box 8.9: Adaptation Fnancing for the Poor and the Need for Systems Transition: Eastern Indonesian Islands

Summary

A 4-year project in Nusa Tenggara Barat Province, Indonesia, aimed to stimulate an adaptation pathways process. The goal was to support climate resilient development in a context with low stakeholder capacity, high poverty, and rapid environmental and social change. On these archipelagic islands, livelihoods are predominantly rural, far from political and urban centres. The project focused on the integrated top-down and bottom-up development planning that could enable climate resilient development at the local level, linked to provincial and national plans.

Lessons learned

- Substantial gradients in both climate and livelihoods in the island geographies necessitate fine-scale planning and make it difficult to scale up.
- Infrastructural investments, including roads, ports, and irrigation, are crucial to climate-resilient development. If not well designed, such investments are prone to maladaptation, such as exposure to sea level rise.
- Although some development interventions are delivering climate resilience, such outcomes are often haphazard, rather than strategically conceived, coordinated, and delivered. (Butler et al., 2016)

[END BOX 8.9 HERE]

New financial instruments can help to support investment in, for example, ecosystem-based adaptation. For example, green bonds have shown their ability to raise significant amounts of capital in support of projects with environmental/ climate benefits. The green bond market has quickly developed since the European Investment Bank launched the first green bond in 2007, with issuance growing to $257.7 billion in 2019, up more than 50 percent on the previous year (CPI, 2019). Most green bonds focus on energy, buildings and transport infrastructure but green bond issuance to support sustainable agriculture and forestry has grown from $208 million in 2013 to $7.4 billion in 2018 (Wilkins, 2019). The Seychelles issued the world's first 'blue' bond in 2018 with the support of the World Bank. Similar to green bonds, blue bonds earmark the use of bond proceeds for specific purposes, here the sustainable use of marine resources (World Bank, 2018). In 2019, the European Bank for Reconstruction and Development issued the world's first ever dedicated climate resilience bond, raising $700 million. The five-year bond will be used to finance the Bank's projects in climate resilient infrastructure (e.g., water, energy and transport), climate-resilient business, commercial operations, climate-resilient agriculture and ecological systems (Bennett, 2019). While these issuances are still small compared to the overall green bond market, their rapid growth points to enormous opportunities for ecosystem-based adaptation.

Despite the growth of official adaptation funding at international and national levels, for the world's poorest, adaptation to the impacts and opportunities of climate change frequently occurs in response to losses and damages at the individual or household scale, without coordination at larger institutional scales (Section 8.3, 8.4; Barrett, 2014). Discussions of adaptation finance often occur in the context of dwindling resources, and trade-offs: triage decisions about the other investments that societies can tolerate suspending (Warner and Van der Geest, 2013; Tanner et al., 2015). In many poor, vulnerable countries, complex governance challenges, such as budget austerity or corruption, hamper the provision of such support. In the absence of adaptation funding for the poor coordinated at higher scales, the costs of adaptation are borne by the poor at community, kin-group and household scales. Bearing the cost of adaptation, thus, can become, in the short-term, an erosive process of coping that ultimately increases the likelihood that communities and households will remain trapped in poverty (Antwi-Agyei et al., 2018b). In the long-term, these measures financing adaptation may be maladaptive, meaning they ultimately leave the poor at greater risk of experiencing climate change impacts (Section 8.4.5; Rahman and Hickey, 2019). Such circumstances highlight the governance gap that drive the poorest to rely on extreme measures to finance adaptation.

Since the AR5, there is greater documentation of the extreme measures and high-risk income alternatives that the world's poorest commonly take to finance adaptation (Dawson, 2017; Ahmed et al., 2019). While still a controversial topic, clear examples of extreme adaptation finance measures include:

- unauthorized international migration (McLeman, 2018)
- informal small-scale mining of precious metals and minerals (Hilson and Van Bockstael, 2012; Osumanu, 2020)
- illegal poaching of flora and fauna, including participation in illegal timber harvesting (Bolognesi et al., 2015)
- illegal, unregulated or unreported (IUU) fishing, including within marine protected areas, or the coastal zones of neighbouring countries(Tanner et al., 2014)
- utilizing livelihood resources, such as boats, in smuggling activities, including drug and arms trafficking(Belhabib et al., 2020)
- participation in piracy, extortion or kidnapping economies (Staff, 2017)

Enabling conditions for formal adaptation finance for the poorest are needed to reduce reliance on high-risk, extra-legal sources of income (see Section 8.5.2). In general, the antidote to this emerging problem is access to living wages that the poor can rely on to finance adaptation. There are few examples of pro-poor mechanisms, programs or institutions that prioritize coordinated, access to credit for proactively adapting livelihoods of the poor (Agrawal and Perrin, 2009). Institutions can reduce incentives for vulnerable people to engage in high risk activities by including them in the process of adaptation governance, which aims not only at supporting sustainable livelihood practices (such as farming, fishing and forestry), but also guaranteeing land tenure (Wrathall et al., 2019). Critical for risk reduction to the poor is also the ability of authorities across multiple spatial and temporal scales to maintain social protection that are able to reduce the dependency of illegal sources of income at the same time facilitate adaptation (Tenzing, 2020). A range of tools exists for opening access to credit to poor and marginalized people whose livelihoods are most highly vulnerable (Ribot, 2013): climate insurance tools that are designed and targeted at the poorest and which have been properly assessed to ensure they do not undermine other coping strategies such as risk spreading, programs that ease access or subsidize loans for adaptation, mobile banking and mobile-based financial and risk-management tools, impact pay-outs in the form of direct transfers, and institutional supports for hometown associations. International governance arrangements, such as the Warsaw International Mechanism on Loss and Damage, might aim primarily to clear the financing gap between global financial and risk management institutions and the pocketbooks of the poorest (Wrathall et al., 2015).

8.7 Conclusion

The chapter has moved beyond the IPCC WGII AR5 in that the chapter lays out structural elements of vulnerability and provides quantitative information about climate-related vulnerability hotspots globally complemented with the assessment of poverty, local livelihood vulnerability and sustainable development. Also the assessment of non-economic losses and enabling and supportive environments for adaptation are new aspects.

The chapter provides additional evidence on the livelihood resources at local levels that have been impacted by different climate hazards, and globally, that specific hazards (namely, drought and rising temperatures) are more threatening and destabilizing to livelihoods than others. There is robust evidence that coping and adaptive capacities erode with increasing global mean temperature (GMT)—substantial differences are expected between a GMT increase of less than 1.5°C compared to an increase of more than 3°C— and the frequencies of climate hazards, such as heat waves, droughts or floods is likely to increase substantially. Nevertheless, this assessment also revealed that the adverse impacts of climate change for livelihoods and multidimensional poverty differ substantially between different population groups exposed to climate hazards, based on the socio-economic and governance context. Consequently, societal impacts of climate change need to be understood in the broader context of development and the development challenges that influence exposure, vulnerability and adaptation.

There is robust evidence of the impacts of all climate hazards on the key livelihood resources that the poor depend on. There is high confidence that two climate hazards pose high risk to a broad range of livelihood resources: warming trends and droughts. Meanwhile, the livelihood resources that are globally at greatest risk include people's bodily health, food security and agricultural productivity (high confidence). Evidence suggests that the fundamental challenge of climate change to livelihoods is that rising temperatures, drought and other hazards endanger human life, and the lives of plants and animals that humans rely on to survive (high confidence). There is now robust evidence that the impacts of climate change on livelihoods are driving people to migrate in search of alternative incomes, and this tendency will increase with rising temperatures. Of greatest concern are people whose development context is compromised by war, conflict and extreme poverty and inequality, such as refugee populations and displaced people.

This chapter reports quantitative evidence about human vulnerability and therefore identifies various spatial hotspots of vulnerability emerging in regional clusters, and reports that significantly more people are living in highly vulnerable context conditions compared to those living in low vulnerability contexts. The assessment revealed that approximately more than 3 million people are living in countries classified as very highly or highly vulnerable (depending on the assessment method and the number of classes used and countries included). In contrast approximately 2 billion people reside in low or very low vulnerable country contexts. Studies estimate the population in the most vulnerable regions to almost double by the year 2100 (Section 8.4.5.2). When near-term estimates are used, the population growth in highly vulnerable countries is still significantly higher compared to less vulnerable countries. Consequently, this assessment points towards the fact that even if we do not know how societal or community vulnerability will develop in specific areas, it is highly likely that in the future, more people will live in destabilized and highly vulnerable country contexts compared to the population today. However, it is important to note that the scientific literature also underscores that trends in vulnerability differ significantly between different world regions and within countries.

The chapter also advances knowledge in terms of the interconnections between human vulnerability and observed losses and adverse consequences. The assessment shows that statistically relevant differences in observed fatalities per hazard events can not only be explained by hazard intensity and frequency, but are also linked to different levels of vulnerability of a region exposed. Despite all uncertainties about future change, the assessed literature clearly provides an accurate picture of the expected societal impacts of climate change, the requirements for successful adaptation, and the need to address the adaptation gap through the perspective of vulnerability.

The chapter shows that intersectionality approaches are becoming increasingly central to grasping how differential vulnerability to climate hazards is experienced by different social groups. Intersectionality recognises that age, gender, class, race and ethnicity are reinforcing social phenomena shaping social inequalities and experiences of the world which also intersect with climate hazards and vulnerability. Our assessment reveals the central role of maladaptation with *robust new evidence* on negative consequences of interventions on different social groups. Well intentioned adaptation can exacerbate past and existing vulnerabilities and undermine livelihoods. There is also evidence that despite maladaptation, inclusive and sustainable development at the local level can reduce vulnerability.

Since AR5 loss and damage has taken much more central stage in sustainable development, policy and poverty and livelihoods discourse. While there is ambiguity about what constitutes loss and damage the chapter illustrates there is new evidence of observed losses and damages, including slow-onset impacts (e.g., sea level rise and drought). Our assessment reveals that there exists a body of literature that explicitly addresses non-economic losses and that these are experienced everywhere now due to human induced climate change. These are coupled with advancements in the science of extreme event attribution with new focus on adaptation metrics and vulnerability assessments.

This assessment also identifies emerging evidence of linkages between extreme and slow onset events, non-economic loss and damage, and livelihood shifts. Evidence suggests that losses are leading to a range of shifts in livelihoods, which may be easier for some social groups than others and with implications for livelihoods security across transboundary scales. Yet, climate change is only one driver. Untangling the drivers of vulnerability is also critical with use of intersectionality approaches. Our quantification of vulnerability hotspots supports this concern and it will be critical to seek further knowledge on the extent of livelihood shifts among the most vulnerable resulting from specific non-economic loss and damage, for whom, where and at what scale. Gaps in knowledge highlight this as an area that needs further work in order to develop and understand further the full extent and reach of the relationships between extreme and slow onset climate events, non-economic losses, and shifting livelihoods.

This chapter builds from AR5 and 1.5°C Report on key limits to the adaptation of natural and social systems since that are compounded by the effects of poverty and inequality such as on water scarcity, ecosystems alteration and degradation, coastal cities in relation to sea-level rise, cyclones and coastal erosion, food systems and human health (*high confidence*). The climate change risks substantially pose negative impacts on climate-sensitive livelihoods of smallholder farmers, fisheries communities, Indigenous People, urban poor, informal settlements, with limits to adaptation evidenced on the loss income, ecosystems, health, and increasing migration (*high confidence*). It also addresses how ecological thresholds and socio-economic determinants of vulnerabilities are linked to soft and hard adaptation limits, including the potential and magnitude to livelihoods risks in the future. For instance, a hard limit associated to losses of coral reefs at 1.5°C warmer world will lead to substantial loss of income and livelihoods for coastal communities (*high confidence*), including loss of culture and place-based attachment (*medium confidence*). The adaptation hard limits are expected for the Arctic ecosystem, whose threshold will affect residents of Arctic regions dependent on hunting and fishing livelihoods (*high confidence*). New emerging considerations to ecological limits to adaptation such as severe glacier retreat and Amazon Forest dieback, is expected to affect the livelihoods of smallholder's farmers, and Indigenous People through crops yield failures, biodiversity loss, reduced hydropower capacity and heath (*medium evidence*). While a knowledge gap remains on the projected risks of increasing global temperature to climate-sensitive livelihoods among global south countries and specific groups of people, current observations show negative impacts to livelihoods for tens to hundreds of millions of people. Thus, without sustainable, equitable and urgent adaptation measures, maladaptation risks are likely to further increase vulnerability, marginalization, and ecological tipping points among the poor within countries (*medium confidence*).

Evidence on the kinds of enabling environment required paints a complex picture. The assessment highlights the interaction of different capital assets with the broader context of key enablers in shaping the overall enabling environment for adaptation, which itself is highly context-dependent. In this regard, countries present different starting points for adaptation, with some requiring, for example, more of an emphasis on institutional capacity building; others requiring transformation to the broader legal and political conditions. Capitals are not necessarily substitutable but rather act as an assemblage in shaping both perceptions of climate risk and the necessity and appropriateness of actions. At the same time there is *robust evidence* that livelihoods that depend strongly on natural capital for both subsistence and as a source of income are particularly sensitive to climate risks; and are where perhaps adaptive actions are most urgently needed, even with smaller rises in temperature under the most optimistic scenarios. This applies to both the global south and the global north. Investments in any form of capital asset to support adaptation need to be mindful of reinforcing existing inequalities and introducing new ones, particularly if transformation takes place. This also underscores the importance of inclusive, polycentric governance in ensuring the voices of all groups are heard and that wide ranging knowledge types are incorporated in decision making, nevertheless recognising that trade-offs are inevitable.

The chapter also highlights and provides quantitative evidence that adaptation strategies need to go beyond the idea of adapting to warming levels only. Adaptation strategies have to reduce the adaptation gap and therewith reduce human vulnerability independent of a specific climatic hazard. It has been shown that adaptation strategies that explicitly address poverty, inequities and consider also right based approaches can generate co-benefits for resilience building of most vulnerable groups and for sustainable development.

[START FAQ8.1 HERE]

FAQ 8.1: Why are people who are poor and disadvantaged especially vulnerable to climate change and why do climate change impacts worsen inequality?

Poor people and their livelihoods are especially vulnerable to climate change because they usually have fewer assets and less access to funding, technologies and political influence. Combined, these constraints mean they have fewer resources to adapt to climate change impacts. Climate change impacts tend to worsen inequalities due to the fact that they disproportionately affect disadvantaged groups. This in turn further increases their vulnerability to climate change impacts and reduces their ability to cope and recover.

Climate change and related hazards (e.g., droughts, floods, heat stress, etc.) affect many aspects of people's lives—such as their health, access to food and housing, or their source of income such as crops or fish stocks—and many will have to adapt their way of life in order to deal with these impacts. People who are poor and have few resources with which to adapt are thus much more seriously negatively affected by climate-related hazards. If a person or community are not able to cope and adapt to climate-related hazards, this is referred to as 'vulnerability'. For example, if someone who is very rich has their house washed away in a flood, this is terrible, but they often have more resources to rebuild, have insurances that support recovery and maybe even build a house that is no longer in a flood-prone area. Whereas for someone who is very poor and who does not live in a state that provides support, the loss of their house in a flood could mean homelessness. This example shows that the same climate hazard (flood) can have a very different impact on people depending on their vulnerability (their capacity to cope and adapt to hazards).

It is not just poverty that can make people more vulnerable to climate change and climate-related hazards. Disadvantage due to discrimination, gender and income inequalities and lack of access to resources, for example, those with disabilities or of minority groups, can mean these groups have fewer resources with which to prepare and react to climate change and to cope with and recover from its adverse effects and are therefore more vulnerable. This vulnerability can then increase due to climate change impacts in a vicious cycle, unless adaptation measures are supported and made possible.

[END FAQ8.1 HERE]

[START FAQ8.2 HERE]

FAQ 8.2: Which world regions are highly vulnerable and how many people live there?

A mix of multiple development challenges, such as poverty, hunger, conflict and environmental degradation, make countries and whole regions vulnerable to climate change. Many of the people in the most vulnerable situations and in the most vulnerable regions are also highly exposed to climate hazards, such as droughts, floods or sea-level rise at present and will become increasingly so in the future. Studies estimate that around 1.6 to 3.3 billion people are living in regions classified as highly vulnerable to climate change impacts, which is almost twice as many as the approximately 0.8 to 2 billion people who reside in regions classified as least vulnerable. The most vulnerable regions include East, Central and West Africa, South Asia, Micronesia and Melanesia and in Central America.

When a country or region is considered 'vulnerable' to climate change this means that climate hazards (e.g., drought, flood, heatwaves) have a very negative impact because there are a high number of people in these areas lacking the ability or opportunity to cope and adapt to such events, due, for example, to high average poverty, inequality and lack of institutional support. This vulnerability could be due to many different development challenges that all come together and influence each other, such as poverty, lack of access to basic infrastructure services, high numbers of uprooted people, state fragility, low or below average life expectancy and biodiversity degradation. These structural social issues often affect regions for many decades and make it difficult for the state and for individuals to respond to climate change and climate-related hazards.

For example, if a region is already characterized by poverty and struggling to feed its population and provide adequate access to basic infrastructure services such as water and sanitation, this makes them vulnerable. If this region is then faced with an increased number of extremely dry years, this exposes them to drought and will make things even harder and cause more hunger, poverty and worsen health—these are climate impacts. Most vulnerable regions are in Africa, as well as in South Asia, the Pacific and the Caribbean. In these regions there are often multiple neighbouring countries that all are highly vulnerable, for example in Central- and West-Africa. These regional clusters require special attention.

There are also highly vulnerable groups and individuals within less vulnerable regions. For example, marginalised, disadvantaged and poor minorities within highly affluent cities. Programmes that aim to support adaptation to climate change need to focus on reducing the vulnerability of individuals, groups, countries and regions.

[END FAQ8.2 HERE]

[START FAQ8.3 HERE]

FAQ 8.3: How does and will climate change interact with other global trends (e.g., urbanization, economic globalization) and shocks (e.g., COVID-19) to influence livelihoods of the poor?

A range of local, regional and global economic and political processes already underway have put at risk the livelihoods of the poor (which include urbanization, industrialization, technological transformation, monetization of rural economies, increasing reliance on wages, and inequality at national and international levels), and climate change intersects with these processes.

The world's poorest already struggle providing for themselves and their families in their pursuit of livelihoods. Despite hard work there are many factors beyond an individual's control that can make earning a living very difficult. Climate change is one problem among many that put stress on livelihoods. Poor and marginal groups disproportionately bear impacts of climate change, in ways that accelerate transitions from traditional livelihoods, such as rural farming, to wage jobs in urban areas. Where adaptation measures are insufficient and where the poor are excluded from decision-making, these livelihood transitions can be severely destabilizing.

For example, climate change may alter the frequency or intensity of hazards that threaten the viability of a community's traditional farming or fishing livelihoods. Local farmers or fishers are then forced to adapt how they farm or fish or abandon livelihood practices entirely. The latter may mean migrating to a city to find work. As many communities face the same challenge, this intersects with a global trend that is affecting billions of lives and livelihoods—urbanization—as seen in the rapid growth of informal settlements at the peripheries of cities around the world, particularly rapidly growing megacities in Africa, Asia and Latin America. These developments will be accelerated by negative impacts of climate change and increase risks that larger segments of the population enter conditions of persistent poverty.

At the same time, people whose livelihoods have been upended by climate change are subject to new threats, such as the global COVID-19 pandemic, which has shined a light on the plight of the most vulnerable people. Disproportionately severely impacted by COVID-19 were for example the elderly, Indigenous Peoples and Communities of Colour and also the indirect economic consequences particularly hit the poor. Hence, COVID-19 demonstrates that the livelihoods of the poorest and most marginalized are vulnerable to other global trends beyond climate change. Also, most severe impacts are expected in regions that are already characterized by high levels of systemic human vulnerability.

[END FAQ8.3 HERE]

[START FAQ8.4 HERE]

FAQ 8.4: What can be done to help reduce the risks from climate change, especially for the poor?

Public and private investment in different types of assets can help reduce risks from climate change. Exactly which assets require investment depends on the specific situation. However, the provision of access to basic services, such as water and sanitation, education and health care as well as the importance of reducing inequity is shown within the assessment for many regions. The poor have fewer resources to invest, so in poorer countries greater public investment is needed. Legal, social, political, institution and economic interventions can alter human behaviour, though care must be taken that these do not amplify existing inequalities, create new inequalities, or reduce future adaptation options.

Adaptation can help to reduce risks for the poor and requires both public and private investment in various natural assets (e.g., mangroves, farmland, wetlands); human assets (e.g., health, skills, Indigenous Knowledge), physical assets (e.g., mobile phone connectivity, housing, electricity, technology), financial assets (e.g., savings, credit) and social assets (e.g., social networks, membership of organisations such as farmer cooperatives). Often, the poor have the least to invest, so poverty can reduce adaptation options. Sometimes people migrate as a reaction to floods or droughts, though the poorest groups often lack the resources to move. Exactly what needs investing in to reduce risks varies according to the scale and livelihood system in need of adaptation. In general, risks can be reduced through a range of different technological and engineering approaches (for example, building sea defences to reduce storm surge impacts), as well as ecosystem based approaches (such as replanting mangroves, altering the types of crops grown, changing the timing of farming activities, or using climate smart agriculture or agroforestry approaches).

At the same time, legal, social, political, institutional and economic solutions can alter human behaviour (for example, through enforcement of building codes to prevent construction on low lying land prone to flooding; timely provision of weather information and early warning systems; knowledge sharing activities, including adaptation strategies grounded in Indigenous Knowledge; crop insurance schemes; incentives such as payments to stop people cutting down trees or to enable them to plant them, and social protection to provide a safety net in times of crisis).

The poorest groups often require greater public adaptation investments. Efforts to support adaptation need to be mindful of reinforcing existing inequalities and introducing new ones, making sure they are inclusive, culturally sensitive, and that the voices of all groups of people are heard. It is also important that adaptations which reduce immediate risks for the poor do not rule out adaptation options that could help them later on, or which could cause them to increase their emissions. Political will is needed to put people at the centre of climate change risk reduction efforts, including support for their livelihoods.

[END FAQ8.4 HERE]

[START FAQ8.5 HERE]

FAQ 8.5: How do present adaptation and future responses to climate change affect poverty and inequality?

Present adaptation can help to reduce the current and possibly future impacts of climate change. Future responses to climate change can reduce poverty and inequality and even help transition toward climate resilient livelihoods and climate resilient development. Pro-poor adaptation planning is necessary to ensure future risks for the poor are being accounted for and the inequality underlying the poverty is being addressed.

There are many ways in which poverty and inequality are influenced by climate change. The livelihood sources of the poor are likely to be affected and cumulative effects of losses and damages and may influence future poverty. There are cases when present adaptation worsens future poverty and exacerbates inequality—this is called maladaptation. The risks of maladaptation are greater in societies characterized by high inequality, and in many cases the poor and most vulnerable groups are the ones most adversely affected.

Effective decision making in adaptation should be informed by past, present and future climate data, information and scenarios to cater for reliable plans and actions for climate-resilient livelihoods. Adaptation lessons from the past play an important role in decision making regarding responses to climate change. There is an emerging debate on the role of learning, particularly forward-looking (anticipatory) learning, as a key element or important aspect for adaptation and resilience in the context of climate change. Memory, monitoring of key drivers of change, scenario planning, and measuring anticipatory capacity are seen as crucial ingredients for future adaptation and resilience pathways and hence overcoming maladaptation. Moreover, climate resilient development calls for ensuring synergies between adaptation, mitigation and development are maximised, while trade-offs, especially those to the poor, are minimised.

Table of Contents

Executive Summary

Overall Key Messages

Africa has contributed among the least to greenhouse gas emissions, yet key development sectors have already experienced widespread loss and damage attributable to anthropogenic climate change, including biodiversity loss, water shortages, reduced food production, loss of lives and reduced economic growth (*high confidence*[1]). {9.1.1, 9.2, 9.6.1, 9.8.2, 9.10.2, 9.11.1; Box 9.4}

Between 1.5°C and 2°C global warming—assuming localised and incremental adaptation—impacts are projected to become widespread and severe for reduced food production, reduced economic growth, increased inequality and poverty, biodiversity loss, increased human morbidity and mortality (*high confidence*)**. Limiting global warming to 1.5°C is expected to substantially reduce damages to African economies and ecosystems** (*high confidence*). {9.2, 9.6.2, 9.8.2, 9.8.5, 9.10.2, 9.11.2}

Exposure and vulnerability to climate change in Africa are multi-dimensional with socioeconomic, political and environmental factors intersecting (*very high confidence*). Africans are disproportionately employed in climate-exposed sectors: 55–62% of the sub-Saharan workforce employed is in agriculture and 95% of cropland rainfed. In rural Africa, poor and female-headed households face greater livelihood risks from climate hazards. In urban areas, growing informal settlements without basic services increases the vulnerability of large populations to climate hazards, especially women, children and the elderly. {9.8.2, 9.9.1, 9.9.3, 9.11.4; Box 9.1}

Adaptation in Africa has multiple benefits, and most assessed adaptation options have medium effectiveness at reducing risks for present-day global warming, but their efficacy at future warming levels is largely unknown (*high confidence*). {9.3, 9.6.4, 9.8.3, 9.11.4}

Enabling Climate-Resilient Development

Climate-related research in Africa faces severe data constraints, as well as inequities in funding and research leadership that reduce adaptive capacity (*very high confidence*)**.** Many countries lack regularly reporting weather stations, and data access is often limited. From 1990–2019 research on Africa received just 3.8% of climate-related research funding globally: 78% of this funding went to EU and North American institutions and only 14.5% to African institutions. The number of climate research publications with locally-based authors are among the lowest globally and research led by external researchers may focus less on local priorities. Increased funding for African partners, and direct control of research design and resources can provide more actionable insights on climate risks and adaptation options in Africa. {9.1, 9.4.5, 9.5.2}

Adaptation generally is cost effective, but annual finance flows targeting adaptation for Africa are billions of USD less than the lowest adaptation cost estimates for near-term climate change (*high confidence*). Finance has not targeted more vulnerable countries. From 2014–2018 more finance commitments were debt than grants and—excluding multilateral development banks—only 46% of commitments were disbursed (compared to 96% for other development projects). {9.4.1}

Adaptation costs will rise rapidly with global warming (*very high confidence*)**. Increasing public and private finance flows by billions of dollars per year, increasing direct access to multilateral funds, strengthening project pipeline development, and shifting finance from readiness activities to project implementation would help realise transformative adaptation in Africa** (*high confidence*). Concessional finance will be required for adaptation in low-income settings. Aligning sovereign debt relief with climate goals could increase finance by redirecting debt-servicing payments to climate resilience. {9.4.1}

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

Governance for climate resilient development includes: long-term planning, all-of-government approaches, transboundary cooperation and benefit-sharing, development pathways that increase adaptation and mitigation and reduce inequality, and NDC implementation (*high confidence*). {9.3.2, 9.4.2, 9.4.3}

Cross-sectoral 'nexus' approaches provide significant opportunities for large co-benefits and/or avoided damages (*very high confidence*). For example, climate change adaptation benefits pandemic preparedness; 'One Health' approaches benefit human and ecosystem health; and Ecosystem-based Adaptation can deliver adaptation and emissions mitigation (*high confidence*). {9.4.3, 9.6.4, 9.11.5; Box 9.6}

Without cross-sectoral, transboundary and long-term planning, response options in one sector can become response risks, exacerbating impacts in other sectors and causing maladaptation (*very high confidence*)**.** For example, maintaining indigenous forest benefits biodiversity and emissions mitigation, but afforestation—or wrongly targeting ancient grasslands and savannas for reforestation—harms water security and biodiversity, and can increase carbon loss to fire and drought. Planned hydropower projects may increase risk as rainfall changes impact water, energy and food security exacerbating trade-offs between users, including across countries. {9.4.3; Boxes 9.3, 9.5}

Robust legislative frameworks that develop or amend laws to mainstream climate change into their empowerment and planning provisions will facilitate effective design and implementation of climate change responses (*high confidence*). {9.4.4}

Climate information services that are demand-driven and context-specific (e.g., for agriculture or health) combined with climate change literacy can affect the difference between coping and informed, adaptation responses (*high confidence*). Across 33 African countries, 23–66% of people are aware of anthropogenic climate change—with larger variation at subnational scales (e.g., 5–71% among states in Nigeria). Climate change literacy increases with education level but is undermined by poverty, and rates average 12.8% lower for women than men. 71% of Africans aware of climate change agree it should be stopped. Production of salient climate information in Africa is hindered by limited availability of and access to weather and climate data. {9.4.5, 9.5.1, 9.8.4, 9.10.3}

Ecosystem-based adaptation can reduce climate risk while providing social, economic and environmental benefits (*high confidence*). Direct human dependence on ecosystem services in Africa is high. Ecosystem protection and restoration, conservation agriculture practices, sustainable land management, and integrated catchment management can support climate resilience. Ecosystem-based adaptation can cost less than grey infrastructure in human settlements (e.g., using wetlands and mangroves as coastal protection). {9.6.4, 9.7.3, 9.8.3, 9.9.5, 9.12.3; Box 9.7}

Observed Impacts and Projected Risks

Climate

Increasing mean and extreme temperature trends across Africa are attributable to human-induced climate change (*high confidence*). {9.5.1, 9.5.2}

Climate change has increased heat waves (*high confidence*) **and drought** (*medium confidence*) **on land, and doubled the probability of marine heatwaves around most of Africa** (*high confidence*). Multi-year droughts have become more frequent in West Africa, and the 2015–2017 Cape Town drought was three times more *likely*[2] due to human-induced climate change. {9.5.3–7, 9.5.10}

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

Above 2°C global warming, meteorological drought frequency will increase and duration will double from 2 to 4 months over North Africa, the western Sahel and southern Africa (*medium confidence*). {9.5.2, 9.5.3, 9.5.6.}

Frequency and intensity of heavy rainfall events will increase at all levels of global warming (except in North and southwestern Africa), increasing exposure to pluvial and riverine flooding (*high confidence).* {9.5.3–7, 9.7}

Glaciers on the Rwenzoris and Mt. Kenya are projected to disappear by 2030, and by 2040 on Kilimanjaro *(medium confidence*). {9.5.8}

In East and southern Africa, tropical cyclones making landfall are projected to become less frequent but have more intense rainfall and higher wind speeds at increasing global warming (*medium confidence*). {9.5.7}

Heat waves on land, in lakes, and in the ocean will increase considerably in magnitude and duration with increasing global warming (*very high confidence*). Under a 1.5°C-compatible scenario, children born in Africa in 2020 are *likely* to be exposed to 4–8 times more heat waves compared to people born in 1960, increasing to 5–10 times for 2.4°C global warming. The annual number of days above potentially lethal heat thresholds reaches 50–150 in west Africa at 1.6°C global warming, 100–150 in Central Africa at 2.5°C, and 200–300 over tropical Africa for >4°C. {9.5.2, 9.5.3, 9.5.4, 9.5.5, 9.5.6, 9.7.2.1}

Most African countries will enter unprecedented high temperature climates earlier in this century than generally wealthier, higher latitude countries, emphasising the urgency of adaptation measures in Africa (*high confidence*). {9.5.1}

Compound risks

Multiple African countries are projected to face compounding risks from: reduced food production across crops, livestock and fisheries; increasing heat-related mortality; heat-related loss of labour productivity; and flooding from sea level rise, especially in West Africa (*high confidence*). {9.8.2, 9.8.5, 9.9.4, 9.10.2, 9.11.2}

Water

Recent extreme variability in rainfall and river discharge (c. -50% to +50% relative to long-term historical means) across Africa have had largely negative and multi-sector impacts across water-dependent sectors (*high confidence*) {9.7.2, 9.10.2}. Hydrological variability and water scarcity have induced cascading impacts from water-supply provision and/or hydro-electric power production to health, economies, tourism, food, disaster risk response capacity and increased inequality of water access. {Box 9.4}

Extreme hydrological variability is projected to progressively amplify under all climate scenarios relative to the current baseline, depending on region (*high confidence*). Projections of numbers of people exposed to water stress by the 2050s vary widely—decreases/increases by hundreds of millions, with higher numbers for increases—with disagreement among global climate models the major factor driving these large ranges. Populations in drylands are projected to more than double. Projected changes present heightened cross-cutting risks to water-dependent sectors, and require planning under deep uncertainty for the wide range of extremes expected in future. {9.7.1, 9.7.2}

Economy and Livelihoods

Climate change has reduced economic growth across Africa, increasing income inequality between African countries and those in temperate, Northern Hemisphere climates (*high confidence*)**.** One estimate suggests GDP per capita for 1991–2010 in Africa was on average 13.6% lower compared to if climate change had not occurred. Impacts manifest largely through losses in agriculture, as well as tourism, manufacturing, and infrastructure. {9.6.3, 9.11.1}

Climate variability and change undermine educational attainment (*high agreement, medium evidence*). High temperatures, low rainfall, and flooding, especially in the growing season, may mean children are removed from school to assist income generation. Early life undernutrition associated with low harvests can impair cognitive development. {9.11.1.2}

Limiting global warming to 1.5°C is *very likely* to positively impact GDP per capita across Africa. Increasing economic damage forecasts under high-emissions diverge from low-emissions pathways by 2030. Inequalities between African countries are projected to widen with increased warming. Across nearly all African countries, GDP per capita is projected to be at least 5% higher by 2050 and 10–20% higher by 2100 if global warming is held to 1.5°C versus 2°C. {9.11.2}

Food systems

In Africa, climate change is reducing crop yields and productivity (*medium confidence*). Agricultural productivity growth has been reduced by 34% since 1961 due to climate change, more than any other region. Maize and wheat yields decreased on average 5.8% and 2.3%, respectively in sub-Saharan Africa due to climate change in the period 1974–2008. Farmers and pastoralists perceive the climate to have changed and over two thirds of Africans perceive climate conditions for agricultural production have worsened over the past ten years. Woody plant encroachment has reduced fodder availability. {9.4.5, 9.6.1, 9.8.2}

Future warming will negatively affect food systems in Africa by shortening growing seasons and increasing water stress (*high confidence)*. By 1.5°C global warming, yields are projected to decline for olives (North Africa) and Sorghum (West Africa) with a decline in suitable areas for coffee and tea (East Africa). Although yield declines for some crops may be partially compensated by increasing atmospheric CO_2 concentrations, global warming above 2°C will result in yield reductions for staple crops across most of Africa compared to 2005 yields (e.g., 20–40% decline in West African maize yields), even when considering adaptation options and increasing CO_2 (*medium confidence*). Relative to 1986–2005, global warming of 3°C is projected to reduce labour capacity in agriculture by 30–50% in sub-Saharan Africa. {9.8.2}

Climate change threatens livestock production across Africa (*high agreement, low evidence***).** Rangeland net primary productivity is projected to decline 42% for west Africa by 2050 at 2ºC global warming. Vector-borne livestock diseases and the duration of severe heat stress are both projected to become more prevalent under warming. {9.8.2}

Climate change poses a significant threat to African marine and freshwater fisheries (*high confidence*). Fisheries provide the main source of protein for ~30% of Africa's population and support the livelihoods of 12.3 million people. At 1.5°C global warming, marine fish catch potential (MFCP) decreases 3–41% by 2081–2100 relative to 1986–2005, increasing to 12–69% at 4.3°C, with the highest declines for tropical countries. Under 1.7°C global warming, reduced fish harvests could leave 1.2–70 million people vulnerable to iron deficiencies, up to 188 million for vitamin A deficiencies, and 285 million for vitamin B_{12} and omega-3 fatty acids by mid-century. For inland fisheries, 55–68% of commercially harvested fish species are vulnerable to extinction under 2.5°C global warming by 2071–2100. {9.8.5}

Health

Climate variability and change already impacts the health of tens of millions of Africans through exposure to non-optimal temperatures and extreme weather, and increased range and transmission of infectious diseases (*high confidence).* {9.10.1}

Mortality and morbidity will escalate with further global warming, placing additional strain on health and economic systems (*high confidence*). At 1.5°C of global warming, distribution and seasonal transmission of vector-borne diseases is expected to increase, exposing tens of millions more people, mostly in East and Southern Africa (*high confidence*). Above 1.5°C risk of heat-related deaths rises sharply (*high confidence*), with at least 15 additional deaths per 100,000 annually across large parts of Africa. At 2.1°C degrees, thousands to tens of thousands of additional cases of diarrhoeal disease are projected, mainly in Central and East Africa (*medium confidence*). These changes risk undermining improvements in health from future socio-economic development (*high agreement, medium evidence*).{9.10.2}

Human Settlements

Exposure of people, assets and infrastructure to climate hazards is increasing in Africa with rapid urbanisation, infrastructure deficit, and growing population in informal settlements (*high confidence***).**

About one-third of African cities with populations over 300,000 are located in areas that are at high risk from climate hazards. Sub-Saharan Africa is the only region that has recorded increasing rates of flood mortality since the 1990s. {9.9.1, 9.9.2}

High population growth and urbanisation in low-elevation coastal zones will be a major driver of exposure to sea level rise in the next 50 years (*high confidence*). By 2030, 108–116 million people in Africa will be exposed to sea level rise in Africa (compared to 54 million in 2000), increasing to 190–245 million by 2060. {9.9.1, 9.9.4}

Africa's rapidly growing cities will be hotspots of risks from climate change and climate-induced in-migration, which could amplify pre-existing stresses related to poverty, informality, exclusion and governance (*high confidence*)**.** Urban population exposure to extreme heat is projected to increase from 2 billion person-days per year in 1985–2005 to 45 billion person-days by the 2060s (1.7℃ global warming with low population growth) and to 95 billion person-days (2.8℃ global warming with medium-high population growth), with greatest exposure in West Africa. Sensitive populations under 5 and over 64 years old in African cities exposed to heat waves are projected to increase from around 27 million in 2010 to 360 million (SSP1) and 440 million (SSP5) by 2100, for global warming of 1.8℃ and >4℃, respectively. Compared to 2000, urbanization is projected to increase urban land extent exposed to arid conditions by around 700% and exposure to high-frequency flooding by 2,600% across West, Central and East Africa by 2030. {9.9.1, 9.9.2, 9.9.4; Box 9.8}

Migration

Most climate-related migration observed currently is within countries or between neighbouring countries, rather than to distant high-income countries (*high confidence*)**.** Urbanisation has increased when rural livelihoods were negatively impacted by low rainfall. Over 2.6 million and 3.4 million new weather-related displacements occurred in sub-Saharan Africa in 2018 and 2019. {Box 9.8}

Climate change is projected to increase migration, especially internal and rural-to-urban migration (*high agreement, medium evidence*)**.** With 1.7°C global warming by 2050, 17–40 million people could migrate internally in sub-Saharan Africa, increasing to 56–86 million for 2.5°C (>60% in West Africa) due to water stress, reduced crop productivity, and sea level rise. This is a lower-bound estimate excluding rapid-onset hazards such as floods and tropical cyclones. {Box 9.8}

Infrastructure

Climate-related infrastructure damage and repairs will be a financially significant burden to countries (*high confidence*)**.** Without adaptation, aggregate damages from sea level rise and coastal extremes to 12 major African coastal cities in 2050 under medium and high emissions scenarios will be USD 65 billion and USD 86.5 billion, respectively. Potential costs of up to USD 183.6 billion may be incurred through 2100 to maintain existing road networks damaged from temperature and precipitation changes due to climate change. Increased rainfall variability is expected to affect electricity prices in countries highly dependent on hydropower. {9.9.4; Boxes 9.4, 9.5}

Ecosystems

Increasing CO_2 levels and climate change are destroying marine biodiversity, reducing lake productivity, and changing animal and vegetation distributions (*high confidence*)**.** Impacts include repeated mass coral bleaching events in east Africa, and uphill (birds) or poleward (marine species) shifts in geographic distributions. For vegetation, the overall observed trend is woody plant expansion, particularly into grasslands and savannas, reducing grazing land and water supplies. {9.6.1}

The outcome of interacting drivers operating in opposing directions on future biome distributions is highly uncertain. Further increasing CO2 concentrations could increase woody plant cover, but increasing aridity could counteract this, destabilising forest and peatland carbon stores in central Africa (*low confidence*). {9.6.2.1}

African biodiversity loss is projected to be widespread and escalating with every 0.5ºC increase above present-day global warming (*high confidence***).** Above 1.5°C, half of assessed species are projected to lose over 30% of their population or area of suitable habitat. At 2°C, 36% of freshwater fish species are vulnerable to local extinction, 7–18% of species assessed are at risk of extinction, and over 90% of East African coral reefs could be destroyed by bleaching. Above 2°C, risk of sudden and severe biodiversity losses becomes widespread in West, Central and East Africa. Climate change is also projected to change patterns of invasive species spread. {9.6.2}

Climate security

There is increasing evidence linking increased temperatures and drought to conflict risk in Africa (*high confidence*)**.** Agriculturally dependent and politically excluded groups are especially vulnerable to drought-associated conflict risk. However, climate is one of many interacting risk factors, and may explain a small share of total variation in conflict incidence. Ameliorating ethnic tensions, strengthening political institutions, and investing in economic diversification could mitigate future impacts of climate change on conflict. {Box 9.9}

Heritage

African cultural heritage is already at risk from climate hazards, including sea level rise and coastal erosion. Most African heritage sites are neither prepared for, nor adapted to, future climate change (*high confidence*). {9.12}

Adaptation

With global warming increasing above present-day levels the ability of adaptation responses to offset risk is substantially reduced (*high confidence***).** Crop yield losses, even after adaptation, are projected to rise rapidly above 2°C global warming. Limits to adaptation are already being reached in coral reef ecosystems. Immigration of species from elsewhere may partly compensate for local extinctions and/or lead to local biodiversity gains in some regions. However, more African regions face net losses than net gains. At 1.5°C global warming, over 46% of localities face net losses in terrestrial vertebrate species richness with net increases projected for under 15% of localities. {9.6.1.4, 9.6.2.2, 9.8.2.1, 9.8.2.2, 9.8.4}

Technological, institutional, and financing factors are major barriers to climate adaptation feasibility in Africa (*high confidence*). {9.3, 9.4.1}

There is limited evidence for economic growth alone reducing climate damages, but under scenarios of inclusive and sustainable development, millions fewer people in Africa will be pushed into extreme poverty by climate change and negative impacts to health and livelihoods can be reduced by 2030 (*medium confidence*). {9.10.3, 9.11.4}

Gender-sensitive and equity-based adaptation approaches reduce vulnerability for marginalised groups across multiple sectors in Africa, including water, health, food systems and livelihoods (*high confidence*). {9.7.3, 9.8.3, 9.9.5, 9.10.3, 9.11.4; Boxes 9.1, 9.2}

Integrating climate adaptation into social protection programs, such as cash transfers, public works programmes and healthcare access, can increase resilience to climate change (*high confidence*). Nevertheless, social protection programs may increase resilience to climate-related shocks, even if they do not specifically address climate risks. {9.4.2, 9.10.3, 9.11.4}

The diversity of African indigenous knowledge and local knowledge systems provide a rich foundation for adaptation actions at local scales (*high confidence*). African indigenous knowledge systems are exceptionally rich in ecosystem-specific knowledge used for management of climate variability. Integration of indigenous knowledge systems within legal frameworks, and promotion of indigenous land tenure rights can reduce vulnerability. {9.4.4; Box 9.1, Box 9.2}

Early warning systems based on targeted climate services can be effective for disaster risk reduction, social protection programmes, and managing risks to health and food systems (e.g., vector-borne disease and crops) (*high confidence*). {9.4.5, 9.5.1, Box 9.2, 9.8.4, 9.8.5, 9.10.3, 9.11.4}

Risk-sensitive infrastructure delivery and equitable provision of basic services can reduce climate risks and provide net financial savings (*high confidence*). However, there is limited evidence of pro-active climate adaptation in African cities. Proactive adaptation policy could reduce road repair and maintenance costs by 74% compared to a reactive policy. Adapting roads for increased temperatures and investment in public transport are assessed as 'no regret' options. In contrast, hydropower development carries risk of regrets due to damages when a different climate than was expected materializes. Energy costs for cooling demands are projected to accumulate to USD 51.3 billion in 2035 at 2°C global warming and to USD 486.5 billion in 2076 at 4°C. {9.8.5}

Reduced drought and flood risk, and improved water and sanitation access, can be delivered by: water-sensitive and climate scenario planning, monitored groundwater use, waterless on-site sanitation, rainwater harvesting and water reuse, reducing risk to human settlements, food systems, economies, and human health (*high confidence*). {9.8, 9.9, 9.10, 9.11}

Water sector adaptation measures show medium social and economic feasibility but low feasibility for most African cities due to technical and institutional restrictions, particularly for large supply dams and centralised distribution systems (*medium confidence*). {9.3.1, 9.7.3} Use of integrated water management, water supply augmentation, and establishment of decentralised water management systems can reduce risk. Integrated water management measures including sub-national financing, demand management through subsidies, rates and taxes, and sustainable water technologies can reduce water insecurity caused by either drought or floods (*medium confidence*). {9.7.3; Box 9.4}

Agricultural and livelihood diversification, agroecological and conservation agriculture practices, aquaculture, on-farm engineering, and agroforestry can increase resilience and sustainability of food systems in Africa under climate change (*medium confidence*). However, smallholder farmers tend to address short-term shocks or stresses by deploying coping responses rather than transformative adaptations. Climate information services, institutional capacity building, and strategic financial investment can help overcome these barriers to adaptation (*medium confidence*). {9.4.5, 9.8.3, 9.8.5}

African countries and communities are inadequately insured against climate risk, but innovative index-based insurance schemes can help transfer risk and aid recovery, including in food systems (*medium confidence*). Despite their potential, uptake of climate insurance products remains constrained by lack of affordability, awareness and product diversity. {9.4.5, 9.8.4, 9.11.4.1}

Human migration is a potentially effective adaptation strategy across food systems, water, livelihoods and in climate-induced conflict areas, but can also be maladaptive if vulnerability is increased, particularly for health and human settlements (*high confidence*). Migration of men from rural areas can aggravate the work burden faced by women. The more agency migrants have (that is, degree of voluntarity and freedom of movement) the greater the potential benefits for sending and receiving areas (*high agreement, medium evidence*).{9.3, 9.8.3, 9.9.1–3, 9.10.2.2.2; Boxes 9.8, 9.9; Cross-Chapter Box MIGRATE in Chapter 7}

9.1 Introduction

9.1.1 Point of Departure

This chapter assesses the scientific evidence on observed and projected climate change impacts, vulnerability and adaptation options in Africa. The assessment refers to five African sub-regions – North, West, Central, East and southern – closely following the African Union (AU), but including Mauritania in West Africa and Sudan in North Africa because much of the literature assessed places these countries in these regions (Figure 9.1). Madagascar and other island states are addressed in Chapter 15.

Africa has contributed among the least to historical greenhouse gas emissions (GHG) responsible for anthropogenic climate change and has the lowest per capita GHG emissions of all regions currently (*high confidence*) (Figure 9.2). Yet Africa has already experienced widespread impacts from anthropogenic climate change (*high confidence*) (Table 9.1; Figure 9.2).

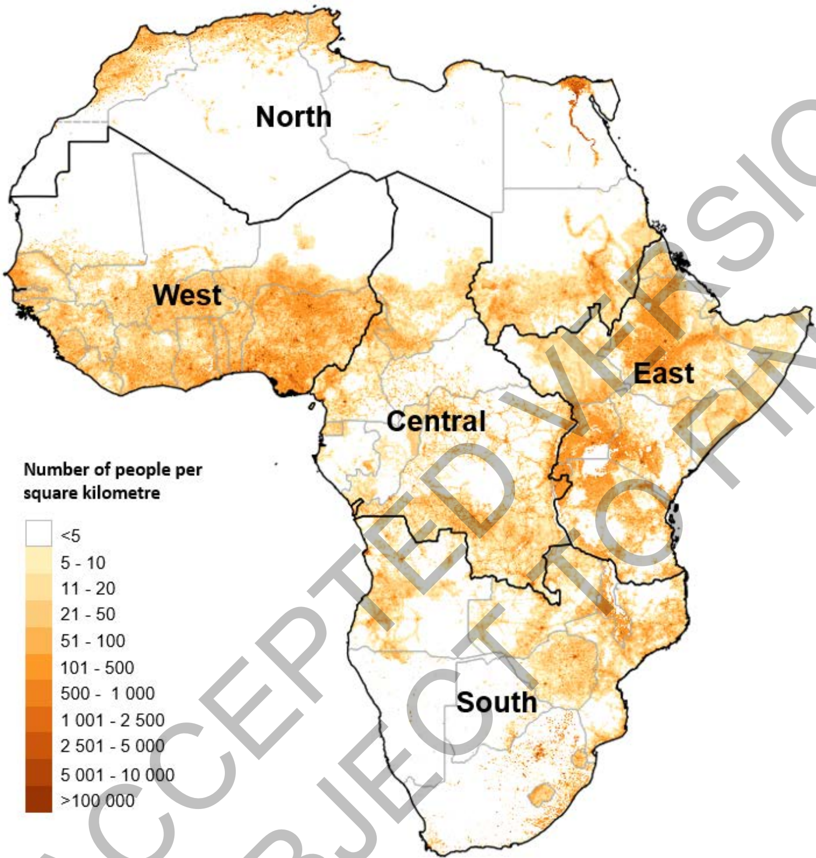

Figure 9.1: The 5 Regions of Africa used in this chapter, also showing estimated population density in 2019. The population of Africa was estimated at 1.312 billion for 2020, which is about 17% of the world population but this is projected to grow to around 40% of world population by 2100 (UNDESA, 2019a). Although 57% of the African population currently live in rural areas (43% urban), Africa is the most rapidly urbanising region globally and is projected to transition to a majority urban population in the 2030s with a 60% urban population by 2050 (UNDESA, 2019b). The 2019 Gross Domestic Product (GDP) per capita in constant 2010 averaged USD 2,250 across 43 countries reporting data, ranging from USD 202 (Burundi) to USD 8,840 (Gabon), with 40% of the population of sub-Saharan Africa living below the international poverty line of USD 1,90 per day in 2018 (World Bank, 2018). The highest life expectancy at birth is 67 (Botswana and Senegal) and the lowest is 52 (Central African Republic) (World Bank, 2018). Grid-cell population density data for mapping are from (Tatem, 2017; WorldPop, 2021).

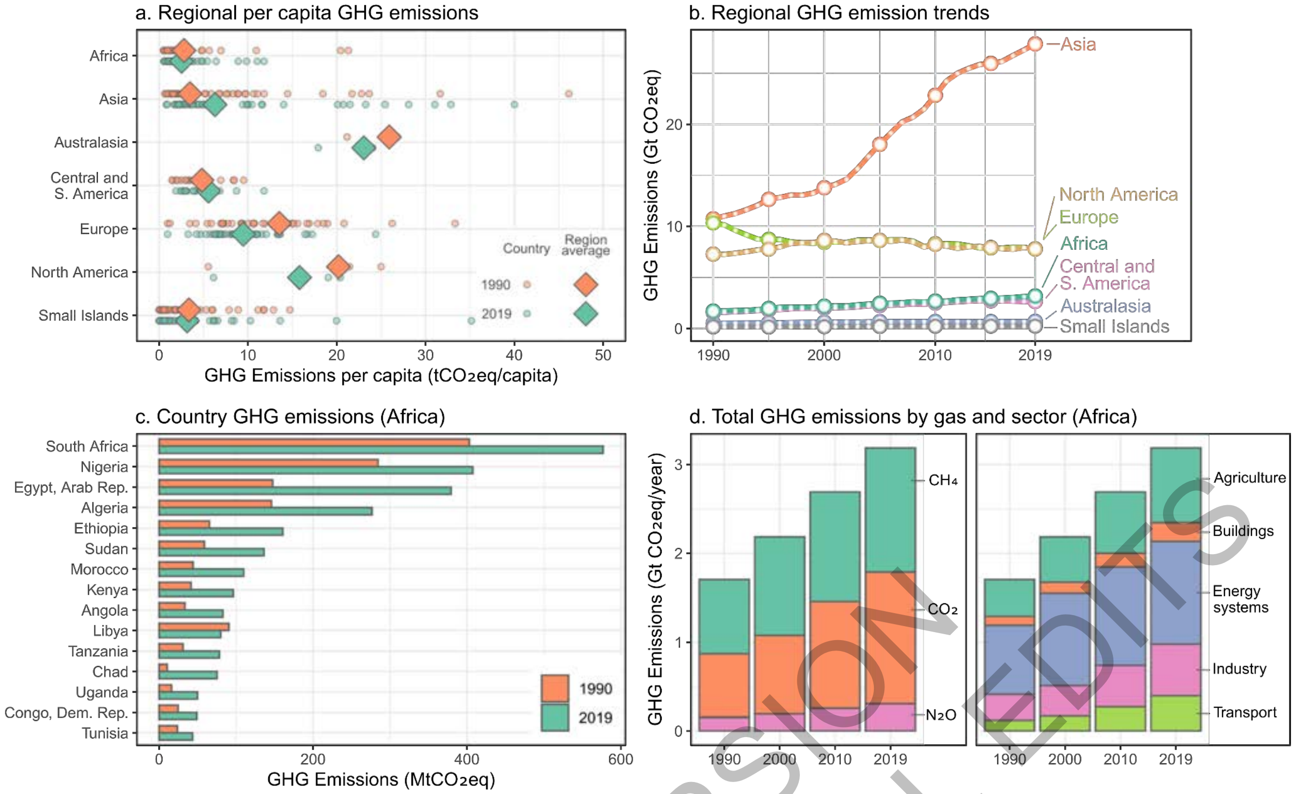

Figure 9.2: Historical greenhouse gas (GHG) emission trends for Africa compared to other world regions: (a) Per person GHG emissions by region and growth from 1990-2018 (circles represent countries, diamonds represent the region average). (b) Total GHG emissions by region since 1990. (c) The total GHG emissions in 1990 and 2018 for the 15 highest emitting countries within Africa. (d) Total emissions in Africa since 1990, broken down by GHG (left) and sector (right). Methane and CO_2 emissions comprise an almost equal share of greenhouse gas emissions in Africa, with the largest emissions sectors being energy and agriculture (Crippa et al., 2021). Agriculture emissions in panel (d) do not include land use, land use change and forestry (LULUCF CO2). One-hundred-year global warming potentials consistent with WGI estimates are used. Emissions data are from (Crippa et al., 2021), compiled by Chapter 2 of WGIII.

Since AR5, there have been notable policy changes in Africa and globally. The Paris Agreement, 2030 Sustainable Development Goals (SDGs), the Sendai Framework and Agenda 2063 emphasise interlinked aims to protect the planet, reduce disaster risk, end poverty and ensure all people enjoy peace and prosperity (AU, 2015; UNFCCC Paris Agreement, 2015; UNISDR Sendai Framework, 2015; United Nations General Assembly, 2015). To match these interlinked ambitions, this chapter assesses risks and response options both for individual sectors and cross-sectorally to assess how risks can compound and cascade across sectors, as well as the potential feasibility and effectiveness, co-benefits and trade-offs and potential for maladaptation from response options (Simpson et al., 2021b; Williams et al., 2021).

9.1.2 Major Conclusions from Previous Assessments

Based on an analysis of 1,022 mentions of Africa or African countries across the three AR6 Special Reports, the following main conclusions emerged.

- Hot days, hot nights and heatwaves have become more frequent; heatwaves have also become longer (*high confidence*). Drying is projected particularly for West and southwestern Africa (*high confidence*) (IPCC, 2018c; Shukla et al., 2019).
- Climate change is contributing to land degradation, loss of biodiversity, bush encroachment and spread of pests and invasive species (SR1.5, SRCCL, SROCC).
- Climate change has already reduced food security through losses in crop yields, rangelands, livestock and fisheries, deterioration in food nutritional quality, access and distribution and price spikes. Risks to crop yields are substantially less at 1.5°C compared with 2°C of global warming, with a large reduction

in maize cropping areas projected even for 1.5°C, as well as reduced fisheries catch potential (SR1.5, SRCCL, SROCC).
- Increased deaths from undernutrition, malaria, diarrhoea, heat stress and diseases related to exposure to dust, fire smoke and other air pollutants are projected from further warming (IPCC, 2018c; Shukla et al., 2019).
- The largest reductions in economic growth for an increase from 1.5°C to 2°C of global warming are projected for low- and middle-income countries, including in Africa (IPCC, 2018c).
- Climate change interacts with multidimensional poverty, among other vulnerabilities. Africa is projected to bear an increasing proportion of the global exposed and vulnerable population at 2°C and 3°C of global warming (IPCC, 2018c).
- Poverty and limited financing continue to undermine adaptive capacity, particularly in rapidly growing African cities (Shukla et al., 2019).
- Large-scale afforestation and bioenergy can reduce food availability and ecosystem health (IPCC, 2018c) (SRCCL 2019).
- Transitioning to renewable energy would reduce reliance on wood fuel and charcoal, especially in urban areas, with co-benefits including reduced deforestation, desertification, fire risk and improved indoor air quality, local development and agricultural yield (Shukla et al., 2019).
- Sustainable use of biodiversity, conservation agriculture, reduced deforestation, land and watershed restoration, rainwater harvesting and well-planned reforestation can have multiple benefits for adaptation and mitigation, including water security, food security, biodiversity, soil conservation and local surface cooling (IPBES, 2018; Shukla et al., 2019).
- Climate resilience can be enhanced through improvements to early warning systems, insurance, investment in safety nets, secure land tenure, transport infrastructure, communication, access to information and investments in education and strengthened local governance (Shukla et al., 2019).
- Scenarios of socio-environmental change are underused in decision-making in Africa (IPBES, 2018).
- Africa's rich biodiversity together with a wealth of indigenous knowledge and local knowledge is a key strategic asset for sustainable development (IPBES, 2018).

9.1.3 What's New on Africa in AR6?

1. Increased confidence in observed and projected changes in climate hazards, including heat and precipitation.
2. Increased regional, national and sub-national observed impacts and projected risks.
3. Loss and damage assessment.
4. Increased quantification of projected risks at 1.5°C, 2°C, 3°C and 4°C of global warming (Section 9.2; Figure 9.6).
5. Improved assessment of sea level rise risk (Sections 9.9 and 9.12).
6. Increased quantification of risk across all sectors assessed.
7. Expanded assessment of adaptation feasibility and effectiveness and limits to adaptation (Figure 9.7).
8. Assessment of adaptation finance (Section 9.4.1).
9. Increased assessment of how climate risk and adaptation and mitigation response options are interlinked across multiple key development sectors (Section 9.4.3; Boxes 9.4 and 9.5).

9.1.4 Extent of Climate Change Impacts Across Africa

In many parts of southern, East and West Africa, temperature or precipitation trends since the 1950s are attributable to anthropogenic climate change and several studies document the impacts of these climate trends on human and natural systems (*high confidence*) (Figure 9.3; Sections 9.5.6 and 9.5.7). Nevertheless, research into attribution of trends to anthropogenic climate change or climate impacts remains scarce for multiple regions, especially in North and Central Africa. This illustrates an 'attribution gap' where robust evidence for attributable impacts is twice as prevalent in high compared to low-income countries globally (Callaghan et al., 2021). Most studies on climate impacts in Africa have focused on terrestrial ecosystems or water, with fewer on marine ecosystems, agriculture, migration and health and well-being (Callaghan et al., 2021). Specific factors driving these knowledge gaps include limited data collection, data access and research funding for African researchers (see next section).

Figure 9.3: Climate impacts on human and natural systems are widespread across Africa, as are climate trends attributable to human-induced climate change. This machine-learning-assisted evidence map shows the presence of historical trends in temperature and precipitation attributable to human-induced climate change (pinks vs. greys) and the amount of evidence (intensity of colours) documenting the impacts of these climate trends on human and natural systems (e.g., ecosystems, agriculture, health) across Africa. 'Robust' indicates more than 5 studies document impacts per grid cell. A 'high' amount of evidence indicates more than 20 studies documented impacts for a grid cell. Climate impact studies from the literature were identified and categorised using machine learning. A language representation model was trained on a set of 2,373 climate impact studies coded by hand. This supervised machine learning model identified 102,160 published studies predicted to be relevant for climate impacts globally; references to places in Africa were found in 5,081 studies (5% of global studies). Temperature trends were calculated from 1951-2018 and precipitation from 1951-2016. Hatching shows regions where trends in both temperature and precipitation are attributable to human-induced climate change. Data from (Callaghan et al., 2021).

9.1.5 Extent of Climate Change Data and Research Gaps Across Africa

Since AR5, there have been rapid advances in climate impacts research due to increased computing power, data access and new developments in statistical analysis (Carleton and Hsiang, 2016). However, sparse and intermittent weather station data limit attribution of climate trends to anthropogenic climate change for large areas of Africa, especially for precipitation and extreme events, and hinder more accurate climate change projections (Otto et al., 2020) (Section 9.5.2; Figure 9.3). Outside of South Africa and Kenya, digitally accessible data on biodiversity is limited (Meyer et al., 2015). Lack of comprehensive socioeconomic data also limits researchers' ability to predict climate change impacts. Ideally, multiple surveys over time are needed to identify effects of a location's changing climate on changing socioeconomic conditions. Twenty-five African countries conducted only one nationally representative survey that could be used to construct measures of poverty during 2000-2010 and 14 conducted none over this period (Jean et al., 2016). Because of these challenges, much of what is known about climate impacts and risks in Africa relies on evidence from global studies that use data largely from outside Africa (e.g., Zhao et al., 2021). These studies generate estimates of average impacts across the globe, but may not have the statistical power to distinguish whether African nations display differential vulnerability, exposure or adaptive capacity. In sections of this chapter, we have relied when necessary on such studies, as they often provide best available evidence for Africa.

Increasing data coverage and availability would increase the ability to discern important differences in risk both among and within African countries.

Climate-related research in Africa faces severe funding constraints with unequal funding relationships between countries and with research partners in Europe and North America (*high confidence*). Based on analysis of over 4 million research grants from 521 funding organisations globally, it is estimated from 1990-2020 USD 1,26 billion funded Africa-related research on climate impacts, mitigation and adaptation. This represents only 3.8% of global funding for climate-related research – a figure incommensurate with Africa's high vulnerability to climate change (Overland et al., 2021) (Box 9.1; Chapter 8). Almost all funding for Africa-related climate research originates outside Africa and goes to research institutions outside Africa (Blicharska et al., 2017; Bendana, 2019; Siders, 2019; Overland et al., 2021). From 1990–2020, 78% of funding for Africa-related climate research flowed to institutions in Europe and the United States – only 14.5% flowed to institutions in Africa (Overland et al., 2021) (Figure 9.4). Kenya (2.3% of total funding) and South Africa (2.2%) are the only African countries among the top 10 countries in the world in terms of hosting institutions receiving funding for climate-related research on Africa (Overland et al., 2021).

These unequal funding relations influence inequalities in climate-related research design, participation, and dissemination between African researchers and researchers from high-income countries outside Africa, in ways that can reduce adaptive capacity in Africa (*very high confidence*). Those empowered to shape research agendas can shape research answers: climate research agendas, skills gaps and eligible researchers are frequently defined by funding agencies, often from a Global North perspective (Vincent et al., 2020a). Larger funding allocations for research focused on Ghana, South Africa, Kenya, Tanzania and Ethiopia are reflected in higher concentrations of empirical research on impacts and adaptation options in these countries, and there is a general lack of adaptation research for multiple of the most vulnerable countries in Africa (Figure 9.5) (Callaghan et al., 2021; Overland et al., 2021; Sietsma et al., 2021; Vincent and Cundill, 2021). The combination of Northern-led identification of both knowledge and skills gaps can result in projects where African partners are positioned primarily as recipients engaged to support research and/or have their 'capacity built' rather than also leading research projects on an equal basis (Vincent et al., 2020a; Trisos et al., 2021). Analysis of >15,000 climate change publications found for over 75% of African countries 60–100% of climate change publications on these countries did not include a single local author, with authorship dominated by researchers from richer countries outside Africa (Pasgaard et al., 2015). This can reduce adaptive capacity in Africa as researchers at Global North institutions may shape research questions and outputs for a Northern audience rather than providing actionable insights on priority issues for African partners (Pasgaard et al., 2015; Nago and Krott, 2020). Moreover, in order to access research publications in a timely manner, many researchers in Africa are forced to use shadow websites bypassing journal paywalls (Bohannon, 2016). Ways to enhance research partnerships to produce actionable insights on climate impacts and solutions in Africa include increased funding from African and non-African sources, projects funded by non-African agencies, increasing direct control of resources for African partners and having African research and user priorities set research questions, identify skills gaps and lead research, open access policies for research outputs (ESPA Directorate, 2018; Vogel et al., 2019; Vincent et al., 2020a; IDRC, 2021; Trisos et al., 2021).

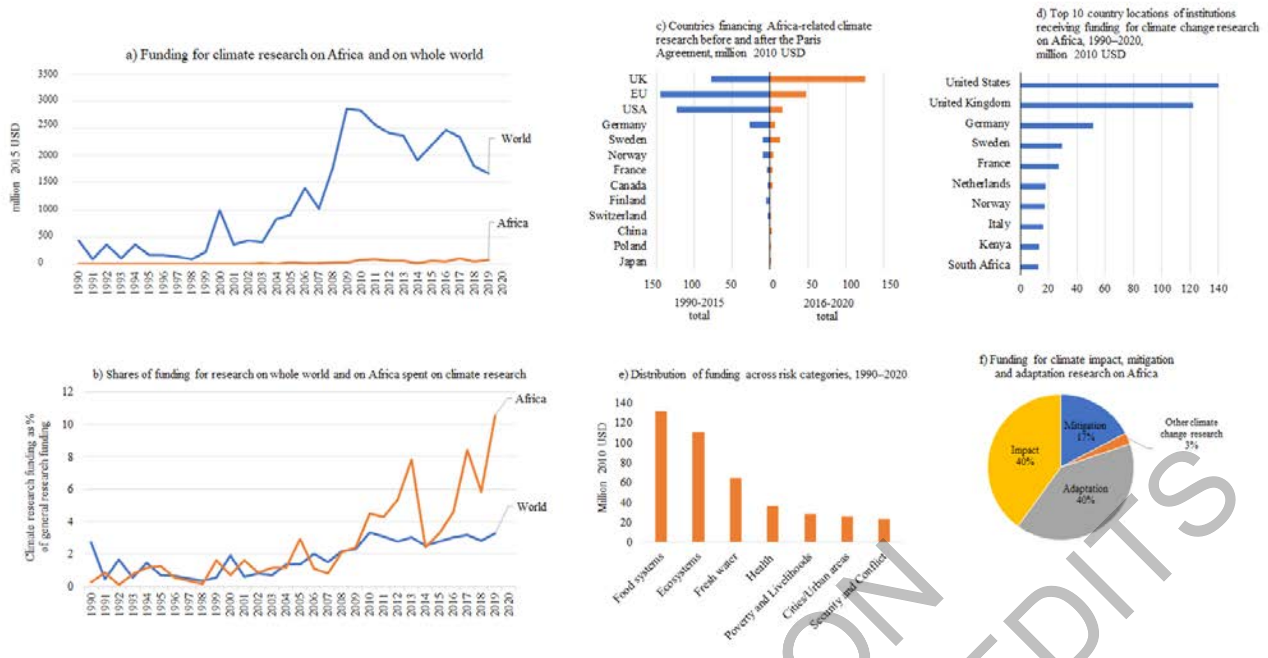

Figure 9.4: Climate-related research on Africa receives a small proportion of global climate research funding (a, b), with most funding for climate-related research on Africa flowing to institutions based in the Europe and the USA (d). Major funding countries are the UK, EU, USA, Germany and Sweden (d) . Funding comes mainly from government organisations with private philanthropy providing only around 1% (Overland et al., 2021). Africa-related climate research funding focuses mostly on food systems, ecosystems and freshwater, while security and conflict and urban areas have received the least (e). Research on climate mitigation received only 17% of funding while climate impacts and adaptation each received 40% (f). Since 2010, climate research has made up a larger share (5%) of Africa-related research funding than is the case for research globally (3%) with a greater proportion of this Africa-focused climate funding going to social sciences and humanities (28%) than is the case globally (12%) (Overland et al., 2021). Data are from an analysis of 4,458,719 research grants in the Dimensions database with a combined value of USD 1.51 trillion awarded by 521 funding organisations globally (Overland et al. 2021). The Dimensions database is the world's largest database on research funding flows (Overland et al. 2021). It draws on official data from all major funding organisations in the world, mainly government research councils or similar institutions. Note: The South African National Research Foundation is the only African research funding body that is sufficiently large to be included in Dimensions.

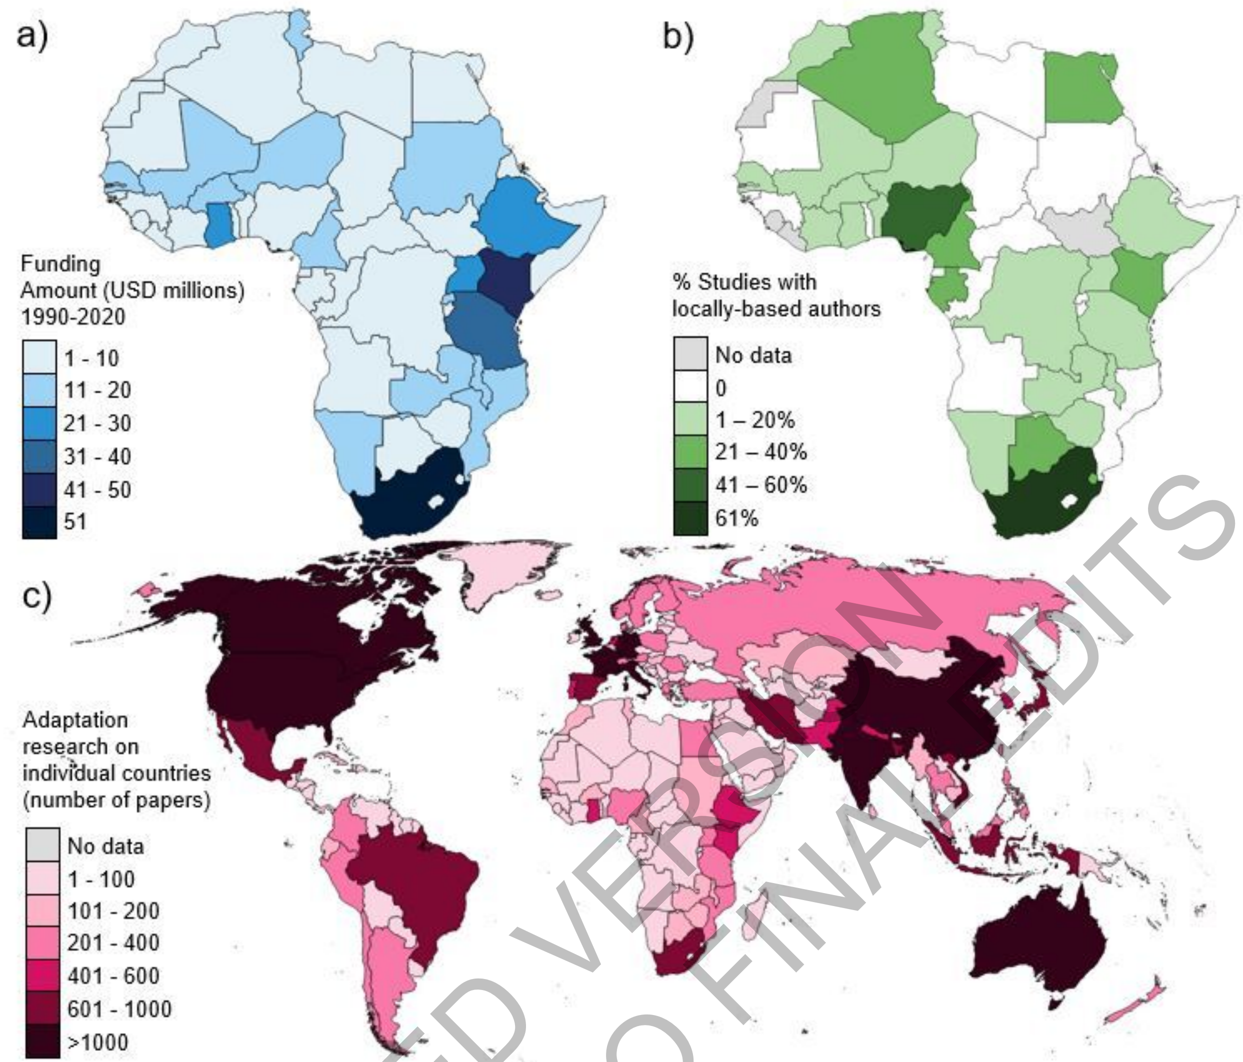

Figure 9.5: Major gaps in climate change research funding, participation and publication exist within Africa, and for Africa compared to the rest of the world. (a) Funding: Amount of climate change research funding focused on African countries 1990-2020 (Overland et al., 2021). Considering population size, research on Egypt and Nigeria stands out as particularly underfinanced (b) Participation: Percentage of climate change papers (impacts and adaptation) published on a given country that also include at least one based in that country (Pasgaard et al. 2015). (c) Number of publications of climate change adaptation research focused on individual countries identified from a global sample of 62,191 adaptation-relevant peer-reviewed articles published from 1988-2020 (Sietsma et al., 2021). There is a general lack of adaptation-related research on many vulnerable countries in Africa. Topic biases in adaptation-relevant research also exist where research focuses more on disaster and development-related topics in Southern countries (but published authors from the global North), while Northern countries dominate governance topics (Sietsma et al., 2021).

9.1.6 Loss and Damage from Climate Change

Assessment of impacts, vulnerability, risks and adaptation highlights climate change is leading to irreversible and existential impacts across Africa which breach current and projected adaptation limits (Table 9.1) (Cross-Chapter Box LOSS in Chapter 17).

Table 9.1: Loss and damage from climate change across sectors covered in this report. Loss and damage arise from adverse climate-related impacts and risks from both sudden-onset events, such as floods and cyclones, and slower-onset processes, including droughts, sea level rise, glacial retreat and desertification and includes both include both economic (e.g., loss of assets and crops) and non-economic types (e.g., loss of biodiversity, heritage and health) (UNFCCC Paris Agreement, 2015; IPCC, 2018a; Mechler et al., 2020). Section marked with * and in bold highlights Loss and Damage attributed to anthropogenic climate change (16.1.3).

Sector	**Loss and damage from climate change**	**Observed**	**Projected**
Ecosystems	Local, regional and global extinction	9.6.2	9.6.2

	Reduced ecosystem goods and services	9.6.1; 9.6.2	9.6.2
	Declining natural coastal protection and habitats	9.6.1; 9.6.2	9.6.2
	Altered ecosystem structure and declining ecosystem functioning	9.6.1	9.6.2
	Nature–based tourism	9.6.3	9.6.3
	Biodiversity loss	**9.6.2***	
Water	Declining lake and river resources	9.7.1	9.7.2
	Reduced hydro-electricity and irrigation	9.7.2; 9.9.1 -	9.7.2; 9.9.3; Box 9.5
	Disappearing glaciers	**9.5.9***; 9.7.1	9.5.9
	Reduced groundwater recharge and salinization	-	9.7.2
	Drought	**Box 9.4***	
Food systems	Reduced crop productivity and revenues	**9.7.2***, 9.8.1; 9.8.2; 9.11.1; Box 9.5	9.8.2; 9.8.3; Box 9.5
	Increased livestock mortality and price shocks	9.8.2	9.8.2
	Decreased fodder and pasture availability	9.8.2	9.8.2
	Reduced fisheries catch and fisher livelihoods	9.6.1; 9.8.5	9.8.5
Human settlements and Infrastructure	Loss or damage to formal and informal dwellings	9.9.2	9.9.4
	Damage to transport systems	9.9.2	9.9.4
	Damage to energy systems	9.9.2	9.7.2; 9.9.4
	Water supply, sanitation, education and health infrastructure	9.9.2; 9.10; 9.11.1	9.7.3; 9.9.4; 9.10; 9.11.1
	Migration	9.9.1; Box 9.8	9.9.4; Box 9.8
Health	Loss of life	**9.9.2***; 9.10.2; Box 9.9	9.9.4; 9.10.2
	Loss of productivity	9.10.3; 9.11.1	9.10.2; 9.11.2
	Reduced nutrition	9.8.1; 9.10.2	9.10.2
Economy, poverty and Livelihoods	Loss of livelihoods, jobs and income	9.9.2; 9.10.2; 9.11.1	9.10.2; 9.11.2
	Reduced productive land	9.8.2	9.8.2
	Reduced economic growth and increased inequality	**9.11.1***; Box 9.5	9.11.2
	Community and involuntary displacement	9.9.3; Box 9.8	9.9.4; Box 9.8
	Reduced labour productivity and earning potential	9.11.1	9.11.2
	Delayed and poorer education progress	9.11.1	9.11.1
	Reduced tourism	9.6.3	9.5.9, 9.6.3, 9.12.2
	Increased urban in-migration	9.8.1; 9.9.1; Table Box 9.8	9.9.4; Table Box 9.8
Heritage	Loss of traditional cultures and ways of life	Box 9.2; 9.12.1	9.12.2
	Loss of language and knowledge systems	-	9.12.1
	Damage to heritage sites	9.12.1	9.12.2

9.2 Key Risks for Africa

A key risk is defined as a potentially severe risk. In line with AR5, 'severity' relates to dangerous anthropogenic interference with the climate system, the prevention of which is the ultimate objective of the UNFCCC as stated in its Article 2 (Oppenheimer et al., 2014). The process for identifying key risks for Africa included reviewing risks from the Africa chapter of AR5, and assessing new evidence on observed impacts and projected risks in this chapter.

Several key risks were identified for both ecosystems and people including species extinction and ecosystem disruption, loss of food production, reduced economic output and increased poverty, increased disease and loss of human life, increased water and energy insecurity, loss of natural and cultural heritage, and compound extreme events harming human settlements and critical infrastructure (Table 9.2). In order to provide a sector and continent-level perspective, the key risks aggregate across different regions and combine multiple risks within sectors. For detailed assessments of observed impacts and future risks within each sector and each sub-region of Africa, see the sector-specific sections of this chapter (Sections 9.6.1 and 9.12.1).

Several expert elicitation workshops of lead and contributing authors were held to develop 'burning embers' assessing how risk increases with further global warming for a subset of key risks, specifically risk of food production losses, risk of biodiversity loss and risk of mortality and morbidity from heat and infectious disease (Figure 9.6). These key risks were selected in part because of underlying assessment work in the chapter to connect multiple studies to observed impacts and/or risk at increasing global warming levels (Sections 9.6.2, 9.8.2, 9.8.5.2 and 9.10.2).

All three of these key risks are assessed to have already transitioned completely into moderate risk—that is, negative impacts have been detected and attributed to climate change—before the 2010–2020 level of global warming (1.09°C) (IPCC, 2021), with *medium confidence* for increased mortality and morbidity and *high confidence* for losses of food productivity and biodiversity (Figure 9.6). For biodiversity, these impacts include repeated mass die-offs of coral reefs due to marine heat (Section 9.6.1.4), reductions in lake productivity due to warming (Section 9.6.1.3), and woody encroachment of grasslands and savannas due to increased atmospheric CO_2 concentrations (Section 9.6.1.1), with negative impacts on livelihoods (Section 9.6.1). For food production, climate change impacts include up to 5.8% mean reduction in maize productivity due to increased temperatures in sub-Saharan Africa (Section 9.8.2.1 and 9.8.2.2) and reduced fisheries catches due to increased temperatures, especially in tropical regions (Section 9.8.2). For health, climate change impacts include increased mortality and morbidity from changes in the distribution and incidence of malaria and cholera and the direct effects of increasing temperatures (Section 9.10.2).

In scenarios with low adaptation (that is largely localised and incremental), the transition to high risk—widespread and severe impacts—has already begun at the current level of global warming for biodiversity loss (*high confidence*), and begins below 1.5°C global warming for both food production (*medium confidence*) and mortality and morbidity from heat and infectious disease (*high confidence*). Across all risks, the best estimate for the transition to high risk is at 1.5°C of global warming, with transition to high risk completing before 2°C (Figure 9.6). Projected impacts considered high risk around 1.5°C include: across more than 90% of Africa, more than 10% of species are at risk of local extinction (Figure 9.6; Table 9.1); the further expansion of woody plants into grass-dominated biomes (Section 9.6.2.1); 9% declines in maize yield for West Africa and 20–60% decline in wheat yield for southern and northern Africa, as well as declines in coffee and tea in East Africa and sorghum in West Africa (Figures 9.22 and 9.23; Section 9.8.2.1 and 9.8.2.2), and >12% decline in marine fisheries catch potential for multiple West African countries, potentially leaving millions at risk of nutritional deficiencies (Figure 9.25; Section 9.8.5); tens of millions more people exposed to vector-borne diseases in East and southern Africa (malaria), and North, East and southern Africa (dengue, zika), increased risk of malnutrition in Central, East and West Africa, and more than 15 additional deaths per 100,000 annually due to heat in parts of West, East and North Africa (Figures 9.32 and 9.35; Sections 9.10.2 and 9.9.4.1).

The transition from high to very high risk—that is severe and widespread impacts with limited ability to adapt—begins either at or just below 2°C for all three risks (Figure 9.6). The assessed temperature range for the transition to very high risk is wider for food production than for biodiversity and health. Projected impacts for food include: 10–30% decline in marine fisheries catch potential for the Horn of Africa region and southern Africa and more than 30% decline for West Africa at 2°C global warming, with greater declines at higher levels of warming (Section 9.8.2). Beyond 2°C global warming, over 50% of commercially important freshwater fish species across Africa are projected to be vulnerable to extinction (Figure 9.26). Between 2°C and 4°C, wheat, maize and rice yields are projected, on average, to be lower than 2005 yields across all regions of Africa. From 2°C global warming, over 40% losses in rangeland productivity are projected for western Africa. By 3.75°C, severe heat stress may be near year-round for cattle across tropical Africa (Figure 9.24). Multiple countries in West, Central and East Africa are projected to be at risk from simultaneous negative impacts on crops, fisheries and livestock (Thiault et al., 2019) (9.8.2; 9.8.5).

The best estimate for the onset of very high risk for biodiversity and health is at 2.1°C. Projected impacts considered very high risk for biodiversity include potential destabilisation of the African tropical forest carbon sink, risk of local extinction of more than 50% of plants, vertebrate and insect species across one-fifth of Africa, 7–18% of African species at risk of total extinction including, a third of freshwater fish, and more than 90% warm-water coral reefs lost (Section 9.6.2). For health, projected impacts considered high risk include potentially lethal heat exposure for more than 100 days per year in West, Central and East Africa, with more than 50 additional heat-related deaths per 100,000 annually across large parts of Africa, and hundreds of millions more people exposed to extreme heat in cities (Section 9.5, 9.10.2 and 9.9.4.1; Figure 9.35), tens to hundreds of thousands of additional cases of diarrhoeal disease in East, Central and West Africa, and tens of millions more people exposed to mosquito-borne arboviruses like dengue or zika in North, East and southern Africa (Section 9.10.2).

The feasibility and effectiveness of existing adaptation options under current levels of warming are assessed in Section 9.10.2 and adaptation options considering future levels of warming are assessed in the chapter section for each sector.

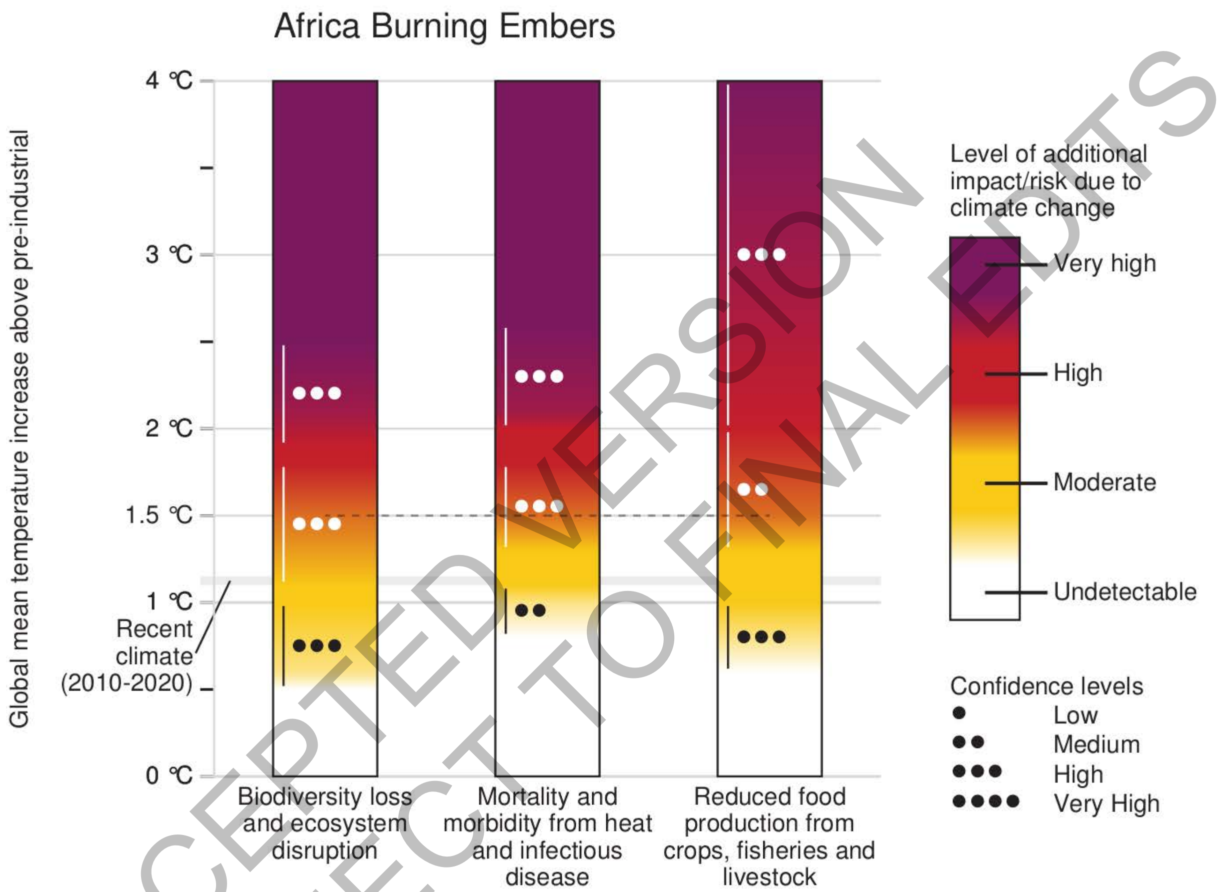

Figure 9.6: Burning Embers showing increasing risk due to climate change for selected key risks in Africa. Projected increase is assessed for global warming increasing above pre-industrial levels (1850–1900). All three risks are assessed to have already transitioned to moderate risk by the recent level of global warming 2010–2020 (1.09°C). Risks are characterized as undetectable, moderate, high, or very high, and the transition between risk levels as a function of global warming is represented by the colour change of each bar (IPCC, 2021). For range of global warming levels for each risk transition used to make this figure see Supplementary Material Table SM 9.1.

Table 9.2: Key risks from climate change in Africa

Key climate change risk	Climate impact driver	Vulnerability	Chapter section
Local or global extinction of species and reduction or irreversible loss of ecosyste§ms and their services, including freshwater, land and ocean ecosystems	Increasing temperatures of freshwaters, ocean and on land; heatwaves; precipitation changes (both increases and decreases); increased atmospheric CO_2	Vulnerability highest among poorly dispersing organisms (plants) and species with narrow and disappearing niches (e.g. mountain endemics), and is exacerbated by non-	9.6

	concentrations; sea level rise; ocean acidification	climate hazards (e.g. habitat loss for agriculture or afforestation projects); Vulnerability is high for Protected Areas surrounded by transformed land preventing species' dispersal and areas with limited elevational gradients that reduce their potential to act as climate refugia	
Loss of food production from crops, livestock and fisheries	Increasing temperatures and heat waves for freshwaters, ocean and on land; precipitation changes; drought; increased atmospheric CO_2 concentrations	High for low-income coastal and riparian communities whose livelihood depends on healthy ocean and freshwater ecosystems, and for populations reliant on fish for protein and micronutrients. Vulnerability is high for many food producers dependent on rainfall and temperature conditions, including subsistence farmers, the rural poor, and pastoralists. Lack of access to climate information and services increases vulnerability.	9.8
Mortality and morbidity from heat and infectious diseases	Increasing temperatures; heatwaves; precipitation change (both increases and decreases)	Vulnerability is highest for the elderly, pregnant women, individuals with underlying conditions, immune-compromised individuals (e.g., from HIV), and young children. Regions without vector control programmes in place or without detection and treatment regimens. Inadequate insulation in housing in informal settlements in urban heat islands. Inadequate improvements in public health systems. Inadequate water and sanitation infrastructure, especially in rapidly expanding urban areas and informal settlements.	9.10

Reduced economic output and growth, and increased inequality and poverty rates	Increased temperatures; reduced rainfall; extreme weather events	Conditions underlying severe risk are lower income growth, higher population levels, low rates of structural economic change with more of the labour force engaged in agriculture and other more climate-exposed sectors due in part to physical labour outdoors.	9.11
Water and energy insecurity due to shortage of irrigation and hydropower.	Heat and drought	High reliance on hydropower for national electricity generation, especially East and Southern African countries. Planned for high reliance on irrigated food production. Concentrations of hydropower plants within river basins experiencing similar rainfall and run-off patterns. Limited electricity trade between major river basins.	9.7, 9.9, Box 9.5
Cascading and compounding risks of loss of life, livelihoods and infrastructure in human settlements.	Extreme heat; floods; drought; sea level rise and associated coastal hazards; compound climate hazards (e.g., coinciding heat and drought)	Coastal and low-lying urban areas and those in dryland regions with rapidly growing populations. People living in informal settlements. Increased magnitude of heat waves due to urban heat island effects. Climate-shocks to municipal revenues (e.g., from water). Unaffordable maintenance of transport and protective infrastructure with increasing climate impacts. Greater water resource demand from urban and non-urban populations and key economic sectors	9.9

9.3 Climate Adaptation Options

9.3.1 Adaptation Feasibility and Effectiveness

Based on a systematic assessment of observed climate adaptation responses in the scientific literature covering 827 adaptation response types in 553 studies (2013–2021), and expert elicitation process, 24 categories of adaptation responses in Africa were identified (Williams et al., 2021). This assessment excluded autonomous adaptation in ecosystems, such as migration and evolution of animal and plant species.

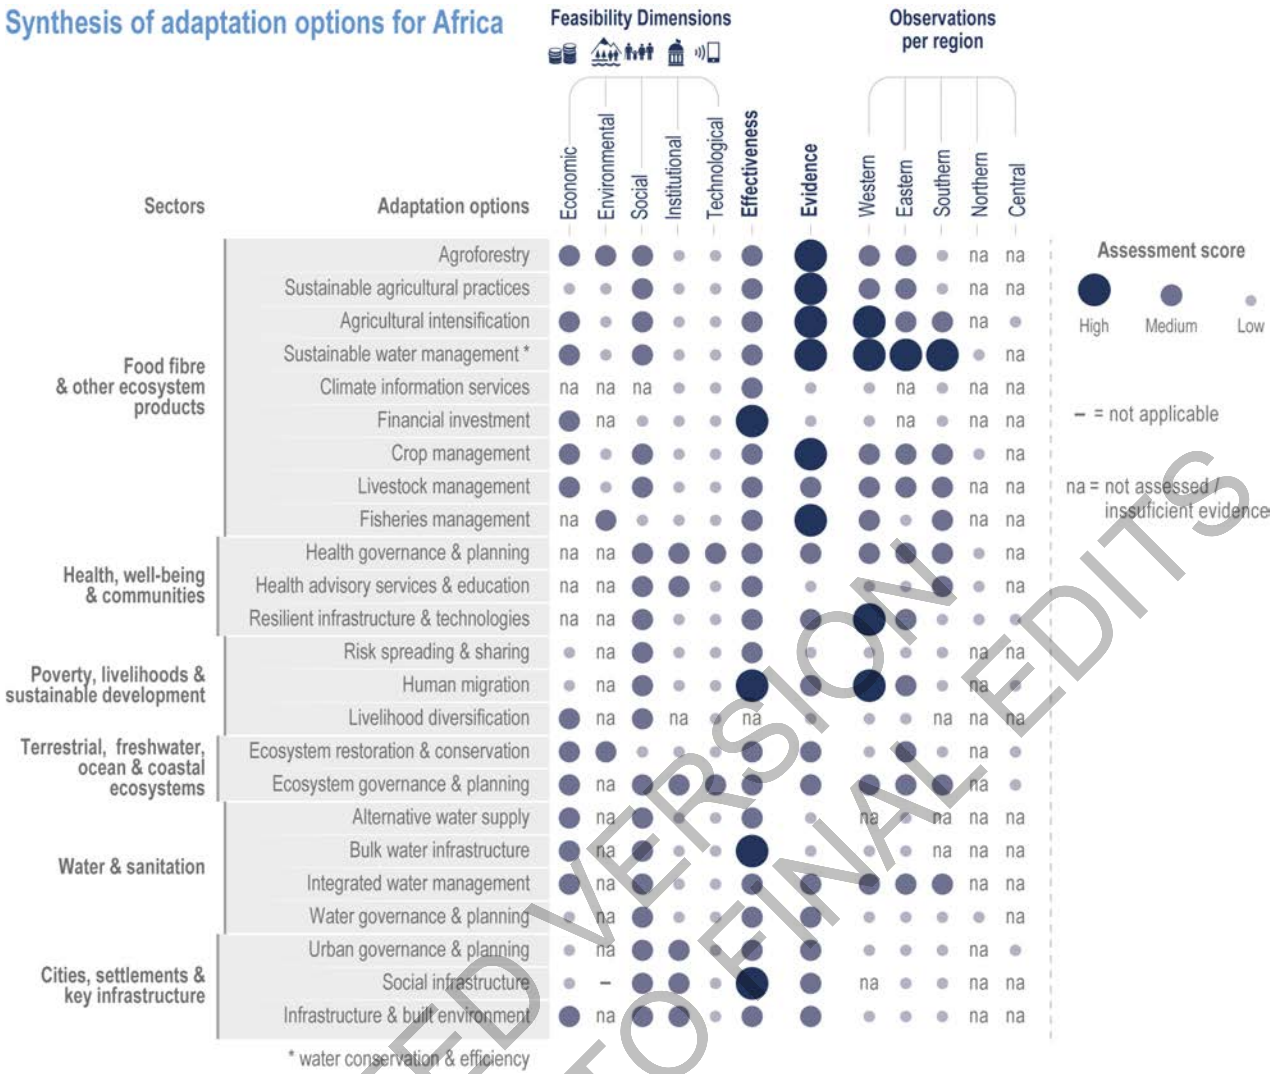

Figure 9.7: Assessment of feasibility of observed climate adaptation responses under current climate conditions for 24 categories of adaptation responses across regions of Africa. The assessment comprised evaluation of each adaptation category along six feasibility dimensions: economic viability, environmental sustainability, social validity, institutional relevance, technological availability, and potential for risk reduction (considering current climate conditions) (Williams et al., 2021). Fifty-six experts on the African region were consulted using a structured, expert-driven elicitation process to increase the coverage and robustness of the continent-wide adaptation feasibility and effectiveness assessment in Williams et al. (2021). Assessment included both peer-reviewed articles and grey literature.

At the current global warming level, 83% of adaptation response categories assessed showed medium potential for risk reduction (that is, mixed evidence of effectiveness). Bulk water infrastructure (including managed aquifer recharge, dams, pipelines, pump stations, water treatment plants and distribution networks), human migration, financial investment for agricultural intensification, and social infrastructure (including decentralised management, strong community structures and informal support networks) show high potential for risk reduction (high evidence of option's effectiveness) (Sections 9.6.4 and 9.7.3; Boxes 9.8, 9.9, 9.10 and 9.11). However, there was limited evidence to assess the continued effectiveness of these options at higher global warming levels (Williams et al., 2021) with some options, such as bulk water infrastructure (particularly large dams), expected to face increasing risk with continued warming with damages cascading to other sectors (see Box 9.5), while others, such as crop irrigation and adjusting planting times, may increasingly reach adaptation limits above 1.5°C and 2°C global warming (Sections 9.8.3 and 9.8.4)

The majority of adaptation studies were in West and East Africa (Ghana, Ethiopia, Kenya and Tanzania), followed by southern Africa, with the least coming from Central and North Africa (Figure 9.7) (Williams et al., 2021). Most studies were on adaptation actions in the food sector, with the least on health (Figure 9.7). The five adaptation response categories with the highest number of reported actions were sustainable water management (food sector), resilient infrastructure and technologies (health sector), agricultural intensification (food sector), human migration (poverty and livelihoods) and crop management (food sector).

No adaptation response categories were assessed to have high feasibility of implementation. Technological barriers dominate factors limiting implementation (92% of adaptation categories have low technological feasibility) followed by institutional barriers (71% of adaptation categories have low institutional feasibility). This assessment matches review studies finding institutional responses to be least common in Africa and highlight inadequate institutional capacities as key limits to human adaptation (Berrang-Ford et al., 2021; Thomas et al., 2021) (Cross-Chapter Box FEASIB in Chapter 18). Feasibility is higher for the social dimension of adaptation responses (with moderate feasibility for 88% of categories). The largest evidence gap is for environmental feasibility for which 67% could not be assessed due to insufficient evidence (Figure 9.7).

Sustainable Water Management (SWM) includes rainwater harvesting for irrigation, watershed restoration, water conservation practices (e.g., efficient irrigation) and less water-intensive cropping (also see Section 9.8.3), and was the most reported adaptation response in the food sector. SWM was assessed with medium economic and social feasibility and low environmental, institutional and technological feasibility. The feasibility of this adaptation category may depend largely on socioeconomic conditions (Amamou et al., 2018; Harmanny and Malek, 2019; Schilling et al., 2020), as many African farmers cannot afford the cost of sustainable water management facilities (Section 9.8.4).

Resilient Infrastructure and Technologies (RIT) for health include improved housing to limit exposure to climate hazards (Stringer et al., 2020), and improved water quality, sanitation and hygiene infrastructure (e.g., technology across all sectors to prevent contamination and pollution of water, improved water, sanitation and hygiene (WASH) approaches such as promotion of diverse water sources for water supply, improving health infrastructure) (Section 9.10.3). Overall, RIT had medium social feasibility and low institutional and technological feasibility. Bulk water infrastructure was assessed to have high effectiveness, but low institutional and technological feasibility. Increasing variability in climate and environmental challenges has made sustainable and resilient infrastructure design a key priority (Minsker et al., 2015). RIT is, however, generally new in the African context (Cumming et al., 2017) and that may be why there is limited evidence to assess some of its dimensions (economic and environmental feasibility). Construction of resilient public water infrastructures that include safeguards for sanitation and hygiene are expensive and, across national and local levels, planning for its construction poses multiple challenges (Choko et al., 2019).

Agricultural intensification (including mixed cropping, mixed farming, no soil disturbance, mulching) in many smallholder farming systems remains a key response option to secure food for the growing African population (Nziguheba et al., 2015; Ritzema et al., 2017). Yet this option faces low environmental, institutional and technological feasibility (Figure 9.7). Social and economic feasibility is higher, but barriers include high cost of farm inputs (land, capital and labour), lack of access to timely weather information and lack of water resources can make this option quite challenging for African smallholder farmers (Kihila, 2017; Williams et al., 2019b) (Sections 9.8.1 and 9.11.4).

Crop management includes adjusting crop choices, planting times, or the size, type and location of planted areas (Altieri et al., 2015; Nyagumbo et al., 2017; Dayamba et al., 2018). This option faces environmental, institutional and technological barriers to feasibility. Social and economic barriers to implementation are fewer. Factors such as tenure and ownership rights, labour requirements, high investment costs and lack of skills and knowledge on how to use the practices are reported to hinder implementation of crop management options by smallholder farmers (Muller and Shackleton, 2013; Nyasimi et al., 2017). For instance, when improved seed varieties are available, high price limits access for rural households (Amare et al., 2018) (see Sections 9.8.3 and 9.8.4).

Human migration was assessed to have high potential for risk reduction (Rao et al., 2019; Sitati et al., 2021) (Cross-Chapter Box MIGRATE in Chapter 7, Box 9.8). However, it had low feasibility for economic, institutional and technological dimensions, with limited evidence on environmental feasibility. Institutional factors such as the implementation of top-down policies have been reported as limiting options for coping locally, resulting in migration (Brockhaus et al., 2013). Limited financial and technical support for migration limits the extent to which it can make meaningful contributions to climate resilience (Djalante et al., 2013;

Trabacchi and Mazza, 2015). International and domestic remittances are an important resource that can help aid recovery from climate shocks, but inadequate finance and banking infrastructure can limit cash transfers (Box 9.8). Male migration can increase burdens of household and agricultural work, especially for women (Poudel et al., 2020; Rao et al., 2020; Zhou et al., 2020). The more agency migrants have (that is, degree of voluntarity and freedom of movement), the greater the potential benefits for sending and receiving areas (*high agreement, medium evidence*) (Cross-Chapter Box MIGRATE in Chapter 7, Box 9.8)

Adaptation options within a number of categories, including sustainable agriculture practices, agricultural intensification, fisheries management, health advisory services and education, social infrastructure, infrastructure and built environment and livelihood diversification were observed to reduce socioeconomic inequalities (Williams et al., 2021). Whether adaptation options reduce inequality can be a key consideration enhancing acceptability of policies and adaptation implementation (Islam and Winkel, 2017) (Box 9.1; Section 9.11.4).

9.3.2 Adaptation Co-Benefits and Trade-Offs with Mitigation and SDGs

Synergies between the adaptation and progress towards the Sustainable Development Goals (SDGs) present potential co-benefits for realising multiple objectives towards Climate Resilient Development in Africa, increasing the efficiency and cost-effectiveness of climate actions (Cohen et al., 2021). However, designing adaptation policy under conditions of scarcity, common to many African countries, can inadvertently lead to trade-offs between adaptation options, as well as between adaptation and mitigation options, can reinforce inequality, and fail to address underlying social vulnerabilities (Kuhl, 2021).

Adaptation options such as access to climate information, provision of climate information services, growing of early maturing varieties, agroforestry systems, agricultural diversification and growing of drought-resistant varieties of crops may deliver co-benefits, providing synergies that result in positive outcomes. For instance, in SSA drylands including northern Ghana and Burkina Faso and large parts of the Sahel, migration as a result of unfavourable environmental conditions closely linked to climate change has often provided opportunities for farmers to earn income (SDG 1) and mitigate the effects of climate-related fluctuations in crop and livestock productivity (SDG 2) (Zampaligré et al., 2014; Antwi-Agyei et al., 2018; Wiederkehr et al., 2018). Renewable energy can mitigate climate effects (SDG 13), improve air quality (SDG 3), wealth and development (SDGs 1, 2).

Different types of irrigation including drip and small-scale irrigation can contribute towards increased agricultural productivity (SDG 2), improved income (SDG 1) and food security (SDG 2) and increase resilience to long-term changes in precipitation (SDG 13) (Bjornlund et al., 2020). In Kenya and Tanzania, small-scale irrigation provides employment opportunities and income to both farmers and private businesses (SDGs 8 and 9) (Lefore et al., 2021; Simpson et al., 2021c). Land management practices including the use of fertilizers and mulching have also been highlighted as adaptation options improving soil fertility for better yields (SDG 2) and delivering opportunities to reduce the climate change effects (SDG 13) (Muchuru and Nhamo, 2019).

Climate smart agriculture (CSA) offers opportunities for smallholder farmers to increase productivity (SDG 2), build adaptive capacity whilst reducing the emission of greenhouse gases (SDG 13) from agricultural systems (Lipper et al., 2014; Mutenje et al., 2019). CSA practices including conservation agriculture, access to climate information, agroforestry systems, drip irrigation, planting pits and erosion control techniques (Partey et al., 2018; Antwi-Agyei et al., 2021) can improve soil fertility, increase yield and household food security (Zougmoré et al., 2016; Zougmoré et al., 2018), thereby contributing to the realisation of SDG 2 in Africa (Mbow et al., 2014).

On the contrary, adaptation actions may induce trade-offs with mitigation objectives, as well as other adaptation and developmental outcomes, delivering negative impacts and compromising the attainment of the SDGs. For example, increased deployment of renewable energy technologies can drive future land use changes (Frank et al., 2021) and threaten important biodiversity areas if poorly deployed (Rehbein et al., 2020). The use of early-maturing or drought-tolerant crop varieties may increase resilience (SDGs 1, 2), but adoption by smallholder farmers can also be hindered by affordability of seed. Cultivation of biodiesel crops also can hinder food security (SDG 2) at local and national levels (Tankari, 2017; Brinkman et al., 2020).

Additionally, the use of fertilizers in intense systems can result in increased environmental degradation (Akinyi et al., 2021). When farmers migrate, it puts pressure on inadequate social services provision and facilities at their destination (SDG 8) and leads to reduced farm labour and a deterioration of the workforce and assets (SDG 2) (Gemenne and Blocher, 2017a), which negatively affects farm operations and non-migrants, particularly women, elderly and children, at the point of origin (Nyantakyi-Frimpong and Bezner-Kerr, 2015; Ahmed et al., 2016; Otto et al., 2017; Eastin, 2018). Farmers may also miss critical periods during the farming season that eventually makes them food insecure (SDG 2) and vulnerable to climate change (SDG 13) (Antwi-Agyei et al., 2018). Migrants should be supported to reduce their overall shocks to climate vulnerability at the points of origin and destination. Small-scale irrigation infrastructure if not managed properly, may lead to negative environmental effects and compromise the integrity of riparian ecosystems (SDG 15) (Loucks and van Beek, 2017) and serve as breeding grounds for malaria-causing mosquitoes (SDG 3) (Attu and Adjei, 2018).

9.4 Climate Resilient Development

Climate resilient development (CRD) is a process of implementing greenhouse gas mitigation and adaptation measures to support sustainable development for all (Denton et al., 2014; Andrijevic et al., 2020; Owen, 2020; Cornforth et al., 2021). It emphasises equity as a core element of sustainable development as well as conditions for inclusive and sustained economic growth, shared prosperity and decent work for all, taking into account different levels of national development and capacities as encoded in the SDGs (Section 9.3.2; Chapter 18, Section 18.1). This chapter section identifies five key dimensions of CRD for Africa: climate finance, governance, cross-sectoral and transboundary solutions, adaptation law and climate services and literacy.

9.4.1 Climate Finance

Access to adequate financial resources is crucial for climate change adaptation (Cross-Chapter Box FINANCE in Chapter 17). Since the Copenhagen Accord (UNFCCC, 2009), and then extended by the Paris Agreement (UNFCCC Paris Agreement, 2015 see Article 4.4, and also 4.8, 4.9), developed countries are expected to scale up climate finance for developing countries toward a collective goal of USD 100 billion per year by 2020, with a balanced allocation between adaptation and mitigation.

9.4.1.1 How Much Adaptation Finance is Needed?

There is limited research providing quantitative estimates of adaptation costs across Africa. Adaptation costs in Africa have been estimated at USD 7–15 billion per year by 2020 (Schaeffer et al., 2013), corresponding to USD 5–11 per capita per year. The African Development Bank estimates costs of near-term adaptation needs identified in the Intended NDCs (INDCS) of African countries as USD 7.4 billion per year from 2020, recognising INDCs describes only a limited subset of adaptation needs (AfDB, 2019). Many African countries, particularly Least Developed Countries (LDCs), express a stronger demand for adaptation finance – a study of financial demands in INDCs for 16 African countries suggests a ratio around 2:1 for adaptation to mitigation finance with demand for Eritrea and Uganda approximately 80% for adaptation (Zhang and Pan, 2016).

Adaptation costs in Africa are expected to rise rapidly as global warming increases (*high confidence*). A meta-analysis of adaptation costs identified in 44 NDCs and NAPs from developing countries estimated a median adaptation cost around USD 17 per capita per year for 2020–2030 (Chapagain et al., 2020). Adaptation cost estimates for Africa increase from USD 20–50 billion per year for RCP2.6 in 2050 (around 1.5°C of warming), to USD18–60 billion per year for just over 2°C, to USD 100–437 billion per year for 4°C of global warming above pre-industrial levels (Schaeffer et al., 2013; UNEP, 2015; Chapagain et al., 2020). Focusing on individual sectors, the average country-level cost is projected to be USD 0.8 billion per year for adapting to temperature-related mortality under 4°C global warming (Carleton et al., 2018), with cumulative energy costs for cooling demand projected to reach USD 51 billion by 2°C and USD 486 billion by 4°C global warming (Parkes et al., 2019). Transport infrastructure repair costs are also projected to be substantial (Section 9.8.2) More precise estimates are limited by methodological difficulties and data gaps for costing adaptation, uncertainties about future levels of global warming and associated climate hazards, and ethical choices such as the desired level of protection achieved (Fankhauser, 2010; Hallegatte et al., 2018; UNFCCC, 2018) (Cross-Chapter Box FINANCE in Chapter 17). As such, existing estimates are expected to substantially underestimate eventual costs with adaptation costs possibly 2–3 times higher than current global estimates by 2030, and 4–5 times higher by 2050 (UNEP, 2016a).

9.4.1.2 Benefit-Cost Ratios in Adaptation

Although analysts face challenges related to the nature of climate change impacts (Sussman et al., 2014) and data limitations (Li et al., 2014) when estimating all costs and benefits for adaptation measures in specific contexts, adaptation generally is cost-effective (*high confidence*). The Global Commission on Adaptation estimated the benefits and costs of five illustrative investments and found benefit-cost ratios ranging from 2:1 to 10:1. However, it also noted that 'actual returns depend on many factors, such as economic growth and demand, policy context, institutional capacities and condition of assets' (The Global Commission on Adaptation, 2019). A review of ex-ante cost-benefit analyses for 19 adaptation-focused projects in Africa financed by the Green Climate Fund (GCF) shows benefit-cost ratios in a similar range. Using a 10% discount rate, as used by many of GCF's accredited entities, the benefit-cost ratio for individual projects ranges from 0.9:1 to 7.3:1, the median benefit-cost ratio is 1.8:1 and total ratio across all 19 projects is 2.6:1. When using lower discount rates, as some entities do for climate projects, the benefit-cost ratio is even higher, reflecting the front-loaded costs and back-loaded benefits of many adaptation investments. Using a 5% discount rate, the overall benefit-cost ratio of the GCF projects is 3.5:1, with a range from 1:1 to 11.5:1 and a median ratio of 2.4:1 (Breitbarth, 2020). In addition, many proposals have activities for which further benefits were not estimated due to the difficulty of attributing benefits directly to the intervention. The benefits of adaptation measures for infrastructure and others with clear market impacts are often easier to estimate than for policy interventions and where markets may not exist, such as ecosystem services (Li et al., 2014).

9.4.1.3 How Much Finance is Being Mobilised?

The amounts of finance being mobilised internationally to support adaptation in African countries are billions of USD less than adaptation cost estimates, and finance has targeted mitigation more than adaptation (*high confidence*). The OECD (2020) estimates an average of USD 17.3 billion per year in public finance targeting mitigation and adaptation from developed countries to Africa from 2016-2018, with adaptation expected to be a small share of this amount: Of the global total only 21% in 2018 targeted adaptation (there is no breakdown provided for Africa). Analysis of OECD data that is reported by the funders, covering bilateral and multilateral funding sources, estimated international public finance (grants and concessional lending) committed to Africa for climate change for 2014-2018 at USD 49.9 billion: 61% (30.6 billion) for mitigation, 33% (16.5 billion) for adaptation and 5% (2.7 billion) for both objectives simultaneously (Savvidou and Atteridge, 2021) (Figure 9.8a). This equates to an average of USD 3.8 billion per year targeting adaptation (Savvidou and Atteridge, 2021). In per capita terms, only two countries (Djibouti and Gabon) were supported with more than USD 15 per person per year, most were supported with less than USD 5 per person per year (Savvidou and Atteridge, 2021).

The multilateral development banks (MDBs) report 43% of their climate-related commitments to sub-Saharan Africa in 2018 targeted adaptation (EBRD et al., 2021). Sources other than international public finance are more difficult to track and there is limited data on Africa (Cross-Chapter Box FINANCE in Chapter 17). Considering a wider range of finance types (including private flows and domestic mobilisation), an estimated annual average of roughly USD 19 billion in climate finance for 2017-2018 went to sub-Saharan Africa, of which only 5% was for adaptation (CPI, 2019; Adhikari and Safaee Chalkasra, 2021). The mobilisation of private finance by developed country governments, through bilateral and multilateral financial support, is lower in Africa relative to other world regions. Globally, in 2016-2018, Africa made up only 17% of mobilised private finance relevant for climate change (OECD, 2020).

Strong differences exist among African sub-regions. Finance commitments targeting adaptation increased from 2014-2018 for East and West Africa but decreased in Central Africa (Savvidou and Atteridge, 2021) (Figure 9.8b). Climate-related finance was >50% for adaptation in 19 countries, while 26 received >50% for mitigation (Savvidou and Atteridge, 2021).

African countries expect grants to play a crucial role in supporting adaptation efforts because loans add to already high debt levels that exacerbate fiscal challenges, especially in light of high sovereign debt levels from the COVID-19 pandemic (Bulow et al., 2020; Estevão, 2020). From 2014-2018, more finance commitments targeting adaptation in Africa were debt instruments (57%) than grants (42%) (Savvidou and Atteridge, 2021) (Figure 9.8c).

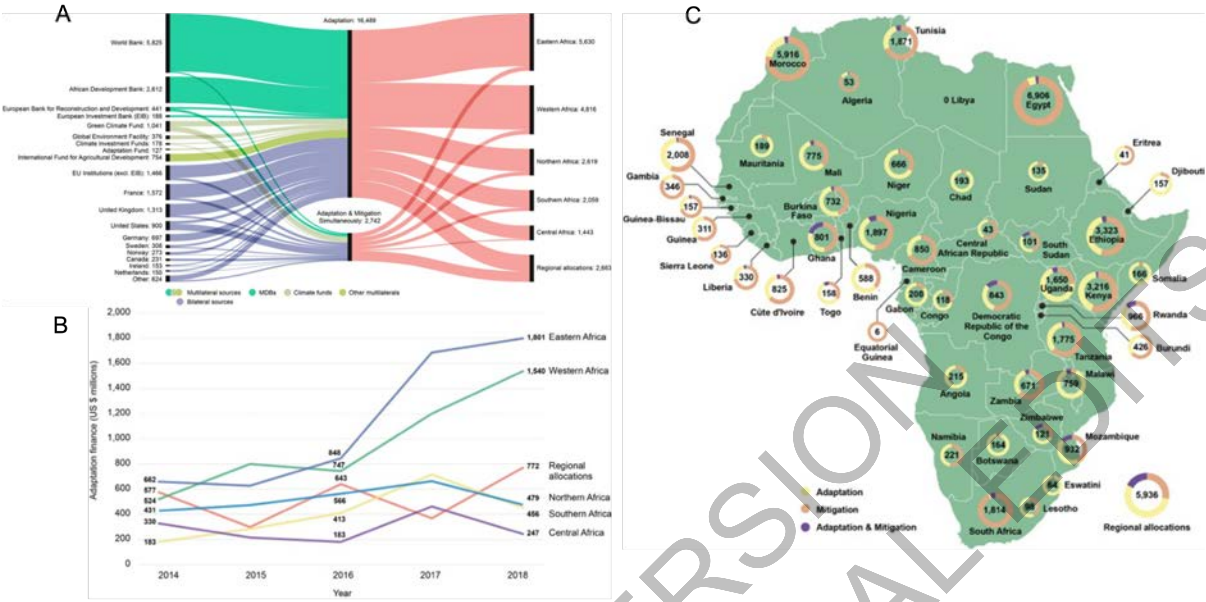

Figure 9.8: Finance targeting climate adaptation by sector and percentages of climate finance commitments that have been disbursed in Africa (2014-2018) as reported to OECD. (a) Flows of committed finance targeting adaptation, (b) trend over time in international development finance commitments targeting adaptation in Africa, and (c) country-level shares of total climate finance that targeted adaptation or mitigation or both simultaneously. Source: (Savvidou and Atteridge, 2021).

For Africa combined, the sectors targeted with most support for adaptation are Agriculture and Water Supply and Sanitation, which account for half of total adaptation finance from 2014-2018 (Figure 9.9a). The sectoral distribution has changed little over these years, suggesting adaptation planners and funders are maintaining a relatively narrow view of where support is needed and how to build climate resilience (Savvidou and Atteridge, 2021).

However, to understand actual expenditure on adaptation, it is necessary to look at disbursements (that is, the amounts paid out versus committed amounts). Low ratios of disbursements to commitments suggest difficulties in project implementation. Disbursement ratios for climate-related finance from all funders other than MDBs (for which data is not published) in Africa are very low (Savvidou and Atteridge, 2021) (Figure 9.9b). Only 46% of 2014–2018 commitments targeting adaptation were dispersed (Savvidou and Atteridge, 2021). Regions faring worst are North Africa (15%), Central Africa (33%) and West Africa (33%) (Figure 9.9c). These disbursement ratios for adaptation and mitigation finance in Africa are lower than the global average (Savvidou and Atteridge, 2021), which suggests greater capacity problems in implementing climate-related projects and, in turn, means lost opportunities to build resilience and adaptive capacity and a wider gap in adaptation finance for Africa (Omari-Motsumi et al., 2019).

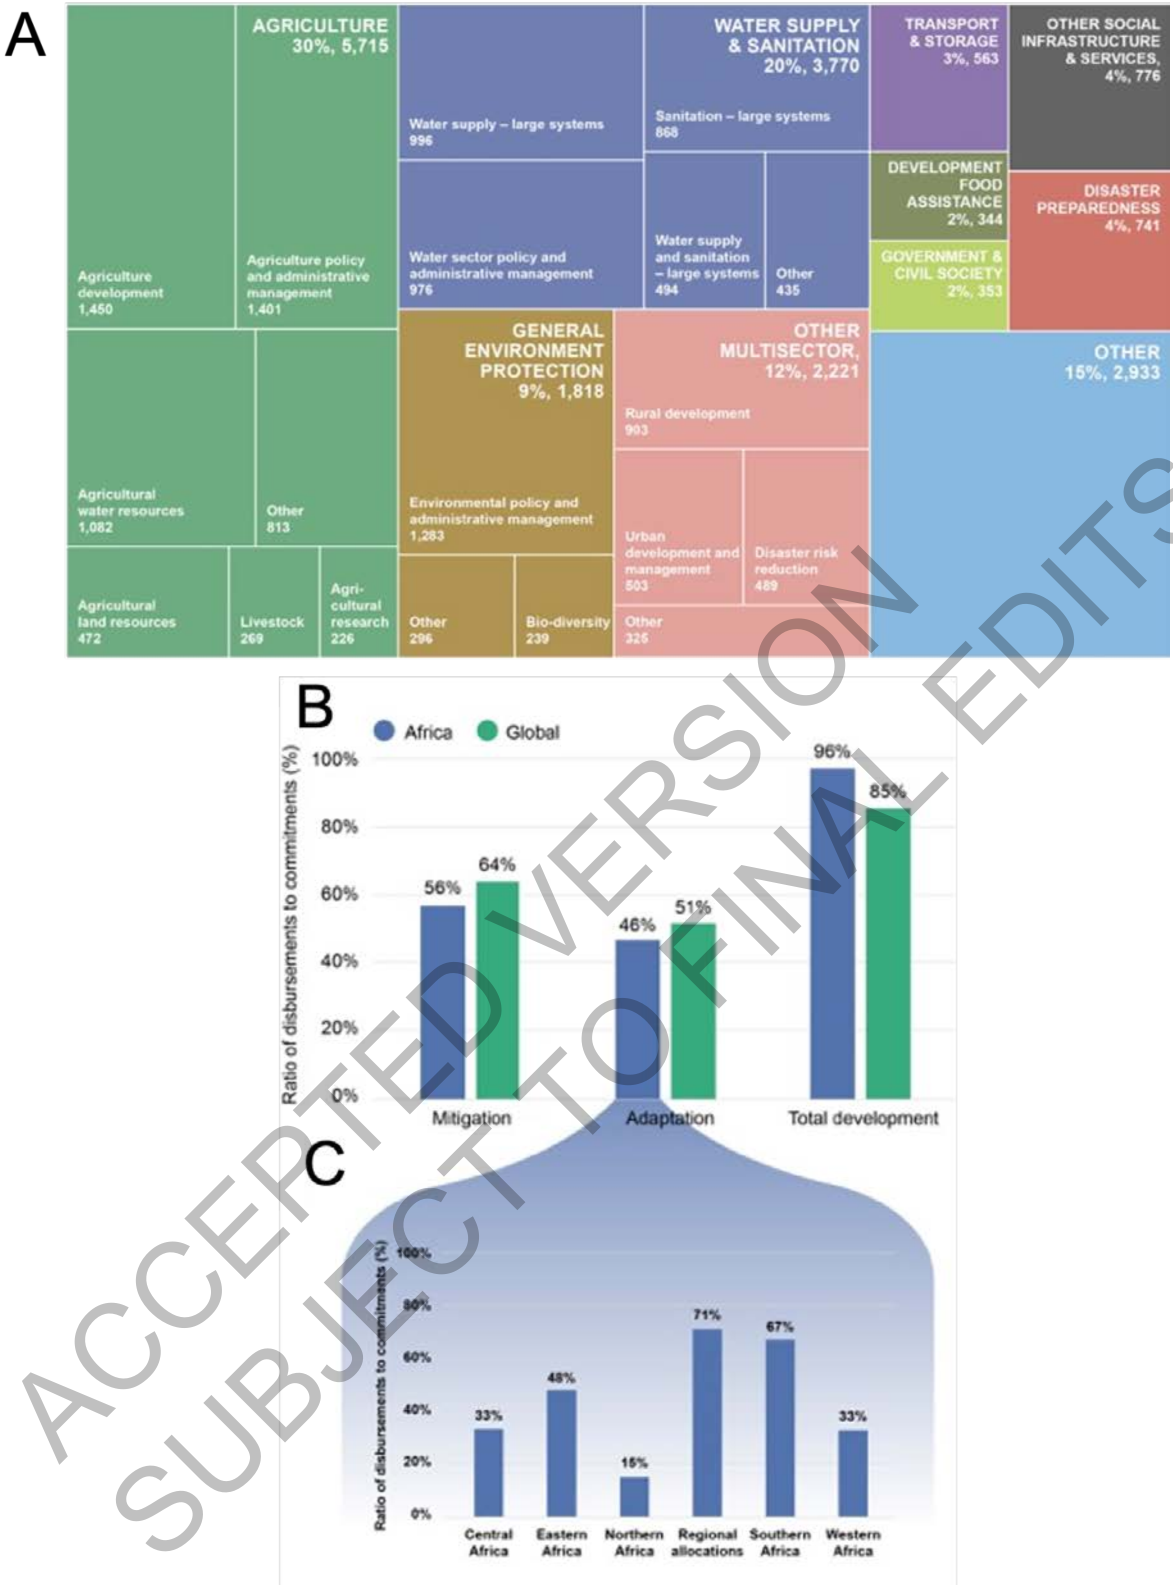

Figure 9.9: (a) Sectoral distribution of adaptation finance commitments to Africa 2014-2018 (Savvidou and Atteridge, 2021). Disbursement ratio (disbursements expressed as percentage of commitments) targeting mitigation, adaptation and for total development finance, (b) disbursement ratios for Africa compared to global average, and (c) disbursement ratios for adaptation finance broken down by each African sub-region. 2014-2018 (for all funders reporting to OECD except Multilateral Development Banks). Source: (Savvidou and Atteridge, 2021).

9.4.1.4 What are the Barriers and Enabling Conditions for Adaptation Finance?

The present situation reflects not only an insufficient level of finance being mobilised to support African adaptation needs (Section 9.4.1) but also problems in accessing and using funding that is available. The direct access modality introduced by the Adaptation Fund and GCF, whereby national and regional entities from developing countries can be accredited to access funds directly, is aimed at reducing transaction costs for recipient countries, increasing national ownership and agency for adaptation actions, and enhancing decision-making responsibilities by national actors, thereby contributing to strengthening local capacity for sustained and transformational adaptation (CDKN, 2013; Masullo et al., 2015). Indeed, direct-access projects from the Adaptation Fund tend to be more community focussed than indirect-access projects (Manuamorn and Biesbroek, 2020). Country institutions in Africa, however, are struggling to be accredited for direct access because of the complicated, lengthy and bureaucratic processes of accreditation, which requires, for example, strong institutional and fiduciary standards and capacity to be in place (Brown et al., 2013; Omari-Motsumi et al., 2019). As of December 2019, over 80% of all developing countries had no national Direct Access Entities (DAEs) (Asfaw et al., 2019). Capacity to develop fundable projects in Africa is also inadequate. An analysis of proposals submitted to the GCF up to 2017 revealed that, while African countries were able to submit proposals to the GCF, they had the lowest percentage of approvals (39%) compared to all other regions (Fonta et al., 2018). This suggests the quality of proposals and therefore the capacity to develop fundable proposals remains inadequate in the region.

Even when accredited, some countries experience significant institutional and financial challenges in programming and implementing activities to support concrete adaptation measures (Omari-Motsumi et al., 2019). Low disbursement ratios suggest inadequate capacity to implement projects once they are approved (Savvidou and Atteridge, 2021). Systemic barriers have been highlighted in relation to the multilateral climate funds, including funds not providing full-cost adaptation funding, capacity barriers in the design and implementation of adaptation actions (including the development of fundable project proposals) and barriers in recognising and enabling the involvement of sub-national actors in the delivery and implementation of adaptation action (Omari-Motsumi et al., 2019). As of 2017, most GCF disbursements to Africa (61.9%) were directed to support national stakeholders' engagement with regards to readiness activities, with only 11% directed to support DAEs in implementation of concrete projects/pipeline development (Fonta et al., 2018). While supporting readiness activities is important for strengthening country ownership and institutional development, research suggests adaptation finance needs to shift towards implementation of concrete projects and more pipeline development if the goal of transformative and sustained adaptation in Africa is to be realised (Fonta et al., 2018; Omari-Motsumi et al., 2019). The source of these problems needs to be better understood so that the prospects for future climate-related investments can be improved and institutional strengthening and targeted project preparation can be supported (Omari-Motsumi et al., 2019; Doshi and Garschagen, 2020; Savvidou and Atteridge, 2021).

Some progress has been made in supporting developing countries to enhance their adaptation actions. The process to formulate and implement NAPs was established by parties under the UNFCCC to support developing countries identify their vulnerabilities, and determine their medium- and long-term adaptation needs (UNFCCC Paris Agreement, 2015). NAPs provide a means of developing and implementing strategies and programmes to address those needs. In 2016, the parties agreed for the GCF to fund up to USD 3 million per country for adaptation planning instruments, including NAPs. However, accessing funding through the GCF for NAP formulation is challenging (Fonta et al., 2018) and, as of October 2020, four years after the decision to fund NAPs, only six African countries had completed their NAPs (UNFCCC NAP Central). The next step is to convert adaptation planning documents into programming pipeline projects that are fundable and implementable, which presents a significant barrier to enhanced adaptation action (Omari-Motsumi et al., 2019).

Adaptation finance has not been targeted more towards more vulnerable countries (Barrett, 2014; Weiler and Sanubi, 2019; Doshi and Garschagen, 2020; Savvidou and Atteridge, 2021). Reasons for this include fast-growing middle-income countries offering larger gains in emission reductions, so finance has favoured mitigation in these economies, even within sub-Saharan Africa, and as more climate finance uses debt instruments, mitigation projects are further preferred because returns are perceived to be more certain (Rai et al., 2016; Lee and Hong, 2018; Carty et al., 2020; Simpson et al., 2021c).

Many adaptation interventions for most vulnerable countries and communities provide no adequate financial return on investments and can therefore only be funded with concessional public finance (Cross-Chapter Box

FINANCE in Chapter 17). Yet, public funds alone are insufficient to meet rapidly growing adaptation needs. Public mechanisms can help leverage private sector finance for adaptation by reducing regulatory, cost and market barriers through blended finance approaches, public-private partnerships, or innovative financial instruments and structuring in support of private sector requirements for risk and investment returns, such as green bonds (Cross-Chapter Box FINANCE in Chapter 17). Subnational actors can be core agents to conceptualize, drive, and deliver adaptation responses and unlock domestic resources in the implementation of adaptation action (CoM SSA, 2019; Omari-Motsumi et al., 2019), provided they are sufficiently resourced and their participation and agency are supported.

Many African countries are at high risk of debt distress, especially due to the COVID-19 pandemic, and will need to decrease their debt levels to have the fiscal space to invest in climate resilience (Estevão, 2020; Dibley et al., 2021). As of mid-2021, the G20's Debt Service Suspension Initiative is providing temporary relief for repayment of bilateral credit, but this has largely not been taken up by private lenders (Dibley et al., 2021; World Bank, 2021). The total external debt servicing payments combined for 44 African countries in 2019 were USD 75 billion (World Bank, 2018), far exceeding discussed levels of near-term climate finance. Aligning debt relief with Paris Agreement goals could provide an important channel for increased financing for climate action, for example, by allowing African countries to use their debt-servicing payments to finance climate change mitigation and adaptation (Fenton et al., 2014). Governments can disclose climate risks when taking on sovereign debt, and debt-for-climate resilience swaps could be used to reduce debt burdens for low-income countries while supporting adaptation and mitigation (Dibley et al., 2021).

9.4.2 Governance

9.4.2.1 Governance Barriers

Overcoming governance barriers is a precondition to ensure successful adaptation and climate-resilient development (Pasquini et al., 2015; Owen, 2020). Despite the ambitious climate targets across African countries and renewed commitments in recent years (Zheng et al., 2019; Ozor and Nyambane, 2020), governance barriers include, among others, slow policy implementation progress (Shackleton et al., 2015; Taylor, 2016), incoherent and fragmented approaches (Zinngrebe et al., 2020; Nemakonde et al., 2021), inadequate governance systems to manage climate finance (Granoff et al., 2016; Banga, 2019), poor stakeholder participation (Sherman and Ford, 2014), gender inequalities (Andrijevic et al., 2020), unaligned development and climate agendas (Musah-Surugu et al., 2019; Robinson, 2020), elite capture of climate governance systems (Kita, 2019), hierarchical and complex state bureaucracy (Meissner and Jacobs, 2016; Biesbroek et al., 2018) and weak, non-existent or fragmented subnational institutions (Paterson et al., 2017; Musah-Surugu et al., 2019). Further, adaptation planning involves cross-cutting themes, multiple actors and institutions with different objectives, jurisdictional authority and levels of power and resources, yet there is often a lack of coordination, clear leadership or governance mandates (Shackleton et al., 2015; Leck and Simon, 2018) and unequal power relations between African countries and developed countries can hinder progress on governance of financial markets, budget allocations and technology transfer to address addressing climate technology gaps in Africa (Rennkamp and Boyd, 2015; Olawuyi, 2018).

Policy implementation can be slow due to the absence of support mechanisms and dependency on funding by international partners (Leck and Roberts, 2015; Ozor and Nyambane, 2020). In many countries, commitment to climate policy objectives is low (Naess et al., 2015), particularly in light of competing development imperatives and post-COVID-19 recovery efforts (Caetano et al., 2020), although COVID-19 recovery efforts offer significant opportunities for health, economic and climate resilience co-benefits (Sections 9.4.3 and 9.11.5; Cross-Chapter Box COVID in Chapter 7). Another challenge relates to long-term planning and decision-making which is hampered by uncertainty related to future socio-economic and GHG emissions scenarios (Coen, 2021), political cycles and short-term political appointment terms (Pasquini et al., 2015).

Lack of community agency in climate governance affects ability for citizen-led climate interventions in Africa (Antwi-Agyei et al., 2015; Mersha and Van Laerhoven, 2016). This is attributed partly to low civic education, limited participation power of citizens and tokenism due to perceived lack of immediate benefits (Odei Erdiaw-Kwasie et al., 2020), as well as low rates of climate change literacy in many regions (Simpson et al., 2021a) (Section 9.4.3). Participation in climate policy also extends to the private sector, which has been relatively uninvolved in adaptation discussions to date (Crick et al., 2018).

Africa requires substantial resources and support to adapt to the unavoidable consequences of climate change, a pertinent climate justice concern for governments. However, the mechanisms needed to redress current power imbalances, structural and systemic inequality are often absent (Saraswat and Kumar, 2016) (see Section 9.11.4) and policies that underpin environmental justice concerns, including distributive justice, participation, recognition and capability (Shi et al., 2016; Chu et al., 2017) are also needed.

9.4.2.2 Good Governance

Good governance can contribute to positive climate outcomes and climate-resilient development in Africa through long-term planning, development-focused policy environments, the development of robust and transformational policy architecture, inclusive participation and timely implementation of NDCs (Bataille et al., 2016; Werners et al., 2021) (see Table 9.3 for examples).

Table 9.3: Characteristics and examples of governance that contribute towards climate-resilient development in Africa

Governance characteristic	Example
Long-term development planning	Countries are mainstreaming adaptation into their long-term development cycles (UNFCCC Adaptation Committee, 2019). For example, Burkina Faso's National Adaptation Plan elaborates its perspective to 2050 and links to its development pathways (Government of Burkina Faso, 2015). Many African countries are also enhancing the adaptation components of their long-term low emissions strategies.
Climate justice and inequality-focused policies	Climate policies can be designed to include specific policy mechanisms (e.g., carbon taxes, renewable energy subsidies) to maximise developmental gains while reducing inequality (Andrijevic et al., 2020). For example, revenues from a carbon tax can be used to increase social assistance programs that benefit poor people and reduce their vulnerability to climate change (Hallegatte et al., 2016). Climate risk management can be integrated into social protection and assistance programs, such as public works programs that increase climate resilience (9.11)
Interlinkages between adaptation and development pathways	Cross-sectoral and multi-level governance approaches can harness synergies with the SDGs, Paris Agreement and Agenda 2063 aspirations, helping to counter the adaptation deficit, promote sustainable resource use and contribute to poverty reduction (Niang et al., 2014; IPBES, 2018; Roy et al., 2018b). Ghana, Namibia, Rwanda and Uganda all link adaptation with disaster risk reduction in their NDCs (UNFCCC Adaptation Committee, 2019).
High-level engagement	Climate policies, traditionally overseen by environment ministries, are increasingly receiving priority from finance and planning ministries. Zambia's Climate Change Secretariat is currently led by the Ministry of Finance (Government of the Republic of Zambia, 2010), while Tanzania's environmental division sits in the office of the Vice-President (Governmet of the United Republic of Tanzania, 2011).
All-of-government approach	In Kenya, the Climate Change Directorate is the secretariat for the National Climate Change Commission, serving as an overarching mechanism to coordinate sectoral and county level action (Government of the Republic of Kenya, 2018). In South Africa, the National Committee on Climate Change, the Intergovernmental Committee on Climate Change and the Presidential Climate Change Commission have been established to enhance intergovernmental and multisectoral coordination on climate action (Climate Action Tracker, 2021).
Participatory engagement	Polycentric, bottom-up and locally implemented approaches are more able to include the emergence of new actors (e.g., city networks, multinational companies and sub-state entities), new instruments and levels (soft law instruments or transnational dynamics) and new guiding principles and values (fairness, transparency and co-participation) (Leal Filho et al., 2018; Sapiains et al., 2021). Case studies include the community-based, participatory scenario planning approach used in Malawi to generate information for farmers from seasonal forecasts, as well as the integration of climate risk into Lusaka's Strategic Plan through engagement with city planners (Conway and Vincent, 2021; Vincent and Conway, 2021). Many innovative solutions have been designed to promote participation, such as Pamoja Voices toolkits in pastoralist communities in Northern Tanzania (Greene et al., 2020).

Inclusive and diverse stakeholders	Kenya's Climate Change Directorate has a designated team to integrate gender into its national climate policies (Murray, 2019), while Seychelles' National Climate Change Council has allocated a seat exclusively for a youth candidate (Government of The Seychelles, 2020). Tanzanian Climate-Smart Agriculture Alliance supports the integration of farmers and builds strategic alliances to support climate processes (Nyasimi et al., 2017).
Partnerships	Ghana, Kenya, Uganda and Zambia are developing anticipatory scenarios for low-carbon climate-resilient development pathways for the agricultural sector, aimed at informing input into national climate policy (Balié et al., 2019). This science to policy to practice interface is bridged through the inclusion of policymakers, practitioners and academics (Dinesh et al., 2018). In Lusaka, Durban and other African cities, processes of engagement and learning have built the trust and capacities needed to inform city-scale, climate-resilient decisions and associated actions (Taylor et al., 2021a; Taylor et al., 2021b).
NDC implementation	Rwanda has developed an indicator-based Monitoring, Reporting and Verification (MRV) framework for tracking its NDC implementation and associated financial flows (Government of Republic of Rwanda, 2020). Zambia has also integrated gender indicators into its NDC implementation plan and is incorporating gender considerations into its MRV framework (Murray, 2019).

African governments are developing and revising ambitious adaptation policies that are enforceable and aligned with wider societal development goals, including an enabling environment for finance and investment in the jobs and skills development necessary to support a just transition (ILO, 2019) (Section 9.4.5). If appropriately designed, such institutions offer the opportunity to foster adaptive governance which is collaborative, multi-level and decentralised, offering integration of policy domains, flexibility and an emphasis on non-coerciveness and adaptation (Ruhl, 2010).

Coordination across multiple sectors, supported with leadership from the highest levels of government, has shown to improve implementation effectiveness and anticipated scaling up (Rigaud et al., 2018). This high-level engagement promotes the inclusion of climate resilience and adaptation targets in national planning and budgeting. Financial and capacity support is essential (Adenle et al., 2017; UNEP, 2021), as is the tracking of national progress towards development goals (Box 9.6).

In Africa, climate governance occurs in a context of deep inequality and asymmetric power relations – both within countries and between countries – making adequate mechanisms for multi-stakeholder participation essential (Sapiains et al., 2021). This requires creation of avenues for the voices of marginalised groups in policy processes and enabling policy environments that can catalyse inclusive action and transformational responses to climate change (Totin et al., 2018; Revi et al., 2020; Ziervogel et al., 2021), safeguarding protection against the climate harms of the most vulnerable in society, particularly of women and children (see also Box 9.1). Community-based natural resource management in pastoral communities was observed to improve institutional governance outcomes through involving community members in decision-making, increasing the capacity of these communities to respond to climate change (Reid, 2014).

Specific indicators can be included in the performance metrics and monitoring frameworks for each sector, policy intervention and budget planning cycle (Wojewska et al., 2021). Many countries in Africa are also revamping their institutional coordination mechanisms to reflect an all-of-government approach and partnership with non-State stakeholders with diverse capabilities and expertise (see examples from Rwanda and Zambia in Table 9.3). This includes Cape Town's drought response in 2017/2018 where non-State actors actively partnered with the state response around water management/savings practices (Simpson et al., 2020a; Simpson et al., 2020b; Cole et al., 2021b).

9.4.3 Cross-Sectoral and Transboundary Solutions

Climate change does not present its problems and opportunities conveniently aligned with traditional sectors, so mechanisms are needed to facilitate interactions and collaborations between people working in widely different sectors (Simpson et al., 2021b). Traditional risk assessments typically only consider one climate hazard and one sector at a time, but this can lead to substantial misestimation of risk because multiple climate risks can interact to cause extreme impacts (Zscheischler et al., 2018; Simpson et al., 2021b).

Because multiple risks are interlinked and can cascade and amplify risk across sectors, cross-sectoral approaches that consider these interlinkages are essential for climate-resilient development, especially for managing trade-offs and co-benefits between SDGs, mitigation and adaptation responses (Liu et al., 2018a).

In Africa, placing cross-sectoral approaches at the core of climate-resilient development provides significant opportunities to deliver large benefits and/or avoids damages across multiple sectors including water, health, ecosystems and economies (*very high confidence*) (Boxes 9.5, 9.6 and 9.7). They can also prevent adaptation or mitigation action in one sector, exacerbating risks in other sectors and resulting in maladaptation, for example, from large-scale dam construction or large-scale re/afforestation (e.g., water-energy-food nexus and large-scale tree planting efforts) (Boxes 9.3 and 9.5).

Cross-sectoral or 'nexus' approaches can improve the ability of decision-makers to foresee and prevent major climate impacts. Barriers to developing nexus approaches arise from rigid sectoral planning, regulatory and implementation procedures, entrenched interests and power structures and established sectoral communication structures. Opportunities for overcoming these barriers include creating a dedicated home for co-development of nexus risk assessment and solutions, promoting co-leadership of projects by multiple sectors, specific budget allocations for nexus projects, facilitating and coordinating services, compiling useful strategies into toolkits, ameliorating inequitable power relations among participants and measuring progress on nexus approaches through metrics (Palmer et al., 2016; Baron et al., 2017).

Beyond cross-sectoral collaboration, international cooperation is vital to avert dangerous climate change as its impacts reach beyond the jurisdiction of individual states. International good practice and regional agreements, protocols and policies together recognise that regional integration, cooperative governance and benefit-sharing approaches are cornerstones of effective resource security and climate change responses in Africa (Jensen and Lange, 2013; World Bank, 2017a; Dombrowsky and Hensengerth, 2018). Natural resource development, particularly governance of shared river basins, exemplifies opportunities for governance responses for African nations that can be cooperative, regionally integrated and climate-resilient.

In Africa, climate vulnerability crosses geopolitical divides as regional clusters of fragile and high vulnerability countries exist, emphasising the need for transboundary cooperation (Birkmann et al., 2021; Buhaug and von Uexkull, 2021). Natural resource security is increasingly reliant on transboundary governance, regional integration and cooperation (Namara and Giordano, 2017). There are 60 international or shared river basins on the continent, a function of colonial divides and topography, with some basins shared by four or more countries (UNECA, 2016; Popelka and Smith, 2020). Climate changes which result in impact and risk pathways across country boundaries and regions (although with different levels of impact) accelerate the urgency for integrated approaches to manage and benefit from shared resources and promote their security for populations and economies (Namara and Giordano, 2017; Frame et al., 2018; Carter et al., 2021). At the same time, natural resources such as water generate economic benefits shared across boundaries, such as hydroelectric power generation and regional food security (Dombrowsky and Hensengerth, 2018).

Poor governance, particularly at the transboundary level, can undermine water security and climate change is likely to add new challenges to pre-existing dynamics, emphasising the necessity of formal transboundary arrangements (Jensen and Lange, 2013; UNECA, 2016). Further, it can constrain access to critical financial resources at a time when it is needed most. This is particularly the case when climate impact pathways manifest at the transboundary level (Challinor et al., 2018; Simpson et al., 2021b), but where the need to protect sovereign interests can block regionally integrated institutional arrangements that are pivotal for accessing the multilateral climate funds for transboundary climate investments that include resilient infrastructure and greater water benefits across Africa's shared river basins (Carter et al., 2021) (Cross-Chapter Box INTEREG in Chapter 16).

In response, the African Development Bank is supporting two of the most climate-vulnerable and larger African river basins to leverage GCF and GEF funds to finance Programmes for Integrated Development and Adaptation to Climate Change (PIDACC). PIDACC finance is approved at the multinational level in the Niger basin which is shared by 9 West and Central African States (AfDB, 2018c; GCF, 2018a), while a PIDACC proposal is currently under development for the Zambezi basin (Zambezi Watercourse Commission, 2021).

Stakeholders across Africa are recognising the scale and severity of transboundary risks to water. Such risks are twofold in nature, arising both from potential impacts due to climate change and from responses to climate change (Simpson et al., 2021b). This awareness amongst stakeholders is leading to increasingly progressive approaches to natural resource development which can also reduce risk across boundaries within regions. For example, river basin organisations (RBOs) in southern Africa such as the Orange-Senqu and the Okavango River Basin Commissions are revising treaties considered to predate the interrelated issues of climate change, growing populations and water scarcity (OKACOM, 2020). In parts of West Africa, where climate change is characterised by reduction of precipitation (Barry et al., 2018), regionally integrated and climate-resilient economic investments for water resource development are enabled by the Senegal River Basin Organisation (OMVS) which emphasises programme and project development, financing and implementation in ensuing work plans (World Bank, 2020e), as does the Nile Basin Initiative (NBI) in North and East Africa (Schmeier, 2017; Blumstein and Petersen-Perlman, 2021).

Enhanced transboundary governance arrangements suggest that countries are joining forces to coherently manage and protect natural resources (Spalding-Fecher et al., 2014; AfDB, 2021). Underlying governance issues and political economy interests block or advance such transitions to regionally integrated resource management and benefit-sharing, the market drivers of water security (AMCOW, 2012; Soliev et al., 2015). Angola, for example, outlines regional adaptation as a priority and one of its unconditional adaptation strategies (which is already funded) is enhancing resilience in the Benguela fisheries system, a project shared with Namibia and South Africa (GEF and FAO, 2021). Another example is The Great Green Wall for the Sahara and Sahel Initiative which was launched in 2007, with the aim of tackling land degradation in Africa (UNCCD, 2020). This transboundary project, led by the African Union Commission, is being implemented in more than 20 countries across Africa's Sahel region, in cooperation with international partners including UNCCD, GEF and the World Bank among others. Approximately USD 10 billion have been mobilised and/or promised for this initiative (UNCCD, 2020). Such statements demonstrate the increasing identification of transboundary risks and approaches to manage and adapt to them as areas of 'common concern' that require cooperative adaptation actions. Accelerating strengthened transboundary water and climate governance needs to integrate these climate drivers of compromised water security. The role of institutions such as OVMS and the NBI have demonstrated they can be played in influencing economic behaviour among riparian countries of shared river basins highlighting that institutions are an integral part of climate governance in evolving economic systems (Hodgson, 2000).

9.4.4 Climate Change Adaptation Law in Africa

9.4.4.1 The Rise of Climate Change Adaptation Law

Robust legislative frameworks, both climate change specific and non-specific, can foster adaptive responses to climate change, particularly in Least Developed Countries (LDCs) (Nachmany et al., 2017). As discussed in Chapter 17, there are multiple reasons for this. The successful implementation of policy objectives across the continent is often contingent upon or at least supported by an underlying legislative framework (Averchenkova and Matikainen, 2017; Scotford et al., 2017). There are also wider systemic and structural reasons for developing climate change legislation, including the promotion of coordination within government, its policy entrenching role, its symbolic value and its potential to support climate finance flows (Nachmany et al., 2017; Scotford and Minas, 2019).

Legal systems, however, also have the potential to be maladaptive. Laws may be brittle, often assuming and reinforcing a static state, and the boundary of the law may not align to the relevant location, scale or impact (Craig, 2010; Arnold and Gunderson, 2013; Wenta et al., 2019). This necessitates the review and revision of existing laws to remove such barriers and foster adaptive management (Craig, 2010; Ruhl, 2010; Cosens et al., 2017) and, where necessary, the promulgation of new laws.

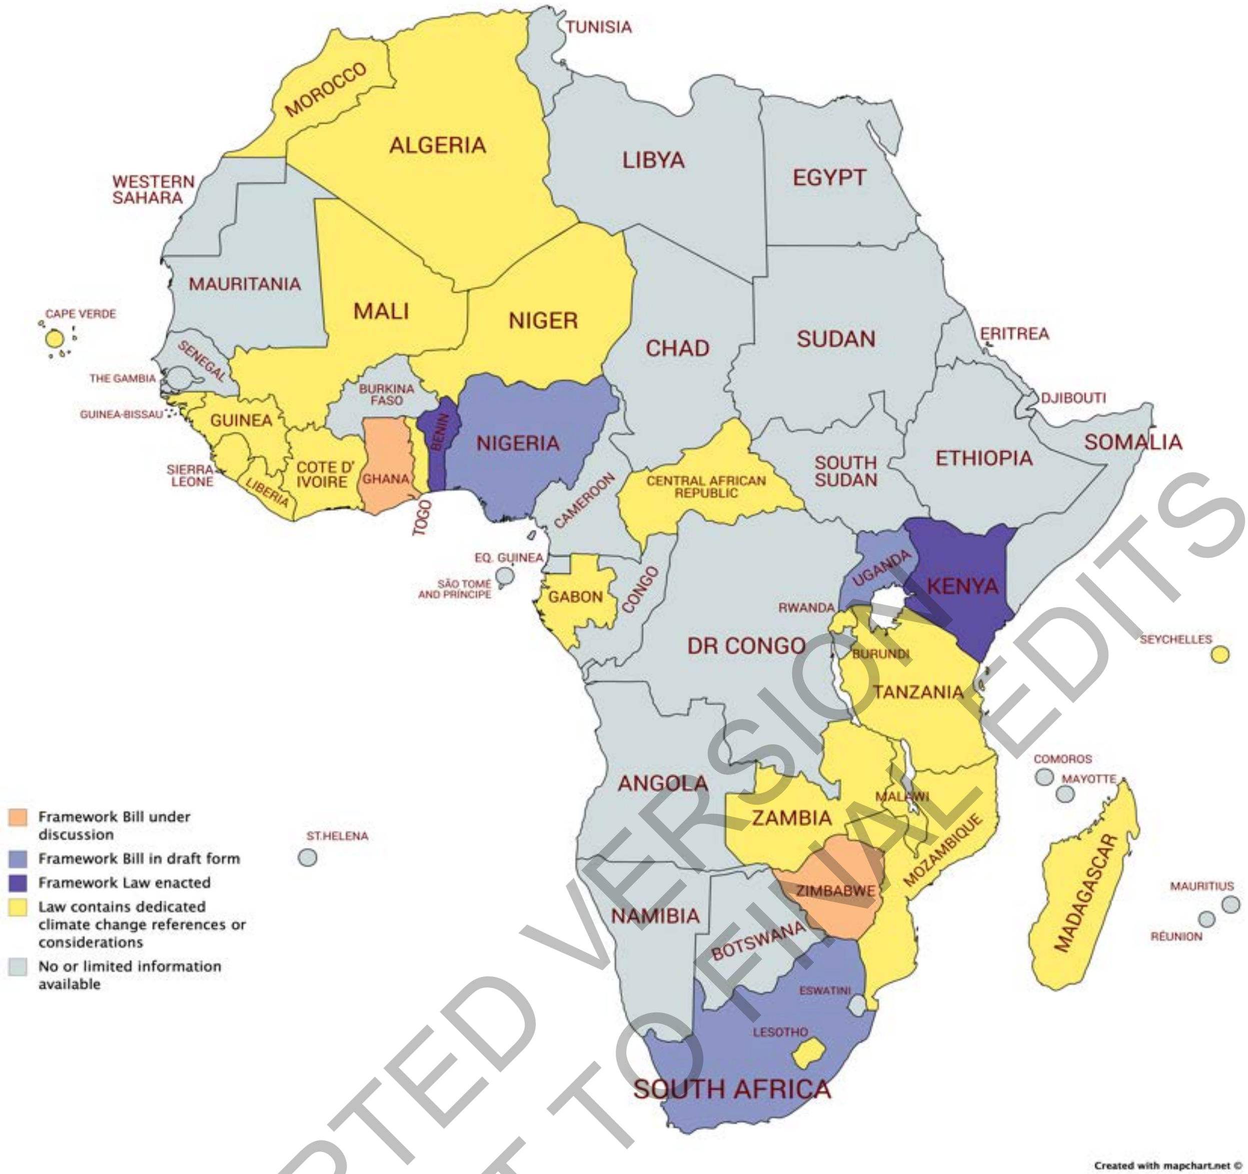

Figure 9.10: Progress in development of climate change framework law in Africa derived from an analysis of public databases of African laws (author's own map), data drawn from (Government of Niger, 1998; Government of Liberia, 2002; Government of Algeria, 2004; Government of Tanzania, 2004; Government of Central African Republic, 2008; Government of Lesotho, 2008; Government of Togo, 2008; Government of Guinea Bissau, 2011; Government of Ivory Coast, 2012; Government of Rwanda, 2012; Government of Sierra Leone, 2012; Government of Cape Verde, 2014; Government of Morocco, 2014; Government of Mozambique, 2014; Government of Madagascar, 2015; Government of the Seychelles, 2015; Government of Gabon, 2016; Government of Kenya, 2016; Government of Mali, 2016; Government of Zambia, 2016; Government of Malawi, 2017; Government of Nigeria, 2017; Government of Benin, 2018; Government of Ghana, 2018; Government of South Africa, 2018; Government of Uganda, 2018; Government of Zimbabwe, 2019 sources quoted as of September 2019).

There has been a rise in framework and sectoral climate change laws across Africa, as illustrated in Figure 9.10 above. The map illustrates the two framework statutes which have been promulgated in Benin and Kenya, as well as the three framework Bills which have been drafted in Nigeria, South Africa and Uganda. There are also discussions taking place in Zimbabwe and Ghana regarding the potential development of a draft framework Climate Change Bill. A review of the climate change framework laws indicates evidence of cross-pollination in design across African jurisdictions, creating the potential for a unique and regionally appropriate body of law with a strong focus on adaptation responses (Rumble, 2019). As discussed in Chapter 17, however, there remains the need for in-country expert input on how the domestic legal landscape may influence their operation, and for each jurisdiction to independently interrogate its adaptation needs and objectives (Scotford et al., 2017).

Numerous African states have also included dedicated climate change-related provisions within various existing statutes which regulate the environment or disaster management. For example, Tanzania's Environmental Management Act 20 of 2004 contains dedicated provisions to address climate change. Rwanda's Law on Environment 48/2018 also contains detailed provisions on mainstreaming climate change into development planning processes, education on climate change, vulnerability assessments and the promotion of measures to enhance adaptive capacity. Some countries have also developed laws dedicated to a specific aspect of adaptation. For example, the Conservation and Climate Adaptation Trust of Seychelles Act 18 of 2015 establishes a trust fund to finance climate change adaptation responses in Seychelles. Similarly, many countries including Algeria, Burkina Faso, Djibouti, Ghana, Namibia, Malawi, Mauritius, Madagascar, Mozambique, Tanzania and South Africa have dedicated disaster management laws. At this stage, it is still too early to determine whether these laws are having any substantive influence in strengthening resilience and reducing vulnerability and, as discussed in Chapter 17, this is identified as a knowledge gap requiring further research.

9.4.4.2 Common Themes in Framework Laws

Laws are now being developed to formalise and entrench institutional structures, specifying their mandate, function, membership and related procedures. A useful example of such an approach can be found in the Nigerian Climate Change Bill which establishes the National Climate Council on Climate Change headed and chaired by the Vice-President, with a wide membership of Ministers, the Chairmen of the Governors' Forum and Association of Local Governments, as well as the private sector and non-governmental organisation (NGO) representatives.

Climate change framework laws can play an instrumental role in achieving mainstreaming by directing relevant actors to integrate adaptation considerations into existing mandates, operations and planning instruments (Rumble, 2019). By way of example, the South African Draft Climate Change Bill contains a general duty to 'coordinate and harmonise the policies, plans, programmes and decisions of the national, provincial and local spheres of government' to achieve, among other things, the climate change objectives of the Bill and national adaptation objectives.

Another common theme is the requirement to develop national climate change adaptation strategies and plans. Many laws further entrench their longevity by requiring them to be subject to strong community participation and consultation, as demonstrated by the Kenyan Climate Change Act and the Nigerian Climate Change Bill.

9.4.4.3 Local Climate Change Laws and Indigenous Knowledge Systems

The Paris Agreement acknowledges, in Article 7.5, that adaptation should be based on and guided by, among other things, 'traditional knowledge, knowledge of indigenous peoples and local knowledge systems'. The accumulated knowledge within indigenous knowledge systems is particularly important as it can assist governments in determining how the climate is changing, how to characterise these impacts and provide lessons for adaptation (Salick and Ross, 2009). In this context, indigenous knowledge systems can play an important role in the effective design of local laws (Mwanga, 2019) as well as national laws. Doing so can contribute to the success of climate change response strategies, including enhancing local participation and the implementation of community-based and ecosystem-based adaptations (Chanza and de Wit, 2016; Mwanga, 2019). For example, the Makorongo Village Forest Management By-Law in Tanzania codifies local customary practices relating to forest management and sustainable harvesting with associated dual adaptation and mitigation benefits and includes all villagers in the decision-making processes relating to forest management (Mwanga, 2019). The inclusion of beneficial indigenous knowledge systems within local by-laws is contingent on the active involvement of members of the indigenous community and awareness of climate change considerations within the local sphere of government, and a willingness to foster such practices (Mwanga, 2019).

In addition to the advancement of indigenous knowledge in adaptive responses, it has been suggested that the protection of the rights of indigenous peoples can have adaptive benefits, in particular through the protection of land tenure rights (Ayanlade and Jegede, 2016). It has been argued that doing so will protect indigenous peoples' lands and resources from overconsumption, secure the recognition of their cultural stewardship over the environment, provide the financial incentive for land stewardship and promote the application of their unique knowledge on the sustainable development of that land and its preservation (Jaksa, 2006; Ayanlade and Jegede, 2016). Not only can a lack of protection of indigenous legal tenure undermine these objectives, but a number of African laws may actively work against them. For example, a review of Tanzanian and Zambian laws highlighted existing provisions that empowered the state to terminate or criminalise the occupation of vacant, undeveloped or fallow lands, which undermined the occupation by indigenous peoples of forests and other uncultivated lands (Ayanlade and Jegede, 2016).

9.4.5 Climate Services, Perception and Literacy.

Policy actors across Africa perceive that anthropogenic climate change is already impacting their locales through a range of negative socioeconomic and environmental effects (Pasquini, 2020; Steynor and Pasquini, 2020). They are highly concerned about and motivated to address these impacts (Hambira and Saarinen, 2015; Pasquini, 2020). Transformative responses to the impacts of climate change facilitate climate-resilient development and are informed by perceptions of climate variability and change and climate change literacy (Figure 9.11).

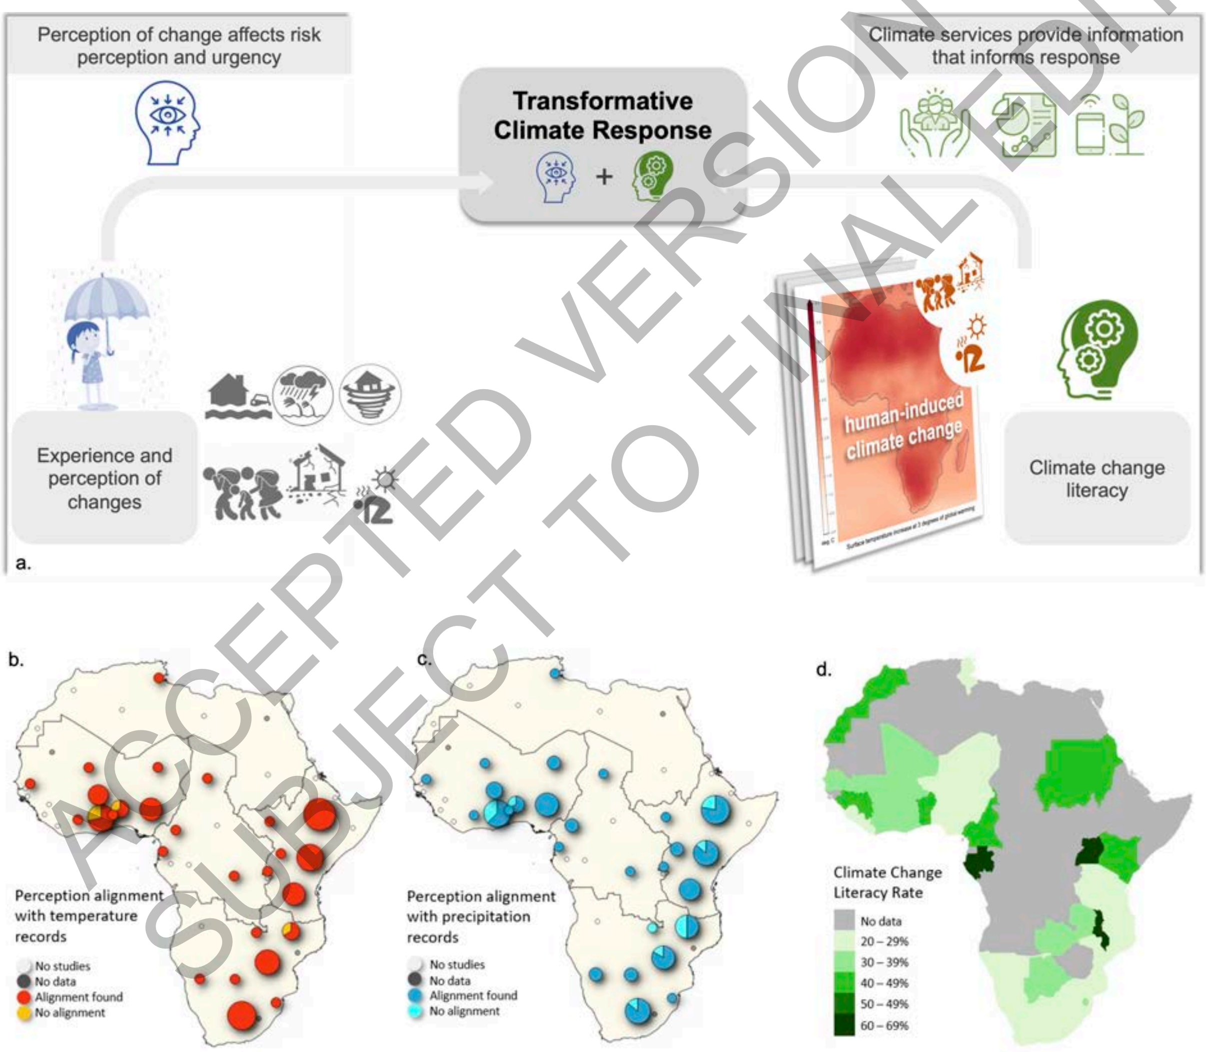

Figure 9.11: The importance of climate services and climate change literacy for more transformative responses to climate change in Africa (adapted from Simpson et al., 2021a). Climate services promote Climate Resilient Development by providing climate information for adaptation decision-making (Street, 2016; Vaughan et al., 2018). However, scalable uptake of climate services relies on climate risk perception of users which is largely driven in Africa by experience and perception of local climate changes (Jacobs and Street, 2020; Steynor et al., 2020b; Steynor and Pasquini, 2020). Perception of climate change in Africa can occur without the knowledge of its anthropogenic causes and its effect on risk, as awareness of the concept of climate change is generally low across Africa (Lee et al., 2015; Alemayehu and Bewket, 2017; Andrews and Smirnov, 2020). This can lead to coping responses to climate change which fall short of adaptation. Climate change literacy can fill this knowledge gap and, together with climate services,

extend responses to climate change to include consideration of future risk through awareness of the anthropogenic cause of climate change and its effect on risk (IPCC, 2019b; Simpson et al., 2021a). Maps a-c: (a) Percentage of times scholarship on Africa record that perception of temperature changes (left), (b) precipitation changes (centre), aligned with available meteorological or climate records for 144 country studies across 33 African countries (Size of bubble indicates number of studies per country for both Panels a and b; Panel b, alignment with temperature changes is indicated for all studies within a country in red, and articles indicating no alignment in orange; while in panel c, alignment with precipitation changes is indicated per country in dark blue and articles indicating no alignment in light blue). Panel c) country-level rates of climate change literacy for 33 African countries (that is, percentage of the population that have heard about climate change and think that human activity is wholly or partly the cause of climate change) (adapted from Simpson et al., 2021a).

9.4.5.1 Climate Information and Services

Climate services (CS) broadly include the generation, tailoring and provision of climate information for use in decision-making at all levels of society (Street, 2016; Vaughan et al., 2018). There is a range of climate service providers in Africa, including primarily National Meteorological and Hydrological Services (NMHS) and partner institutions, complemented by NGOs, the private sector and research institutions (Snow et al., 2016; Harvey et al., 2019), which offer the potential for public-private partnerships (Winrock, 2018; Harvey et al., 2019).

International development funding has progressed the provision of climate services and, together with technological advances and capacity-building initiatives, has increased the reliability of climate services across Africa (Vogel et al., 2019). Most CS investments have been towards the agricultural sector, with other focal sectors including pastoralism, health, water, energy and disaster risk reduction having only small CS initiatives directed towards them (Nkiaka et al., 2019; Carr et al., 2020). Despite this focus and investment, however, there remains a mismatch between the supply and uptake of CS in Africa as information is often inaccessible, unaffordable, not relevant to context or scale and is poorly communicated (Singh et al., 2018; Antwi-Agyei et al., 2021) (Table 9.4; Sections 9.4.1.5.1 and 9.13.4.1). Observational data required for effective regional climate services, including trend analyses, seasonal climate assessment, modelling and model evaluation, is sparse and often of poor quality (Figure 9.11) and usually requires payment which renders it unaffordable (Winrock, 2018).

A number of these challenges may be addressed through the transdisciplinary co-production of climate services (Alexander and Dessai, 2019; Vogel et al., 2019; Carter et al., 2020). Co-production of climate services involves climate information producers, practitioners and stakeholders, and other knowledge holders participating in equitable partnerships and dialogues to collaboratively identify climate-based risk and develop scale-relevant climate information to address this risk (Table 9.4) (Vincent et al., 2018; Carter et al., 2020).

Table 9.4: Challenges and opportunities for Climate Services in Africa for the supply and uptake of climate services.

Challenges	*Opportunities/Solutions*	*References*	*Examples of Programmes that address these challenges. Reproduced from (Carter et al., 2020) with permission.*
Supply of climate services			
Poor infrastructure (e.g., non-functioning observational networks; limited Internet bandwidth; lack of climate modelling capacity; keeping pace with changing technology).	• International funding for observation networks, data rescue and data sharing • Regular NMHS budgets from governments • Public-private partnerships	(Winrock, 2018; Harvey et al., 2019) (Snow et al., 2016; World Bank Group, 2016; Winrock, 2018; Cullmann et al., 2020; Meque et al., 2021)	*East Africa and the West African Sahel (ENACTS programme).* Work with NMHS to provide enhanced services by overcoming the challenges of data quality, availability and access. Creation of reliable climate information suitable for national and local decision-making using station observations and satellite data to provide greater accuracy in smaller space and time scales.

Fragmented delivery of climate services.	• Greater collaboration between the NMHS and sector-specific specialists to create a central database of sector-based climate services	(Winrock, 2018; Hansen et al., 2019a)	*Rwanda (RCSA programme).* improving climate services and agricultural risk management at local and national government levels in the face of a variable and changing climate
Mismatch in timescales: short-term information more desirable, e.g., seasonal predictions as opposed to decadal or end of century projections.	• Co-production of CS climate service products	(Jones et al., 2015; Vincent et al., 2018; Hansen et al., 2019a; Carr et al., 2020; Sultan et al., 2020)	*Burkina Faso (BRACED project).* Strengthening technical and communication capacities of national meteorological services to enable partners to jointly develop forecasts tailored to support agro-pastoralists.
Development funding interventions operate on timescales that inhibit or restrict effective adaptation and neglect to build in considerations for sustainability post the funded intervention.	• Co-production of climate service CS products • Endogenously driven climate services (services that are developed by regional actors, not by remote, usually developed nation actors)	(Vincent et al., 2018; Vogel et al., 2019) (Vincent et al., 2020a)	*Burkina Faso (BRACED project).* Actors recognised the need to ensure continuation of climate services post-project. Burkina Faso NMHS (ANAM) and National Council for Emergency Assistance and Rehabilitation (CONASUR) budgeted for the continued communication of climate services and training of focal weather intermediaries. Local radio stations agreed to continue transmitting climate services.
Use of climate services			
Insufficient access to usable data, including station data, and information suited to the decision context (including accessibility limitations based on gender and social inequalities)	• Capacity development initiatives for CS providers, intermediaries (including extension agents, NGO workers and others) and users • User needs assessments • Consistent monitoring and evaluation of climate services interventions	(Jones et al., 2015; Winrock, 2018; Hansen et al., 2019a; Hansen et al., 2019c; Mercy Corps, 2019; Nkiaka et al., 2019; Carr et al., 2020; Cullmann et al., 2020; Gumucio et al., 2020; Sultan et al., 2020) (Figure 9.11)	*Kenya, Ethiopia, Ghana, Niger and Malawi (ALP Programme).* Co-production of relevant information for decision-making and planning at seasonal time scales. The methods and media for communication and messages differ between different users. Strong emphasis on participation by women.
Limited capacity of users to understand or request appropriate CS products	• Co-production of climate service products • Capacity development	(Snow et al., 2016; Singh et al., 2018; Vincent et al., 2018; Nkiaka et al., 2019; Daniels et al., 2020)	*Cities in Zambia, Namibia, Mozambique, Zimbabwe, Botswana, Malawi and South Africa (FRACTAL programme).* Repeated interactions between each represented sector to learn and more completely understand the different contexts of each represented party and build understanding through an ethic of collaboration for solving climate-related problems in each unique city.

Lack of user trust in the information	• Co-production of climate service products • Combine scientific and indigenous forecasts • Demonstrate added value of the climate service	(Vincent et al., 2018; Nkiaka et al., 2019; Vaughan et al., 2019; Vogel et al., 2019; Nyadzi et al., 2021)	*Tanzania (ENACTS programme).* Co-production to inform malaria decisions systematically and change relationships, trust, and demand in a manner that had not been realised through previous singular and siloed approaches.
Socio-economic, and institutional barriers (limited professional mandates, financing limitations, institutional cooperation)	• Regular NMHS budgets from governments • Public-private partnerships • Supportive institutions, policy frameworks and individual capacity and agency	(Snow et al., 2016; World Bank Group, 2016; Winrock, 2018; Harvey et al., 2019; Vincent et al., 2020b)	

However, the effectiveness of co-production processes are hindered by aspects such as inequitable power relationships between different types of knowledge holders (e.g., scientists and practitioners), inequitable distribution of funding between developed country versus African partners that favours developed country partners, an inability to develop sustained trust relationships as a result of short-funding cycles, a lack of flexibility due to product-focused engagements and the scalability of co-production to enable widespread reach across Africa as the process is usually context-specific (*high confidence*) (Vincent et al., 2018; Vogel et al., 2019; Vincent et al., 2020a).

Despite these challenges, the inclusive nature of co-production has had a positive influence on the uptake of climate services into decision-making where it has been applied (Vincent et al., 2018; Vogel et al., 2019; Carter et al., 2020; Chiputwa et al., 2020) (Table 9.4; Figure 9.12) (*medium confidence*), through sustained inter/transdisciplinary relationships and capacity development (Norström et al., 2020), strategic financial investment (Section 9.13.4.1), fostering of ownership of resulting products and the combining of scientific and other knowledge systems (Carter et al., 2020; Steynor et al., 2020a). There is *high confidence* that together with improved institutional capacity building and strategic financial investment, climate services can help African stakeholders adapt to projected climate risks (Section 9.13.4.1; Figure 9.11).

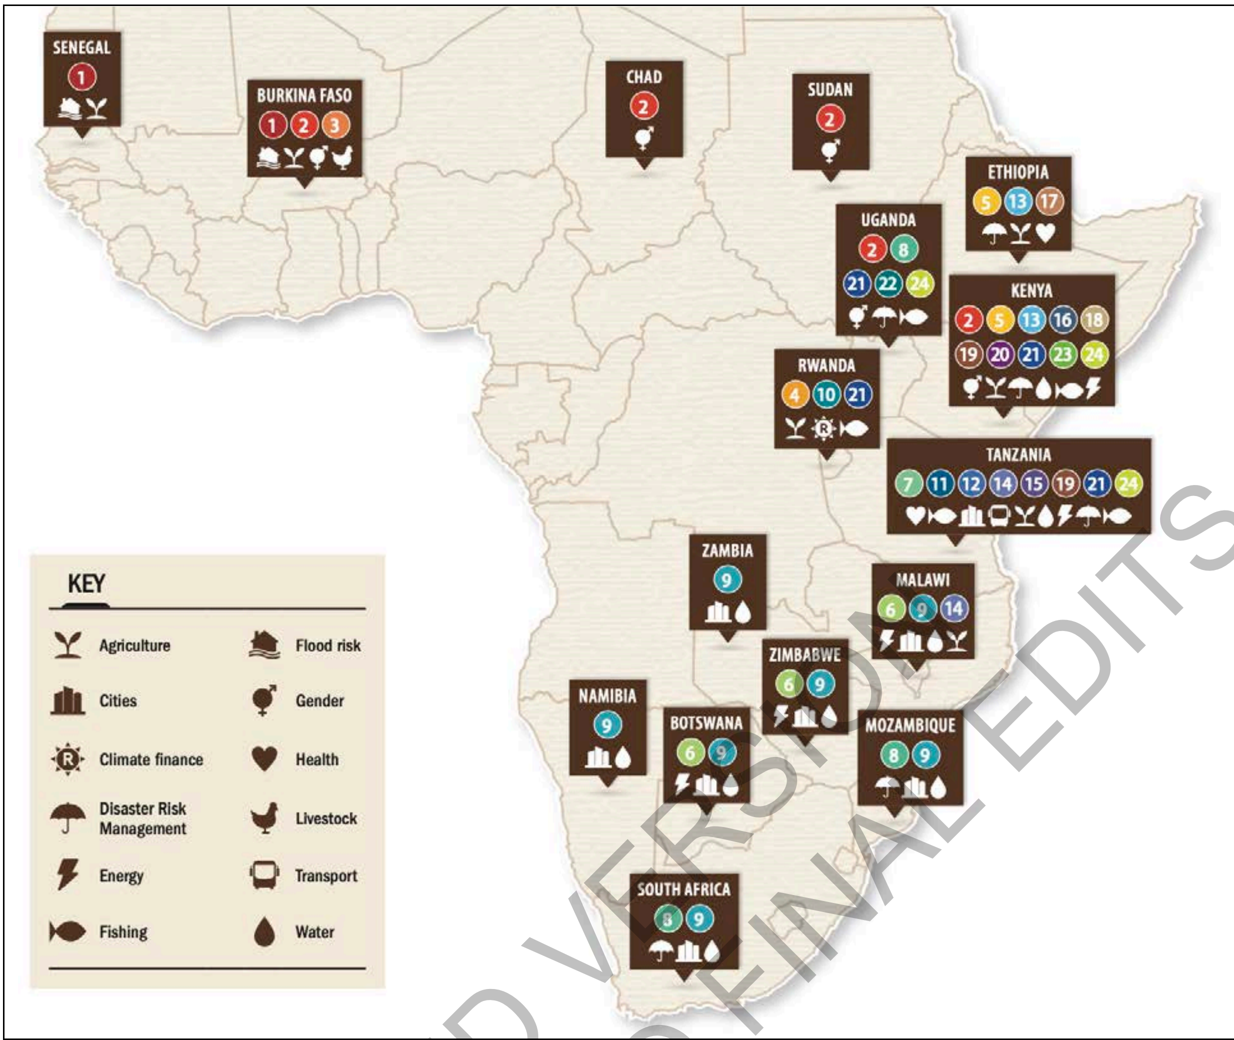

Figure 9.12: Case studies of co-production programmes, the countries they occurred in, sectors involved (icons – see key) and programmes under which the engagements occurred (numbers). Programmes listed are (1) AMMA-2050, (2,3) BRACED, (4) RCSA, (5) ALP, (6) Climate Risk Narratives, (7) ENACTS, (8) FATHUM, (9) FRACTAL, (10) FONERWA, (11) MHEWS, (12) Resilient Transport Strategic Assessment , (13) RRA, (14) UMFULA, (15) IRRP, (16) PRISE, (17) NMA ENACTS, (18) REACH, (19) DARAJA, (20) ForPAc, (21) HIWAY, (22) HyCRYSTAL, (23) SCIPEA, (24) Weather Wise. See Carter et al. (2020) for details and outcomes of each engagement. Source (Carter et al., 2020).

9.4.5.2 Community Perceptions of Climate Variability and Change

Perceptions of climate variability and change affect whether and how individuals and institutions act, and thus contribute to the success or failure of adaptation policies related to weather and climate (Silvestri et al., 2012; Arbuckle et al., 2015; Simpson et al., 2021a).

A recent Afrobarometer study covering 34 African countries found 67% of Africans perceive climate conditions for agricultural production to have worsened over time, and report drought as the main extreme weather event to have worsened in the past decade (Selormey et al., 2019). Of these participants, across all socioeconomic strata, 71% of those who were aware of the concept of climate change agreed that it needs to be stopped, but only 51% expressed confidence about their ability to make a difference. East Africans (63%) were almost twice as likely as North Africans (35%) to report that the weather for growing crops had worsened. Additionally, people engaged in occupations related to agriculture (farming, fishing or forestry) were more likely to report negative weather effects (59%) than those with other livelihoods (45%) (Selormey et al., 2019). Similar perceptions have been reported among a diversity of rural communities in many sub-Saharan African countries (Asiyanbi, 2015; Mahl et al., 2020; Simpson et al., 2021a).

Rural communities, particularly farmers, have been the most studied groups for climate change perception. They perceive the climate to be changing, most often reporting changes in rainfall variability, increased dry spells, decreases in rainfall and increased temperatures or temperature extremes, and perceive these changes to bring a range of negative socioeconomic and environmental effects (Alemayehu and Bewket, 2017; Liverpool-Tasie et al., 2020; Simpson et al., 2021a). In some cases, farmers' perceptions of changes in weather and climate frequently match climate records for decreased precipitation totals, increased drought frequency, shorter rainy season and rainy season delay and increased temperatures (Rurinda et al., 2014; Boansi et al., 2017; Ayanlade et al., 2018) (Figure 9.11), but not in all cases or not for all perceived changes, with common discrepancies in perceived lower rainfall totals (Alemayehu and Bewket, 2017; Ayal and Leal Filho, 2017; Simpson et al., 2021a).

Farming experience, access to extension services and increasing age are the most frequently cited factors positively influencing the perceptions of climate changes (Alemayehu and Bewket, 2017; Oduniyi and Tekana, 2019). Personal experience of climate-related changes and their impacts appears to be an important factor influencing perceptions through shaping negative associations, for example, experience of flash floods (Elshirbiny and Abrahamse, 2020) or direct effect on economic activity, indicating that perception is not restricted to crop farmers (Liverpool-Tasie et al., 2020). However, perception commonly has misconceptions about the causes of climate change which has implications for climate action (Elshirbiny and Abrahamse, 2020), highlighting the importance of climate change literacy.

9.4.5.3 Climate Change Literacy

Understanding the human cause of climate change has been shown to be a strong predictor of climate change risk perception (Lee et al., 2015) and a critical knowledge foundation that can affect the difference between coping responses and more informed and transformative adaptation (Oladipo, 2015; Mutandwa et al., 2019) (Figure 9.11). At a minimum, climate change literacy includes both having heard of climate change and understanding it is, at least in part, caused by people (Simpson et al., 2021a). However, large inequalities in climate change literacy exist between and within countries and communities across Africa.

The average national climate change literacy rate in Africa is only 39% (country rates range from 23-66%) (Figure 9.11). Of 394 sub-national regions surveyed by Afrobarometer, 8% (37 regions in 16 countries) have a climate change literacy rate lower than 20%, while only 2% (8 regions) score higher than 80% which is common across European countries (Simpson et al., 2021a). Striking differences exist when comparing sub-national units within countries. Climate change literacy rates in Nigeria range from 71% in Kwara to 5% in Kano, and within Botswana from 69% in Lobatse to only 6% in Kweneng West (Simpson et al., 2021a). Education is the strongest positive predictor of climate change literacy, particularly tertiary education, but poverty decreases climate change literacy and climate change literacy rates average 12.8% lower for women than men (Simpson et al., 2021a).

As the identified drivers of climate change literacy overlap with broader developmental challenges on the continent, policies targeting these predictors can potentially yield co-benefits for both climate change adaptation as well as progress towards SDGs, particularly education and gender equality (Simpson et al., 2021a). Progress towards greater climate change literacy affords a concrete opportunity to mainstream climate change within core national and sub-national developmental agendas in Africa towards more climate-resilient development pathways. Synergies with climate services can also overcome gendered deficits, for example, although women are generally less climate change aware and more vulnerable to climate change than men in Africa, they are generally more likely to adopt climate-resilient crops when they are climate change aware and have exposure to extension services (Acevedo et al., 2020; Simpson et al., 2021a).

[START BOX 9.1 HERE]

Box 9.1: Vulnerability Synthesis

Vulnerability in Africa is socially, culturally and geographically differentiated among climatic regions, countries and local communities, with climate change impacting the health, livelihoods and food security of different groups to different extents (Gan et al., 2016; Onyango et al., 2016a; Gumucio et al., 2020). This synthesis emphasises intersectional diversity within vulnerable groups as well as their position within dynamic social and cultural contexts (Wisner, 2016; Kuran et al., 2020), and highlights the differential impacts of climate change and restricted adaptation options available to vulnerable groups across African countries (see also Cross-Chapter Box GENDER in Chapter 18).

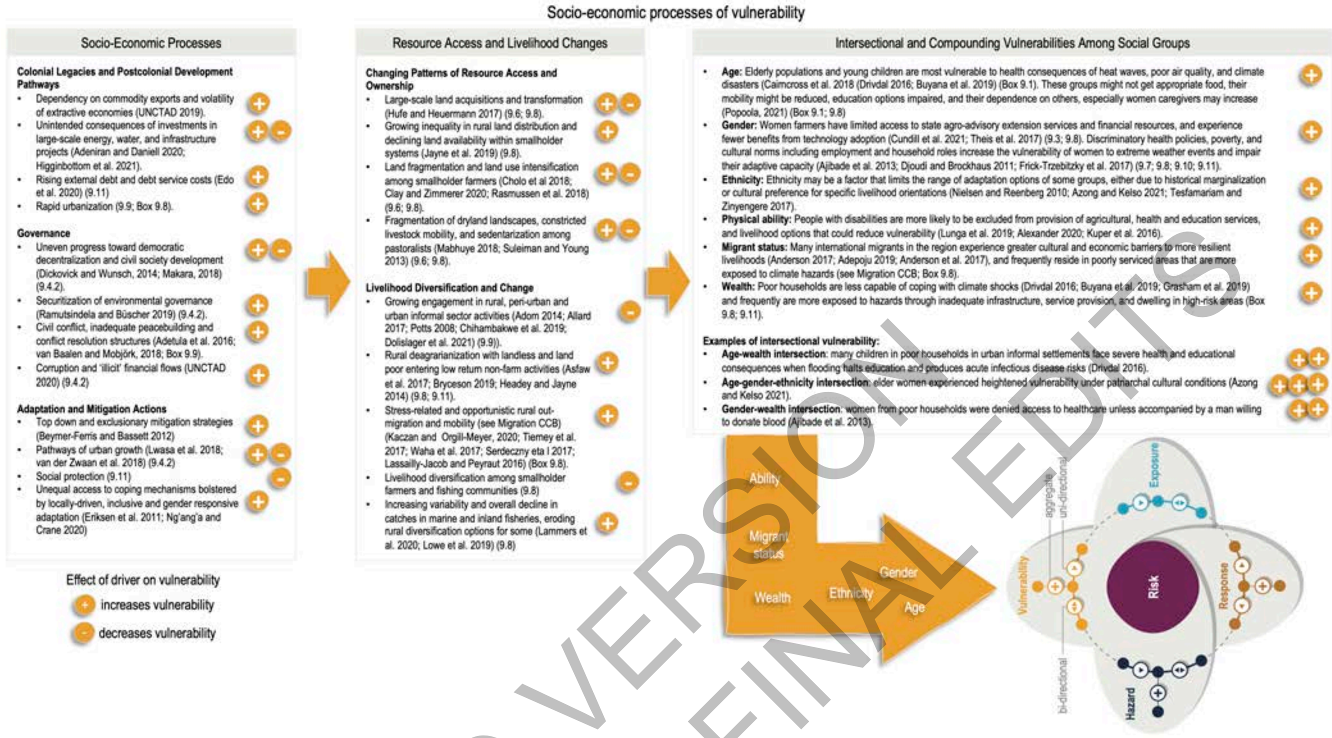

Figure Box 9.1.1: Factors contributing to the progression of vulnerability in African contexts considering their socioeconomic processes, resource access and livelihood changes, and intersectional vulnerability among social groups. Figure reflects a synthesis of vulnerability across sections of this chapter and highlights the compounding interactions of multiple dimensions of vulnerability (Potts, 2008; Nielsen and Reenberg, 2010; Akresh et al., 2011; Eriksen et al., 2011; Beymer-Farris and Bassett, 2012; Davis et al., 2012; Adom, 2014; Akello, 2014; Dickovick, 2014; Headey and Jayne, 2014; Otzelberger, 2014; Conteh, 2015; Huntjens and Nachbar, 2015; Spencer, 2015; Adetula et al., 2016; Djoudi et al., 2016; Kuper et al., 2016; Stark and Landis, 2016; Allard, 2017; Anderson, 2017; Asfaw et al., 2017; Hufe and Heuermann, 2017; Hulme, 2017; Paul and wa Gĩthĩnji, 2017; Rao et al., 2017; Serdeczny et al., 2017; Tesfamariam and Zinyengere, 2017; Tierney et al., 2017; Waha et al., 2017; Chihambakwe et al., 2018; Cholo et al., 2018; Jenkins et al., 2018; Keahey, 2018; Lwasa et al., 2018; Makara, 2018; Nyasimi et al., 2018; Petesch et al., 2018; Schuman et al., 2018; Theis et al., 2018; van Baalen and Mobjörk, 2018; van der Zwaan et al., 2018; Adepoju, 2019; Adzawla et al., 2019b; Bryceson, 2019; Grasham et al., 2019; Jayne et al., 2019a; Lowe et al., 2019; Lunga et al., 2019; OGAR and Bassey, 2019; Onwutuebe, 2019; Ramutsindela and Büscher, 2019; Sulieman and Young, 2019; Torabi and Noori, 2019; Adeniran and Daniell, 2020; Alexander, 2020; Clay and Zimmerer, 2020; Devonald et al., 2020; Dolislager et al., 2020; Edo et al., 2020; Kaczan and Orgill-Meyer, 2020; Lammers et al., 2020; World Bank, 2020b; Asiama et al., 2021; Azong and Kelso, 2021; Birgen, 2021; Paalo and Issifu, 2021).

Vulnerability and exposure to the impacts of climate change are complex and affected by multiple, interacting non-climatic processes, which together influence risk including socioeconomic processes (Lwasa et al., 2018; UNCTAD, 2020), resource access and livelihood changes (Jayne et al., 2019b), and intersectional vulnerability among social groups (Rao et al., 2020) (Figure Box 9.1.1). Socioeconomic processes encompass broader social, economic and governance trends, such as expanded investment in large energy and transportation infrastructure projects (Adeniran and Daniell, 2020), rising external debt (Edo et al., 2020), changing role of the state in social development (Dickovick, 2014), environmental management (Ramutsindela and Büscher, 2019) and conflict, as well as those emanating from climate change mitigation and adaptation projects (Beymer-Farris and Bassett, 2012; van Baalen and Mobjörk, 2018; Simpson et al., 2021b). These macro trends shape both urban and rural livelihoods, including the growing diversification of rural livelihoods through engagement in the informal sector and other non-farm activities, and are mediated by complex and intersecting factors like gender, ethnicity, class, age, disability and other dimensions of social status that influence access to resources (Luo et al., 2019). Research increasingly highlights the intersectionality of multiple dimensions of social identity and status that are associated with greater susceptibility to loss and harm (Caparoci Nogueira et al., 2018; Li et al., 2018).

Arid and semi-arid countries in the Sahelian belt and the greater Horn of Africa are often identified as the most vulnerable regions on the continent (Closset et al., 2017; Serdeczny et al., 2017). Particularly vulnerable groups include pastoralists (Wangui, 2018; Ayanlade and Ojebisi, 2019), fishing communities (Belhabib et al., 2016; Muringai et al., 2019a), small-scale farmers (Ayanlade et al., 2017; Mogomotsi et al., 2020) (see Section 9.8.1) and residents of formal and informal urban settlements (see Section 9.9.2). Research has identified key macro drivers as well as the multiple dimensions of social status that mediate differential vulnerability in different African contexts. For example, the contemporary vulnerability of small-scale rural producers in semi-arid northern Ghana has been shaped by colonial economic transformations (Ahmed et al., 2016), more recent neoliberal reforms reducing state support (Fieldman, 2011) and the disruption of local food systems due to increasing grain imports (Nyantakyi-Frimpong and Bezner-Kerr, 2015). Age interacts with other dimensions of social status, shaping differential vulnerability in several ways. Projected increases in mean temperatures and longer and more intense heat waves (Figure Box 9.1.1) may increase health risks for children and elderly populations by increasing risks associated with heat stress (Bangira et al., 2015; Cairncross et al., 2018). Temperature extremes are associated with increased risk of mortality in Ghana, Burkina Faso, Kenya and South Africa, with greatest increases among children and the elderly (Bangira et al., 2015; Amegah et al., 2016; Omonijo, 2017; Wiru et al., 2019) (see Section 9.10.2.3.1).

Rural African women are often disadvantaged by traditional, patriarchal decision-making processes and lack of access to land – issues compounded by kinship systems (that, is matrilineal or patrilineal), migrant status, age, type of household, livelihood orientation and disability in determining their adaptive options (Ahmed et al., 2016) (sees Section 9.8.1 and 9.11.1.2; Box 9.8). Differential agricultural productivity between men and women is about 20–30% or more in dryland regions of Ethiopia and Nigeria (Ghanem, 2011) and challenges women's ability to adapt to climate change. Limited access to agricultural resources and limited benefits from agricultural policies, compounded by other social and cultural factors, make women more vulnerable to climatic risks (Shukla et al., 2021). Kinship systems can contribute to their vulnerability and capacity to adapt. Women in matrilineal systems have greater bargaining power and have access to more resources than those in patrilineal systems (Chigbu, 2019; Robinson and Gottlieb, 2021) (see Sections 9.8.1 and 9.11.1.2).

Knowledge Gaps and Recommendations

The differential impacts of climate change on and adaptation options available to vulnerable groups in Africa are a critical knowledge gap. More research is needed to examine the intersection of different dimensions of social status on climate change vulnerability in Africa (Thompson-Hall et al., 2016; Oluwatimilehin and Ayanlade, 2021). More analysis of vulnerability based on gender and other social and cultural factors is needed to fully understand the impacts of climate change, the interaction of divergent adaptive strategies, as well as the development of targeted adaptation and mitigation strategies, for example, for women in patrilineal kinship systems, people living with disabilities, youth, girls and the elderly. Finally, there is an urgent need to build capacity among those conducting vulnerability assessments, so that they are familiar with this intersectionality lens.

Additional information and capacity development through education and early warning systems could enhance vulnerable groups' ability to cope and adapt their livelihoods (Jaka and Shava, 2018). However, some groups of people may struggle to translate information into actual changes (Makate et al., 2019; McOmber et al., 2019). Lack of access to assets and social networks, for example, among older populations, are critical limitations to locally-driven or autonomous adaptation and limit potential benefits from planned adaptation actions (e.g., adoption of agricultural technologies or effective use of early warning systems). There is an urgent need for societal and political change to realise potential benefits for these vulnerable groups in the long term (Nyasimi et al., 2018). There is a need for gender-sensitive climate change policies in many African countries and gender-responsive policies, implementation plans and budgets for all local-level initiatives (Wrigley-Asante et al., 2019).

[END BOX 9.1 HERE]

9.5 Observed and Projected Climate Change

This section assesses observed and projected climate change over Africa. In Working Group I of the IPCC AR6 (WGI), four chapters make regional assessments of observed and projected climate change (Doblas-Reyes et al., 2021; Gutiérrez et al., 2021; Ranasinghe et al., 2021; Seneviratne et al., 2021), which facilitates a more nuanced assessment in this section of climate and ocean phenomena that impact African systems.

9.5.1 Climate Hazards in Africa

Human-caused temperature increases are detected across Africa and many regions have warmed more rapidly than the global average (Figure 9.13a) (Ranasinghe et al., 2021) and a signal of increased annual heatwave frequency has already emerged from the background natural variability over the whole continent (Engdaw et al., 2021) (Figure 9.14). However, detection of statistically significant rainfall trends is evident in only a few regions (Figure 9.13b), and in some regions different observed precipitation datasets disagree on the direction of rainfall trends (Panitz et al., 2013; Sylla et al., 2013; Contractor et al., 2020). The uncertainty of observed rainfall trends results from a number of sources, including high interannual and decadal rainfall variability, different methodologies used in developing rainfall products and a lack of and poor quality of rainfall station data (Figure 9.15) (Gutiérrez et al., 2021).

With increased greenhouse gas emissions, mean temperature is projected to increase over the whole continent, as are temperature extremes over most of the continent (Figure 9.16a,b). Increased mean annual rainfall is projected over the eastern Sahel, eastern East Africa and Central Africa (Figures 9.16c and 9.14). In contrast, reduced mean annual rainfall and increased drought (meteorological and agricultural) are projected over southwestern Southern Africa and coastal North Africa, with drought in part as a result of increasing atmospheric evaporative demand due to higher temperatures (Figure 9.16e) (Ukkola et al., 2020; Ranasinghe et al., 2021; Seneviratne et al., 2021). The frequency and intensity of heavy precipitation are projected to increase across most of Africa, except northern and southwestern Africa (Figures 9.16d and 9.14).

Most African countries are expected to experience high temperatures unprecedented in their recent history earlier in this century than generally wealthier, higher latitude countries (*high confidence*). As low latitudes have lower internal climate variability (e.g. low seasonality), low-latitude African countries are projected to have their populations exposed to large increases in frequency of daily temperature extremes (hotter than 99.9% of their historical records) earlier in the 21st century compared to generally wealthier nations at higher latitudes (Harrington et al., 2016; Chen et al., 2021; Doblas-Reyes et al., 2021; Gutiérrez et al., 2021). Although higher warming rates are projected over high latitudes during the first half of this century, societies and environments in low-latitude, low-income countries are projected to become exposed to unprecedented climates before those in high latitude, developed countries (Frame et al., 2017; Harrington et al., 2017; Gutiérrez et al., 2021). For example, beyond 2050, in Central Africa and coastal West Africa 10 months of every year will be hotter than any month in the period 1950–2000 under a high emissions scenario (RCP8.5) (Harrington et al., 2017; Gutiérrez et al., 2021). Ambitious, near-term mitigation will provide the largest reductions in exposure to unprecedented high temperatures for populations in low-latitude regions, such as across tropical Africa (Harrington et al., 2016; Frame et al., 2017).

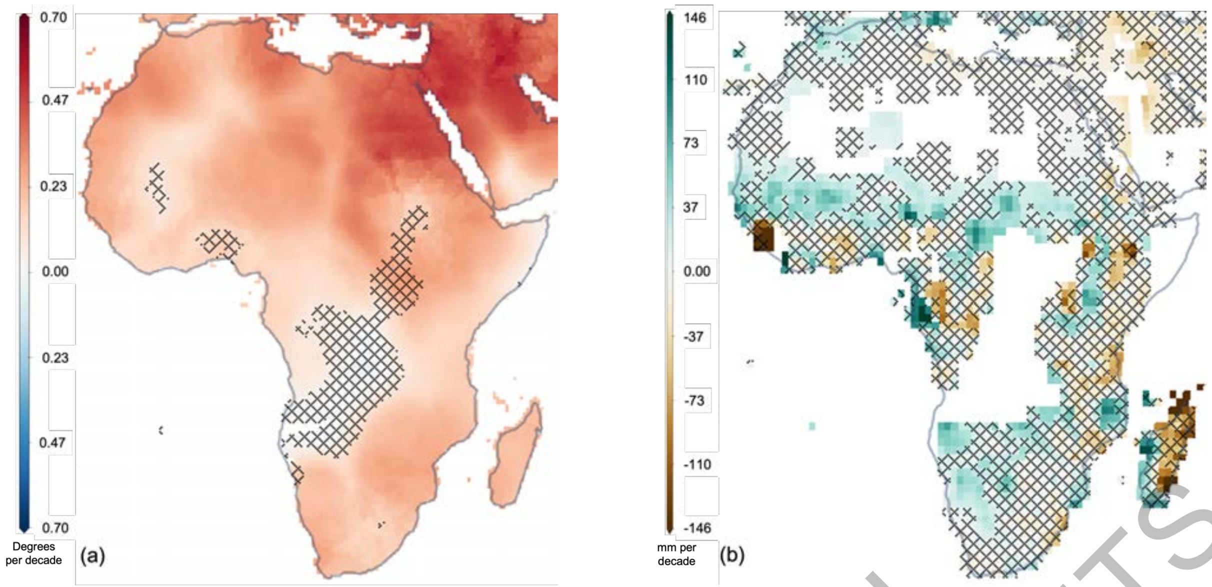

Figure 9.13: Mean observed trends calculated for the common 1980-2015 period in (a) 2-meter temperature in degrees Celsius per decade and (b) precipitation in millimetres per decade with respect to the climatological mean over this period. The Climate Research Unit Time Series data (CRU TS) are used to compute temperature trends and the Global Precipitation Climatology Centre data (GPCC) precipitation trends. Regions with no 'x' hatching indicate statistically significant trends over this period. The figures are derived from (Gutiérrez et al., 2021).

9.5.1.1 Station Data Limitations

Sustained station observation networks (Figure 9.15) are essential for the long-term analysis of local and regional climate trends, including for temperature and rainfall, the calibration of satellite-derived climate products, development of gridded climate datasets using interpolated and blended station-satellite products that form the baseline from which climate change departures are measured, development and running of early warning systems, climate projection and impact studies and extreme event attribution studies (Harrison et al., 2019; Otto et al., 2020). However, production of salient climate information in Africa is hindered by limited availability of and access to weather and climate data, especially in Central and North Africa (Figure 9.15) (Coulibaly et al., 2017; Hansen et al., 2019a). Existing weather infrastructure remains suboptimal for development of reliable early warning systems (Africa Adaptation Initiative, 2018; Krell et al., 2021). For example, it is estimated only 10% of ground-based observation networks are in Africa, and that 54% of Africa's surface weather stations cannot capture data accurately (Africa Adaptation Initiative, 2018; World Bank, 2020d). Some programmes are trying to address this issue, including the trans-African hydro-meteorological observatory (van de Giesen et al., 2014), the West African Science Service Centre on Climate Change and Adaptive Land Management (WASCAL) (Salack et al., 2019), the Southern African Science Service Centre for Climate Change, Adaptive Land Management (SASSCAL) (Kaspar et al., 2015) and AMMA-CATCH (Galle et al., 2018). However, the sustainability of observation networks beyond the life of these programmes is uncertain as many African National Meteorological and Hydrology Services experience structural, financial and technical barriers to maintaining these systems (Section 9.4.5).

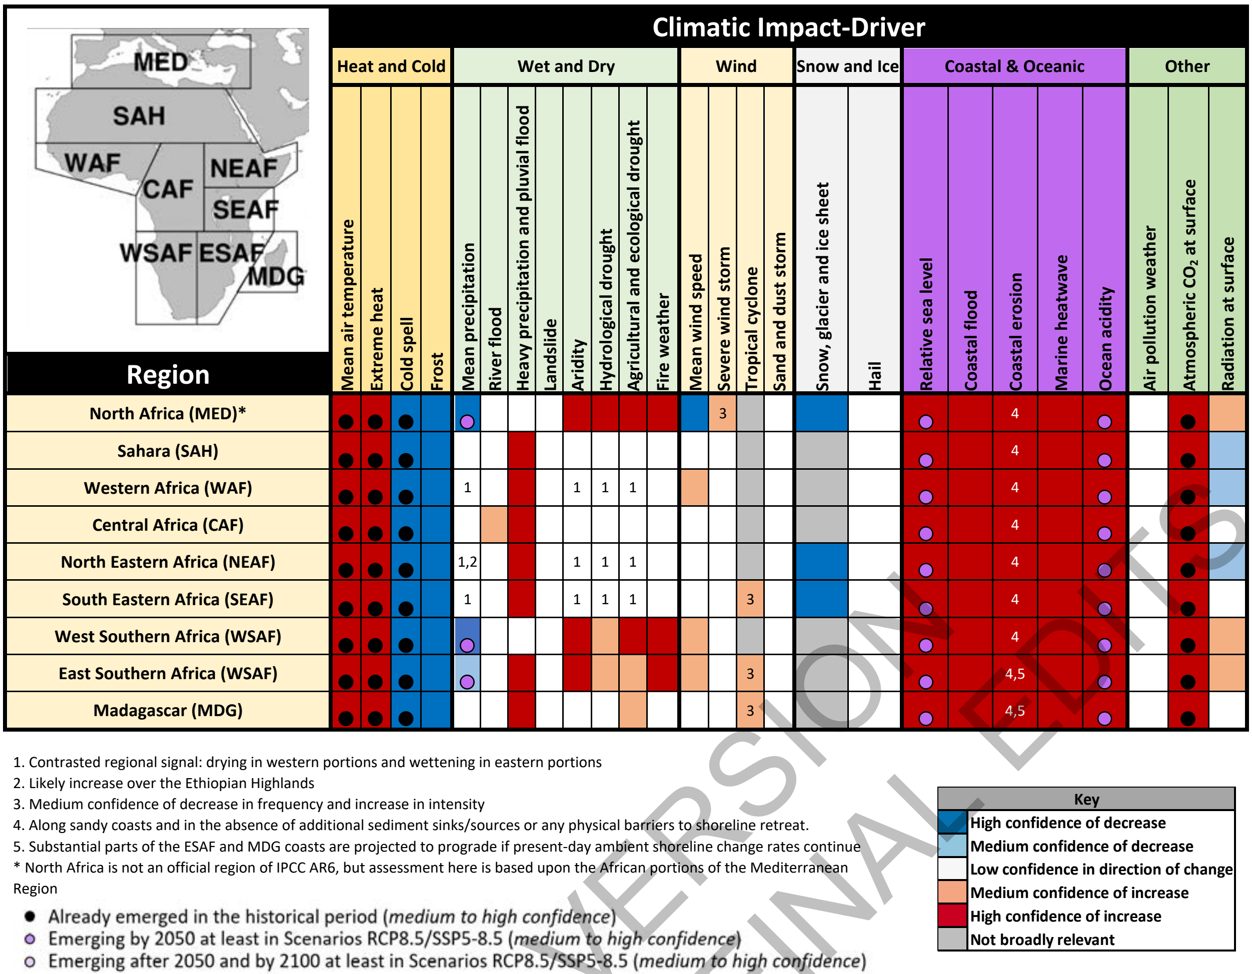

Figure 9.14: Summary of confidence in direction of projected change in climatic impact-drivers (CIDs) in Africa, representing their aggregate characteristic changes for mid-century for medium emission scenarios RCP4.5, SSP3–4.5, SRES A1B, or higher emissions scenarios (e.g., RCP8.5, SSP5–RCP8.5), within each AR6 WGI region (inset map) approximately corresponding to global warming levels between 2°C and 2.4°C (for CIDs that are independent of sea-level rise). CIDs are drivers of impacts that are of climatic origin (that is, physical climate system conditions including means and extremes) that affect an element of society or ecosystems. The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural inter-annual variability if found with at least *medium confidence* (dots). Emergence of a climate change signal or trend refers to when a change in climate (the 'signal') becomes larger than the amplitude of natural or internal variations (the 'noise'). The figure is a modified version of Table 12.3 in Chapter 12 (Ranasinghe et al., 2021), please see this chapter for definitions of the various climate impact drivers and the basis for confidence levels of the assessment. Please note these WGI regions do not directly correspond to the regionalisation in this chapter nor do we assess climate risks for Madagascar.

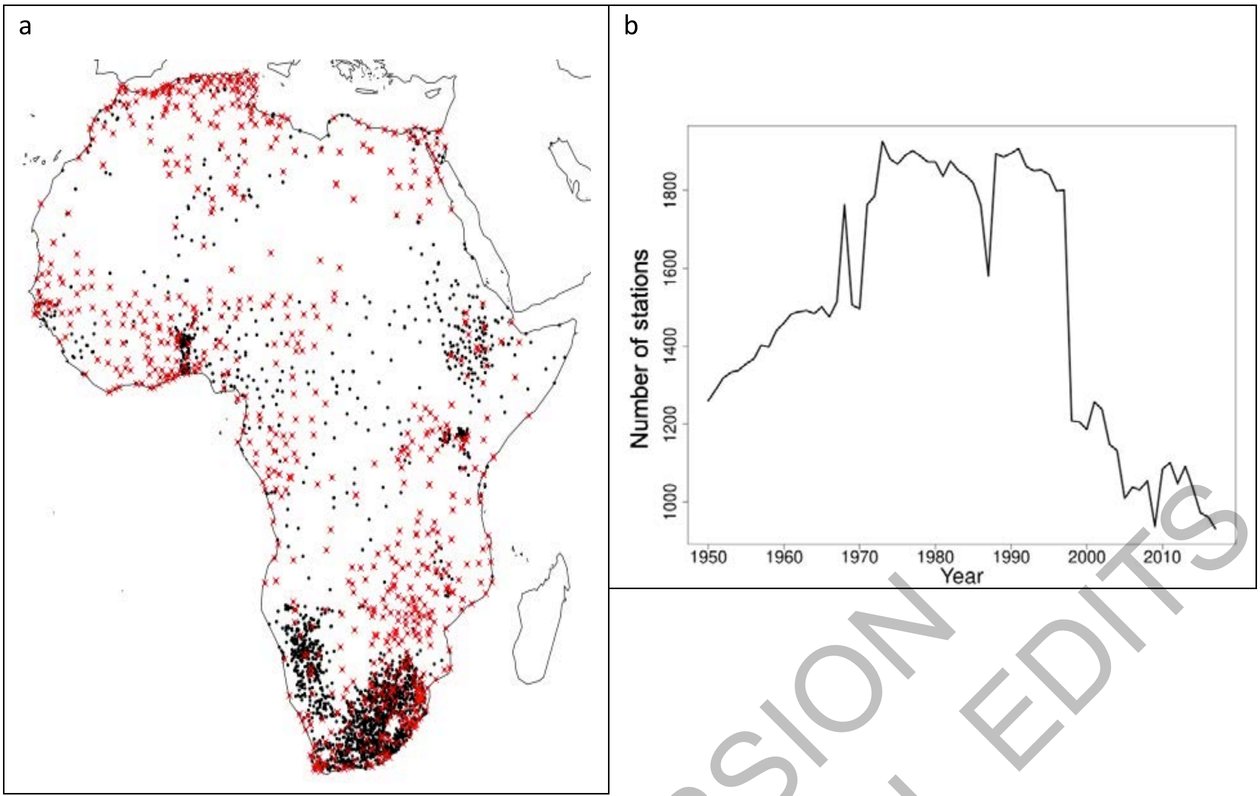

Figure 9.15: Large regions of Africa lack regularly reporting and quality-controlled weather station data. Stations in Africa with quality-controlled station data used in developing the Rainfall Estimates on a Gridded Network (REGEN) interpolated rainfall product (Harrison et al., 2019). Panel (a) provides a spatial representation of stations across the continent since 1950 as black dots and red crosses, where red crosses represent stations that were still active in 2017. Panel (b) demonstrates the decline in operational stations or stations with quality-controlled data since *circa* 1998, which is largely a function of declining networks in a subset of countries. Figure is derived from (Contractor et al., 2020).

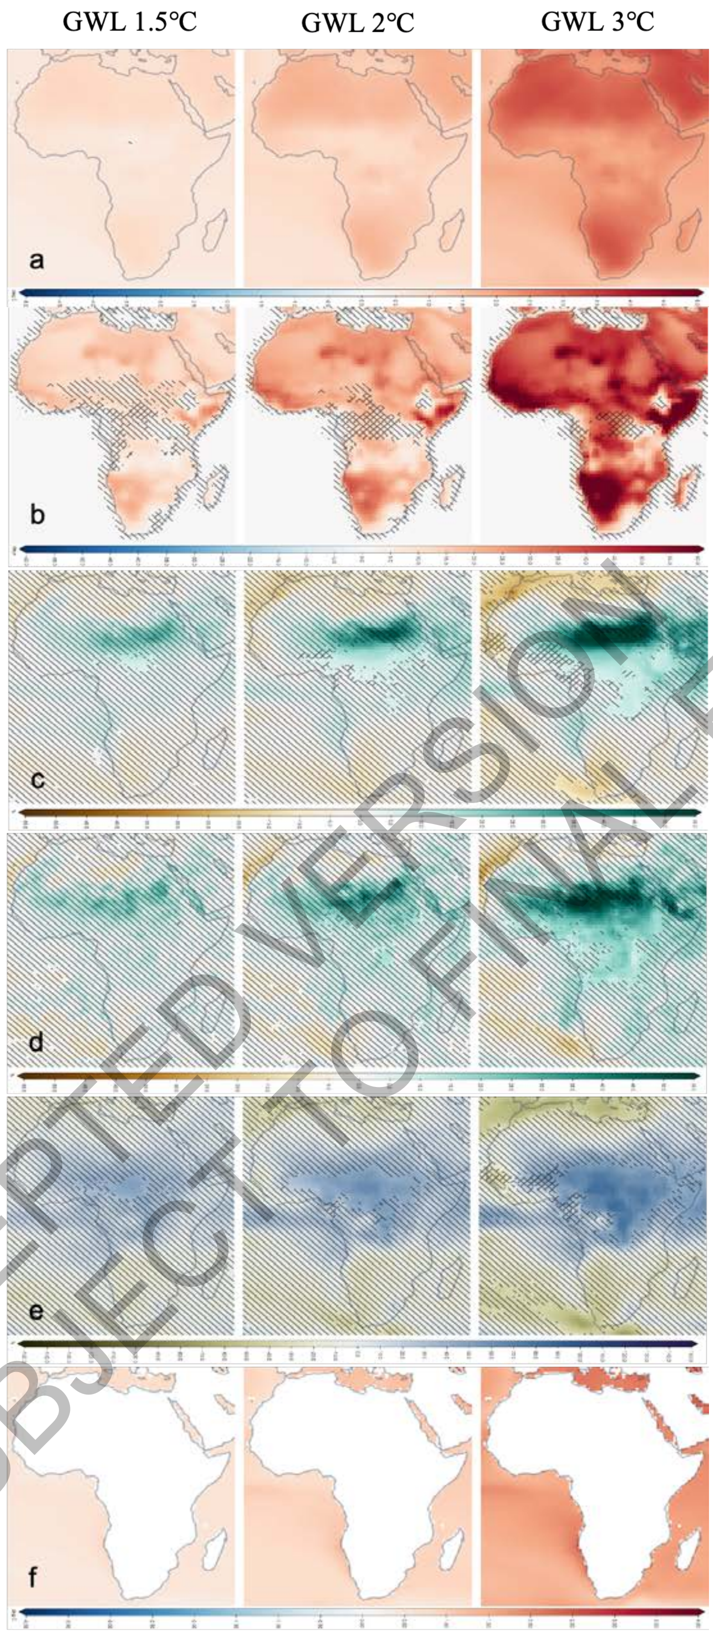

Figure 9.16: Projected changes of climate variables and hazards (relative to 1995–2014 average) at 1.5°C, 2°C and 3°C of global warming above pre-industrial (1850–1900). Rows are (a) Increase in mean annual temperature; (b) Increase in number of days per year above 35 °C; (c) Change in average annual rainfall (%); (d) Change in heavy precipitation represented by maximum 5-day precipitation (%); (e) Change in drought represented as the six-month standardized precipitation index (%). Negative changes indicate areas where drought frequency, intensity and/or duration is projected to increase. Positive changes show the opposite; (f) Increase in mean annual sea surface temperature (°C). All figures are derived from the WGI Interactive Atlas and show results from between 26 to 33 CMIP6 global climate models, depending on the climate variable. CMIP6 models include improved representations of physical, biological and chemical processes as well as higher spatial resolutions compared to previous CMIP5 models (WGI CH3). Three

categories of trend robustness are shown in the projection figures: (1) No hatching indicates a projected change is robust and likely greater than natural climate variability (that is, ≥66% of models show change greater than natural variability, and ≥80% of all models agree on sign of change); (2) Diagonal lines (\) indicate no robust change (<66% of models show change greater than natural variability); (3) Crossed lines (X) indicate conflicting signals where at least 66% of the models show change greater than natural variability, but <80% of all models agree on direction of change (Gutiérrez et al., 2021).

9.5.2 North Africa

9.5.2.1 Temperature

Observations

Mean and seasonal temperatures have increased at twice the global rate over most regions in North Africa due to anthropogenic climate change (Ranasinghe et al., 2021) (Figures 9.13a and 9.14) (*high confidence).* Increasing temperature trends are particularly strong since the 1970s (between 0.2°C/decade and 0.4°C/decade), especially in the summer (Tanarhte et al., 2012; Donat et al., 2014a; Lelieveld et al., 2016). Similar warming signals have been observed since the mid-1960s over the Sahara and the Sahel (Fontaine et al., 2013; Moron et al., 2016). Trends in mean maximum (TX) and minimum (TN) temperatures range between +2°C and +3°C per century over North Africa, and the frequencies of hot days (TX >90th percentile, TX90p) and tropical nights (TN >20°C), as well as the frequencies of warm days and nights, roughly follow these mean TX and TN trends (Fontaine et al., 2013; Moron et al., 2016; Ranasinghe et al., 2021; Seneviratne et al., 2021). Warm spell duration has increased in many North African countries (Donat et al., 2014a; Filahi et al., 2016; Lelieveld et al., 2016; Nashwan et al., 2018) and heatwave magnitude and spatial extent have increased across North Africa since 1980, with an increase in the number of events since 2000 that is beyond the level of natural climate variability (Russo et al., 2016; Ceccherini et al., 2017; Engdaw et al., 2021).

Projections

At 1.5°C, 2°C and 3°C of global warming above pre-industrial levels, mean annual temperatures in North Africa are projected to be on average, 0.9°C, 1.5°C and 2.6°C warmer than the 1994–2005 average respectively (Figure 9.16a). Warming is projected to be stronger in summer than winter (Lelieveld et al., 2016; Dosio, 2017). The number of hot days is *likely* to increase by up to 90% by the end of the century under RCP8.5 (global warming level [GWL] 4.4°C) (Gutiérrez et al., 2021; Ranasinghe et al., 2021) and hot nights and the duration of warm spells to increase in the first half of the 21st century in both intermediate and high emission scenarios (Patricola and Cook, 2010; Vizy and Cook, 2012; Lelieveld et al., 2016; Dosio, 2017; Filahi et al., 2017). Heatwaves are projected to become more frequent and intense even at 1.5°C of global warming (Gutiérrez et al., 2021; Ranasinghe et al., 2021). Children born in 2020, under a 1.5°C-compatible scenario will be exposed to 4–6 times more heatwaves in their lifetimes compared to people born in 1960; this exposure increases to 9–10 times more heatwaves for emission reduction pledges, limiting global warming to 2.4°C (Thiery et al., 2021).

9.5.2.2 Precipitation

Observations

Mean annual precipitation decreased over most of North Africa between 1971–2000 (Donat et al., 2014a; Hertig et al., 2014; Nicholson et al., 2018; Zittis, 2018), with a gradual recovery to normal or wetter conditions in Algeria and Tunisia since 2000 and over Morocco since 2008 (Nouaceur and Murărescu, 2016). Since the 1960s days with more than 10 mm of rainfall have decreased and the number of consecutive dry days have increased in the eastern parts of North Africa, while in the western parts of North Africa heavy rainfall and flooding has increased (Donat et al., 2014a). Aridity, the ratio of potential evaporation to precipitation, has increased over the Mediterranean and North Africa due to significant decreases in precipitation (Greve et al., 2019).

Projections

Mean annual precipitation is projected to decrease in North Africa at warming levels of 2°C and higher (*high confidence*) with the most pronounced decreases in the northwestern parts (Schilling et al., 2012; Filahi et al., 2017; Barcikowska et al., 2018; Ranasinghe et al., 2021) (Figures 9.14 and 9.16c). Meteorological drought over Mediterranean North Africa in CMIP5 and CMIP6 models are projected to increase in duration from approximately 2 months during 1950–2014 to approximately 4 months in the period 2050–2100 under RCP8.5 and SSP5-85 (Ukkola et al., 2020). Extreme rainfall (monthly maximum 1-day rainfall – RX1day) in the region is projected to decrease (Donat et al., 2019).

During 1984–2012, North Africa experienced a decreasing dust trend with North African dust explaining more than 60% of global dust variations (Shao et al., 2013). Dust loadings and related air pollution hazards (from fine particles that affect health) are projected to decrease in many regions of the Sahara as a result of decreased wind speeds (Evan et al., 2016; Ranasinghe et al., 2021).

9.5.3 West Africa

9.5.3.1 Temperature

Observations

Observed mean annual and seasonal temperatures have increased 1–3°C since the mid-1970s with the highest increases in the Sahara and Sahel (Cook and Vizy, 2015; Lelieveld et al., 2016; Dosio, 2017; Nikiema et al., 2017; Gutiérrez et al., 2021; Ranasinghe et al., 2021) (Figure 9.13a) and positive trends in mean annual maximum (TX) and minimum (TN) of 0.16°C and 0.28°C per decade, respectively (Mouhamed et al., 2013; Moron et al., 2016; Russo et al., 2016; Barry et al., 2018). The frequency of very hot days (TX >35°C) and tropical nights has increased by 1–9 days and 4–13 nights per decade between 1961–2014 (Moron et al 2016), and cold nights have become less frequent (Fontaine et al., 2013; Mouhamed et al., 2013; Barry et al., 2018). In the 21st century, heatwaves have become hotter, longer and more extended compared to the last two decades of the 20th century (Mouhamed et al., 2013; Moron et al., 2016; Russo et al., 2016; Barbier et al., 2018).

Projections

At 1.5°C, 2°C and 3°C of global warming above pre-industrial levels, mean annual temperatures in West Africa are projected to be on average, 0.6°C, 1.1°C and 2.1°C warmer than the 1994–2005 average respectively (Figure 9.16a). Under mid- and high-emission scenarios end of century summer temperatures are projected to increase by 2°C and 5°C, respectively (Sylla et al., 2015a; Russo et al., 2016; Dosio, 2017). The annual number of hot days is projected to increase at all global warming levels with larger increases at higher warming levels (Figure 9.16b). By 2060 the frequency of hot nights is projected to be almost double the 1981–2010 average at GWL 2°C (Dosio, 2017; Bathiany et al., 2018; Gutiérrez et al., 2021; Ranasinghe et al., 2021). Heatwave frequency and intensity are projected to increase under all scenarios, but limiting global warming to 1.5°C leads to a decreased heatwave magnitude (–35%) and frequency (–37%) compared to 2°C global warming (Dosio, 2017; Weber et al., 2018; Nangombe et al., 2019). Children born in 2020, under a 1.5°C-compatible scenario will be exposed to 4–6 times more heatwaves in their lifetimes compared to people born in 1960; this exposure increases to 7–9 times more heatwaves at GWL 2.4°C (Thiery et al., 2021).

The number of dangerous heat days (TX >40.6°C) is projected to increase from approximately 60 per year in 1985–2005 to approximately 110, 130 and 140 under RCPs 2.6, 4.5 and 8.5, respectively, in the 2060s and to 105, 145 and 196 in the 2090s (Rohat et al., 2019). Over tropical West Africa, heat-related mortality risk through increased heat and humidity is 6–9 times higher than the 1950–2005 average at GWL 2°C, 8–15 times at GWL 2.65°C and 15–30 times at GWL 4.12°C (Ahmadalipour and Moradkhani, 2018) (Coffel et al., 2018). The number of potentially lethal heat days per year is projected to increase from <50 during 1995–2005 to 50–150 at GWL 1.6°C, 100–250 at GWL 2.5°C and 250–350 at GWL 4.4°C, with highest increases in coastal regions (Mora et al., 2017). Increasing urbanization concentrates this exposure in cities, such as Lagos, Niamey, Kano and Dakar (Coffel et al., 2018; Rohat et al., 2019) (Section 9.9.3.1).

9.5.3.2 Precipitation

Observations

Negative trends in rainfall accompanied by increased rainfall variability were observed between 1960s–1980s over West Africa (Nicholson et al., 2018; Thomas and Nigam, 2018), caused by a combination of anthropogenic aerosols and greenhouse gases emitted between 1950s–1980s (Booth et al., 2012; Wang et al., 2016; Giannini and Kaplan, 2019; Douville et al., 2021). Declining rainfall trends ended by 1990 due to the growing influence of greenhouse gasses and reduced cooling effect of aerosol emissions, with a trend to wetter conditions emerging in the mid-1990s accompanied by more intense, but fewer precipitation events (Sanogo et al., 2015; Sylla et al., 2016; Kennedy et al., 2017; Barry et al., 2018; Bichet and Diedhiou, 2018a; Bichet and Diedhiou, 2018b; Thomas and Nigam, 2018). A shift to a later onset and end of the West African monsoon is also reported in West Africa and Sahel (*low confidence*) (Chen et al., 2021; Ranasinghe et al., 2021). Between 1981–2014 the Gulf of Guinea and the Sahel have experienced more intense precipitation events (Panthou et al., 2014; Bichet and Diedhiou, 2018a; Panthou et al., 2018) and the frequency of mesoscale storms has tripled (Taylor et al., 2017; Callo-Concha, 2018). Extreme heavy precipitation indices show increasing trends from 1981–2010 (Barry et al., 2018), increasing high flow events in large Sahelian rivers as well as small to mesoscale catchments leading to pluvial and riverine flooding (Douville et al., 2021). Meteorological, agricultural and hydrological drought in the region has increased in frequency since the 1950s (*medium confidence*) (Seneviratne et al., 2021).

Projections

West African rainfall projections show a gradient of precipitation decrease in the west and increase in the east (*medium confidence*) (Dosio et al., 2021; Gutiérrez et al., 2021; Ranasinghe et al., 2021) (Figure 9.14). This pattern is evident at 1.5°C of global warming and the magnitude of change increases at higher warming levels (Schleussner et al., 2016b; Kumi and Abiodun, 2018; Sylla et al., 2018) (Figure 9.16c). A reduction in length of the rainy season is projected over the western Sahel through delayed rainfall onset by 4 to 6 days at global warming levels of 1.5°C and 2°C (Kumi and Abiodun, 2018; Douville et al., 2021; Gutiérrez et al., 2021). Although there are uncertainties in rainfall projections over the Sahel (Klutse et al., 2018; Gutiérrez et al., 2021), CMIP6 models project monsoon rainfall amounts to increase by approximately 2.9% per degree of warming (Jin et al., 2020; Wang et al., 2020a), therefore, at higher levels of warming and towards the end of the century, a wetter monsoon is projected in the eastern Sahel (*medium confidence*).

The frequency and intensity of extremely heavy precipitation are projected to increase under mid- and high-emission scenarios (Sylla et al., 2015b; Diallo et al., 2016; Akinsanola and Zhou, 2019; Giorgi et al., 2019; Dosio et al., 2021; Li et al., 2021; Seneviratne et al., 2021) (Figure 9.16d). However, heavy rainfall statistics from global and regional climate models may be conservative as very-high-resolution, convection-permitting climate models simulate more intense rainfall than these models (Stratton et al., 2018; Berthou et al., 2019; Han et al., 2019; Kendon et al., 2019).

At 2°C global warming, West Africa is projected to experience a drier, more drought-prone and arid climate, especially in the last decades of the 21st century (Sylla et al., 2016; Zhao and Dai, 2016; Klutse et al., 2018). The duration of meteorological drought duration is projected to increase from approximately 2 months during 1950–2014 to approximately 4 months in the period 2050–2100 under RCP8.5 and SSP5–8.5 (Ukkola et al., 2020). Increased intensity of heavy precipitation events combined with increasing drought occurrences will substantially increase the cumulative hydroclimatic stress on populations in West Africa during the late 21st century (Giorgi et al., 2019).

9.5.4 Central Africa

9.5.4.1 Temperature

Observations

Mean annual temperature across Central Africa has increased by 0.75°C–1.2°C since 1960 (Aloysius et al., 2016; Gutiérrez et al., 2021). The number of hot days, heatwaves and heatwave days increased between 1979–2016 (Hu et al., 2019) and cold extremes have decreased (Aguilar et al., 2009; Seneviratne et al., 2021) (Figure 9.14). Uncertainties associated with the poor ground-based observation networks in the region and associated observational uncertainties (Section 9.5.1.1) result in an assessment of *medium confidence* in an increase in the number of heat extremes over the region.

Projections

At 1.5°C, 2°C and 3°C of global warming above pre-industrial levels, mean annual temperatures in Central Africa are projected to be on average, 0.6°C, 1.1°C and 2.1°C warmer than the 1994–2005 average, respectively (Figure 9.16a). By the end of the century (2070–2099), warming of 2°C (RCP4.5) to 4°C (RCP8.5) is projected over the region (Aloysius et al., 2016; Fotso-Nguemo et al., 2017; Diedhiou et al., 2018; Mba et al., 2018; Tamoffo et al., 2019) and the number of days with maximum temperature exceeding 35°C is projected to increase by 150 days or more at GWL 4.4°C (Gutiérrez et al., 2021; Ranasinghe et al., 2021). According to CMIP6 and CORDEX models, the annual average number of days with maximum temperature exceeding 35°C will increase between 14–27 days at GWL 2°C and 33–59 days at GWL 3°C above the 61–63 days for 1995–2014 (Gutiérrez et al., 2021; Ranasinghe et al., 2021) (*high confidence*). The number of heatwave days is projected to increase and extreme heatwave events may last longer than 180 days at GWL 4.1°C (Dosio, 2017; Weber et al., 2018; Spinoni et al., 2019). Children born in 2020, under a 1.5°C-compatible scenario will be exposed to 6–8 times more heatwaves in their lifetimes compared to people born in 1960; this exposure increases to 7–9 times more heatwaves at GWL 2.4°C (Thiery et al., 2021). The number of potentially lethal heat days per year is projected to increase from <50 during 1995–2005 to 50–75 at GWL 1.6°C, 100–150 at GWL 2.5°C and 200–350 at GWL 4.4°C (Mora et al., 2017).

9.5.4.2 Precipitation

Observations

The severe lack of station data over the region leads to large uncertainty in the estimation of observed rainfall trends and *low confidence* in changes in extreme rainfall (Figure 9.13b) (Creese and Washington, 2018; Gutiérrez et al., 2021; Ranasinghe et al., 2021). There is some evidence of drying since the mid-20th century through decreased mean rainfall and increased precipitation deficits (Gutiérrez et al., 2021), as well as increases in meteorological, agricultural and ecological drought (*medium confidence*) (Seneviratne et al., 2021). However, there is spatial heterogeneity in annual rainfall trends between 1983–2010 ranging from –10 to +39 mm per year (Maidment et al., 2015), with a decline in mean seasonal April–June precipitation of –69 mm per year in most regions except in the northwest (Zhou et al., 2014; Hua et al., 2016; Klotter et al., 2018; Hu et al., 2019). Southern and eastern Central Africa were identified as drought hotspots between 1991–2010 (Spinoni et al., 2014).

Projections

Under low emission scenarios and at GWL 1.5 and GWL 2°C there is *low confidence* in projected mean rainfall change over the region (Figure 9.16c). At GWL 3°C and GWL 4.4°C an increased mean annual rainfall of 10–25% is projected by regional climate models (Coppola et al., 2014; Pinto et al., 2015) and the intensity of extreme precipitation will increase (*high confidence*) (Sylla et al., 2015a; Diallo et al., 2016; Dosio et al., 2019; Gutiérrez et al., 2021; Ranasinghe et al., 2021; Seneviratne et al., 2021) (Figure 9.16c,d). This is projected to increase the likelihood of widespread flood occurrences before, during and after the mature monsoon season (Figure 9.14).

Convection permitting simulations (4.5 km spatial resolution) simulate increased dry spell length not apparent at coarser resolutions, suggesting drying in addition to more intense extreme rainfall (Stratton et al., 2018). Although reduced drought frequency is indicated in Figure 9.16e, the SPI metric does not account for the effect of increased temperature on drought (increased moisture deficit), and metrics that account for this indicate slightly increased drought frequency or no change (Spinoni et al., 2020). Therefore, there is *low confidence* in projected changes of drought frequency over the region (Figure 9.14).

9.5.5 East Africa

9.5.5.1 Temperature

Observations

Mean temperatures over the region have increased by 0.7°C–1°C from 1973 to 2013, depending on the season (Ayugi and Tan, 2018; Camberlin, 2018). Increases in TX and TN are evident across the region accompanied by significantly increasing trends of warm nights, warm days and warm spells (Russo et al., 2016; Gebrechorkos et al., 2019; Nashwan and Shahid, 2019). The greatest increases are found in northern and central regions.

Projections

At 1.5°C, 2°C and 3°C of global warming above pre-industrial levels, mean annual temperatures in East Africa are projected to be on average, 0.6°C, 1.1°C and 2.1°C warmer than the 1994–2005 average respectively (Figure 9.16a). Highest increases are projected over the northern and central parts of the region and the lowest increase over the coastal regions (Otieno and Anyah, 2013; Dosio, 2017). The magnitude and frequency of hot days are projected to increase from GWL 2°C and above with larger increases at higher GWLs (Dosio, 2017; Bathiany et al., 2018; Dosio et al., 2018; Kharin et al., 2018) (Figure 9.16a,b). At GWL 4.6°C a number of East African cities are projected to have an up to 2000-fold increase in exposure to dangerous heat (days >40.6 °C) compared to 1985–2005 including Blantyre-Limbe, Lusaka and Kampala, (Mora et al., 2017; Rohat et al., 2019). Children born in 2020, under a 1.5°C-compatible scenario will be exposed to 3–5 times more heatwaves in their lifetimes compared to people born in 1960; this exposure increases to 4–9 times more heatwaves at GWL 2.4°C (Thiery et al., 2021). The number of potentially lethal heat days per year is projected to increase from <50 during 1995–2005 to <50 at GWL 1.6°C, 50–120 at GWL 2.5°C and 150–350 at GWL 4.4°C with largest increases at the coast (Mora et al., 2017), highlighting the new emergence of dangerous heat conditions in these areas.

9.5.5.2 Precipitation

Observations

Over Equatorial East Africa the short rains (October–November–December) have shown a long-term wetting trend from the 1960s until present (Manatsa and Behera, 2013; Nicholson, 2015; Nicholson, 2017), which is linked with western Indian Ocean warming and a steady intensification of Indian Ocean Walker Cell (Liebmann et al., 2014; Nicholson, 2015).

In contrast, the long rainfall season (March-April-May) has experienced a long-term drying trend between 1986 and 2007, with rainfall declines in each of these months and a shortening of the wet season (Rowell et al., 2015; Wainwright et al., 2019). Unlike previous decades, since around 2000 the long rains have exhibited a significant relationship with the El Niño-Southern Oscillation (Park et al., 2020), as multiple droughts have occurred during recent La Niña events and when the western to central Pacific SST gradient was La Niña-like (Funk et al., 2015; Funk et al., 2018a). Wetter-than-average rainfall years within this long-term drying trend are often associated with a stronger amplitude of the Madden-Julian Oscillation (Vellinga and Milton, 2018).

In the northern, summer rainfall region (June–September), a decline in rainfall occurred in the 1960s and rainfall has remained relatively low, while interannual variability has increased since the late 1980s (Nicholson, 2017); the cause of this drying trend is uncertain.

Since 2005, drought frequency has doubled from once every six to once every three years and has become more severe during the long and summer rainfall seasons than during the short rainfall season (Ayana et al., 2016; Gebremeskel Haile et al., 2019). Several prolonged droughts have occurred predominantly within the arid and semi-arid parts of the region over the past three decades (Nicholson, 2017).

Projections

Higher mean annual rainfall, particularly in the eastern parts of east Africa are projected at GWL 1.5°C and 2°C by 25 CORDEX models (Nikulin et al., 2018; Osima et al., 2018). The additional 0.5°C of warming from 1.5°C increases average dry spell duration by between two and four days, except over southern Somalia where this is reduced by between two to three days (Hoegh-Guldberg et al., 2018; Nikulin et al., 2018; Osima et al., 2018; Weber et al., 2018).

During the short rainy season, a longer rainfall season (Gudoshava et al., 2020) and increased rainfall of up to over 100 mm on average is projected over the eastern horn of Africa and regions of high/complex topography at GWL 4.5° C (Dunning et al., 2018; Endris et al., 2019; Ogega et al., 2020).

During the long rainy season, there is *low confidence* in projected mean rainfall change (Gutiérrez et al., 2021). Although some studies report projected increased end of century rainfall (Otieno and Anyah, 2013; Kent et al., 2015), the mechanisms responsible for this are not well-understood and a recent regional model study has detected no significant change (Cook et al., 2020b). Projected wetting is opposite to the observed drying trends, giving rise to the 'East African rainfall paradox' (Rowell et al., 2015; Wainwright et al., 2019). In other parts of East Africa, no significant trend is evident (Ogega et al., 2020), agreement on the sign of change is low, and in some regions, CMIP5 and CORDEX data show opposite signs of change (Lyon et al., 2017; Lyon and Vigaud, 2017; Osima et al., 2018; Kendon et al., 2019; Ogega et al., 2020).

Heavy rainfall events are projected to increase over the region at global warming of 2°C and higher (*high confidence*) (Nikulin et al., 2018; Finney et al., 2020; Ogega et al., 2020; Li et al., 2021). Drought frequency, duration and intensity are projected to increase in Sudan, South Sudan, Somalia and Tanzania but decrease or not change over Kenya, Uganda and Ethiopian highlands (Liu et al., 2018c; Nguvava et al., 2019; Haile et al., 2020; Spinoni et al., 2020).

9.5.6 Southern Africa

9.5.6.1 Temperature

Observations
Mean annual temperatures over the region have increased by between 1.04°C and 1.44°C over the period 1961–2015 depending on the observational dataset (Gutiérrez et al., 2021) and in northern Botswana and Zimbabwe increasing 1.6°C–1.8°C between 1961–2010 (Engelbrecht et al 2015). The annual number of hot days have increased in southern Africa over the last four decades (Ceccherini et al., 2017; Kruger and Nxumalo, 2017b; Kruger and Nxumalo, 2017a) and there is increasing evidence of increased heat stress impacting agriculture and human health (Section 9.10.2). The occurrence of cold extremes, including frost days, have decreased (Kruger and Nxumalo, 2017b) (Figure 9.14).

Projections
At 1.5℃, 2℃ and 3°C of global warming above pre-industrial levels, mean annual temperatures in southern Africa are projected to be on average, 1.2℃, 2.3℃ and 3.3℃ warmer than the 1994–2005 average respectively (Figure 9.16a). The annual number of heatwaves is projected to increase by between 2–4 (GWL 1.5°C), 4–8 (GWL 2°C) and 8–12 (GWL 3°C) and hot and very hot days are *virtually certain* to increase under 1.5°C and 2°C of global warming (Engelbrecht et al., 2015; Russo et al., 2016; Dosio, 2017; Weber et al., 2018; Seneviratne et al., 2021). Cold days and cold extremes are projected to decrease under all emission scenarios with the strongest decreases associated with low mitigation (Iyakaremye et al., 2021). Children born in 2020, under a 1.5°C-compatible scenario will be exposed to 3–4 times more heatwaves in their lifetimes compared to people born in 1960, although in Angola this is 7–8 times; at GWL 2.4°C this exposure increases to 5–9 times more heatwaves (>10 times in Angola) (Thiery et al., 2021).

9.5.6.2 Precipitation

Observations
Mean annual rainfall has increased over parts of Namibia, Botswana and southern Angola during 1980–2015 by between 128 and 256 mm (Figure 9.13b). Since the 1960s decreasing precipitation trends have been detected over the South African winter rainfall region (*high confidence*) and the far eastern parts of South Africa (*low confidence*) (Engelbrecht et al., 2009; Kruger and Nxumalo, 2017b; Burls et al., 2019; Lakhraj-Govender and Grab, 2019; Gutiérrez et al., 2021; Ranasinghe et al., 2021). The frequency of dry spells and agricultural drought in the region has increased over the period 1961–2016 (Yuan et al., 2018; Seneviratne et al., 2021), the frequency of meteorological drought increased by between 2.5–3 events per decade since 1961 (Spinoni et al 2019) and the probability of the multi-year drought over the southwestern cape of South Africa increased by a factor of three in response to global warming (Otto et al., 2018). The number and intensity of extreme precipitation events have increased over the last century (Kruger and Nxumalo, 2017b; Ranasinghe et al., 2021; Sun et al., 2021), and in the Karoo region of southern South Africa, long-term station data show an increasing trend in annual rainfall of greater than 5 mm per decade over the period 1921–2015 (Kruger and Nxumalo, 2017b).

Projections
Mean annual rainfall in the summer rainfall region is projected to decrease by 10–20%, accompanied by an increase in the number of consecutive dry days during the rainy season under RCP8.5 (Kusangaya et al., 2014; Engelbrecht et al., 2015; Lazenby et al., 2018; Maúre et al., 2018; Spinoni et al., 2019). The western parts of the region are projected to become drier, with increasing drought frequency, intensity and duration

likely under RCP8.5 (*high confidence*) (Engelbrecht et al., 2015; Liu et al., 2018b; Liu et al., 2018c; Ukkola et al., 2020) (Figures 9.16c,e and 9.14), including multi-year droughts (Zhao and Dai, 2016; Dosio, 2017).

Dryness in the summer rainfall region is expected to increase at 1.5°C and higher levels of global warming (Hoegh-Guldberg et al., 2018) and together with higher temperatures will enhance evaporation from the region's mega-dams and reduce soil-moisture content (Engelbrecht et al., 2015) (Section 9.7.1). Increases in drought frequency and duration are projected over large parts of southern Africa at GWL 1.5°C (Liu et al., 2018b; Liu et al., 2018c; Seneviratne et al., 2021) and unprecedented extreme droughts (compared to the 1981–2010 period) emerge at GWL 2°C (Spinoni et al., 2021). Meteorological drought duration is projected to increase from approximately 2 months during 1950–2014 to approximately 4 months in the mid-to-late-21st century future under RCP8.5 (Ukkola et al., 2020). Heavy precipitation in the southwestern region is projected to decrease (Donat et al., 2019) and increase in the eastern parts of southern Africa at all warming levels (Li et al., 2021; Seneviratne et al., 2021).

9.5.7 Tropical cyclones

There is limited evidence of an increased frequency of Category 5 tropical cyclones in the southwestern Indian Ocean (Fitchett et al., 2016; Ranasinghe et al., 2021; Seneviratne et al., 2021) and more frequent landfall of tropical cyclones over central to northern Mozambique (Malherbe et al., 2013; Muthige et al., 2018). There is a projected decrease in the number of tropical cyclones making landfall in the region at 1°C, 2°C and 3°C of global warming, however, they are projected to become more intense with higher wind speeds so when they do make landfall the impacts are expected to be high (*medium confidence*) (Malherbe et al., 2013; Muthige et al., 2018; Ranasinghe et al., 2021).

9.5.8 Glaciers

Total glacial area on Mount Kenya decreased by 121×10^3 m^2 (44%) during 2004–2016 (Prinz et al., 2016), Kilimanjaro from 4.8 km^2 in 1984 to 1.7 km^2 in 2011 (Cullen et al., 2013) and, in the Rwenzori Mountains, from ~2 km^2 in 1987 to ~1 km^2 in 2003 (Taylor et al., 2006). Declining glacial areas in East Africa are linked to rising air temperatures (Taylor et al., 2006; Hastenrath, 2010; Veettil and Kamp, 2019), and in the case of Kilimanjaro and Mount Kenya, declining precipitation and atmospheric moisture (Mölg et al., 2009a; Mölg et al., 2009b; Prinz et al., 2016; Veettil and Kamp, 2019).

Glacial ice cover is projected to disappear before 2030 on the Rwenzori Mountains (Taylor et al., 2006) and Mount Kenya (Prinz et al., 2018) and by 2040 on Kilimanjaro (Cullen et al., 2013). The loss of glaciers is expected to result in a loss in tourism revenues, especially in mountain tourism (Wang and Zhou, 2019).

9.5.9 Teleconnections and Large-Scale Drivers of African Climate Variability

The El Niño-Southern Oscillation (ENSO), Indian Ocean dipole (IOD) and southern annular mode (SAM) are the primary large-scale drivers of African seasonal and interannual climate variability. The diurnal temperature range tends to be greater during La Niña than El Niño in northeastern Africa (Hurrell et al., 2003; Donat et al., 2014a), and in southern Africa, the El Niño warming effect has been stronger for more recent times (1979–2016) compared to earlier period (1940–1978) (Lakhraj-Govender and Grab, 2019). In East Africa, ENSO and IOD exert an interannual control on particularly October–November–December (short rains) and June–July–August–September seasons. In southern Africa, El Niño is associated with negative rainfall and positive temperature anomalies with the opposite true for La Niña. The SAM exerts control on rainfall in the southwestern parts of the region and a positive SAM mode is often associated with lower seasonal rainfall in the region (Reason and Rouault, 2005). The SAM shows a systematic positive trend over the last five decades (Niang et al., 2014).

There is no clear indication that climate change will impact the frequencies of ENSO and IOD (Stevenson et al., 2012; Endris et al., 2019), although there is some indication that extreme ENSO events and extreme phases of the IOD, particularly the positive phase, may become more frequent with implications for extreme events associated with these features, such as drought (Collins et al., 2019; Cai et al., 2021; Seneviratne et al., 2021). Under high emission scenarios, a positive trend in SAM is projected to continue through the 21st century, however, under low emission scenarios, this trend is projected to be weak or even negative given the potential for ozone hole recovery (Arblaster et al., 2011).

9.5.10 African Marine Heatwaves

Marine heatwaves are periods of extreme warm sea surface temperature that persist for days to months and can extend up to thousands of kilometres (Hobday et al., 2016; Scannell et al., 2016), negatively impacting marine ecosystems (Section 9.6.1.4).

The number of marine heatwaves doubled in Mediterranean North Africa and along the Somalian and southern African coastlines from 1982–2016 (Frölicher et al., 2018; Laufkötter et al., 2020) (Oliver et al., 2018), *very likely* as a result of human-induced climate change (Seneviratne et al., 2021). Marine heatwave intensity has increased along the southern African coastline (Oliver et al., 2018). In the ecologically sensitive region west of southern Madagascar, the longest and most intense marine heatwave in the past 35 years was recorded during the austral summer of 2017 in the region, it lasted 48 days and reached a maximum intensity of 3.44°C above climatology (Mawren et al., 2021). Satellite-derived measurements of coastal marine heatwaves may under-report their intensity as measured against coastal *in situ* measurements (Schlegel et al., 2017).

Sea surface temperatures around Africa are projected to increase 0.5°C–1.3°C under GWL1.5 and 1.3°C–2.0°C under GWL3 (Figure 9.16f). Globally, 87% of observed MHWs have been attributed to anthropogenic forcing, and at GWL2.0, nearly all MHWs would be attributable to anthropogenic heating (Frölicher et al., 2018; Laufkötter et al., 2020). Increases in frequency, intensity, spatial extent and duration of marine heatwaves are projected for all coastal zones of Africa. At 1°C and 3.5°C of global warming, the probability of MHW days is between 4–15 times and 30–60 times higher compared to the preindustrial (1861–1880) 99th percentile probability, with highest increases over equatorial and sub-tropical coastal regions (Frölicher et al., 2018) (Figure 9.16). These events are expected to overwhelm the ability of marine organisms and ecosystems to adapt to these changes (Frölicher et al., 2018) (Sections 9.6.1). Reducing emissions and limiting warming to lower levels reduces risk to these systems (*high confidence*) (Hoegh-Guldberg et al., 2018).

[START BOX 9.2 HERE]

Box 9.2: Indigenous Knowledge and Local Knowledge

This box aims at mapping the diversity of indigenous and local knowledge systems in Africa and highlights the potential of this knowledge to enable sustainability and effective climate adaptation. This box builds on the framing of the IPCC system for which 'indigenous knowledge (IK) refers to the understandings, skills and philosophies developed by societies with long histories of interaction with their natural surroundings' (IPCC, 2019b), while 'local knowledge (LK) refers to the understandings and skills developed by individuals and populations, specific to the place where they live' (IPCC, 2019b) (Cross-Chapter Box INDIG in Chapter 18).

Early warning systems and indicators of climate variability

In most African indigenous agrarian systems, local communities integrate IK to anticipate or respond to climate variability (Mafongoya et al., 2017). This holds potential for a more holistic response to climate change, as IK and LK approaches seek solutions that increase resilience to a wide range of shocks and community stresses (IPCC, 2019b). In Africa, IK and LK are exceptionally rich in ecosystem-specific knowledge, with the potential to enhance the management of natural hazards and climate variability (*high confidence*), but there is uncertainty about IK and LK for adaptation under future climate conditions.

Common indicators for the quality of the rain season for local communities in Africa include flower and fruit production of local trees (Nkomwa et al., 2014; Jiri et al., 2015; Kagunyu et al., 2016), insect, bird and animal behaviour and occurrence (Jiri et al., 2016; Mwaniki and Stevenson, 2017; Ebhuoma, 2020) and dry season temperatures (Kolawole et al., 2016; Okonya et al., 2017). Fulani herders in West Africa believe that when 'nests hang high on trees, then rains will be heavy; when nests hang low, rains will be scarce' (Roncoli et al., 2002). In South Africa, LK on weather forecasting is based on the hatching of insects, locust swarm movements and the arrival of migratory birds, which has enabled farmers to make adjustments to cropping practices (Muyambo et al., 2017; Tume et al., 2019). Most of these IK indicators apply to specific communities, and are used for short-term forecasting (e.g., event-specific predictions, such as a violent storm, and onset rain predictions) (Zuma-Netshiukhwi et al., 2013; Mutula et al., 2014). There is evidence of communities that rely heavily on IK and LK indicators to forecast seasonal variability across the continent (Kagunyu et al., 2016; Mwaniki and Stevenson, 2017; Tume et al., 2019). However, their accuracy is debatable, with evidence of both accuracy and inaccuracies due to age-old knowledge losing accuracy because of recent changes in weather conditions (Shaffer, 2014; Adjei and Kyerematen, 2018). There are also some limitations in the transferability of IK across geographical scales, as its understanding is framed by traditional beliefs and cultural practices, historical and social conditions of each community, which vary significantly across communities. This has direct implications for the adoption of IK and LK in national policy and planned adaptation by governments. However, in some parts of Africa, evidence of the integration of IK and LK and scientific-based weather forecasting is increasing (Jiri et al., 2016; Mapfumo et al., 2017; Williams et al., 2020).

IK and LK and climate adaptation

Communities across Africa have long histories of using IK and LK to cope with climate variability, reduce vulnerability and improve the capacity to cope with climate variability (Iloka Nnamdi, 2016; Mapfumo et al., 2017). The adaptation is mostly incremental, such as customary rainwater harvesting practices and planting ahead of rains (Ajibade and Eche, 2017; Makate, 2019), which are used to address the late-onset rains and rainfall variability. Although IK and LK adaptation practices implemented by African communities are incremental, such practices record higher evidence of climate risk reduction compared to practices influenced by other knowledge types (Williams et al., 2020). African communities have used IK and LK to cope, adapt to and manage climate hazards, mainly floods, wildfires, rainfall variability and droughts (see Table Box 9.2.1) (IPCC, 2018b; IPCC, 2019b).

Table Box 9.2.1: Selected studies where IK and LK have been used to cope with climate variability and climate change impacts in Africa.

Climate Hazard	Adaptation/Coping Strategy	Indigenous Group, Community, Country	Evidence
Floods	Use IK to predict floods (village elders acted as meteorologists) and use LK to prepare coping mechanisms (social capital); place valuable goods on higher ground, raise the floor level; leave the field uncultivated when facing flood/drought; indigenous earthen walls to protect homesteads from flooding; planting of culturally flood-immunising indigenous plants.	Coastal communities in Nigeria; Oshiwambo communities in the northern region of Namibia; Matabeleland and Mashonaland provinces in Zimbabwe; communities in Nyamwamba watershed, Uganda; subsistent farmers in Mount Oku and Mbaw, Cameroon; Akobo in South Sudan.	(Fabiyi and Oloukoi, 2013; Hooli, 2016; Lunga and Musarurwa, 2016; Bwambale et al., 2018; Tume et al., 2019)
Wildfires	Early burning to prevent the intensity of the late-season fires	Smallholders in Mutoko, Zimbabwe; Khwe and Mbukushu communities in Namibia	(Mugambiwa, 2018; Humphrey et al., 2021)
Rainfall variability	Change crop type (from maize to traditional millet and sorghum); no weeding; forecasting, rainwater harvesting; women perform rituals rainmaking, seed dressing and crop maintenance as adaptation measures; mulching	Communities in Accra, Ghana; small-scale farmers in Ngamiland in Botswana; Malawi; Zimbabwe; Women in Dikgale, South Africa, agropastoral smallholders in Ntungamo, Kamuli and Sembabule in Uganda.	(Codjoe et al., 2014; Nkomwa et al., 2014; Lunga and Musarurwa, 2016; Rankoana, 2016b; Mugambiwa, 2018; Mfitumukiza et al., 2020; Mogomotsi et al., 2020)
Droughts	Traditional drying of food for preservation (to consume during short	Communities in Accra, Ghana; Malawi; South Africa, Uganda; Smallholder	(Egeru, 2012; Gebresenbet and Kefale, 2012; Codjoe et al., 2014; Kamwendo and

	term droughts); harvesting wild fruits and vegetables; herd splitting by pastorals	farmers in Mutoko, Zimbabwe; Agro-pastoralists in Makueni, Kenya; Pastoralists in South Omo, Ethiopia	Kamwendo, 2014; Okoye and Oni, 2017; Mugambiwa, 2018)
Drought related water scarcity	Traditional rainwater harvesting to supplement both irrigation and domestic water; indigenous water bottle technology for irrigation.	Smallholder farmers in Beaufort, South Africa	(Ncube, 2018)

IK and LK and coping strategies in Table Box 9.2.1 are supportive measures that communities cannot solely rely upon, but which can be used to complement other adaptation options to increase community resilience.

African indigenous language and climate change adaptation

The diversity of African languages is crucial for climate adaptation. Africa has over 30% of the world's indigenous languages (Seti et al., 2016) which are exceptionally rich in ecosystem-specific knowledge on biodiversity, soil systems and water (Oyero, 2007; Mugambiwa, 2018). Taking into consideration the low level of literacy in Africa, especially among women and girls, indigenous languages hold great potential for more effective climate change communication and services that enable climate adaptation (Brooks et al., 2005; Ologeh et al., 2018; IPCC, 2019b). African traditional beliefs and cultural practices place great value on the natural environment, especially land as the dwelling place of the ancestors and source of livelihoods (Tarusarira, 2017) (see Section 9.12).

Limitations of African IK *and* ***LK in climate adaptation***

Studies on IK and LK and climate change adaptation conducted in various African countries and across ecosystems indicate that indigenous environmental knowledge is negatively affected by several factors. Local farmers who depend on this knowledge system for their livelihoods hold the view that African governments do not support and promote it in policy development. Most government agricultural extension workers still consider IK as unscientific and unreliable (Seaman et al., 2014; Mafongoya et al., 2017). At the national level, there is a lack of recognition and inclusion of IK and LK in adaptation planning by African governments, partly because most of the IK and LK in African local communities remains undocumented, but also because IK and LK are inadequately captured in the literature (Ford et al., 2016; IPCC, 2019b). It is predominantly preserved in the memories of the elderly and is handed down orally or by demonstration from generation to generation. It gradually disappears due to memory gaps, and when those holding the knowledge die or refuse to pass it to another generation, the knowledge becomes extinct (Rankoana, 2016a). The way in which IK is transmitted, accessed and shared in most African societies is not smooth (IIED, 2015). IK is also threatened by urbanisation, which attracts rural migrants to urban areas where IK and LK use is limited (Fernández-Llamazares et al., 2015). Further, most African societies that use IK were once colonised, whereby the African indigenous ways of knowing were devalued and marginalised (Bolden et al., 2018). There are concerns about the effectiveness of both IK indicators and related adaptation responses by communities to predict and adapt to weather events under future climate conditions (Speranza et al., 2009; Shaffer, 2014; Hooli, 2016).

Figure Box 9.2.1: Indigenous earth walls *(hayit)* built by indigenous people in Akobo, Jonglei Region, South Sudan to protect their houses/ infrastructure from the worst flood in 25 years occurred in 2019. The wall is 1–2 m high. Photo credit, **Laurent-Charles Levesque**.

[END BOX 9.2 HERE]

9.6 Ecosystems

9.6.1 Observed Impacts of Climate Change on African Biodiversity and Ecosystem Services

9.6.1.1 Terrestrial Ecosystems

The overall continental trend is woody plant expansion, particularly in grasslands and savannas, with woody plant cover increasing at a rate of 2.4% per decade (Stevens et al., 2017; Axelsson and Hanan, 2018) (Figure 9.17). There is also increased grass cover in arid regions in southwestern Africa (Masubelele et al., 2014). There is *high agreement* that this is attributable to increased CO_2, warmer and wetter climates, declines in burned area and release from herbivore browsing pressure, but the relative importance of these interacting drivers remains uncertain (O'Connor et al., 2014; Stevens et al., 2016; García Criado et al., 2020). Woody encroachment is the dominant trend in the western and central Sahel, occurring over 24% of the region, driven primarily by shifts in rainfall timing and recovery from drought (Anchang et al., 2019; Brandt et al., 2019). Remote sensing studies demonstrate greening in southern Africa and forest expansion into water-limited savannas in Central and West Africa (Baccini et al., 2017; Aleman et al., 2018; Piao et al., 2020), with increases in precipitation and atmospheric CO_2 the likely determinants of change (Venter et al., 2018; Brandt et al., 2019; Zhang et al., 2019). These trends of greening and woody plant expansion stand in contrast to the desertification and contraction of vegetated areas highlighted in AR5 (Niang et al., 2014), but are based on multiple studies and longer time series of observations. Reported cases of desertification and vegetation loss, for example, in the Sahel, appear transitory and localised rather than widespread and permanent (Dardel et al., 2014; Pandit et al., 2018; Sterk and Stoorvogel, 2020).

Shifts in demography, geographic ranges and abundance of plants and animals consistent with expected impacts of climate change are evident across Africa. These include uphill contractions of elevational range limits of birds (Neate-Clegg et al., 2021), changes in species distributions previously reported in AR5 (Niang et al., 2014) and the death of many of the oldest and largest African Baobabs (Patrut et al., 2018). An increase in frequency and intensity of hot, dry weather after wildfires led to a long-term decline in plant biodiversity in Fynbos since the 1960s (Slingsby et al., 2017). Increasing temperatures may have contributed to the declining abundance and range size of South African birds (Milne et al., 2015), including Cape Rock-jumper (*Chaetops frenatus*) and Protea Canary (*Serinus leucopterus*), from increased risk of reproductive failure (Lee and Barnard, 2016; Oswald et al., 2020). For hot and dry regions (e.g., Kalahari), there is strong evidence increased temperatures are having chronic sublethal impacts, including reduced foraging efficiency and loss of body mass (du Plessis et al., 2012; Conradie et al., 2019), and are approaching species physiological limits, with heat extremes driving mass mortality events in birds and bats (McKechnie et al., 2021). Vegetation change linked to climate change and increasing atmospheric CO_2 has had an indirect impact on animals. Increased woody cover has decreased the occurrence of bird, reptile and mammal species that require grassy habitats (Péron and Altwegg, 2015; McCleery et al., 2018). Decreased fruit production linked to rising temperatures has decreased the body condition of fruit-dependent forest elephants by 11% from 2008–2018 (Bush et al., 2020).

There is *high agreement* that land use activities counteract or exacerbate climate-driven vegetation change (Aleman et al., 2017; Timm Hoffman et al., 2019). Decreased woody plant biomass in 11% of sub-Saharan Africa was attributed to land clearing for agriculture (Brandt et al., 2017; Ordway et al., 2017). Localised loss of tree cover in Miombo woodlands and 16.6±0.5 Mha of forest loss in the Congo basin between 2000-2014 was driven largely by forest clearing and drought mortality (McNicol et al., 2018; Tyukavina et al., 2018).

Vegetation changes interacting with climate and land use change have impacted fire regimes across Africa. The frequency of weather conducive for fire has increased in southern and West Africa and is expected to continue increasing in the 21st century under both RCP2.6 and RCP8.5 (Betts et al., 2015; Abatzoglou et al., 2019). Increased grass cover in arid regions introduced fire into regions where fuel was previously insufficient to allow fire spread, such as the arid Karoo in South Africa (du Toit et al., 2015; Strydom and Savage, 2016). In contrast, shrub encroachment, increased precipitation (Zubkova et al., 2019), vegetation fragmentation and cropland expansion have reduced fire activity in many African grasslands and savannas (Andela and van der Werf, 2014; Probert et al., 2019). These drivers are expected to negate the effect of increasing fire weather and ultimately lead to a reduction in the total burned area under RCP4.5 and RCP8.5 (Knorr et al., 2016; Moncrieff et al., 2016; Wu et al., 2016).

9.6.1.2 Vegetation Resilience

African ecosystems have a long evolutionary association with fire, large mammal herbivory and drought (Maurin et al., 2014; Charles-Dominique et al., 2016). The maintenance of biodiversity depends on natural disturbance regimes. Natural regrowth of savanna plant biomass in southern Africa compensated for biomass removal through human activities (McNicol et al., 2018), and rapid recovery occurred after the 2014-2016 extreme drought (Abbas et al., 2019). During the same drought event, browsing and mixed feeder herbivores were resilient, but grazers declined by approximately 60% and were highly dependent on drought refugia (Abraham et al., 2019). African tropical forests remained a carbon sink through the record drought and temperature experienced in the 2015–2016 El Niño, indicating resilience in the face of extreme environmental conditions (Bennett et al., 2021). This is likely due to the presence of drought-tolerant species and floristic and functional shifts in tree species assemblages (Fauset et al., 2012; Aguirre-Gutiérrez et al., 2019). This resilience indicates that there is the capacity to recover from disturbances and short-term change. But resilience has limits and beyond certain points, change can lead to irreversible shifts to different states (Figure 9.18).

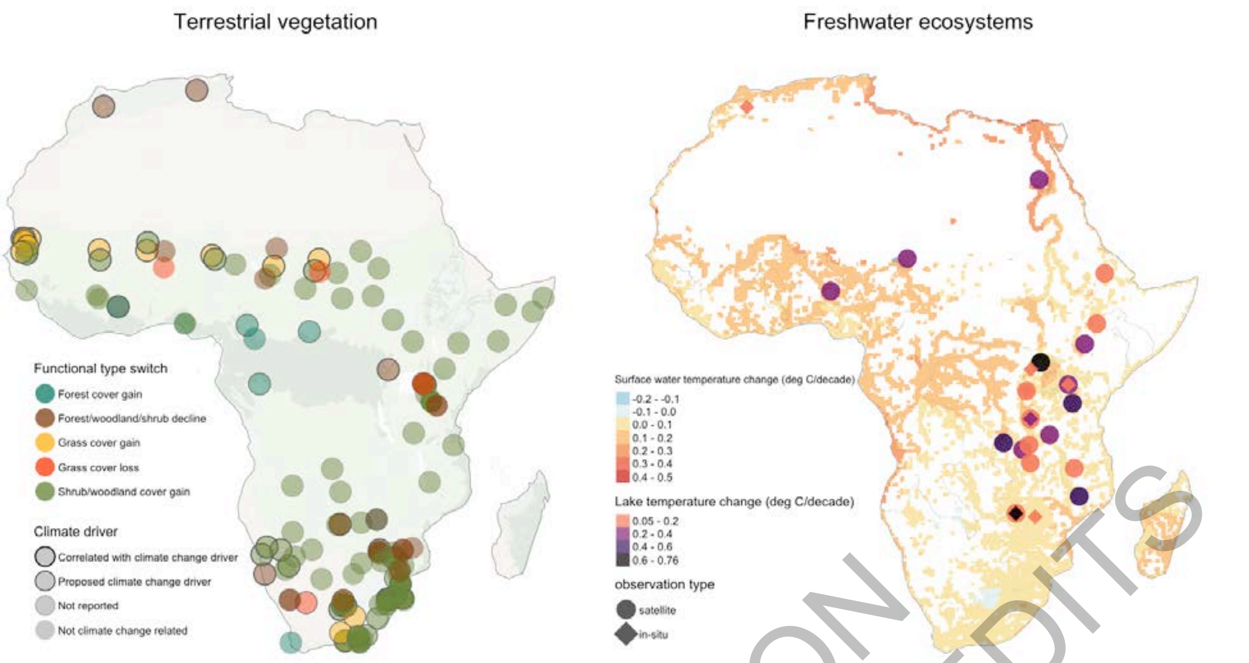

Figure 9.17: Widespread changes to African vegetation have been reported, especially increasing woody plant cover in many savannas and grasslands, with 37% of these changes proposed to be driven by anthropogenic climate change and increased CO_2. The warming of lakes and rivers has been detected across Africa and is attributed to climate change. Data on vegetation change was gathered from 156 studies published between 1989 and 2021. Climatic changes, mostly associated with changes in rainfall, are enhancing grass production in arid grasslands and savannas, and causing grass expansion into semi-desert regions with notable increases in the Sahel and southern Africa. Tropical forest expansion into mesic savannas is occurring on the fringes of the central African tropical forest. Interactions between land use, climate change and increasing atmospheric CO_2 concentrations are causing a widespread increase in woody plant cover encroachment in tropical savannas and grasslands. Some tree death and woody cover decline associated with climate and land use change have also been recorded across biomes. Of the reported changes to terrestrial vegetation, 24% were explicitly linked to climate change and a further 13% were proposed to be driven by climate change. In 48% of studies, no climate driver was mentioned and in 15% climate change was ruled out as the driver of change. Annual surface water temperatures in African lakes have warmed at a rate of 0.05°C–0.76°C per decade. Both satellite-based measures spanning 1985-2011 and *in situ* measurements spanning 1927-2014 agree on this warming trend. Other surface waters across Africa warmed from 1979-2018 at a rate of between 0.05°C and 0.5°C per decade (Woolway and Maberly, 2020). Vegetation change data were taken from a larger, global literature survey of existing databases supplemented with newer studies documenting changes in tree, shrub and grass cover linked to climate and land use change in natural and semi-natural areas (for further details 2.4.3.5 and Table 2.S.1 in Chapter 2, and see Supplementary Material Table SM 9.2 for Africa vegetation change data and Table SM 9.3 for studies reporting lake warming data).

9.6.1.3 Freshwater Ecosystems

Small climatic variations have large impacts on ecosystem function in Africa's freshwaters (Ndebele-Murisa, 2014; Ogutu-Ohwayo et al., 2016). Warming of water temperatures from 0.2°C to 3.2°C occurred in several lakes over 1927–2014 and has been attributed to anthropogenic climate change (Ogutu-Ohwayo et al., 2016); Figure 9.17). Increased temperature, changes in rainfall, and reduced wind speed altered the physical and chemical properties of inland water bodies, affecting water quality and productivity of algae, invertebrates and fish (*high confidence*). In deeper lakes, warmer surface waters and decreasing wind speeds reduced shallow waters mixing with nutrient-rich deeper waters, reducing biological productivity in the upper sunlit zone (Ndebele-Murisa, 2014; Saulnier-Talbot et al., 2014). In several lakes, climate change was identified as causing changes in insect emergence time (Dallas and Rivers-Moore, 2014) and in loss of fish habitats (Natugonza et al., 2015; Gownaris et al., 2016). This set of changes can harm human livelihoods, for example, from reduced fisheries productivity (Ndebele-Murisa, 2014; Ogutu-Ohwayo et al., 2016) (9.8.5) and reduced water supply and quality (Section 9.7.1).

9.6.1.4 Marine Ecosystems

Anthropogenic climate change is already negatively impacting Africa's marine biodiversity, ecosystem functioning and services by changing physical and chemical properties of seawater (increased temperature, salinity and acidification, and changes in oxygen concentration, ocean currents and vertical stratification) (*high confidence*) (Hoegh-Guldberg et al., 2014; Hoegh-Guldberg et al., 2018). Coastal ecosystems in West Africa are among the most vulnerable because of extensive low-lying deltas exposed to sea level rise, erosion, saltwater intrusion and flooding (Belhabib et al., 2016; UNEP, 2016b; Kifani et al., 2018). In southern Africa, shifting distributions of anchovy, sardine, hake, rock lobster and seabirds have been partly attributed to climate change (Crawford et al., 2015; van der Lingen and Hampton, 2018; Vizy et al., 2018), including southern shifts of 30 estuarine and marine fish species attributed to increased temperature and changes in water circulation from decreased river inflow (Augustyn et al., 2018). Warming sea surface temperatures inhibiting nutrient mixing reduced phytoplankton biomass in the western Indian Ocean by 20% since the 1960s, potentially reducing tuna catches (Roxy et al., 2016).

Mangroves, seagrasses and coral reefs support nursery habitats for fish, sequester carbon, trap sediment and provide shoreline protection (Ghermandi et al., 2019). Climate change is compromising these ecosystem services (*medium confidence*). Marine heatwaves associated with El Niño-Southern Oscillation (ENSO) events triggered massive coral bleaching and mortality over the past 20 years (Oliver et al., 2018). Mass coral bleaching in the western Indian Ocean occurred in 1998, 2005, 2010 and 2015/2016 with coral cover just 30–40% of 1998 levels by 2016 (Obura et al., 2017; Moustahfid et al., 2018). The northern Mozambique Channel has served as a refuge from climate change and biological reservoir for the entire coastal East African region (McClanahan et al., 2014; Hoegh-Guldberg et al., 2018). A southern shift of mangrove species has been observed in South Africa (Peer et al., 2018) with loss in total suitable coastal habitats for mangroves and shifts in the distribution of some species of mangroves and a gain for others (Record et al., 2013). Mangrove cover was reduced 48% in Mozambique in 2000 from tropical cyclone Eline, with 100% mortality of seaward mangroves dominated by *Rhizophora mucronata* (Macamo et al., 2016). Recovery of mangrove species was observed 14 years later in sheltered sites. There is *low confidence* these cyclone-induced impacts are attributable to climate change owing, in part, to a lack of reliable long-term data sets (Macamo et al., 2016). In West Africa, oil and gas extraction, deforestation, canalisation and de-silting of waterways have been the largest factors in mangrove destruction (Numbere, 2019).

9.6.2 Projected Risks of Climate Change for African Biodiversity and Ecosystem Services

9.6.2.1 Projected Biome Distribution

African biomes are projected to shift due to changes in atmospheric CO_2 concentrations and aridity (Figure 9.18). Grassland expansion into the desert, woody expansion into grasslands and forest expansion into savannas are projected for areas of reduced aridity, caused by reduced moisture stress from CO_2 fertilisation under medium (RCP4.5) and high (SRES A2) emissions scenarios (Heubes et al., 2011; Moncrieff et al., 2016). This greening trend may slow or reverse with continued temperature increase and/or in areas of increased aridity (Berdugo et al., 2020). The net impact of these effects on vegetation is highly uncertain (Trugman et al., 2018; Cook et al., 2020a; Martens et al., 2021). The maintenance or re-establishment of natural fire and large mammal herbivory processes can mitigate projected CO_2 and climate-driven changes (Scheiter and Savadogo, 2016; Stevens et al., 2016). Expansion of croplands and pastures will reduce ecosystem carbon storage in Africa, potentially reversing climate- and CO_2-driven greening in savannas (Aleman et al., 2018; Quesada et al., 2018).

Vegetation growth simulated by dynamic vegetation models is often highly sensitive to CO_2 fertilisation. These models project the African tropical forest carbon sink to be stable or strengthened under scenarios of future climate change (Huntingford et al., 2013; Martens et al., 2021). In contrast, statistical modelling suggests it has begun to decline and will weaken further, decreasing from current estimates of 0.66 tonnes of carbon removed from the atmosphere per hectare per year to 0.55 tonnes of carbon (Hubau et al., 2020). Increasing rainfall seasonality and aridity over central Africa (Haensler et al., 2013) threatens the massive carbon store in the Congo Basin's Cuvette Centrale peatlands, estimated at 30.6 billion tonnes (Dargie et al., 2019).

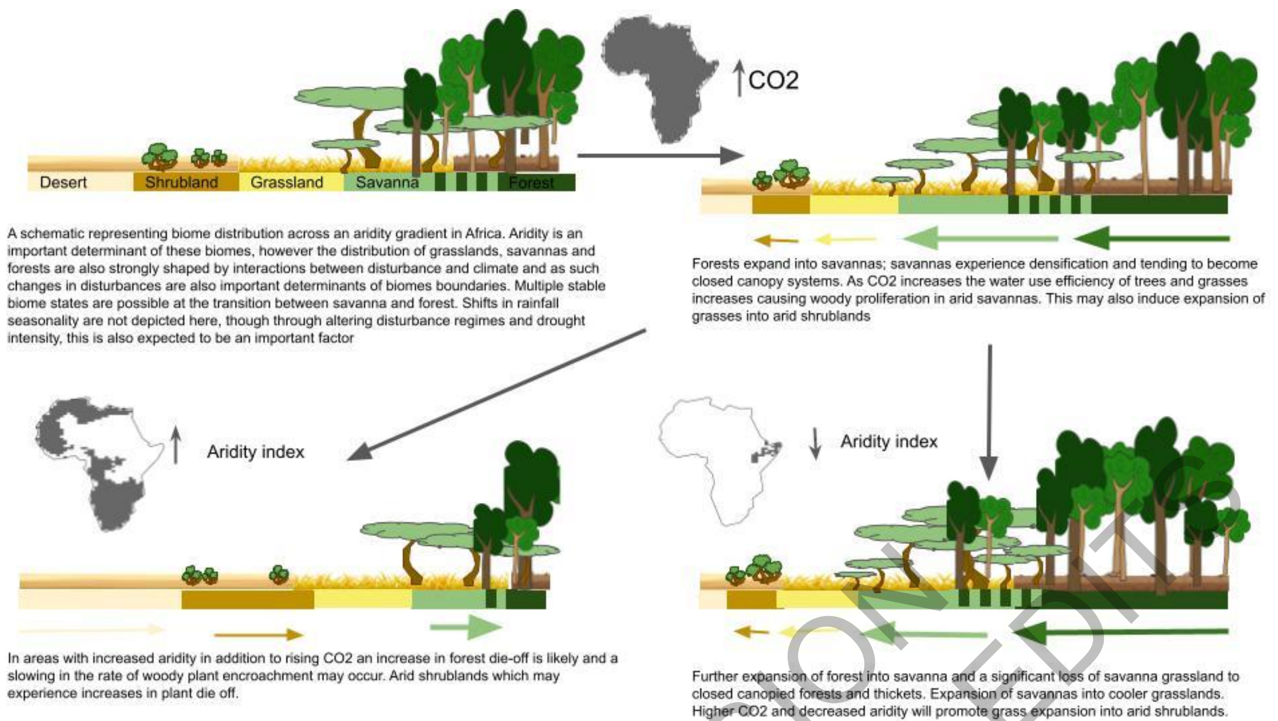

Figure 9.18: Increases in atmospheric CO_2 and changes in aridity are projected to shift the geographic distribution of major biomes across Africa (*high confidence*). Arrows in the diagram indicate possible pathways of biome change from current conditions resulting from changes in CO_2 and aridity. Changes need not be gradual or linear and may occur rapidly if tipping points are crossed. Currently, widespread greening observed in Africa has been at least partially attributed to increasing atmospheric CO_2 concentrations. Future projected increases in aridity are expected to cause desertification in many regions, but it is highly uncertain how this will interact with the greening effect of CO_2. Inset maps show the projected geographical extent of changes in CO_2 concentrations and aridity. CO_2 is projected to increase globally under all future emission scenarios. Aridity index maps show projected change in aridity (calculated as annual precipitation/annual potential evapotranspiration) at around 4°C global warming relative to 1850–1900 (RCP8.5 in 2070–2099) from 34 CMIP5 models (Scheff et al., 2017). Shaded areas indicate regions where >75 % of models agree on the direction of change.

9.6.2.2 Terrestrial Biodiversity

Local extinction is when a species is extirpated from a local site. The magnitude and extent of local extinctions predicted across Africa increase substantially under all future global warming levels (*high confidence*) (Table 9.5; Figure 9.19). Above 2°C the risk of sudden disruption or loss of local biodiversity, increases and becomes more widespread, especially in Central, West and East Africa (Trisos et al., 2020).

Global extinction is when a species is extirpated from all areas. At 2°C global warming, 11.6% of African species (mean 11.6%, 95% CI 6.8–18.2%) assessed are at risk of global extinction, placing Africa second only to South America in the magnitude of projected biodiversity losses (Urban, 2015). At >2°C, 20% of North African mammals may lose all suitable climates (Soultan et al., 2019), and over half of the dwarf succulents in South African Karoo may lose >90% of their suitable habitat (Young et al., 2016). Among the thousands of species at risk, many are species of ecological, cultural and economic importance such as African wild dogs (Woodroffe et al., 2017) and Arabica Coffee (Moat et al., 2019).

With increasing warming, there is a lower likelihood species can migrate rapidly enough to track shifting climates, increasing global extinction risk and biodiversity loss across more of Africa (*high confidence*). Immigration of species from elsewhere may partly compensate for local extinctions and lead to local biodiversity gains in some regions (Newbold, 2018; Warren et al., 2018). However, more regions face net losses than net gains. At 1.5°C global warming, >46% of localities face net declines in vertebrate species richness of >10%, with net increases projected for less than 15% of localities (Barbet-Massin and Jetz, 2015; Newbold, 2018). At >2°C, 9% of species face complete range loss by 2100, regardless of their dispersal ability (Urban, 2015). With >4°C global warming, a net loss of >10% of vertebrate species richness is projected across 85% of Africa (Barbet-Massin and Jetz, 2015; Mokhatla et al., 2015; Newbold, 2018; Warren et al., 2018). Mountain top endemics and species in North and southern Africa are at risk due to disappearing cold climates (Milne et al., 2015; Garcia et al., 2016; Bentley et al., 2018; Soultan et al., 2019). For hot regions such as the Sahara, Congo Basin and Kalahari, no warmer-adapted species are available elsewhere to compensate for local extinctions, so the resilience of local biodiversity will depend entirely on the persistence of species (Burrows et al., 2014; Garcia et al., 2014). The capacity for species to avoid extinction through behavioural thermoregulation, plasticity or evolution is uncertain but will become increasingly *unlikely* under higher warming scenarios (Conradie et al., 2019).

Table 9.5: Risk of local extinction risk increases across Africa with increasing global warming.

Global Warming Level (relative to 1850-1900)	Taxa	% of species at a site at risk of local extinction	Extent across Africa (% of the land area of Africa)	Areas at risk	References
1.5°C	Plants, insects, vertebrates	>10%	>90%	Widespread. Hot and/or arid regions especially at risk, including Sahara, Sahel and Kalahari	Fig. 9.29b (Newbold, 2018; Warren et al., 2018)
>2°C	Plants, insects, vertebrates	>50%	18%	Widespread	(Newbold, 2018; Warren et al., 2018)
>4°C	Plants, insects, vertebrates	>50%	45-73%	Widespread. Higher uncertainty for central African tropical forests due to lower agreement between biodiversity models	Fig. 9.29c (Barbet-Massin and Jetz, 2015; Newbold, 2018; Warren et al., 2018)

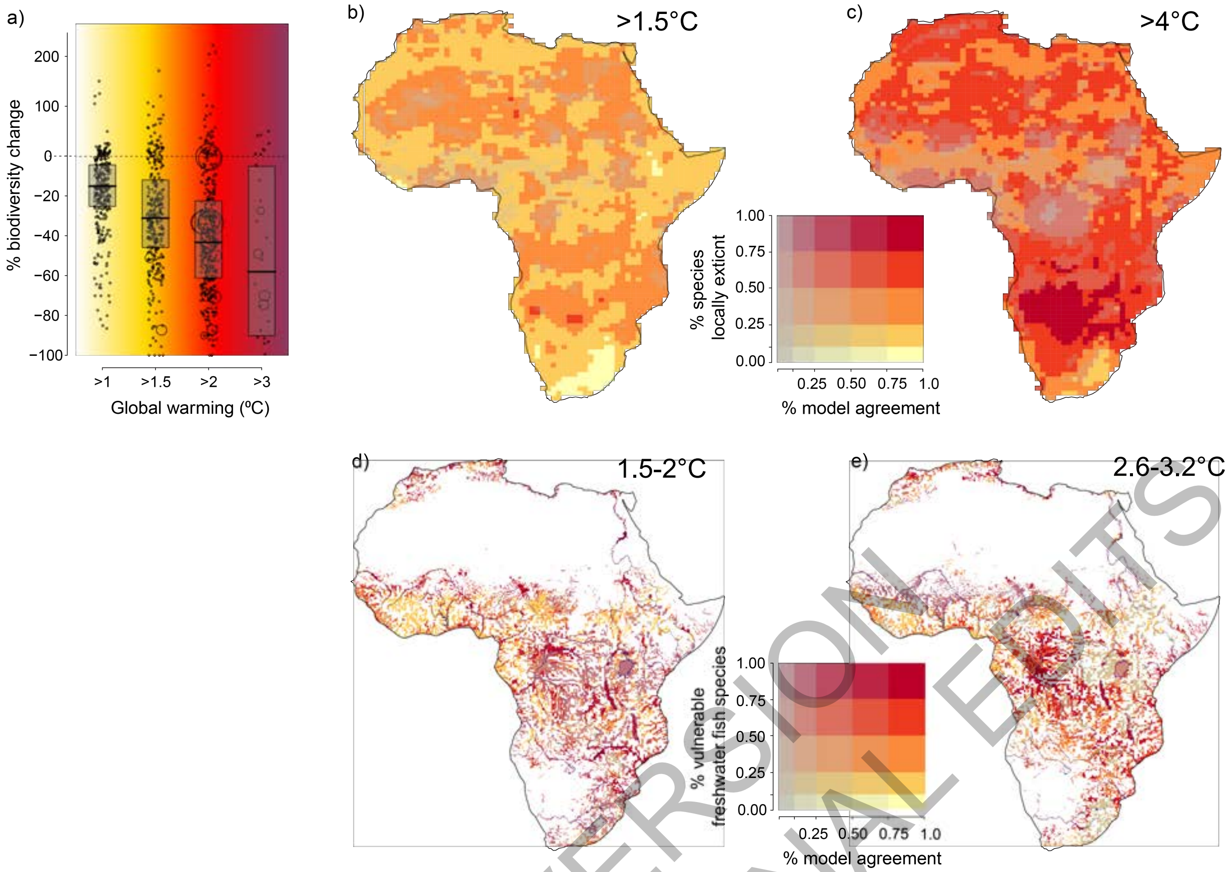

Figure 9.19: The loss of African biodiversity under future climate change is projected to be widespread and increasing substantially with every 0.5°C above the current (2001–2020) level of global warming (*high confidence*). (a) Projected biodiversity loss, quantified as percentage change in species abundance, range size or area of suitable habitat increases with increasing global warming levels (relative to 1850–1900). Above 1.5°C global warming, half of all assessed species are projected to lose >30% of their population, range size or area of suitable habitat, with losses increasing to >40% for >3°C. The 2001–2020 level of global warming is around 1°C higher than 1850–1900 (IPCC, 2021). Boxplots show the median (horizontal line), 50% quantiles (box), and points are studies of individual species or of multiple species (symbol size indicates the number of species in a study). (b–c) The mean projected local extinction of vertebrates, plants and insects within 100 km grid cells increases in severity and extent under increased global warming (relative to 1850–1900). Local extinction >10% is widespread by 1.5°C. Pixel colour shows the projected percentage of species undergoing local extinction and the agreement between multiple biodiversity models. (d–e) The mean projected increase in species of freshwater fish vulnerable to local extinction within 10 km grid cells for future global warming. Around a third of fish species are projected to be vulnerable to extinction by 2°C global warming. Pixel colour shows the projected percentage of species vulnerable to extinction and agreement between multiple vulnerability models. In (a), data were obtained from 22 peer-reviewed papers published since 2012 investigating the impacts of projected climate change on African biodiversity. When a paper provided impact projections for several time periods, climate change scenarios or for more than one species, each impact was recorded as an individual biodiversity impact projection, resulting in a database of 1,165 biodiversity impact projections. Data were initially collected by Manes et al. (2021) as part of a larger literature review for Cross-Chapter Paper 1 on Biodiversity Hotspots and then expanded to include areas outside of African priority conservation areas (see Supplementary Material Table SM 9.4). The literature review was limited to peer-reviewed publications that reported quantifiable risks to biodiversity, eliminating non-empirical studies. In (b–c), projections are based on intersecting current and future modelled species distributions at ~10 km spatial resolution from two recent global assessments of climate change impacts on terrestrial vertebrates (Newbold, 2018; Warren et al., 2018). In (d-e) projections are based on intersecting future species vulnerabilities from two recent assessments of climate change vulnerability of freshwater fish species (Nyboer et al., 2019; Barbarossa et al., 2021).

9.6.2.3 *Marine Ecosystems*

African coastal and marine ecosystems are highly vulnerable to climate change (*high confidence*). At 1.5°C of global warming, mangroves will be exposed to sedimentation and sea level rise, while seagrass ecosystems will be most affected by heat extremes (*high confidence*) (Hoegh-Guldberg et al., 2018) and turbidity (Wong et al., 2014). These risks will be amplified at 2°C and 3°C (*virtually certain*) (Hoegh-

Guldberg et al., 2018). Over 90% of East African coral reefs are projected to be destroyed by bleaching at 2°C of global warming (*very high confidence*) (Hoegh-Guldberg et al., 2018). At around 2.5°C global warming, an important reef-building coral (*Diploastrea heliopora*) in the central Red Sea is projected to stop growing altogether (Cantin et al., 2010). By 2.5°C, suitable habitat of >50% of species are projected to decline for coastal lobster in East and North Africa, with large declines for commercially important *J. lalandii* in southern Africa (Boavida-Portugal et al., 2018). More generally, tropical regions, especially exclusive economic zones in West Africa, are projected to lose large numbers of marine species and may experience sudden declines with extratropical regions having potential net increases as species track shifting temperatures poleward (García Molinos et al., 2016; Trisos et al., 2020).

9.6.2.4 Freshwater Ecosystems

Above 2°C global warming, the proportion of freshwater fish species vulnerable to climate change increases substantially (*high confidence*) (Figure 9.19). At 2°C, 36.4% of fish species are projected to be vulnerable to local or global extinction by 2100, increasing to 56.4% under 4°C warming (average of values from (Nyboer et al., 2019; Barbarossa et al., 2021) (Figure 9.19). Global warming reduces available habitat for freshwater species due to reduced precipitation and increased drought leading to increasing water temperatures above optimal physiological limits in floodplains, estuaries, wetlands, ephemeral pools, rivers and lakes (Dalu et al., 2017; Kalacska et al., 2017; Nyboer and Chapman, 2018). Along the Zambezi River, projected flow reductions could cause a 22% reduction in annual spawning habitat and depletion of food resources for fry and juvenile fish that could impede fish migration and reduce stocks (Kangalawe, 2017; Martínez-Capel et al., 2017; Tamatamah and Mwedzi, 2020). More aquatic species will have the capacity to cope with 2°C compared to 4°C global warming, with more negative effects on physiological performance at 4°C (Dallas, 2016; Pinceel et al., 2016; Zougmoré et al., 2016; Nyboer and Chapman, 2017; Ross-Gillespie et al., 2018). Endemic, specialised fish species will have a lower capacity to adjust to elevated water temperatures compared to hardier generalist fishes (McDonnell and Chapman, 2015; Nyboer and Chapman, 2017; Lapointe et al., 2018; Reizenberg et al., 2019). More work is needed to understand the risk for invertebrates (Dallas and Rivers-Moore, 2014; Cohen et al., 2016), and to understand the potential effects of reduced mixing of water and other climate risks on freshwater biodiversity.

9.6.2.5 Climate Change & Ecosystem Services

Direct human dependence on provisioning ecosystem services in Africa is high (Egoh et al., 2012; IPBES, 2018). For example, natural forests provided 21% of rural household income across 11 African countries (Angelsen et al., 2014) and wild-harvested foods (including fisheries) provide important nutrition to millions of Africans, including through important micronutrients and increased dietary diversity (Powell et al., 2013; Baudron et al., 2019a) (Sections 9.8.2.3 and 9.8.5)

Climate change has affected ecosystem services in Africa by reducing fish stocks, crop and livestock productivity and water provisioning due to heat and drought (see Sections 9.8.2.1, 9.8.2.2, 9.8.2.4 and 9.8.5.1). Woody encroachment is decreasing cattle production and water supply (Smit and Prins, 2015; Stafford et al., 2017), but can also provide forage for goat production, as well as resins, fuelwood and charcoal (Reed et al., 2015; Stafford et al., 2017; Charis et al., 2019). Local communities perceive climate change to have decreased crop and livestock productivity, reduced wild food availability and reduced forest resources across Africa (Onyekuru and Marchant, 2014) (see Sections 9.8.2.1, 9.8.2.2, 9.8.2.4 and 9.8.2.3).

With global warming >3°C, and with high population growth and agricultural expansion (SSP3, 2081–2100), 1.2 billion Africans are projected to be negatively affected by pollution of drinking water from reduced water quality regulation by ecosystems and 27 million people affected by reduced coastal protection by ecosystems (Chaplin-Kramer et al., 2019). The number of people affected reduces to 0.4 billion and 22 million under a sustainable development scenario with global warming below 2°C (SSP1, 2081–2100). The African tropical forest carbon sink has been more resilient than Amazonia to recent warming but may already have peaked, and this service is predicted to decline with further warming, reducing 14% by the 2030s (Hubau et al., 2020; Sullivan et al., 2020). This declining carbon storage may be offset by CO_2 fertilisation (*low confidence*) (Martens et al., 2021). Climate change is projected to shift the geographic distribution of important human and livestock disease vectors (see Section 9.8.2.4 and 9.10.2). Changes in rainfall seasonality compounded with land privatisation and population growth may adversely impact nomadic and semi-nomadic pastoralists who follow shifting patterns of greening vegetation (Van Der Ree et al., 2015).

9.6.2.6 Invasive Species

Invasive species threaten African ecosystems and livelihoods (Ranasinghe et al., 2021). For instance, economic impacts were estimated at USD 1 billion per year for smallholder maize farmers in East Africa (Pratt et al., 2017). Climate change is projected to change patterns of invasive species spread (*high confidence*). The area of suitable climate for *Lantana camara* is projected to contract (Taylor et al., 2012) and to expand for *Prosopis juliflora* (Sintayehu et al., 2020). Bioclimatic suitability for fall armyworm, a major threat to maize, is projected to decrease in Central Africa but expand in southern and West Africa (Zacarias, 2020), and to expand for coffee berry borer (*H. hampei*) in Uganda and around Mount Kenya (Jaramillo et al., 2011). Climate suitability for tephritid fruit flies is projected to decrease in central Africa (Hill et al., 2016). Increased water temperature is projected to favour invasive over local freshwater fish populations and shift the range of invasive aquatic plants in South Africa (Hoveka et al., 2016; Shelton et al., 2018). Alterations to lake and river connectivity are predicted to modify invasion pathways in Lake Tanganyika and water hyacinth coverage may increase with warmer waters in Lake Victoria (Masters and Norgrove, 2010; Plisnier et al., 2018).

9.6.3 Nature-Based Tourism in Africa

Nature-based tourism is important for African economies and jobs. Tourism contributed 8.5% of Africa's 2018 GDP (World Travel and Tourism Council, 2019a) with Wildlife tourism contributing a third of tourism revenue (USD 70.6 billion), supporting 8.8 million jobs (World Travel and Tourism Council, 2019b).

Climate change is already negatively affecting tourism in Africa (*high confidence*). The 2015–2018 Cape Town drought caused severe water restrictions, reducing tourist arrivals and spending with associated job losses (Dube et al., 2020). Anthropogenic climate change increased the likelihood of drought by a factor of five to six (Pascale et al., 2020). Extreme heat days have increased across South African national parks since the 1990s (van Wilgen et al., 2016). This reduces animal mobility, decreasing animal viewing opportunities (Dube and Nhamo, 2020). Tourists and employees also fear heat stress (Dube and Nhamo, 2020). Visitors to South Africa's national parks preferred to visit in cool-to-mild temperatures (Coldrey and Turpie, 2020). Extreme weather conditions disrupted tourist activities and damaged infrastructure at Victoria Falls, Hwange National Park, Kruger National Park and the Okavango Delta (Dube et al., 2018; Dube and Nhamo, 2018; Mushawemhuka et al., 2018; Dube and Nhamo, 2020). Rainfall variability and drought alters wildlife migrations, affecting tourist visits to the Serengeti (Kilungu et al., 2017). Reduced tourism decreases revenue for national park management (van Wilgen et al., 2016).

Future climate change is projected to further negatively affect nature-based tourism. Decreased snow and forest cover may reduce visits to Kilimanjaro National Park (Kilungu et al., 2019). Woody plant expansion in savanna and grasslands reduce tourist's game viewing experience and negatively impact conservation revenues (Gray Emma and Bond William, 2013; Arbieu et al., 2017). Visitation rates to South African national parks, based on mean monthly temperatures, are projected to decline 4% with 2°C global warming (Coldrey and Turpie, 2020). Sea level rise and increased intensity of storms is projected to reduce beach tourism due to beach erosion (Grant, 2015; Amusan and Olutola, 2017). Tourism in the Victoria Falls, Okavango and Chobe hydrological systems may be negatively affected by heat and increased variability of rainfall and river flow (Saarinen et al., 2012; Dube and Nhamo, 2019). Increased extreme heat will increase air turbulence and weight restrictions on aircraft, which could make air travel more uncomfortable and expensive to African destinations (Coffel and Horton, 2015; Dube and Nhamo, 2019).

9.6.3.1 Protected Areas and Climate Change

African protected areas store around 1.5% of global land ecosystem carbon stocks and support biodiversity (Gray et al., 2016; Melillo et al., 2016; Sala et al., 2018). They also support livelihoods and economies, such as through nature-based tourism and improved fisheries (Brockington and Wilkie, 2015; Mavah et al., 2018; Ban et al., 2019).

Climate change and land use change will interact to influence the effectiveness of African protected areas (*high confidence*). Species representation in the existing African protected area network is projected to decrease due to species range shifts for mammals, bats, birds and amphibians (Hole et al., 2009; Baker et al., 2015; Payne and Bro-Jørgensen, 2016; Smith et al., 2016; Phipps et al., 2017). Species ability to disperse between areas to track shifting climates is increasingly impaired by land transformation and fencing, which also impact seasonal wildlife migrations (Lovschal et al., 2017; Sloan et al., 2017). On land, only 0.5% of the African protected area network is connected through low-impact landscapes (Ward et al., 2020). Linear transport infrastructure (e.g., roads, railways, pipelines) and fencing from proposed 'development corridors' are projected to bisect over 400 protected areas and degrade around 1,800 more (Laurance et al., 2015). Climate change could increase human-wildlife conflict as resultant resource shortages cause communities to move into protected areas for harvesting or livestock grazing, or wildlife to move out of protected areas and into contact with people (Mukeka et al., 2018; Kupika et al., 2019; Hambira et al., 2020). See Section 9.1.4 for the role of land and ocean protected areas in climate change adaptation.

9.6.4 Ecosystem-Based Adaptation in Africa

Ecosystem-based adaptation (EbA) uses biodiversity and ecosystem services to assist people to adapt to climate change (Swanepoel and Sauka, 2019). Africa's Nationally Determined Contributions (NDCs) show 36% of adaptation actions identified by 52 countries are considered to be EbA (Figure 9.20).

EbA can reduce climate impacts and there is high agreement EbA can be more cost-effective than traditional grey infrastructure when a range of economic, social and environmental benefits are also accounted for (Table 9.6) (Baig et al., 2016; Emerton, 2017; Chausson et al., 2020). This is particularly relevant in Africa where climate vulnerabilities are strongly linked to natural resource-based livelihood practices and existing grey infrastructure levels are low in many regions (Dube et al., 2016; Reid et al., 2019). However, financial constraints limit EbA project implementation (Mumba et al., 2016; Swanepoel and Sauka, 2019).

Evidence for EbA in Africa is largely case study based and often anecdotal (Reid et al., 2018). There is *high agreement* that costs, challenges and negative outcomes of EbA interventions are still poorly understood (Reid, 2016; Chaplin-Kramer et al., 2019), despite limited evidence for the efficacy of context-specific applications at different scales (Doswald et al., 2014).

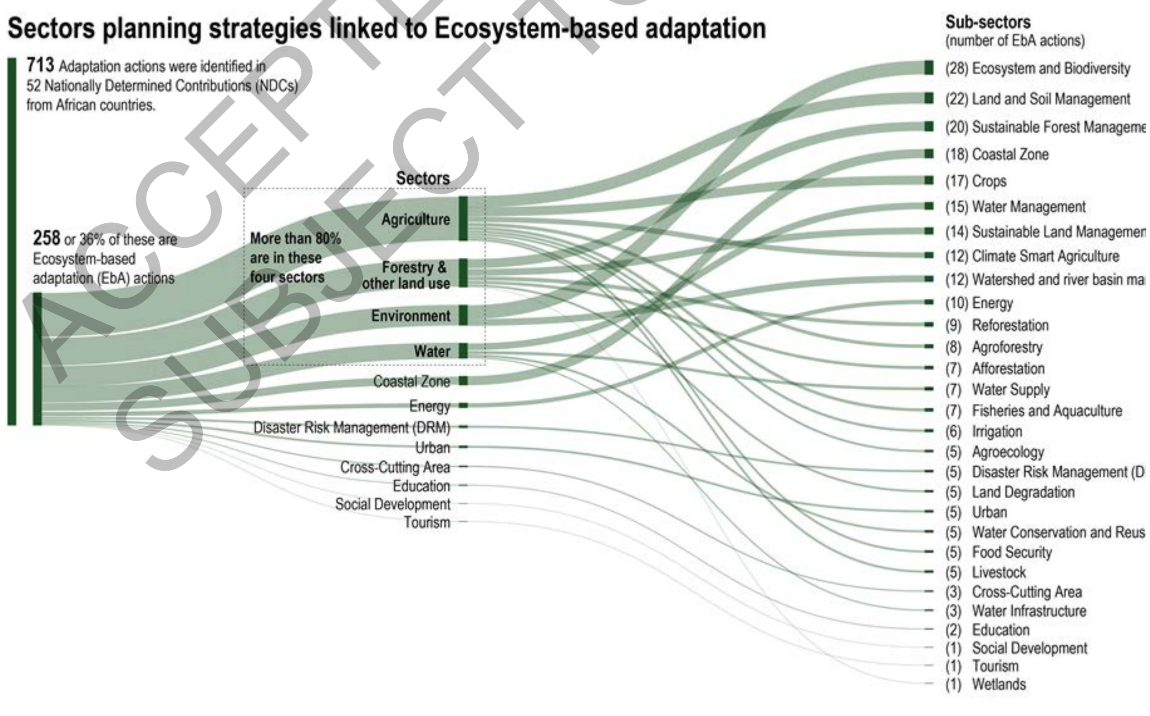

Figure 9.20: Over a third (36%) of all adaptation actions identified in the NDCs of 52 African countries are Ecosystem-based Adaptations (EbA). Of these actions ± 83% fall within the Agriculture, Land Use/Forestry, Environment and Water sectors. The EbA actions identified from the NDCs span 12 primary sectors and 29 sub-sectors.

Table 9.6: The beneficial outcomes of Ecosystem-based Adaptation (EbA) actions and assessed confidence in these outcomes. Assessment is provided for EbA options in the four most prevalent EbA sectors identified in the Nationally Determined Contributions of 52 African countries (Figure 9.20). See Chapter 2.6.3 and 3.6.2 of this report for further assessment of EbA approaches in terrestrial, freshwater and marine systems.

Sector	EbA Action(s)	Outcome(s)	Confidence	Source(s)
Agriculture	Conservation agriculture	Improved soil and water conservation	*High*	(Thierfelder et al., 2017)
		Improved agricultural productivity and drought resilience	*Medium*	(Pittelkow et al., 2015; Thierfelder et al., 2017; Adenle et al., 2019)
	Diversified crop varieties	Improved agricultural productivity and drought resilience	*High*	(Shiferaw et al., 2014; Tesfaye et al., 2016; Thierfelder et al., 2017)
Environment	Ecosystem protection and restoration	Carbon sequestration and storage	*High*	(Melillo et al., 2016; Griscom et al., 2017; FAO, 2018a)
		Stepping stones for species migrating due to climate change	*Medium*	(Beale et al., 2013; Roberts et al., 2020)
		Increased ecosystem resilience to disturbance	*High*	(Anthony et al., 2015; Sierra-Correa and Cantera Kintz, 2015; Kroon et al., 2016; Roberts et al., 2017)
		Livelihood diversification opportunities from ecotourism, resource harvesting, and rangelands (among others)	*Medium*	(Lunga and Musarurwa, 2016; Bedelian and Ogutu, 2017; Agyeman, 2019; Kupika et al., 2019; Naidoo et al., 2019)
Forestry & Other Land Use	Restoration/ Reforestation Sustainable forestry and land management	Restoration of degraded ecosystems and enhanced carbon sequestration	*High*	(Mugwedi et al., 2018)
		Reducing pressure on forests for food and energy needs	*Medium*	(Peprah, 2017; Zegeye, 2018)
Water	Integrated catchment management	Improved flood attenuation capacity	*High*	(Bradshaw et al., 2007; Mwenge Kahinda et al., 2016; Rawlins et al., 2018)
		Improved resilience of freshwater ecosystems	*High*	(Ndebele-Murisa, 2014; Natugonza et al., 2015; Lowe et al., 2019; Tamatamah and Mwedzi, 2020)

9.6.4.1 Terrestrial Ecosystems

Improved ecosystem care and restoration are cost-effective for carbon sequestration while providing multiple environmental, social and economic co-benefits (Griscom et al., 2017; Shukla et al., 2019). Protecting and restoring natural forests and wetlands reduces flood risk across multiple African countries (Bradshaw et al., 2007). In Kenya, enclosures for rangeland regeneration diversified income sources, which could increase the adaptive capacity of local people (Mureithi et al., 2016; Wairore et al., 2016). Sustainable agroforestry in semi-arid regions provides income sources from fuelwood, fruit and timber and reduces exposure to drought, floods and erosion (Quandt et al., 2017). Forest protection in Zimbabwe maintains honey production during droughts, providing food supply options if crops fail (Lunga and Musarurwa, 2016). Community-based natural resource management in pastoral communities improved institutional governance outcomes through involving community members in decision-making, increasing the capacity of these communities to respond to climate change (Reid, 2014).

EbA can also increase ecological resilience. Re-introduction of fire and large mammals can restore ecosystem services, enhance adaptive capacity and benefit people by combatting woody encroachment, restoring grazing and increasing streamflow (Asner et al., 2016; Stafford et al., 2017; Cromsigt et al., 2018). Herbivores can also reduce fuel loads in areas facing increased fire risk (Hempson et al., 2017).

Protected areas can be ‘stepping stones' that facilitate climate-induced species range shifts (Roberts et al., 2020), preserve medicinal plant diversity despite climate change (Kaky and Gilbert, 2017) and provide livelihood diversification opportunities (Table 9.6). Protecting 30% of sub-Saharan Africa's land area could reduce the proportion of species at risk of extinction by around 60% in both low and high warming scenarios (Hannah et al., 2020). The role of protected areas in EbA can be strengthened by: (i) increasing coverage of diverse environments and high carbon storage ecosystems, (ii) habitat restoration, (iii) maintaining intact habitat, (iv) participatory, equitable conservation and adaptation strategies; (v) cooperation across borders and (vi) adequate monitoring (Gillson et al., 2013; Rannow et al., 2014; Midgley and Bond, 2015; Pecl et al., 2017; Dinerstein et al., 2019; Roberts et al., 2020).

[START BOX 9.3 HERE]

Box 9.3: Tree Planting in Africa

Due to widespread deforestation and forest degradation (Malhi et al., 2014), future scenarios to limit global warming include large-scale reforestation and afforestation (Griscom et al., 2017; Bastin et al., 2019). Africa has been targeted through the AFR100 (https://afr100.org) to plant ~1 million km^2 of trees by 2030 (Bond et al 2019). Maintaining existing indigenous forest and indigenous forest restoration is a win-win, maximising benefits to biodiversity, adaptation and mitigation (Griscom et al., 2017; Watson et al., 2018; Lewis et al., 2019) (*high confidence)*.

Yet many areas targeted by AFR100 erroneously mark Africa's open ecosystems (grasslands, savannas, shrublands) as degraded and suitable for afforestation (Figure Box 9.3.1) (Veldman et al., 2015; Bond et al., 2019) *(high confidence)*. These ecosystems are not degraded, they are ancient ecosystems that evolved in the presence of disturbances (fire/herbivory) (Maurin et al., 2014; Bond and Zaloumis, 2016; Charles-Dominique et al., 2016). Afforestation prioritises carbon sequestration at the cost of biodiversity and other ecosystem services (Veldman et al., 2015; Bond et al., 2019). Furthermore, it remains uncertain how much carbon can be sequestered as, compared to grassy ecosystems, afforestation can reduce belowground carbon stores and increase aboveground carbon loss to fire and drought (Yang et al., 2019; Wigley et al., 2020b; Nuñez et al., 2021). Thus, afforested areas may store less carbon than ecosystems they replace (Dass et al., 2018; Heilmayr et al., 2020). Afforestation would reduce livestock forage, eco-tourism potential and water availability (Gray Emma and Bond William, 2013; Anadón et al., 2014; Cao et al., 2016; Stafford et al., 2017; Du et al., 2021), and may reduce albedo thereby increasing warming (Baldocchi and Penuelas, 2019; Bright et al., 2015).

Exotic tree species are often selected for planting (e.g., *Pinus* spp or *Eucalyptus* spp), but in parts of Africa, they have become invasive (Zengeya, 2017; Witt et al., 2018), increasing fire hazards and decreasing biodiversity and water resources (Nuñez et al., 2021) *(high confidence)*. Negative impacts of afforestation on ecosystems are not restricted to plantations of exotic species; they extend to inappropriate planting of native forest species (Slingsby et al., 2020).

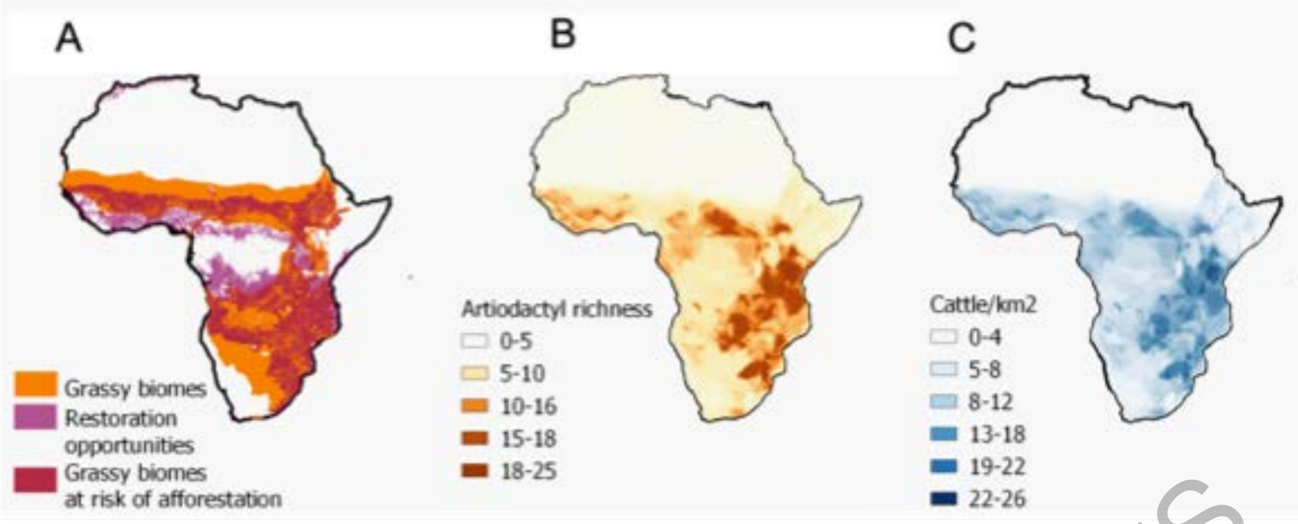

Figure Box 9.3.1: Proposed tree planting plans in Africa are focused on (a) non-forested ecosystems like savannas, grasslands and shrublands which (b) host uniquely adapted biodiversity and (c) offer important ecosystem services like grazing which supports subsistence and commercial agriculture. Figure adapted from (Bond et al., 2019).

[END BOX 9.3 HERE]

9.6.4.2 Freshwater Ecosystems

EbA can mitigate flooding and increase the resilience of freshwater ecosystems (Table 9.6). Adaptation in African freshwater ecosystems is heavily influenced by non-climate anthropogenic factors, including land use change, water abstraction and diversion, damming and overfishing (Dodds et al., 2013; Kimirei et al., 2020; UNESCO and UN-Water, 2020). Wetlands and riparian areas support biodiversity, act as natural filtration systems and serve as buffers to changes in the hydrological cycle, thereby increasing the resilience of freshwater ecosystems and the people that rely on them (Ndebele-Murisa, 2014; Musinguzi et al., 2015; Lowe et al., 2019). However, national adaptation programmes of action, national adaptation plans and national communications rarely consider the ecological stability of ecosystems safeguarding the very water resources they seek to preserve (Kolding et al., 2016). Some countries have mandated the protection of riparian zones, but implementation is low (Musinguzi et al., 2015; Muchuru and Nhamo, 2018). Protecting terrestrial areas surrounding Lake Tanganyika benefited fish diversity (Britton et al., 2017). Afforestation reduces water availability but forest restoration and removing invasive plant species can increase water flows in regions facing water insecurity from climate change (Chausson et al., 2020; Le Maitre et al., 2020). Regular, long-term monitoring of African freshwaters would improve understanding of responses to climate change. General principles for this type of monitoring were developed for Lake Tanganyika (Plisnier et al., 2018) and could be applied to develop harmonised, regional monitoring of African lakes, rivers and wetlands (Tamatamah and Mwedzi, 2020)

9.6.4.3 Marine and Coastal Ecosystems

Marine and coastal ecosystems such as mangroves, seagrass and coral reefs provide storm protection and food security for coastal communities (*high confidence*) (IPCC, 2019c). Restoring reef systems reduced wave height in Madagascar (Narayan et al., 2016), but there is limited evidence for the efficacy of coral reef restoration at large scales with increased warming (3.6.3). Populations at risk from storm surge and/or sea level rise coincide with areas of high coastal EbA potential from Mozambique to Somalia, and coastlines of the Gulf of Guinea, Gambia, Guinea-Bissau and Sierra Leone (Jones et al., 2020). Understanding hotspots of EbA potential is particularly important for West Africa with some of the highest levels of human dependence on marine ecosystems at high risk from climate change and large populations vulnerable to sea level rise (Selig et al., 2018; Trisos et al., 2020) (Sections 9.9.3.1 and 9.8.5.2).

Marine protected areas (MPAs) can yield multiple adaptation benefits, such as buffering species from extinction and increasing fish stocks, as well as storing large amounts of carbon (Edgar et al., 2014; Roberts et al., 2017; Lovelock and Duarte, 2019). However, this potential of MPAs will reach limits with increased warming (Roberts et al., 2017). For example, MPAs cannot prevent coral bleaching at scale and mass die-offs are well-described from MPAs following climate shocks (Bates et al., 2019; Bruno et al., 2019). Although prioritising MPA coverage of climate refugia, such as the northern Mozambique channel, may offer some increased resilience (McClanahan et al., 2014).

9.7 Water

Much of Africa experiences very high hydrological variability in all components of the water cycle, with important implications for people and ecosystems. Most of the continent's water is stored in groundwater (660,000 km^3), which is 20 times more than the water stored in the lakes and 100 times more than the annual renewable water resources (MacDonald et al., 2012). The accessible volume of groundwater via wells and springs is smaller than these estimates (Xu et al., 2019). Africa has 63 transboundary river basins (UNEP, 2010), 72 mapped transboundary aquifers (Nijsten et al., 2018) and 33 transboundary lakes (ILEC and UNEP, 2016), reflecting a highly water-connected and interdependent socio-ecological system across countries, extending also to the coastal areas of the continent (see Section 4.1, Figure 4.1).

9.7.1 Observed Impacts from Climate Variability and Climate Change

Climate impacts on water are occurring against a backdrop of increasing temperatures and changes in rainfall, with increased seasonal and interannual variability, droughts in some regions, and increased frequency of heavy rainfall events (see Section 9.5). In West Africa, declines in river flows have been attributed to declining rainfall and increasing temperature, drought frequency and water demand (Biao, 2017; Thompson et al., 2017; Descroix et al., 2018). In Central Africa, the Congo river demonstrates inter-decadal shifts but no long-term trend (Mahe et al., 2013; Alsdorf et al., 2016), however, recently observed falling water levels in its upper and middle reaches are attributed to climate change (von Lossow, 2017).

A review of river flow and lake level changes in 82 basins in eastern and southern Africa regions for 1970–2010 showed mixed trends: 51% had decreasing trends ranging from 10–49% and 11% increasing trends ranging from 7–60% (Schäfer et al., 2015). However, in southern Africa as a whole, river flows have mostly decreased *(high confidence)* (Dallas and Rivers-Moore, 2014). In East Africa, large rivers such as the Tana show increasing flow (1941–2016) related to increased rainfall in the highlands, with little influence of flow regulation by a series of dams (Langat et al., 2017). The Nile river basin has been experiencing a mainly increasing rainfall trend upstream and decreasing trend downstream (Onyutha et al., 2016). The observed changes are driven by a complex coupling of changes in climate, land use and water demand.

Observed climate changes in Africa (see Section 9.5) have led to changes in river flow and runoff (Dallas and Rivers-Moore, 2014; Wolski et al., 2014) and high fluctuations in lake levels *(high confidence)* (Natugonza et al., 2016; Ogutu-Ohwayo et al., 2016; Gownaris et al., 2018). Shallow lakes respond dramatically to hydrological changes, for example, Lake Chilwa has dried up completely nine times in the last century (Wilson, 2014), while Lake Chad shrunk by 90% between 1963 and 2000 (Gao et al., 2011). However, recent analyses indicate that Lake Chad's water levels have been stable since 2000 due to infilling from groundwater resources (Buma et al., 2018; Pham-Duc et al., 2020). Other factors such as deforestation and increased water use in upstream tributaries also contribute to lake shrinking (Mvula et al., 2014). Water levels in Kenya's mostly shallow rift lakes have been rising since 2010, with some exceeding historical record high levels (Schagerl and Renaut, 2016; Olago et al., 2021). The recent 10-year rising trend is partly attributed to increased rainfall and changing land uses (Onywere and John M. Mironga, 2012; Olago et al., 2021). Changes in water level fluctuations of 13 African lakes have been positively correlated with primary and overall production (Gownaris et al., 2018), and will have important consequences for freshwater ecosystems and related ecosystem goods and services (see Sections 9.6.1.3 and 9.8.5). Other effects of observed climate changes in Africa include higher episodic groundwater recharge, particularly in drylands, from heavy rainfall events that are in some cases related to El Niño-Southern Oscillation and the Indian Ocean Dipole (Taylor et al., 2013; Fischer and Knutti, 2016; Cuthbert et al., 2019; Kotchoni et al., 2019; Myhre et al., 2019), reduced soil moisture, more frequent and intense floods, more persistent and frequent droughts (Douville et al., 2021) and the steady decline and projected disappearance by 2040 of African tropical glaciers (see Section 9.5.9).

The mixed-signal in river flow trends (increase/decrease/no-change) across Africa mirrors the results seen globally for runoff and streamflow (see Section 4.2.3 in Chapter 4). Hydrological extremes are, however, of increasing concern. There has been an increase in drought frequency, severity and spatial extent in recent decades. From 1900–2013, Africa suffered the largest number of drought events globally and registered the second largest number of people affected after Asia (Masih et al., 2014). The likelihood of recent severe climate conditions such as the multi-year Cape Town Drought has increased to due to human-induced climate change (Otto et al., 2018; Pascale et al., 2020) (see Box 9.4), and regional and urban floods (Yuan et al., 2018; Tiitmamer, 2020) and droughts (Funk et al., 2018b; Siderius et al., 2018; Uhe et al., 2018) are expected to increase.

However, between 2010–2020 more people across Africa have been impacted by floods (e.g., related to Cyclone Idai in March 2019) compared to droughts (Lumbroso, 2020). Coastal cities are vulnerable to floods related to rainfall and sea level rise (Musa et al., 2014), as exemplified by the flood disasters experienced in the Niger delta in 2012 which displaced more than 3 million people and destroyed schools, clinics, markets and electricity installations (Amadi and Ogonor, 2015). From 2000–2015, the proportion of people exposed to floods grew by 20–24%, mostly in Africa and Asia, and these numbers will increase under climate change (Tellman et al., 2021). Sectoral impacts from flooding within Africa and globally are further elaborated on in Sections 9.8.2 and 9.8.5.1, Table 9.3 and Section 4.3 in Chapter 4.

[START BOX 9.4 HERE]

Box 9.4: African Cities Facing Water Scarcity

Many African cities will face increasing water scarcity under climate change (Grasham et al., 2019). The Cape Town and Dodoma cases illustrate challenges for both surface and groundwater supply and what adaptation responses have been employed.

The Cape Town Drought (2015-2018)

The Cape Town drought illustrates how a highly diverse African city and its citizens responded to protracted and unanticipated water scarcity. Anthropogenic climate change made the drought five to six times more *likely* (Pascale et al., 2020; Doblas-Reyes et al., 2021). After three consecutive years of low precipitation, Cape Town braced for a 'Day Zero' where large portions of the city would lose water supply (Cole et al., 2021a). The risk of day zero was anticipated to cascade to affect risks to health, economic output and security (Simpson et al., 2021b). The case study highlights the importance of communication, budgetary flexibility, robust financial buffers and insurance mechanisms, disaster planning, intergovernmental cooperation, nature-based solutions, infrastructure transformations and equitable access for climate adaptation in African cities facing water scarcity.

A substantial media campaign was launched to inform residents about the severity of the drought and urge water conservation (Booysen et al., 2019; Hellberg, 2019; Ouweneel et al., 2020). Together with stringent demand management through higher water tariffs, this communication campaign played an important role in reducing consumption from 540 to 280 litres per household per day (Booysen et al., 2019; Simpson et al., 2019a). Revenue from water sales contributes 14% of Cape Town's total revenue, making it the third-largest source of 'own' revenue for the city (Simpson et al., 2019b). However, with an unprecedented reduction in water use, the municipal budget was undermined (Simpson et al., 2020b). Collecting less revenue created a financial shock as the city struggled to recover operating finance, even while new capital requirements were needed for the development of expensive new water supply projects (Simpson et al., 2019b). This financial shock was compounded by the economic stress of poor agricultural and tourism performance brought about by the drought (Shepherd, 2019; Simpson et al., 2021b). As wealthy residents invested in private, off-grid water supplies, the risk of reduced municipal revenue collections from newly off-grid households aggregated with the risk of reduced tourism, increasing the risk to the reputation of the incumbent administration (Simpson et al., 2021b). This demonstrates how a population cohort with a high response capability to water scarcity can reduce risk while simultaneously increasing risks to the municipality and its capacity to provide water to vulnerable residents (Simpson et al., 2020b). Given that city populations in Africa pay 5–7 times more for water than the average price paid in the United States or Europe (Adamu and Ndi, 2017; Lwasa et al., 2018), municipal finance needs to delink operating revenue from potential climate shocks (see Box 8.6 in Chapter 8).

The drought led the municipality to consider a broader diversity of water supply options, including groundwater (CoCT, 2019), developing city-scale slow-onset disaster planning (Cole et al., 2021a) and building an enhanced 'relationship with water' (CoCT, 2019; Madonsela et al., 2019). This shift in approach is displayed in the recognition of nature-based solutions as a priority in water resilience-building efforts (Rodina, 2019) and is signalled in Cape Town's Water Strategy which aims to become a 'water sensitive city' that makes 'optimal use of stormwater and urban waterways for flood control, aquifer recharge, water reuse and recreation' (CoCT, 2019).

The drought required cooperation between multiple spheres of government, and the management of a broad range of stakeholders and political entities (Nhamo and Agyepong Adelaide, 2019; Cole et al., 2021a). The case highlights how a lack of coordination between essential organs of state and political entities can reduce response efficacy (Rodina, 2019). Despite significant investments in water security by public and private entities, one-quarter of Cape Town's population remains in persistent conditions of water stress, emphasising the challenge and importance of inclusive solutions that address the persistent social and economic stressors which affect vulnerability to water scarcity (Enqvist and Ziervogel, 2019).

Sustaining intensive groundwater use in a dryland city under climate change: Dodoma, Tanzania

Since 1954, the Makutapora wellfield in semi-arid, central Tanzania has supplied safe water to the city of Dodoma. Substantial rises in wellfield pumping and population growth have increased freshwater demand in Dodoma and dependence upon the Makutapora Wellfield, currently the sole perennial source of piped water to the city. Yet, there is high uncertainty of groundwater recharge rates (Nkotagu, 1996; Taylor et al., 2013) which rely on intense seasonal rainfall associated with the El Niño-Southern Oscillation (ENSO) and the Indian Ocean Dipole (IOD) modes of climate variability (e.g., 2 to 7 years) to contribute disproportionately to recharge (Taylor et al., 2013; Kolusu et al., 2019).

Defining a sustainable pumping rate for the Makutapora wellfield is complicated by the variable and episodic nature of groundwater replenishment in this dryland environment. For example, groundwater recharge during the 1997/1998 El Niño event, the strongest El Niño event of the 20th century, accounted for nearly 20% of all of the recharge received from 1955–2010 (Taylor et al., 2013), highlighting the vital role interannual groundwater storage plays in enabling adaptation to climate variability and change in drylands. The disproportionate contribution of intense seasonal rainfalls to the replenishment of the Makutapora wellfield, consistent with observations from across sub-Saharan Africa (Cuthbert et al., 2019), suggests that groundwater in drylands are currently naturally resilient to climate change. However, it remains unclear whether climate change will strengthen or weaken the influence of ENSO and IOD on rainfall (Brown et al., 2020) and thereby affect the predictability of groundwater recharge.

As freshwater demand in Tanzania's rapidly growing capital is projected to increase substantially in the coming decades, questions remain as to whether the capacity of the Makutapora wellfield can meet some or all of this demand. Nature-based solutions to improve the resilience of wellfield abstraction to increased pumpage and climate change include Managed Aquifer Recharge (MAR). The sharing of general lessons learned from other cities in dryland Africa employing MAR, such as Windhoek in Namibia (Murray et al., 2018), could prove invaluable.

[END BOX 9.4 HERE]

9.7.2 Projected Risks and Vulnerability

9.7.2.1 Projected Risks

By 2050, up to 921 million additional people in Africa could be exposed to climate change-related water stress, while up to 459 million could experience reduced exposure (Dickerson et al., 2021). This large variance in numbers and direction of change is related to uncertainties in climate models and non-climate factors like population growth and water withdrawals (Dickerson et al., 2021). The baseline for most of the projected risks presented here is 1971–2000.

In West Africa, significant spatial variability in river flow is projected in the upper reaches of several rivers, with no clear pattern overall (Roudier et al., 2014) and large uncertainties in estimations of change in runoff (Roudier et al., 2014; Bodian et al., 2018). In some higher altitude regions, like the Niger Inland Delta in West Africa, river flows and water levels are expected to increase (*medium confidence*) (Aich et al., 2014; Thompson et al., 2017). In the Lower Niger Basin, combined average annual rainfall and erosivity for all the climatic models in all scenario shows increasing rainfall amounts are projected to result in an increasing average change in rainfall-runoff erosivity of about 14%, 19% and 24% for the 2030s, 2050s and 2070s, with concomitant increase in soil loss of 12%, 19% and 21% (Amanambu et al., 2019). In the Volta River system, increasing wet season river flows (+36% by 2090s) and Volta lake outflow (+5% by 2090s) are anticipated under RCP8.5 (*medium confidence*) (Awotwi A et al., 2015; Jin et al., 2018). In the Volta River basin, compared to 1976–2005, drought events are projected to increase by 1.2 events per decade at around 2°C to 1.6 events per decade at around 2.5°C global warming, and drought area extent is projected to increase by 24% to 34% (Oguntunde et al., 2017). In Central Africa, runoff in the Congo River system may increase by up to 50% (RCP8.5), especially in the wet season, enhancing flood risks in the entire Congo basin, particularly in the central and western parts (CSC, 2013). Average river flows are expected to increase in most parts of Central Africa, with expected increases in total potential hydropower production (Ludwig et al., 2013).

In North Africa, in the upper White Nile basin, Olaka et al. (2019) project a 25% and 5 to 10% (RCP4.5) increase in the intensification of future annual rainfall in the eastern and western parts of the Lake Victoria Basin, respectively, with corresponding variability in future river discharge ranging from 5 to 26%. In the upper Blue Nile basin, models also indicate up to 15% increase in runoffs in wet-season and up to −24% decreasing in dry-season 2021–2040 (RCP8.5) (Ayele et al., 2016; Siam and Eltahir, 2017; Meresa and Gatachew, 2018). The increase of precipitation in wet-season indicates a higher possibility of flash floods while decreased runoffs in dry-season further intensify existing shortage of irrigation water demand (Ayele et al., 2016; Siam and Eltahir, 2017; Meresa and Gatachew, 2018). The annual flow and revenues from hydropower production and irrigated agriculture of the Blue Nile River at Khartoum are projected to increase under maximum but are expected to decrease under minimum and median projected changes in streamflow for 2041–2070 and 2071–2100, respectively (Tariku et al., 2021). The Middle Draa valley in Morocco is expected to experience more severe droughts and the estimation of the water balance suggests a lack of supply in the future (Karmaoui et al., 2016).

In East Africa, Liwenga et al. (2015) show that it will *likely* be warmer and wetter in the Great Ruaha River region and with increasing seasonal variation and extremes towards the end of the century. A similar observation is made for the River Pangani, with mean river flow being about 10% higher in the 2050s relative to the 1980–1999 period, associated with a 16–18% increase in rainfall in its upper catchment (Kishiwa et al., 2018). However, at more local scales, the projections cover a range of slight declines to significant increases in mean annual rainfall amounts (Gulacha and Mulungu, 2017). In the Tana River basin in Kenya, water yield is projected to increase progressively under RCP4.5 and RCP8.5 relative to the baseline period 1983–2011 but is characterised by distinct spatial heterogeneity (Muthuwatta et al., 2018).

In southern Africa, reductions in rainfall over the Limpopo and Zambezi river basins under 1.5°C and 2°C global warming could have adverse impacts on hydropower generation, irrigation, tourism, agriculture and ecosystems (Figure Box 9.5.1) (Maúre et al., 2018), although model projections of strong early summer drying trends remain uncertain (Munday and Washington, 2019).

Changes in the amplitude, timing and frequency of extreme events such as droughts and floods will continue to affect lake levels, rates of river discharge and runoff and groundwater recharge (*high confidence*) (Gownaris et al., 2016; Darko et al., 2019), but with disparate effects at regional, basin and sub-basin scales, and at seasonal, annual and longer timescales. The increased frequency of extreme rainfall events under climate change (Myhre et al., 2019) is projected to amplify groundwater recharge in drylands (Jasechko and Taylor, 2015; Cuthbert et al., 2019). However, declining trends in rainfall and snowfall in some areas of North Africa (Donat et al., 2014b) are projected to continue in a warming world (Seif-Ennasr et al., 2016), restricting groundwater recharge from meltwater flows, exacerbating the salinisation and depletion of groundwater (Hamed et al., 2018) and increasing the risk of reduced soil moisture (Petrova et al., 2018) in this region where groundwater abstraction is greatest (Wada et al., 2014).

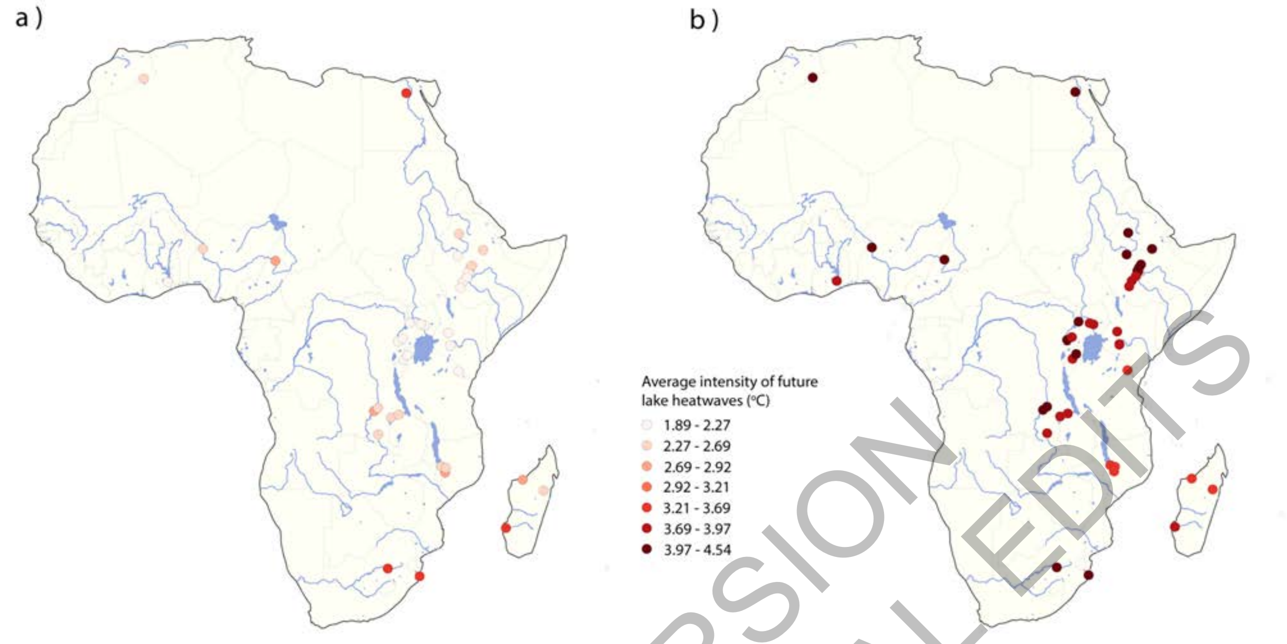

Figure 9.21: Climate change is projected to increase the intensity of lake heatwaves across Africa. Projected increases in average intensity of lake heatwaves (°C) under (a) 1.8°C global warming (RCP2.6 in 2070–2099) and (b) 4.2°C global warming (RCP8.5 in 2070–2099). Each lake is represented by a point. Data were extracted from (Woolway et al., 2021).

Lake surface temperatures across Africa are expected to rise in tandem with increasing global warming. Lake heatwaves, periods of extreme warm lake surface water temperature, are projected to become hotter and longer (Figure 9.21), with heatwaves more than 300 days per year in many lakes for global warming of 4.2°C (Woolway et al., 2021). Lake warming is expected to have adverse consequences for aquatic biodiversity, habitats, water quality and disruption of current lake physical processes and circulation patterns (Kraemer et al., 2021).

9.7.2.2 Vulnerability

Climate change is projected to reduce water availability and increase the extent of water scarcity (Mekonnen and Hoekstra, 2016), particularly in southern and North Africa, while other regions will be more affected by increased hydrological variability over temporally short to interannual timescales (see Section 9.6.2). African countries are considered to be particularly at risk due to their underlying vulnerabilities (IPCC, 2014; UNESCO and UN-Water, 2020), yet the continents' water resources are still inadequately quantified and modelled (Müller Schmied et al., 2016; Reinecke et al., 2019), constraining sustainable management practices (Cuthbert et al., 2019; Hughes, 2019).

Hydrological fluctuations are associated with drought, flood and cyclone events which have had multi-sector impacts (Siderius et al., 2021) (see Sections 4.3 and 4.5 in Chapter 4), including: reduced crop production (D'Odorico et al., 2018), migration and displacement (Siam and Eltahir, 2017; IDMC, 2018), food insecurity and extensive livestock deaths (Nhamo et al., 2018), electricity outages (Gannon et al., 2018), increased incidence of cholera (Olago et al., 2007; Sorensen et al., 2015; Houéménou et al., 2020) and increased groundwater abstraction amplifying the risk from sea level rise of saline intrusion (Hamed et al., 2018; Ouhamdouch et al., 2019).

The literature shows significant gender-differentiated vulnerability and intersectional vulnerability to climate change impacts on water in Africa (Fleifel et al., 2019; Grasham et al., 2019; Mackinnon et al., 2019; Dickin et al., 2020; Lund Schlamovitz and Becker, 2020), although studies are generally lacking in northern Africa (Daoud, 2021). Women and girls are in most cases more impacted than men/boys by customary water practices as adult females are the primary water collectors (46% in Liberia to 90% in Cote d'Ivoire), while more female than male children are associated with water collection (62% compared with 38%, respectively) (Graham et al., 2016). Women and girls face barriers toward accessing basic sanitation and hygiene resources, and 71% of studies reported a negative health outcome, reflecting a water-gender-health nexus (Pouramin et al., 2020). These differential vulnerabilities are crucial for informing adaptation, but are still relatively under-researched, more so for the urban poor than rural communities (Grasham et al., 2019; Mackinnon et al., 2019; Lund Schlamovitz and Becker, 2020).

9.7.3 Water Adaptation Options and their Feasibility

9.7.3.1 Reducing Risk through a Systems Approach to Water Resources Planning and Management

An integrated systems and risk-based approach to the design and management of water resources at scale is generally accepted as a practical and viable way of underpinning the resilience of water systems to climate change and human pressures (Duffy, 2012; García et al., 2014). Such approaches confer multiple benefits to nature and society at scale and enhance efficiency gains through technology and management improvements, but their full implementation has not yet been realised (Weinzierl and Schilling, 2013; McDonald et al., 2014; UN Environment, 2019). Drylands are particularly singled out as ignored areas that require Integrated Water Resource Management approaches (Stringer et al., 2021) (Section 9.3.1). Appropriate nature-based solutions that are applicable at scale should be identified and strongly embedded in these approaches to deliver multiple benefits while maintaining the integrity of ecosystems and biodiversity (UN Environment, 2019) (see Sections 9.6.4, 9.8.5, and Box 4.6). Furthermore, adaptation options are often influenced or constrained by institutions, regulation, availability, distribution, price and technologies (McCarl et al., 2016). Thus, institutional capacity to manage complex water supply systems under rapidly increasing demand and climate change stress is critical in achieving water security for African cities, particularly as cities become more dependent on alternative and distant water sources (Padowski et al., 2016).

9.7.3.2 Adopting Nexus Lenses

The water-energy-food (WEF) nexus explicitly recognises the strong interdependencies of these three sectors and their high levels of exposure to climate change (Zografos et al., 2014; Dottori et al., 2018) (see Box 9.5). With increasing societal demands on more variable water resources under climate change, an intensification of WEF competition and trade-offs are projected (D'Odorico et al., 2018; Dottori et al., 2018). Other interacting factors, for example, the increasing number of transnational investments in land resources can lead to localised increased competition for water resources (Messerli et al., 2014; Breu et al., 2016; Chiarelli et al., 2016). Understanding such nexus inter-linkages can help characterise risks to water resource security, identify co-benefits and clarify the range of multi-sectoral actors involved in and affected by development decisions (Kyriakarakos et al., 2020). Major barriers and entry points for greater integration include coordination of horizontal policy and integration of climate change adaptation actions (England et al., 2018), capturing the scarcity values of water and energy embedded in food/energy products (Allan et al., 2015), and inclusion of community-based organisations such as water resource user associations (Villamayor-Tomas et al., 2015) and agricultural cooperatives (Kyriakarakos et al., 2020).

[START BOX 9.5 HERE]

Box 9.5: Water-Energy-Food Nexus

The water-energy-food (WEF) nexus explicitly recognises the strong interdependencies of these three sectors and their high levels of exposure to climate change. Risks can be transmitted from one WEF sector to the other two with cascading risks to human health, cities and infrastructure (Conway et al., 2015; Mpandeli et al., 2018; Nhamo et al., 2018; Yang and Wi, 2018; Ding et al., 2019; Simpson et al., 2021b). For example, increasing demand for water for agricultural and energy production is driving an increasing competition over water resources between food and energy industries which, among other effects, compromises the nutritional needs of local populations (Zografos et al., 2014; Dottori et al., 2018). Drought events, such as in southern

Africa during the 2015/16 El Niño, have been associated with major multi-sector impacts on food security (over 40 million food-insecure people and extensive livestock deaths) and reduced energy security through disruption to hydropower generation (associated in Zambia with the lowest rate of real economic growth in over 15 years)(Nhamo et al., 2018). The WEF nexus of the Nile and Zambezi river basins, which include many of Africa's largest existing hydropower dams, have received the most attention. In these two regions where socioeconomic development is already driving up demand, projections indicate that water scarcity may be exacerbated by drying (Munday and Washington, 2019) and increased flow variability (Siam and Eltahir, 2017). However, for Africa more widely, very few studies fully integrate all three WEF nexus sectors and rarely include an explicit focus on climate change.

In Africa, the climate risks that the water, energy and food sectors will face in the future are heavily influenced by the infrastructure decisions that governments make in the near term. The African Union's Programme for Infrastructure Development (PIDA), along with other national energy plans (jointly referred to as PIDA+), aim to increase hydropower capacity nearly six-fold, irrigation capacity by over 60% and hydropower storage capacity by over 80% in major African river basins (Cervigni et al., 2015). The vast majority of hydropower additions would occur in the Congo, Nile, Zambezi and Niger river basins, and the majority of the irrigation capacity additions would occur in the Niger, Nile and Zambezi River basins (Huber-Lee et al., 2015) (Figure Box 9.5.1).

Climate change risk to the productivity of this rapidly expanding hydropower and irrigation infrastructure compound the overall WEF nexus risk. Future levels of rainfall, evaporation and runoff will have a substantial impact on hydropower and irrigation production. Climate models disagree on whether climates will become wetter or dryer in each river basin. Cervigni et al. (2015) modelled revenues from the sale of hydroelectricity and irrigated crops in major African river basins under different climate scenarios between 2015 and 2050 (Figure Box 9.5.1). The study found that hydropower revenues in the driest climate scenarios could be 58% lower in the Zambezi River basin, 30% lower in the Orange basin and 7% lower in the Congo basin relative to a scenario with current climate conditions. Hydropower revenues in the wettest climate scenario could be more than 20% higher in the Zambezi River basin and 50% higher in the Orange basin. The biggest risk to the production of irrigated crops is in the eastern Nile where irrigation revenue could be 34% lower in the driest scenario and 11% higher in the wettest than in a scenario without climate change (Cervigni et al., 2015).

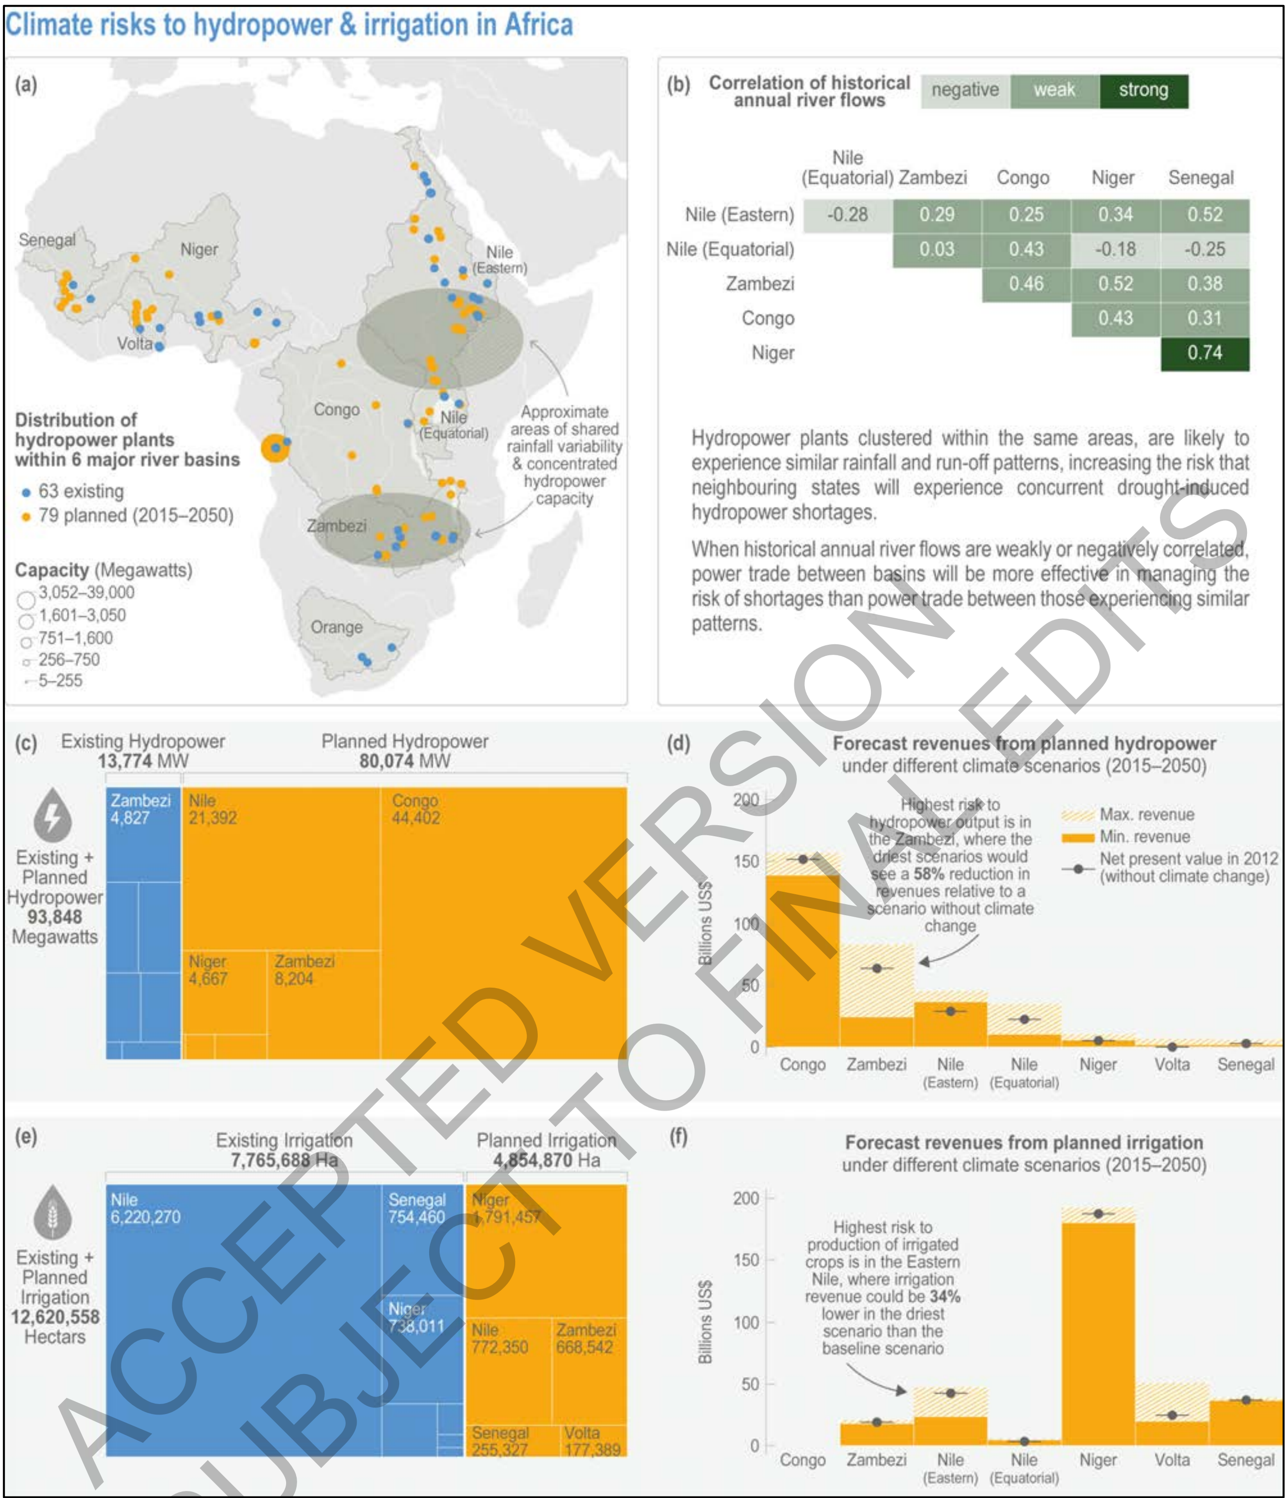

Figure Box 9.5.1: Climate risks to hydropower and irrigation in Africa. The map shows the location and size of existing (blue) and planned (red) hydropower plants in African governments' infrastructure expansion plans, 2015–2050. The bar graphs show the forecast revenues for hydropower and irrigation infrastructure from 2015-2050 in each river basin. Hydropower revenues refer to net present value of hydroelectricity produced in each river basin over the period, and irrigation revenues refer to the crop revenues per hectare for each crop multiplied by the number of hectares of each crop across the basin. Dark blue dots show forecasted revenues from 2015–2050 of existing irrigation and hydropower in major African river basins in a scenario without further climate change (i.e., based on historical data). Red dots show how hydropower and irrigation revenues are expected to increase as new hydropower and irrigation infrastructure is added in a scenario without climate change. Blue and green bars illustrate the range of forecasted revenue from 2015–2050 from new and existing hydropower and irrigation under 121 different climate futures. In river basins with a wide range of potential outcomes, such as the eastern Nile and Zambezi River, there is significant uncertainty around revenue forecasts based on historical trends. All figures are estimates of the net present value of revenues, using a discount rate of 3%, and are in 2012 USD billions. The 121 potential climate futures were derived using different General Circulation Models (GCMs), Representative Concentration Pathways (RCPs), and downscaling methods. IPCC AR4 and AR5 provided data from 22 and 23 GCMs, respectively. These were evaluated across two or three emissions pathways, including RCP4.5 and RCP8.5. The Bias Corrected Spatial Disaggregation (BCSD) method of downscaling was then used to derive 99 potential climate futures. An additional 22 climate futures (11 GCMs driven by the RCP4.5 and RCP8.5 emissions pathways) were produced using the Empirical Statistical Downscaling Methods developed at the Climate Systems Analysis Group at the University of Cape Town.. Data sourced from (Cervigni et al., 2015).

Studies have used the river basin as a unit of analysis and adopted sophisticated techniques to assess and present trade-offs between competing uses. For example, Yang and Wi (2018) consider the WEF nexus in the Great Ruaha tributary of the Rufiji River in Tanzania motivated by an observed decrease in streamflow during the dry season in the 1990s, but without an explicit focus on climate. Yang and Wi (2018) show sensitivity of water availability for irrigated crop production to warming, and sensitivity of hydropower generation and ecosystem health to changes in precipitation and dam development. Understanding of WEF nexus interlinkages can help characterise risks and identify entry points and the relevant institutional levels for cross-sectoral climate change adaptation actions (England et al., 2018). An integrated response can be enhanced through the inclusion of community-based organisations, such as water resource user associations and the wide range of other multi-sectoral actors involved in and affected by development decisions. Capturing the scarcity values of water and energy embedded in food and other products can help identify the co-benefits and costs of integrated adaptation (Allan et al., 2015).

[END BOX 9.5 HERE]

9.7.3.3 Climate-Proofing Water Infrastructure

While natural variability in the hydrological cycle has always been considered by water resources planners and engineers (Müller Schmied et al., 2016; Muller, 2018), many countries will have to take into consideration the range of historically unprecedented extremes expected in the future. Increasingly, the provision of urban water security is dependent on the functioning of complex bulk water infrastructure systems consisting of dams, inter-basin transfers, pipelines, pump stations, water treatment plants and distribution networks (McDonald et al., 2014). Risk-based studies on the potential climate change risks for water security show that there are benefits when risks are reduced at the tails of the distribution - floods and droughts—even if there is little benefit in terms of changes in the mean (Arndt et al., 2019). When risk is taken into account in an integrated (national) bulk water infrastructure supply system, the overall impact of climate change on the average availability of water to meet current and future demands is significantly reduced (Cullis et al., 2015). Further, stemming leakages and enhancing efficiency through technology and management improvements is important in building climate-resilient water conveyance systems (UN Environment, 2019). African cities could leap-frog through the development phases to achieve a water sensitive city ideal, reaping benefits such as improved liveability, reduced flooding impacts, safe water and overall lower net energy requirements and avoid making the mistakes developed countries' cities have made (Fisher-Jeffes et al., 2017) (Brodnik et al., 2018). However, the challenge of large proportions of the population lacking access to even basic water supply and sanitation infrastructure (Armitage et al., 2014) must be simultaneously and effectively addressed, particularly in light of other major exacerbating factors like the COVID-19 pandemic (Section 9.11.5).

9.7.3.4 Decision Support Tools for Managing Complex Water Systems

Many studies in Africa use the river basin as a unit of analysis at scale and adopt sophisticated model-based techniques to assess climate change impacts on hydrology under different climate and development scenarios, thereby presenting trade-offs between competing uses such as hydropower generation, irrigation and ecosystem requirements (Yang and Wi, 2018; Ahmed, 2020) (Section 9.12.1). However, longer (multi-decadal) hydrological datasets and model improvements are required (Taye et al., 2015), and models should incorporate the quantification of the wider benefits, risks and political opportunities arising from reservoir development to better inform decision-makers to achieve a higher level of (transboundary) cooperation (Digna et al., 2016; Nijsten et al., 2018). Collaboration between scientists and policy-makers to address the complexity of decision-making under uncertainty (Steynor et al., 2016) (Pienaar and Hughes, 2017), coupled with community involvement in participatory scenario development and participatory GIS to aid in collaborative planning that is context-specific (Muhati et al., 2018; Álvarez Larrain and McCall, 2019) are powerful tools for more beneficial adaptive and resilience building actions.

9.7.3.5 Other Adaptation Options

Climate change is projected to increase dependence upon groundwater withdrawals in most parts of Africa as an adaptive strategy to amplified variability in precipitation and surface water resources, highlighting the need for conjunctive surface-groundwater management and rainwater harvesting (Cobbing and Hiller, 2019; Taylor et al., 2019). Alternative water supply options such as desalination, managed aquifer recharge, stormwater harvesting and re-use (direct and indirect, potable and non-potable), all require significant amounts of energy and are complex to operate and maintain. A failure to provide a source of reliable energy and the capacity to implement, maintain, and operate these systems is a significant contributor to water scarcity risks in Africa (Muller and Wright, 2016). Soft adaptation options include increasing water use efficiency, chaning agricultural practices, more appropriate water pricing (Olmstead, 2014) and enhancing capacity to tackle groundwater overexploitation (Kuper et al., 2016), among others (see Section 9.10.2.4; Sections 4.6 and 4.7 in Chapter 4).

9.7.3.6 Mainstreaming Gender Across all Adaptation Options

Gender is important in building resilience and adaptation pathways to global environmental change (Ravera et al., 2016). It is well-established that women, in most societies, have accumulated considerable knowledge about water resources, including location, quality and storage methods because they are primarily responsible for the management of water for household water supply, sanitation and health, and for productive uses in subsistence agriculture (UN-Water, 2006). As gender-differentiated relationships are complex, adaptation should take into account intersectional differences such as homeownership, employment and age (Harris et al., 2016), educational, infrastructural and programmatic interventions (Pouramin et al., 2020), aspects of protection and safety (Mackinnon et al., 2019), barriers to adaptation and gendered differences in the choice of adaptation measures (Mersha and Van Laerhoven, 2016), the complex power dynamics of existing social and political relations (Djoudi et al., 2016; Rao et al., 2017) and inclusion and empowerment of women in the management of environmental resources (Makina and Moyo, 2016). Incorporation of gender and water inequities into climate change adaptation would have a significant impact on achieving the SDGs (particularly 1,3,4, 5 and 6), while failure to incorporate gender will undermine adaptation efforts (Bunce and Ford, 2015; Fleifel et al., 2019; Pouramin et al., 2020).

9.8 Food Systems

Ideally, a systems approach (Ericksen, 2008; Rosenzweig et al., 2020) could be used to assess how global environmental changes affect the food sector in Africa, emphasising the complex interactions that exist within the components of the food supply system, including its enabling socioeconomic and biophysical environment (Ingram, 2011; Foran et al., 2014; Tendall et al., 2015), and how food is connected to other critical systems such as energy, water and transportation (Albrecht et al., 2018) (see Box 9.5). Production will not be the only aspect of food security that is impacted by climate change. Processing, storage, distribution and consumption will also be affected. Access to healthy and adequate food in the face of climate change requires resilience across these components of the food system (Adenle et al., 2017). However, most studies on climate change impacts on food in Africa are heavily focused on production only. A significant knowledge gap, therefore, exists around the complex ways in which climate change will interact with broader components of African food systems, and strategies for making these systems more resilient, particularly in a context of rapid population growth and urbanisation across the continent (Adenle et al., 2017; Schmitt Olabisi et al., 2018).

9.8.1 Vulnerability to Observed and Projected Impacts from Climate Change

Agricultural activities are mainly rainfed and subsistence across Africa. The dominant farming system is mixed cereal-livestock (Thornton and Herrero, 2015; Nematchoua et al., 2019), with pastoral systems in East Africa, and commercial livestock and crop systems also representing a significant proportion of the food system in southern Africa (Thornton and Herrero, 2015). Many African regions are vulnerable to food insecurity, facing dwindling food production, food access, stocks and income due to low adaptive capacity (Evariste et al., 2018; Fuller et al., 2018; Bang et al., 2019; Gebre and Rahut, 2021).

Across regions with food systems highly vulnerable to climate change, female farmers, cocoa farmers, pastoralists, plantain farmers, coastal zone communities, rural households and forest communities in central Africa indicate higher vulnerability (Chia et al., 2016; Schut et al., 2016; Nematchoua et al., 2019). Their vulnerability is multidimensional and affected by low adaptive capacity, location, livelihood system, socioeconomic status, gender, age and ethnicity (Perez et al., 2015; Weston et al., 2015; Gebre and Rahut, 2021) (see also Box 9.1).

Across Africa, including West Africa, adverse climate conditions for agricultural and pastoral livelihoods have contributed to rural-to-urban migration patterns and migration among African regions (see Box 9.8) (Baudoin et al., 2014; Abbas, 2017; Gemenne and Blocher, 2017b). Rural to urban migration may increase vulnerability of migrants through exposure to additional risks, including food insecurity (Amadi and Ogonor, 2015; Abbas, 2017). In general, West African countries are characterised by the poor adaptive capacity of rural households (Douxchamps et al., 2015; Dumenu and Obeng, 2016).

In North Africa, livelihoods and economies are strongly dependent on agriculture. Pressure on water demand due to climate change and variability is threatening income, development processes and food security in the region (*high confidence*) (Mohmmed et al., 2018; Khedr, 2019). Increased temperatures and droughts have enhanced the vulnerability of the irrigation sector (Verner et al., 2018; İlseven et al., 2019), and the combined effect of these hazards negatively affects crop and animal production (Mohmmed et al., 2018; Verner et al., 2018). For example, dairy farms in Tunisia are experiencing warmer temperatures above the thermoneutral zone of cows for more than 5 months each year, reducing production efficiency and resulting in significant economic losses (Amamou et al., 2018).

Non-climatic stressors aggravate food insecurity in many parts of the continent, including lack of access to production inputs and land, lack of education and limited income sources, with adverse climate impacts on agriculture reducing education attainment for children (Evariste et al., 2018; Fuller et al., 2018) (Section 9.11.1.2). Geographic and social isolation is another type of social vulnerability, especially for pastoralist communities in East and southern Africa (Sonwa et al., 2017; Basupi et al., 2019). Rural communities often have poor transport networks, limited access to markets or information and fewer livelihood alternatives, and are less able to be informed of risks or be assisted in the event of extreme climate events (Sonwa et al., 2017; Basupi et al., 2019).

Extreme climate events have been key drivers in rising acute food insecurity and malnutrition of millions of people requiring humanitarian assistance in Africa (*high confidence*). Between 2015 and 2019, an estimated 45.1 million people in the Horn of Africa and 62 million people in eastern and southern Africa required humanitarian assistance due to climate-related food emergencies. Children and pregnant women experience disproportionately greater adverse health and nutrition impacts (*very high confidence*) (Gebremeskel Haile et al., 2019) (see Chapter 7, Section 7.2.4).

Future climate warming will *likely* have a substantial impact on food security in Africa and is anticipated to coincide with low adaptive capacity as climate change intensifies anthropogenic stressors, as 85% of Africa's poor live in rural areas and mostly depend on agriculture for their livelihoods (Adams, 2018; Mahmood et al., 2019). This highlights the need to prioritise innovative measures for reducing vulnerabilities in Africa food systems (Fuller et al., 2018; Mahmood et al., 2019).

Climate change impacts could increase the global number of people at risk of hunger in 2050 by 8 million people under a scenario of sustainable development (SSP1) and 80 million people under a scenario of reduced international cooperation and low environmental protection (SSP3), with populations concentrated in sub-Saharan Africa, South Asia and Central America (see Chapter 5, Sections 5.2.2, 5.4.2 and 5.4.3). Global climate impacts on food availability are expected to lead to higher food prices, increasing the risk of hunger for people in African countries, and slow progress towards eradicating child undernutrition and malnutrition in all its forms (see Chapter 7, Section 7.4).

9.8.2 Observed Impacts and Projected Risks to Crops and Livestock

9.8.2.1 Observed Impacts and Projected Risks for Staple Crops

Climate change is already negatively impacting crop production and slowing productivity growth in Africa (*high confidence*) (Iizumi et al., 2018; Ray et al., 2019; Sultan et al., 2019; Ortiz-Bobea et al., 2021). Climate change has reduced total agricultural productivity growth in Africa by 34% since 1961, more than in any other region (Ortiz-Bobea et al., 2021), more than in any other region. Maize yields have decreased 5.8% and wheat yields 2.3%, on average, in sub-Saharan Africa due to climate change in the period 1974–2008 (Ray et al., 2019). Overall, climate change has decreased food total calories across all crops in sub-Saharan Africa by 1.4% on average compared to a no climate change counterfactual since 1970, with up to 10% reductions in Ghana and Zimbabwe (Ray et al., 2019).

Farmers perceive a wide variety of climate threats to crop production including droughts, precipitation variability, a delayed onset and overall reductions in early growing season rainfall and excess heat (Rankoana, 2016a; Elum et al., 2017; Kichamu et al., 2017; Alvar-Beltrán et al., 2020). Farmers attribute these perceived changes as a major driver of yield losses (Ayanlade and Jegede, 2016) (see Section 9.4.5). Over half of surveyed farmers in West Africa perceive increases in crop pests and diseases as due to climate change as the range and seasonality of many pests and diseases change under warming (Callo-Concha, 2018),. Pests and diseases contribute between 10–35% yield losses for wheat, rice, maize, potato and soybean in sub-Saharan Africa (Savary et al., 2019). Recent locust outbreaks in 2019 in East Africa have been linked to climate conditions caused in part by ocean warming (Wang et al., 2020b) (see Box 5.8 in Chapter 5).

Future climate change may increase insect pest-driven losses in Africa for maize, rice and wheat: Compared to 1950–2000, losses may increase by up to 50% at 2°C of global warming (Deutsch et al., 2018). However, many challenges remain in modelling pest and disease under climate change with additional research needed expanding the range of crops and diseases studied (Newbery et al., 2016).

Agriculture in Africa is especially vulnerable to future climate change in part because 90–95% of African food production is rainfed (Adams, 2018). Maize, rice, wheat and soybean yields in tropical regions (20S-20N) are projected to decrease approximately 5% per °C of global warming in a multi-model ensemble (Rosenzweig et al., 2014; Franke et al., 2020). Dryland agricultural areas are especially sensitive to changes in rainfall. For example, without adaptation, substantial yield declines are projected for staple crops in North Africa (Figure 9.3). A recent meta-analysis of 56 studies indicates that, compared to 1995–2005, economic welfare in the agriculture sector in North Africa is projected to decline 5% for 2℃ global warming and 20% for 3℃ global warming, and in sub-Saharan Africa by 5% (2℃) and 10% (3℃) (Moore et al., 2017a), both more pessimistic than previous economic estimates.

A synthesis of projected staple crop impacts across 35 studies for nearly 1040 locations and cases shows on average decreases in crop yields with increasing global warming across staple crops in Africa, including when accounting for CO_2 increases and adaptation measures. For example for maize in West Africa, compared to 2005 yield levels, median projected yields decrease 9% at 1.5℃ global warming and 41% at 4℃, without adaptation (Figure 9.22). However, uncertainties in projected impacts across crops and regions are driven by uncertainties in crop responses to increasing CO_2 and adaptation response, especially for maize in East Africa and wheat in North Africa and East Africa (Figure 9.22) (Hasegawa et al., 2021).

There is also growing evidence that climate change is *likely* beginning to outpace adaptation in agricultural systems in parts of Africa (Rippke et al., 2016). For example, despite the use of adjusted sowing dates and existing heat-tolerant varieties, Sudan's domestic production share of wheat may decrease from 16.0% to 4.5–12.2% by 2050 under RCP8.5 (2.4℃ global warming) (Iizumi et al., 2021).

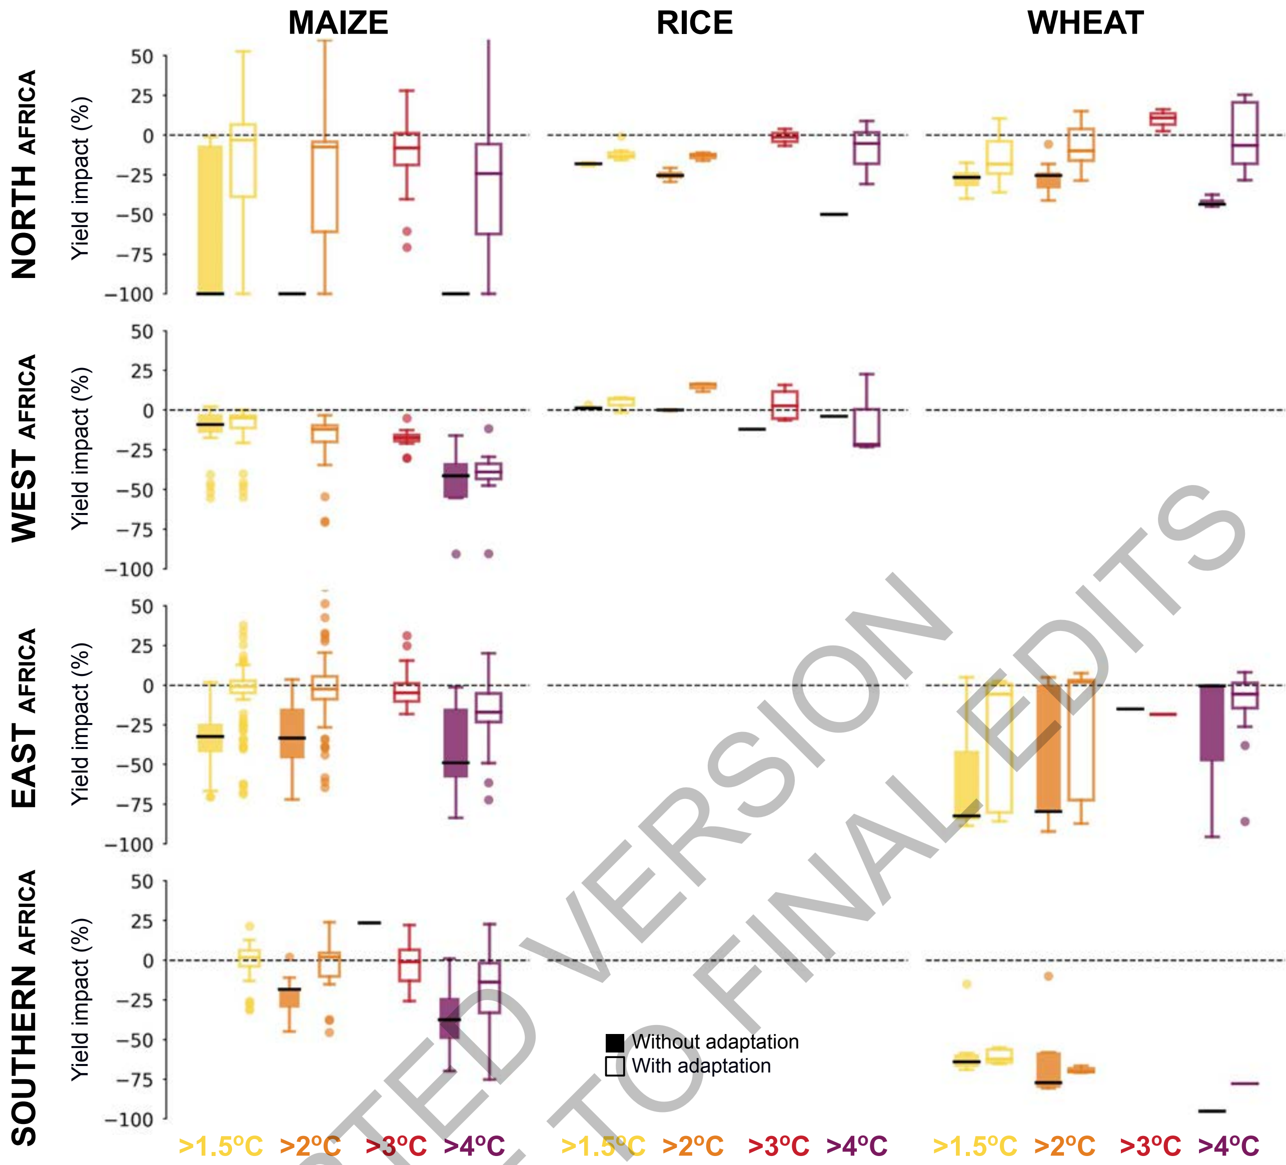

Figure 9.22: Projected yield changes for major crops in Africa due to climate change (compared to 2005 yield levels). Impacts are binned into global warming levels above pre-industrial global mean temperature (1850–1900). Boxplots show a synthesis of projected staple crop impacts, with and without adaptation measures (e.g. planting date, cultivar, tillage or irrigation). On average crop yields are projected to decrease with increasing global warming across staple crops in Africa. The overall adaptation potential to offset yield losses across Africa for rice, maize and wheat reduces with increasing global warming. On average, in projections including adaptation options and yield losses, in the median case, are reduced from –33% to –10% of 2005 levels at 2°C of global warming and from –46% to –23% at 4°C. Data are a synthesis across 35 studies for nearly 1040 locations and cases of projected impacts for regions of Africa for maize, rice and wheat (Hasegawa et al., 2021) (Supplementary Material Table SM 9.5).

Elevated CO_2 concentrations in the atmosphere might mitigate some or all climate-driven losses (Swann et al., 2016; Durand et al., 2018), but there is considerable uncertainty around the CO_2 response (Deryng et al., 2016; Toreti et al., 2020), especially when nutrients such as nitrogen and phosphorus are limiting crop growth. Additional Free-Air Carbon dioxide Enrichment (FACE) experiments are needed in the tropics, particularly on the African continent, to better understand the impacts of increased CO_2 concentrations on the productivity of crops and cultivars grown in Africa under additional temperature impacts and water and nutrient limitations (Ainsworth and Long, 2021). Warming and elevated CO_2 may also change the nutritional content of some crops. By 2050 under RCP8.5 (2.4°C global warming), overall wheat yields and grain protein content may decrease by 10% and 15%, respectively, in North and East Africa, and by over 15% in southern Africa (Asseng et al., 2019). See Chapter 5 for more details on CO_2 impacts and uncertainties.

9.8.2.2 Observed Impacts and Projected Risks on Regional Cash Crops and Food Crops

Few studies have attributed changes in yields of cash crops and other regionally important food crops in Africa to anthropogenic climate change, but recent research suggests yields of cash crops in Africa have already been impacted by climate change, in both a negative and positive manner (Falco et al., 2012; Traore et al., 2013; Ray et al., 2019). For example, between the period 1974–2008, sugarcane yields decreased on average by 3.9% and 5.1% in sub-Saharan Africa and North Africa, respectively, due to climate change, while sorghum yields increased 0.7%, and cassava yield increased 1.7% in sub-Saharan Africa and 18% in North Africa (Ray et al., 2019).

There are also limited studies for assessing projected climate change impacts on important cash crops and food crops other than maize, rice and wheat (Jarvis et al., 2012; Schroth et al., 2016; Awoye et al., 2017). These studies often represent changes at specific sites in a country or assess changes in the yield and/or suitability for cultivating a specific crop across a larger geographic area. Climate change is projected to have overall positive impacts on sugarcane and Bambara nuts in southern Africa, oil palm in Nigeria and chickpea in Ethiopia (*low confidence*) (Figure 9.23).

Climate change is projected to reduce sorghum yields in West Africa (Figure 9.23). For example, across the West African Sahel savanna sorghum yields are projected to decline on average 2% at 1.5°C and 5% at 2°C global warming (Faye et al., 2018). For coffee and tea in eastern Africa, olives in Algeria and sunflower in Botswana and Morocco, we find studies indicating mostly negative impacts on production systems. For example, in Kenya, compared to 2000, optimal habitat for tea production is projected to decrease in area by 27% with yields declining 10% for global warming of 1.8–1.9°C, although yield declines may be reduced at higher levels of warming (Beringer et al., 2020; Jayasinghe and Kumar, 2020; Rigden et al., 2020). Suitable area for tea production may reduce by half in Uganda (Eitzinger et al., 2011; Läderach et al., 2013). In East Africa, the coffee-growing area is projected to shift up in elevation with suitability decreasing 10–30% between 1.5–2°C of global warming (Bunn et al., 2015; Ovalle-Rivera et al., 2015).

For all other crops, there is at least one study that finds low to highly negative impacts for one or several warming levels (Figure 9.23). Mixed results on the direction of change often occur when several contrasting sites with varying baseline climates are studied, and when a study considers the full range of climate scenarios. For example, there are mixed results on the direction of change for impacts of 1.5°C global warming on cassava, cotton, cocoa and millet in West Africa (*low confidence*) (Figure 9.23). In general, there is limited evidence in the direction of change, due to single studies being available for most crop-country combinations (Knox et al., 2010; Chemura et al., 2013; Asaminew et al., 2017; Bouregaa, 2019). Occasionally, two studies agree on the direction and magnitude of change, for example, for potatoes in East Africa, yields are projected to decrease by 11–17% with 3°C of warming (Fleisher et al., 2010; Tatsumi et al., 2011).

Figure 9.23: Projected risks at increasing global warming levels for regionally important cash and food crops in Africa. Insufficient data (ID) indicates there were limited to no published studies that have quantified projected climate change impacts or adaptation options for specific crops under different warming levels (see Supplementary Material Table SM 9.6).

9.8.2.3 Observed Impacts and Projected Risks for Wild-Harvested Food

Wild-harvested foods (e.g., fruits, vegetables and insects) provide dietary diversification and for many people in Africa, wild-harvested food plants may provide a livelihood and/or nutritional safety net when other sources of food fail, such as during drought (Sunderland et al., 2013; Shumsky et al., 2014; Wunder et al., 2014; Baudron et al., 2019b). In Zimbabwe, during lean times, consumption of wild fruits increases, as does their sale to generate income for additional food expenses in poor, rural households (Mithöfer and Waibel, 2004). In Zambia, Mali and Tanzania, household surveys indicate that forest products including wild foods can play an important role in reducing household vulnerability to climate shocks by providing alternative sources of food and income during droughts and floods (Robledo et al., 2012). In the Parklands of West Africa, wild trees are a significant source of wild foods and are thus a place where one might expect wild plant foods to make an important contribution to diets and nutrition (Boedecker et al., 2014; Leßmeister et al., 2015). Non-timber forest products are consumed by an estimated 43% of all households in Burkina Faso (FAO, 2019), and wild vegetables accounted for about 50% of total vegetable consumption in southeastern Burkina Faso (Mertz et al., 2001).

The focus of projected climate change impacts has been almost exclusively on agricultural production, yet climate change could have substantial impacts on the distribution and availability of wild-harvested food plants in Africa (Wessels et al., 2021). Non-cultivated species in Africa are vulnerable to current and future climate changes, with widespread changes in woody plant cover already observed (see Section 9.6.1.1). Evidence about the impacts of climate change on individual wild food species is less consistent. Communities in the Kalahari (Crate and Nuttall, 2016) and Zimbabwe (Sango and Godwell, 2015) report growing scarcity of wild foods (such as wild meat and fruit) perceived to be, at least in part, due to drought and climate change. Shea tree (*Vitellaria paradoxa*) nuts provide fats and oils for the diets of many rural populations in West Africa. In Burkina Faso, global warming of 3°C is projected to reduce area of suitable habitat for the Shea tree by 14% (Dimobe et al., 2020). In southern Africa, 40% of native, wild-harvested food plant species are projected to decrease in geographic range extent at 1.7°C global warming with range reductions for 66% of species projected for 3.5°C (Wessels et al., 2021).

9.8.2.4 Observed Impacts and Projected Risks on Livestock

Livestock systems in Africa are already being affected by changes in climate through increased precipitation variability decreasing fodder availability (Sloat et al., 2018; Stanimirova et al., 2019). More than twice as many countries in Africa have experienced increases in precipitation variability in the last century than decreases (Sloat et al., 2018). Fodder availability is also being impacted by Woody Plant Encroachment—the increase in shrub and tree cover—which has increased by 10% on subsistence grazing lands and 20% on economically important grazing lands in South Africa in the last 60 years (Stevens et al., 2016), and is driven in part by climatic factors (see Section 9.6.1.1). Increased temperature and precipitation have contributed to the expanding range, especially in East and southern Africa, of several ixodid tick species which carry economically important livestock diseases (Nyangiwe et al., 2018).

Pastoralists in Africa perceive the climate as already changing and report more erratic and reduced rainfall, prolonged and more frequent droughts and a rise in temperature (Sanogo et al., 2017; Kimaro et al., 2018). They also report reduced milk production, increased deaths and disease outbreaks in their herds due to malnutrition and starvation resulting from the shortages in forage and water (Kimaro et al., 2018). Additional research is required to attribute precipitation variability to anthropogenic forcing (see Section 9.3), and to evaluate the relative contributions of climate change and management to disease vector extent.

Future climate change will have compounding impacts on livestock, including negative impacts on fodder availability and quality, availability of drinking water, direct heat stress and the prevalence of livestock diseases (Nardone et al., 2010; Rojas-Downing et al., 2017; Godde et al., 2021). Climate change is projected to negatively affect fodder availability (Briske, 2017) because overall rangeland net primary productivity (NPP) by 2050 is projected to decrease 42% under RCP4.5 (2°C global warming) and 46% under RCP8.5 (2.4°C global warming) for western sub-Saharan Africa, compared to a 2000 baseline (Boone et al., 2018). NPP is also projected to decline by 37% in southern Africa, 32% in North Africa and 5% in both East Africa and Central Africa by 2050 under RCP8.5 (2.4°C global warming) (Boone et al., 2018). For example, in Zimbabwe by 2040–2070, net revenues from livestock production, compared to a 2011 survey, are projected to decline by 8–32% under RCP4.5 for 2°C and 11–43% under RCP8.5 for 2.7°C global warming due to a decline in fodder availability (Descheemaeker et al., 2018). The available literature does not comprehensively capture the economic implications of climate-related impacts on livestock production across Africa.

Fodder quality, critical for animal health and weight gain, is at risk from climate change as increases in temperature, elevated CO_2 and water stress have been shown to reduce dry matter digestibility and nitrogen content for C_3 grasses (Augustine et al., 2018), tropical C_4 grasses (Habermann et al., 2019) and fodder crops such as Lucerne/Alfalfa (Polley et al., 2013; Thivierge et al., 2016).

Climate change is projected to threaten water availability for livestock. Droughts in Africa have become more intense, frequent and widespread in the last 50 years (Masih et al., 2014), and progressive increase in droughts between three- and twenty-fold under climate change up to 3°C of warming are projected for most of Africa (9.5). In the Klela basin in Mali by 2050, groundwater recharge is projected to decline by 49% and groundwater storage by 24% under RCP8.5 (2.4°C global warming) compared to the 2006 baseline (Toure et al., 2017). Water availability for livestock during drought is a major concern for many African pastoralists including but not limited to those in Zimbabwe (Dzavo et al., 2019) and Nigeria (Ayanlade and Ojebisi, 2019). Increased livestock mortality and livestock price shocks have been associated with droughts in Africa, as well as being a potential pathway for climate-related conflict (Catley et al., 2014; Maystadt and Ecker, 2014) (see Box 9.9).

Heat stress may already be the largest factor impacting livestock production in many regions in Africa (El-Tarabany et al., 2017; Pragna et al., 2018), as the combination of high temperatures and high relative humidity can be dangerous for livestock and has already decreased dairy production in Tunisia (Amamou et al., 2018). Climate change is projected to increase heat stress for all types of livestock, especially in the tropics (Lallo et al., 2018) (Figure 9.24). More studies quantifying the impact of heat stress on other types of livestock production loss are needed in Africa (Rahimi et al., 2021).

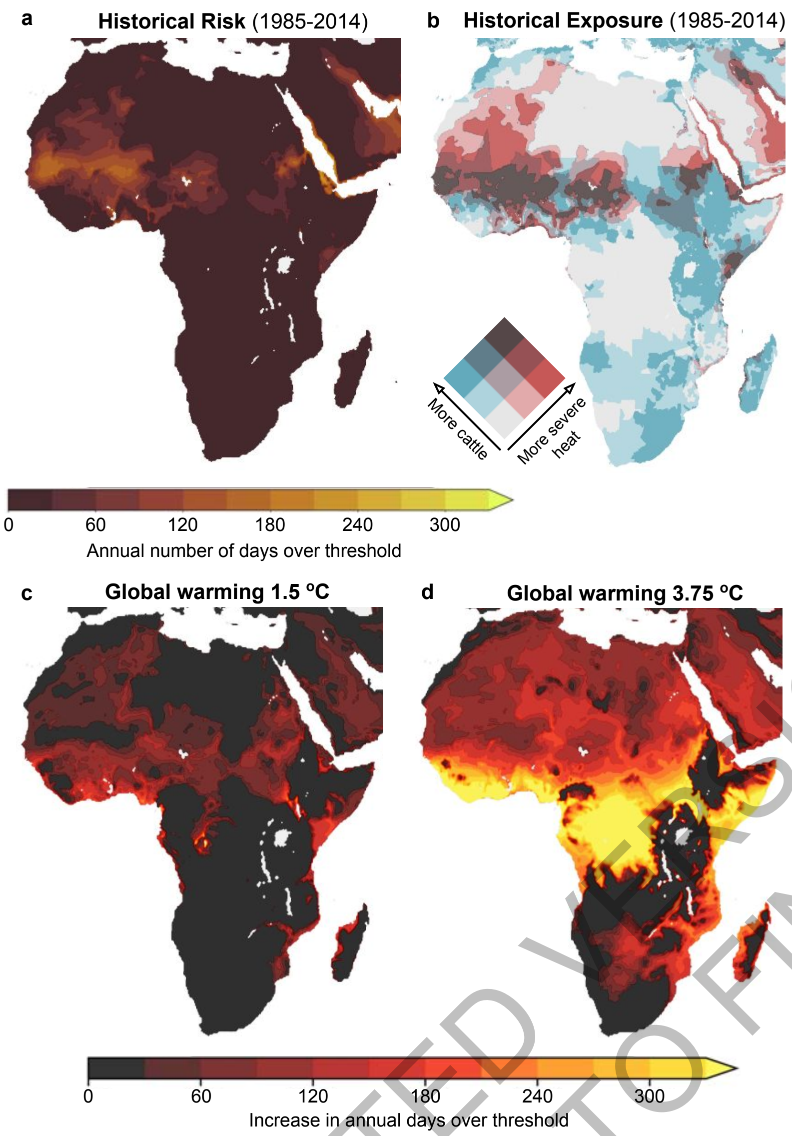

Figure 9.24: Severe heat stress duration for cattle in Africa is projected to increase with increased global warming. (a) Number of days per year with severe heat stress in the historical climate (1985-2014). (b) Historical cattle exposure to severe heat. (Cattle density fromGilbert et al., 2018) . (c and d) Increase in the number of days per year with severe heat stress for global warming of 1.5C and 3.75C above pre-industrial levels (1850-2100). Severe heat stress for cattle is projected to become much more extensive in the future in Africa at increased global warming levels. Strong mitigation would substantially limit the spatial extent and the duration of cattle heat stress across Africa. Heat stress is estimated using THI (Temperature Humidity Index) with a value greater than 79 considered the onset of severe heat stress (Livestock Weather Safety Index) (Lallo et al., 2018). Global warming of 1.5°C used scenario SSP1–2.6 and global warming of 3.75°C used SSP5–8.5, both for 2070–2099 (12 climate models fromO'Neill et al., 2016; Tebaldi et al., 2021) .

Climate change will impact livestock disease prevalence primarily through changes in vector dynamics or range (Abdela and Jilo, 2016; Semenza and Suk, 2018). African Rift Valley Fever (RVF) and Trypanosomiasis are positively associated with extreme climate events (droughts and ENSO) (Bett et al., 2017) and are projected to expand in range under climate change (Kimaro et al., 2017; Mweya et al., 2017). More quantitative estimates of projected risk from diseases are needed.

9.8.3 Adapting to Climate Variability and Change

Agricultural and livelihood diversification are strategies used by African households to cope with climate change, enabling them to spread risks and adjust to shifting climate conditions (Thierfelder et al., 2017; Thornton et al., 2018). This includes adjusting cropping choices, planting times, or size, type and location of planted areas (Altieri et al., 2015; Nyagumbo et al., 2017; Dayamba et al., 2018). In southern Africa, changes in planting dates provide farmers with greater yield stability in uncertain climate conditions (Nyagumbo et al., 2017). In Ghana, farmers are changing planting schedules and using early maturing varieties to cope with late-onset and early cessation of the rainy season (Antwi-Agyei et al., 2014; Bawakyillenuo et al., 2016).

The use of drought-tolerant crop varieties is another adaptation available to African farmers (Hove and Gweme, 2018; Choko et al., 2019). Adoption, however, is hindered by lack of information and training, availability or affordability of seed, inadequate labelling and packaging size for seed supplies and financial constraints (Fisher et al., 2015). Moreover, drought-tolerant varieties do not address changing temperature regimes (Guan et al., 2017).

Crop diversification enhances crop productivity and resilience and reduces vulnerability in smallholder farming systems (McCord et al., 2015; Mulwa and Visser, 2020). In Tanzania, diversified crop portfolios are associated with greater food security and dietary quality (Brüssow et al., 2017). In Kenya, levels of crop diversity are higher in villages affected by frequent droughts, which are the main cause of crop failure (Bozzola and Smale, 2020). They also help control pest outbreaks, which may become more frequent and severe under increased climate variability and extreme events (Schroth and Ruf, 2014). High farming diversity enables households to better meet food needs, but only up to a certain level of diversity (Waha et al., 2018), and the viability of and benefits from mixed-farming are highly context-dependent (Thornton and Herrero, 2015; Weindl et al., 2015).

Agroecological and conservation agriculture practices, such as intercropping, integration of legumes, mulching and incorporation of crop residues, are associated with household food security and improved health status (Nyantakyi-Frimpong et al., 2017; Shikuku et al., 2017). These practices can enhance the benefits of other adaptations, such as planting drought- and heat-tolerant or improved varieties, although effects vary across soil types, geographical zones and social groups (Makate et al., 2019; Mutenje et al., 2019). Non-climatic variables, such as financial resources, access to information and technology, level of education, land security and gender dynamics affect feasibility and adoption (Makate et al., 2019; Mutenje et al., 2019).

To mitigate growing water stress, countries like Tanzania, Uganda, Rwanda and Ethiopia are striving to improve irrigation efficiency (McCarl et al., 2015; Connolly-Boutin and Smit, 2016; Herrero et al., 2016). The feasibility and effectiveness of this adaptation depend on biophysical and socioeconomic conditions (Amamou et al., 2018; Harmanny and Malek, 2019; Schilling et al., 2020). Irrigation is unaffordable for many smallholder farmers and only covers a negligible proportion of the total cultivated area. Nonetheless, in some regions of West Africa, small-scale irrigation, including the digging of ditches, holes and depressions to collect rainwater (Makondo and Thomas, 2018), is widely adopted and promoted to support national food security (Dowd-Uribe et al., 2018).

African farmers are also diversifying their income sources to offset reduced yields or crop losses by shifting labour resources to off-farm work, or by migrating seasonally or longer-term (Kangalawe et al., 2017; Hove and Gweme, 2018). Off-farm activities provide financial resources that rural households need to cope with extreme climate variability (Hamed et al., 2018; Rouabhi et al., 2019). However, in some cases, these off-farm activities can be maladaptive at larger scales, such as when households turn to charcoal production which contributes to deforestation (Egeru, 2016). Whether off-farm activities constitute maladaptation depends on whether resources are available to upgrade skills or support investments that make a new business more lucrative. Without such resources, this option may lead to impoverishment (see Box 5.8 on AFOLU in Chapter 5).

Smallholder farmers' responses tend to address short-term shocks or stresses by deploying coping responses (e.g., selling labour, reducing consumption and temporary migration), rather than longer-term sustainable adaptations (Ziervogel and Parnell, 2014; Jiri et al., 2017). This is partly due to institutional barriers (e.g., markets, credit, infrastructure and information) and resource requirements that are unaffordable to smallholder farmers (Pauline et al., 2017). There is a need for policies that strengthen natural, financial, human and social capitals, the latter being key to household and community resilience, especially where government services may be limited (Mutabazi et al., 2015; Alemayehu and Bewket, 2017). There is evidence that collective action, local organizations and climate information are associated with higher food security, and that institutional interventions are needed to ensure scaling up of adaptations (Thornton et al., 2018).

A range of options is considered potentially effective in reducing future climate change risk, including plant breeding, crop diversification alongside livestock, mixed planting, intercrops, crop rotation and integrated crop-livestock systems (Thornton and Herrero, 2014; Cunningham et al., 2015; Himanen et al., 2016; Farrell et al., 2018; Snowdon et al., 2021) (Chapter 5, Sections 5.4.4 and 5.14.1). However, adaptation limits for crops in Africa are increasingly reached for global warming above 2°C (*high confidence*), and in tropical Africa may already be reached at current levels of global warming (*low confidence*).

Global warming beyond 2°C will place nearly all of sub-Saharan Africa cropland substantially outside of its historical Safe Climate Zone (Kummu et al., 2021) and may exponentially increase the cost of adaptation and residual damage for major crops (Iizumi et al., 2020). Without accounting for CO_2 increases, global-scale studies employing ensembles of gridded crop models for 2°C of global warming find that for adaptation using genetic cultivar change in most of Africa net losses are projected, even with adaptation up to 2°C of global warming for rice, maize, soybean, and wheat (Minoli et al., 2019; Zabel et al., 2021), although model uncertainty is still high (Müller et al., 2021). In contrast, when accounting for CO_2 increases, applying new genetics for rice under warming is projected to fully counteract all climate change-induced losses in Africa up to 3.5°C of global warming, except in West Africa (van Oort and Zwart, 2018).

However, compared to temperate regions, risks of adaptation shortfalls – that is climate change impacts even after adaptation – are generally greater for current agricultural conditions across much of Africa (tropical, arid and semi-arid) (Sun et al., 2019). The overall adaptation potential to offset yield losses across Africa for rice, maize, and wheat wheat reduces with increasing global warming. On average, in projections including adaptation options, yield losses, in the median case, are reduced from –33% to –10% of 2005 levels at 2°C of global warming and from –46% to –23% at 4°C, but estimates vary widely (Hasegawa et al., 2021) (Figure 9.22). Across Africa, the risks of no available genetic varieties of maize for growing season adaptation are higher for East Africa and southern Africa than for Central or West Africa (Zabel et al., 2021). To keep pace with expected rates of climate change, crop breeding, development and adoption must accelerate to meet the challenge (Challinor et al., 2016). Regional modelling has shown very little efficacy for late sowing, intensification of seeding density and fertilizers, water harvesting and other measures for cereals in West Africa at 2°C of global warming (Sultan and Gaetani, 2016; Guan et al., 2017). Historical climate change adaptation by crop migration has been shown in some cases (Sloat et al., 2020) but poses risks to biodiversity and water resources and this option may be limited for maize in Africa by suitable climate shifting completely across national borders and available land at the edges of the continent (Franke et al., 2021). More research is required to evaluate the potential effectiveness and limits of adaptation options in African agriculture under future climate change (see Chapter 5, Section 5.4.4 for more details)

9.8.4 Climate Information Services and Insurance for Agriculture Adaptation

In addition to adaptation in crop, soil and water management, the combination of (i) Climate Information Services (CIS), (ii) institutional capacity building and (iii) strategic financial investment can help African food producers adapt to projected climate risks (Carter et al., 2015; Surminski et al., 2016; Scott et al., 2017; Cinner et al., 2018; Diouf et al., 2019; Hansen et al., 2019a). There is growing evidence of farmers' use of weather and climate information, especially at the short- and medium-time horizon (Carr et al., 2016; Singh et al., 2018). Digital services can contribute to the sustainable intensification of food production globally (Duncombe, 2018; Klerkx et al., 2019). This points to the need for the scientific and development communities to better understand the conditions that enable widespread adoption in Africa.

Although climate services have the potential to strengthen farmers' resilience, barriers to accessibility, affordability and utilisation remain (Krell et al., 2021). Often the information offered is not consistent with what farmers need to know and how they access and process information (Meadow et al., 2015; Singh et al., 2018). Production of salient and credible climate information is hindered by the limited availability of and access to weather and climate data (Coulibaly et al., 2017; Hansen et al., 2019a). The existing weather infrastructure remains suboptimal to enable the development of reliable early warning systems (Africa Adaptation Initiative, 2018; Krell et al., 2021). Of the 1,017 land-based observational networks in the world, only 10% are in Africa, and 54% of Africa's surface weather stations cannot capture data accurately (Africa Adaptation Initiative, 2018; World Bank, 2020d).

Advances in remote sensing and climate analysis tools have allowed the development of weather index insurance products as a potential adaptation option, with Malawi and Ethiopia being early testbeds (Tadesse et al., 2015). These pilot projects were initially sponsored by NGOs, but in the last decade, the private sector has become more active in this sector. The Ghana Agricultural Insurance Pool (GAIP) and Agriculture and Climate Risk Enterprise (ACRE) in Kenya, Tanzania and Rwanda are examples. Despite the potential for weather index insurance, uptake by smallholder farmers in Africa remains constrained by several factors. These include the failure to capture actual crop loss as in traditional crop insurance products, as well as the inability of poor farmers to pay premiums (Elum et al., 2017; Weber, 2019). Weather index insurance could be part of a wider portfolio of risk mitigation services offered to farmers (Tadesse et al., 2015; Weber, 2019). Strategic partnerships between key players (e.g., credit institutions, policymakers, meteorologists, farmer associations, extension services, NGOs) are needed to develop better products and build capacity among smallholder farmers to engage more beneficially with weather index insurance (Singh et al., 2018; Tesfaye et al., 2019).

9.8.5 Marine and Inland Fisheries

9.8.5.1 Observed Impacts of Climate Variability and Change on Marine and Inland Fisheries

Marine and freshwater fisheries provide 19.3% of animal protein intake (Chan et al., 2019) and support the livelihoods of 12.3 million people (de Graaf and Garibaldi, 2015) across Africa. Estimates suggest that fish provides ~30% of the continent's population (approximately 200 million people) with their main source of animal protein and key micronutrients (Obiero et al., 2019). Although marine fisheries account for >50 % of total capture fishery production (Obiero et al., 2019), 2.9 million tonnes of fish are harvested annually from inland water bodies constituting the highest per-capita inland fishery production of any continent (2.56 kg / year / person) (Harrod et al., 2018a; Funge-Smith and Bennett, 2019).

Climate change poses a significant threat to marine and freshwater fisheries and aquaculture in Africa (Blasiak et al., 2017; Harrod et al., 2018a). Severe (>30%) coral bleaching has impacted ~80% of major reef areas in the western Indian Ocean and Red Sea along Africa's eastern coast (Hughes et al., 2018). Biological effects (e.g., changes in primary production, fish distribution) have also occurred (Hidalgo et al., 2018). Range shifts in marine fish species can exacerbate boundary conflicts among fisher communities (Penney et al., 2017; Belhabib et al., 2019). Changes in fish distribution and reductions in catch across inland fisheries are associated with climatic variability by fishing communities (Okpara et al., 2017b; Lowe et al., 2019; Muringai et al., 2019b). Floods and reduced river flow reduces fish catches (Kolding et al., 2019), which scale positively with discharge rates in rivers across Africa (McIntyre et al., 2016). Warming air and water temperatures have altered water stratification patterns in African lakes causing reductions in or redistirbutions of primary productivity and leading to reduced fish biomass (Section 9.6.1.3). Such changes, partially explain reduced fish catches in Lake Tanganyika (Cohen et al., 2016). In some regions, water scarcity has resulted in conflict within and among food production sectors (pastoralists, fishers and farmers) in this region (Okpara et al., 2017b). Small-scale and artisanal fisher communities are ill-equipped to adapt to climate impacts because there are few financially-accessible alternative livelihoods (Belhabib et al., 2016; Ndhlovu and Saito, 2017).

9.8.5.2 Projected Risks of Climate Change to Fisheries

At 4.3°C global warming, maximum catch potential (MCP) from marine fisheries in African Exclusive Economic Zones (EEZs) would decrease by 12–69% by the end of the 21st century relative to recent decades (1986–2005) whereas maintaining warming levels below 1.6°C would decrease MCP by 3–41% (Cheung William et al., 2016) (Figure 9.25). However, by mid-century under 2°C global warming, MCP would decrease by 10 to >30% on the western coast of South Africa, the Horn of Africa and West Africa, indicating these regions could be at risk to declines in MCP earlier in the century than other parts of Africa (Cheung et al., 2016) (Figure 9.25). Declining fish harvests due to sea temperature rise could leave 1.2–70 (median 11.1) million people in Africa vulnerable to deficiencies in iron, and up to 188 million to vitamin A and 285 million to vitamin B_{12} and omega-3 fatty acids by mid-century under 1.7°C global warming (Golden et al., 2016). Maire et al. (2021) assessed the nutritional vulnerabilities of African countries to climate change and overfishing, and found that the four most vulnerable countries ranked on a scale from 0 (low vulnerability) to 100 (high vulnerability) were Mozambique (87), Madagascar (76), Tanzania (61) and Sierra Leone (58). Coral reef habitat in East Africa is projected to decrease, resulting in negative impacts on demersal fish stocks and invertebrates (Hoegh-Guldberg et al., 2018). Central, West and East Africa appear to be at the greatest nutritional risk from sea temperature rise, leading to reduced catch in coastal waters (Golden et al., 2016) (Figure 9.25). In North Africa, a rise in water temperatures is expected to impact the phenology and migratory patterns of large pelagic species (e.g., bluefin tuna, *Thunnus thynnus*) (Hidalgo et al., 2018). Increased sea surface temperatures have been associated with increases in spring and summer upwelling intensity reducing the abundance and larval survival of small pelagic fishes and shellfish in West Africa (Bakun et al., 2015; Tiedemann et al., 2017; Atindana et al., 2020). Ocean warming, acidification and hypoxia are predicted to affect the early life history stages of several marine food species, including fish and crustaceans (Kifani et al., 2018). Climate warming is projected to impact water temperature and horizontal and vertical mixing on the southern Benguela ecosystem, with marked negative effects on the biomass of several important fishery resources by 2050 amplified under 2.5°C compared to 1.7°C global warming (Ortega-Cisneros et al., 2018).

For inland fisheries, 55–68% of commercially harvested fish species will be vulnerable to extinction under 2.5°C global warming by the end of the 21st century (2071–2100) compared to 77–97% under 4.4°C global warming (Figure 9.26). This will increase the number of countries that are at food security risk due to fishery species declines from 10 to 13 (Figure 9.26). Other recent analyses suggest that African countries with the highest inland fisheries production have low- to mid-range projected climate risk (2.4℃–2.6°C local temperature increase compared to other regions with 2.7℃–3.3°C increase by end of centruy) based on a 3.9°C global warming scenario (Harrod et al., 2018b). In regions where inland fishery production is derived primarily from lakes, there is a lower likelihood of reduced catch, especially where precipitation is projected to increase (e.g., African Great Lakes region) (Harrod et al., 2018b). Regions reliant on rivers and floodplains (e.g., Zambezi and Niger basins) are more *likely* to experience downturns in catch, as hydrological dynamics may be altered (Harrod et al., 2018b). Projections suggest that opportunistic species that do well in modified systems (Escalera-vázquez et al., 2017) and small pelagic fishes will remain important components to inland fishery food systems (Kolding et al., 2016; Gownaris et al., 2018; Kolding et al., 2019). Climate adaptation responses that rely on freshwater resources (e.g., hydroelectric power generation, agricultural irrigation) represent threats to inland fisheries (Cowx et al., 2018; Harrod et al., 2018c), by changing flow regimes, reducing water levels, and increasing runoff of pesticides and nutrients (Harrod et al., 2018c).

For both marine and freshwater fisheries, climate-related extreme weather events and flooding may drive the loss of fishing days, cause damage and loss to fishing gear, endanger the lives of fishers and block transportation from damaged roads (Muringai et al., 2021). Fish processing via weather-dependent techniques such as sun drying may be hampered, causing post-harvest losses (Akintola and Fakoya, 2017; Chan et al., 2019).

9.8.5.3 Current and Future Adaptation Responses for Fisheries

Patterns of vulnerability and adaptive capacity are highly context-dependent and vary within and among fishing communities in coastal and riparian areas (Ndhlovu and Saito, 2017; Lowe et al., 2019; D'agata et al., 2020). Interventions that integrate scientific knowledge and fishers' local knowledge while focusing on vulnerable groups are more *likely* to be more successful (Musinguzi et al., 2018; Muringai et al., 2019b). Infrastructure improvements (e.g., storage facilities, processing technologies, transport systems) could reduce post-harvest losses and improve food safety (Chan et al., 2019). Fisher safety can be aided by early warning of severe weather conditions (Thiery et al., 2017), enhanced through communication via mass media and mobile phones (Thiery et al., 2017; Kiwanuka-Tondo et al., 2019). Although changing fishing gears and shifting target species are important adaptation options for artisanal fishers, many have instead expanded their fishing range or increased effort (Musinguzi et al., 2015; Belhabib et al., 2016). Adapting to the impacts of climate change on marine fisheries productivity requires management reforms accounting for shifting productivity and species distributions, such as increasing marine protected areas, strengthening regional trade networks, and increasing the investment and innovation in climate-resilient aquaculture production (Golden et al., 2021). This could yield higher catch and profits in the future relative to today in

50% of African countries with marine territories under 2°C global warming and in 35% under 4.3°C global warming (Free et al., 2020). For inland fisheries, opportunities for adaptation include better integration of inland fisheries into management plans from other sectors (e.g., hydropower and irrigation) (Harrod et al., 2018c; Cowx and Ogutu-Ohwayo, 2019; McCartney et al., 2019). There is growing interest in enhancing the supply of freshwater fishery production from small water bodies and reservoirs in dryland regions of sub-Saharan Africa (Kolding et al., 2016).

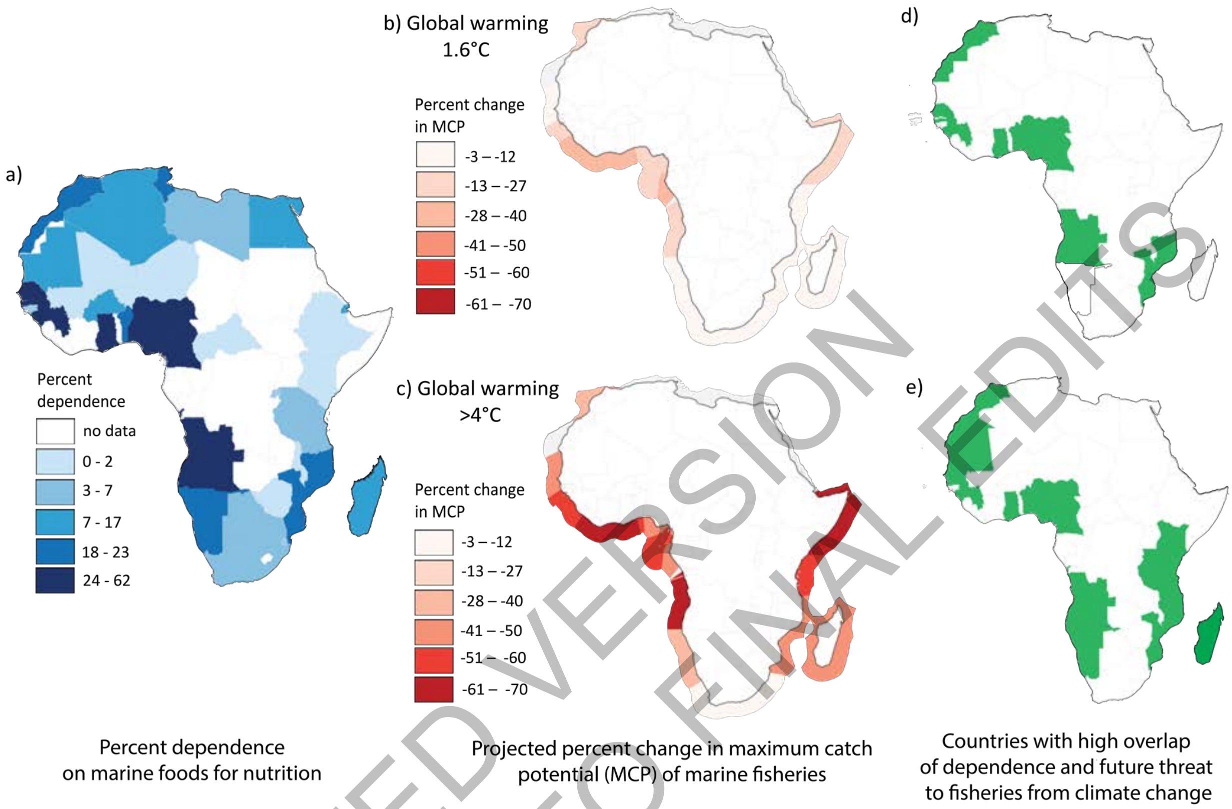

Figure 9.25: Climate change risk to nutrition and catch potential from Marine Fisheries: Panels comparing countries current percent dependence on marine foods for nutrition compared with projected change in maximum catch potential (MCP) from marine fisheries. (a) The percentage of animal sources foods consumed that originate from a marine environment. Countries with higher dependence are indicated by darker shades of blue (Golden et al., 2016). (b–c) Projected percent change in maximum catch potential (MCP) of marine fisheries under 1.6°C global warming (b) and >4°C global warming (c) from recent past (1986–2005) to end of 21st century (2081-2100) in countries' Exclusive Economic Zones (EEZs)(Cheung William et al., 2016). Darker red indicates greater percent reduction [negative values]. (d–e) Countries (in green) that have overlap between high nutritional dependence and high reduction in MCP under two warming scenarios.

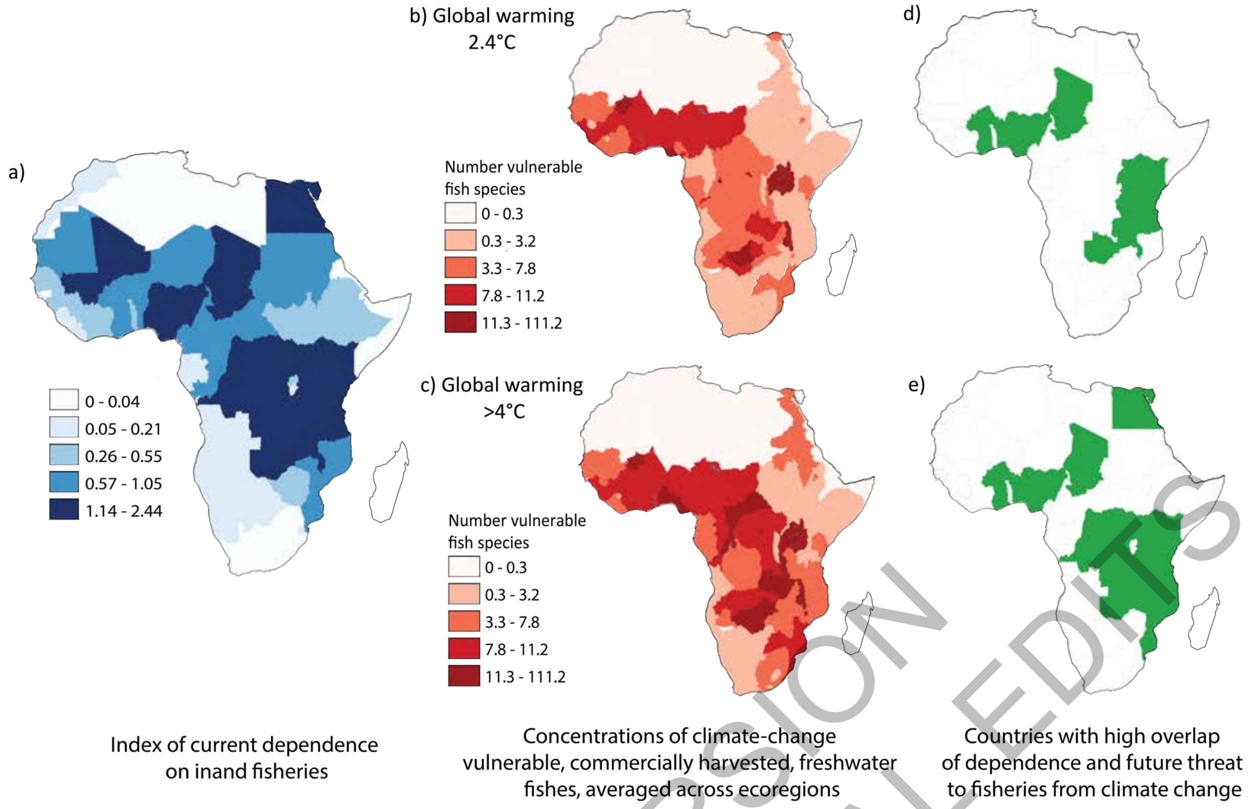

Figure 9.26: Climate change risk to Freshwater Fisheries: Panels comparing countries current dependence on inland fisheries compared with climate change vulnerability of important fishery species. (a) Countries' reliance on inland fisheries was estimated by catch (total, tonnes) (FAO, 2018b; Fluet-Chouinard et al., 2018), per capita catch (kg/person/year) (FAO, 2018b), percent reliance on fish for micronutrients, and percent consumption per household (Golden et al., 2016). Z-scores of each metric were averaged for each country to create a composite index describing 'current dependence on freshwater fish' for each country with darker blue colours indicating higher dependence. (b–c) Projected concentrations (numbers) of vulnerable freshwater fishery species averaged within freshwater ecoregions under >2°C global warming (b) and >4°C global warming (c) estimated from recent past (1961–1992) to the end of the 21st century (2071 to 2100) (Nyboer et al., 2019). Numbers of vulnerable fish species translate to an average of 55–68% vulnerable at >2°C and 77–97% vulnerable at <4°C global warming. Darker reds indicate higher concentrations of vulnerable fish species. (d–e) Countries (in green) that have an overlap between high dependence on freshwater fish and high concentrations of fishery species that are vulnerable to climate change under two warming scenarios

9.9 Human Settlements and Infrastructure

This section assesses climate impacts, risks and adaptation options for human settlements comprising human populations and infrastructure such as buildings, roads and energy across Africa.

9.9.1 Urbanisation, Population and Development Trends

Africa is the most rapidly urbanising region in the world, with an annual urban population growth rate of 3.6% for 2005–2015 (UN-Habitat, 2016). About 57% of the population currently lives in rural areas, the proprotion of the population living in urban areas is projectted to exceed 60% by 2050 (UNDESA, 2019b) (UN-Habitat, 2016). Much of the rapid rate of urbanisation has resulted from the growth of small towns and intermediary cities (African Development Bank et al., 2016).

Approximately 59% of sub-Saharan Africa's urban population resides in informal settlements (in some cities up to 80%), and the population in informal settlements is expected to increase (*very high confidence*) (Taylor and Peter, 2014; UN-Habitat, 2014; UN-Habitat, 2016; UNDP, 2019). These urbanisation trends are compounding the increasing exposure to climate hazards, particularly floods and heatwaves (*high confidence*) (Dodman et al., 2015).

Globally, the highest rates of population growth and urbanisation are taking place in Africa's coastal zones (*high confidence*) (Merkens et al., 2016). Coastal urban populations account for 25–29% of the total population in West, North and southern Africa (OECD/SWAC, 2020). Accounting for a continuing young population, stagnant economies and migration to regional growth centres, projections indicate that the low-lying coastal zone population of sub-Saharan Africa could increase by 175% (2030) and 625% (2060) relative to 24 million in 2000 (Neumann et al., 2015).

Climate-related displacement is widespread in Africa, with increased migration to urban areas in sub-Saharan Africa linked to decreased rainfall in rural areas, increasing urbanisation and affecting household vulnerability (see Box 9.9). Much of this growth can occur in informal settlements which are growing due to both climatic and non-climatic drivers, and which often house temporary migrants, including internally displaced people. Such informal settlements are located in areas exposed to climate change and variability and are exposed to floods, landslides, sea level rise and storm surges in low-lying coastal areas, or alongside rivers that frequently overflow, thereby exacerbating existing vulnerabilities (Satterthwaite et al., 2020).

Sub-Saharan Africa's large infrastructure deficit (quantity, quality and access) with respect to road transport, electricity, water supply and sanitation places the region at the lowest of all developing regions (AfDB, 2018a; Calderon et al., 2018). Adequate infrastructure to support Africa's rapidly growing population is important to raise living standards and productivity in informal settlements (AfDB, 2018b; UN Environment, 2019). Yet planned infrastructure developments, including those related to African Union's Programme for Infrastructure Development (PIDA), along with other energy plans, and China's Belt and Road Initiative (BRI), may increase or decrease both climate change mitigation and adaptation depending on whether infrastructure planning integrates current and future climate change risks (Cervigni et al., 2015; Addaney, 2020) (see Box 9.5).

9.9.2 Observed Impacts on Human Settlements and Infrastructure

African human settlements are particularly exposed to floods (pluvial and fluvial), droughts and heat waves. Other climate hazards are sea level rise and storm surges in coastal areas, tropical cyclones and convective storms. This sub-section provides an assessment of observed impacts and risks from climate hazards in different sub-regions to underscore the relevance of climate-sensitive planning and actions to advance social and economic development, and reduce the loss and damage of property, assets and critical infrastructure.

9.9.2.1 Observed Impacts on Human Settlements

The spatial distribution of climate hazards and observed impacts in terms of total people affected (displaced persons and deaths) during 2010–2020 is shown in Figure 9.27. From 2000–2019 , floods and droughts accounted for 80% and 16%, respectively, of the 337 million affected persons, and a further 32% and 46%, respectively, of 46,078 deaths from natural disasters in Africa (CRED, 2019). Flooding is a major hazard across Africa (Kundzewicz et al., 2014; Douglas, 2017) and is increasing (Zevenbergen et al., 2016; Elboshy et al., 2019). An increase in extreme poverty and up to a 35% decrease in consumption has been associated with exposure to flood shocks (Azzarri and Signorelli, 2020). Globally, only sub-Saharan Africa has recorded increasing rates of flood mortality since the 1990s (Tellman et al., 2021). Economic opportunities, transportation of goods and services, and mobility and access to essential services, including health and education, are greatly hindered by flooding (Gannon et al., 2018). Severe impacts from tropical cyclone landfalls have been recorded in East and southeastern Africa (Rapolaki and Reason, 2018; Cambaza et al., 2019; Chatiza, 2019; Hope, 2019). Cyclones Idai and Kenneth in early 2019 caused flooding of districts in Mozambique, Zimbabwe and Malawi, with substantial loss and damage to infrastructure in the energy, transport, water supply, communication services, housing, health and education sectors, particularly in Mozambique (Figure 9.27; see also Cross-Chapter Box DISASTER in Chapter 4) (Warren, 2019; Dube et al., 2021; Phiri et al., 2021).

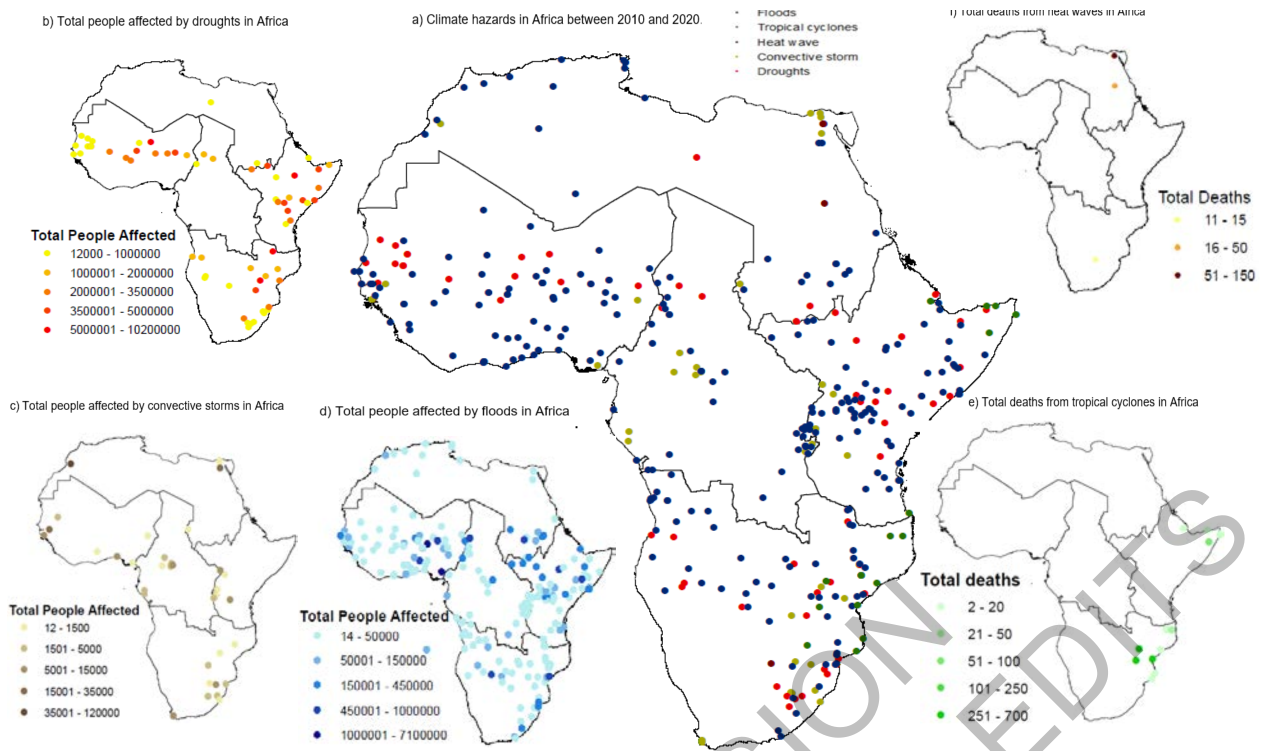

Figure 9.27: From 2010–2020, over 166 million people were reported to be affected by climate hazards across Africa. Maps show (a) location of all reported climate hazards, (b) people affected by droughts, (c) people affected by convective storms, (d) people affected by floods, (e) total deaths from tropical cyclones, and (f) total deaths from heat waves. Source (EMDAT and CRED, 2020). Note, although extreme weather damage databases under report heatwaves (which is indicated in panel (f) by very few deaths), the region has experienced a number of heatwaves and will be affected disproportionately by them in the future under climate change (Harrington and Otto, 2020).

Table 9.7: Case studies of climate hazard impacts and risks to selected human settlements in Africa

Hazard	Country/City	Impact on Human Settlement and Infrastructure	Source
Sea level rise and storm surge	Egypt (North Africa)	December 2010, January 2011, and October 2015: Storm surge of 1.2 m above MSL (typical of the Nile Delta coast: 0.4–0.5 m). Coastal flooding and damage to some coastal structures. Moderate flooding of the Nile Delta lowlands. Alexandria city: Flooding generated by heavy rainfall (2015). Increased turbidity of water sources affected efficiency of water treatment plants leading to reduction of water supplies affecting public health systems. Potable water supply affected by saltwater intrusion. Coastal erosion and property damage.	(Kloos and Baumert, 2015; Abutaleb et al., 2018) (Eldeberky Y, 2015; Yehia et al., 2017)
Drought	Southern Africa	**El Niño Drought 2015–2016**: Western Cape Region Affected 8.6 million people. Losses: >USD 2.2 billion. Power generation reduced by 75% at Kariba dam (Zambia) in 2016, and the Cahora Bassa dam (Mozambique) reduced to 34% of its capacity with widespread impact on electricity supplies across southern Africa.	(Davis-Reddy et al., 2017; Spalding-Fecher et al., 2017) (Brooks, 2019)
	Somalia (East Africa)	**Somalia drought 2016-2017**: 926,000 newly displaced persons reported (Nov. 2016–Oct. 2017). 40% of total drought-related displacements accommodated in Mogadishu, Baidoa, Kismayo; 60% hosted in other secondary cities. Increased population density and overcrowding in Somalia's urban areas. Explosion of new shelters and tents for displaced persons within and in outskirts of cities. In Mogadishu, 34% of new settlements developed within six months.	(Government of Somalia, 2018)
Flooding	Malawi (East Africa)	**Floods 2019**: Approximately 975,600 people affected, 672 injured, 60 persons killed, and 86,976 people displaced. 288,371 houses	(Government of Malawi, 2019)

		damaged. 129 bridges and 68 culverts destroyed. 1841 km of road network estimated at USD 36.1 million destroyed. Total cost of damage and losses: housing sector - USD 106.9 million, energy - USD 3.1 million; water and sanitation - USD 6.4 million; transport - USD 37.0 million. Total cost of destroyed physical assets – USD 157.7 million. Damage and Losses in Blantyre city: housing sector - USD 29.87 million, energy sector - USD 0.38 million and transport sector - USD 1.72 million.	
Tropical cyclone	Mozambique, Zimbabwe and Malawi (Southern Africa)	**Cyclones Idai and Kenneth 2019:** Severe flooding of districts in Mozambique, Zimbabwe, and Malawi; 233,900 houses completely destroyed or damaged in Mozambique. Cyclone Kenneth - about 40,000 houses and 19 health facilities destroyed. Cyclone Idai - destroyed or damaged 1,345 km of transmission lines, 10,216 km of distribution lines, two 90MW generation plants, 30 sub-stations and 4,000 transformers, resulting in estimated damage of USD 133.5 million and loss of USD 47.9 million in the energy sector in Mozambique. 602 and 299 people killed in Mozambique and Zimbabwe respectively; Affected persons - about 1.5 million in Mozambique and 270,000 in Zimbabwe. In Beira (Mozambique) - 60% of city was inundated, 70% of houses damaged or totally destroyed, mostly in the poorest neighbourhood, and 90% of the city's power grid affected. Huge losses and damages to infrastructures in the energy, transport, water supply, communication services, housing, health and education sector were also recorded.	(Cambaza et al., 2019; Chatiza, 2019; Government of Mozambique, 2019; Hope, 2019; Lequechane et al., 2020; Phiri et al., 2021) (Enenkel et al., 2020)
Landslide	Freetown (West Africa)	**August 2017**: At least 500 persons killed and over 600 persons declared missing, >3,000 residents rendered homeless; 349 houses destroyed. Damage to health facilities and educational buildings. Economic cost of landslide and flood: USD 31.6 million.	(Cui et al., 2019) (World Bank, 2017b)
	Uganda (East Africa)	Slopes of Mt. Elgon (2010): More than 350 deaths and 500,000 persons needed to be relocated	(Croitoru et al., 2019)

From 2005–2020, flood-induced damage over Africa was estimated at over USD 4.4 billion, with eastern and western Africa being the most affected regions (EMDAT and CRED, 2020). Total damages in four West African countries (Benin, Cote d'Ivoire, Senegal and Togo) in 2017 were estimated at USD 850 million for pluvial floods and USD 555 million for fluvial floods (Croitoru et al., 2019). Unprecedented economic loss, in terms of goods and properties, estimated by the Nigerian insurance industry at USD 200 million resulted from floods in Lagos in 2011 (Adelekan, 2016). In southern Africa, the highest costs were incurred from flood losses during the period 2000-2015 (UNEP-FI, 2019b; Simpson, 2020).

Business disruptions from climate impacts have implications for deepening poverty (Adelekan and Fregene, 2015). Small and medium enterprises (SMEs) employ 60–90% of workers in many African countries and contribute 40% or more to the GDP in Ghana, Kenya, Nigeria, Zimbabwe, South Africa and Tanzania (Muriithi, 2017). The viability of businesses and economic well-being of large populations employed in SMEs is severely affected by climate hazards as reported for local wind storms in Ibadan (Adelekan, 2012), El Niño-related flooding (Nairobi), drought-induced water supply disruption (Gaborone) and power outages (Lusaka) (Gannon et al., 2018). High water demand due to high rates of urbanisation and population growth, coupled with drought, reduce groundwater levels in cities (e.g., Bouake, Harare, Tripoli, Niamey) and increase saltwater intrusion into groundwater in coastal areas, reducing water availability and water security, particularly for poorer populations not connected to municipal water networks (Aswad et al., 2019; Claon et al., 2020).

Evidence of the impact of heat waves in urban Africa in the current climate is sparse, due in part to low reporting and monitoring (Engelbrecht et al., 2015; Harrington and Otto, 2020). Knowledge is also limited on the interaction of climate change, urban growth and the urban heat island effect in Africa (Chapman et al., 2017). In North Africa, the present day number of high heat-stress nights is around 10 times larger in urban than rural areas (Fischer et al., 2012).

9.9.2.2 Observed Impacts to Road and Energy Infrastructure

The highest transport infrastructure exposures are from floods (Koks et al., 2019), with potentially severe consequences for food security (Fanzo et al., 2018), communication and the economy of affected regions (*high confidence*) (Koks et al., 2019). Eight of the twenty countries with the highest expected annual damages to road and rail assets, relative to the country's GDP, are located in East, West and Central Africa (Koks et al., 2019). Transport impacts compound climate impacts, such as heat stress and air pollution linked to vehicle emissions in Dar es Salaam (Ndetto and Matzarakis, 2014).

African economies that rely primarily on hydropower for electricity generation are particularly sensitive to climate variability (Brooks, 2019). This sensitivity was already felt during the 2015/16 El Niño, in which Malawi, Tanzania, Zambia and Zimbabwe all experienced widespread and prolonged load shedding due to low rainfall. The impact was felt throughout the economy and reflected in reduced GDP growth in Zambia (Conway et al., 2017).

9.9.3 Observed Vulnerabilities of Human Settlements to Climate Risks

Urban vulnerabilities and exposure to climate change are increasing (*medium to high confidence*) and are influenced by patterns of urban settlement and housing characteristics (Satterthwaite, 2017; Godsmark et al., 2019; Williams et al., 2019a). About 70% of African cities are highly vulnerable to climate shocks of which small- and medium-sized towns and cities are more at risk (Verisk Maplecroft, 2018). Flooding was perceived as the most prominent water risk in 75% of 36 sampled cities across African sub-regions, while drought-related water scarcity was indicated as very important/important in 66.7% of cities (OECD, 2021). Almost one-third of African cities with populations of 300,000 or more are located in areas of high exposure to at least one natural hazard, including floods (12%) and droughts (20–25%) (Gu et al., 2015). The coastal cities of East, West and North Africa are particularly vulnerable to the effects of rising sea levels (Abutaleb et al., 2018; IPCC, 2019a).

Globally, sub-Saharan Africa has the largest population living in extreme poverty that are exposed to high flood risk (~71 million people or 55% of global total) (Rentschler and Salhab, 2020). Poverty is a significant factor of flood-induced displacement in Africa, where even small flood exposure can lead to high numbers of displacement (Kakinuma et al., 2020). Africa's large population of urban poor and marginalised groups and informal sector workers, further contribute to high vulnerability to extreme weather and climate change in many settlements (*high confidence*) (Adelekan and Fregene, 2015; IPCC, 2019a; UNDP, 2019).

Other non-climatic stressors which exacerbate vulnerabilities, especially in urban areas, include poor socioeconomic development, weak municipal governance, poor resource and institutional capacities, together with multi-dimensional, location-specific inequalities (*high confidence*) (Dodman et al., 2017; Satterthwaite, 2017).

9.9.4 Projected Risks for Human Settlements and Infrastructure

9.9.4.1 Projected Risks for Human Settlements

The extent of urban areas in Africa exposed to climate hazards will increase considerably and cities will be hotspots of climate risks, which could amplify pre-existing stresses related to poverty, exclusion and governance (*high confidence*) (IPCC, 2018b).

Flooding

Continuing current population and GDP growth trends, the extent of urban land exposed to high-frequency flooding is projected to increase around 270% in North Africa, 800% in southern Africa, and 2600% in mid-latitude Africa by 2030 when compared to 2000, without considering climate change (Güneralp et al., 2015). In addition, global warming is projected to increase frequency and magnitude of river floods in East, Central and West Africa (Alfieri et al., 2017; Gu et al., 2020; Kam et al., 2021). On average across large African river basins, the frequency of flood events with a current return period of 100 years is projected to increase to 1 in 40 years at 1.5°C and 2°C global warming, and 1 in 21 years at 4°C warming, with Egypt, Nigeria, Sudan and DRC in the top 20 countries globally for projected damages (Alfieri et al., 2017). Compared to population in 2000, human displacement due to river flooding in Sub-Saharan Africa is projected to increase 600% by 2066–2096 with moderate-to-high population growth and 2.6°C global warming, with risk reducing to a 200% increase for low population growth and 1.6°C global warming (Kam et al., 2021).

Urban population exposure to tropical cyclone hazards in southeastern Africa, in particular Mozambique, is projected to increase due to the intensification of cyclones and their extended duration associated with warmer sea surface temperatures (Fitchett, 2018; Vidya et al., 2020). Urban damage assessment based on a 10-year flood protection level for Accra shows that without flood protection, there is a 10% probability of a flood occurring annually which could cause USD 98.5 million urban damage, affect GDP by USD 50.3 million and affect 34,000 people (Asumadu-Sarkodie et al., 2015). Many urban households and Africa's growing assets could therefore be exposed to increased flooding (IPCC, 2018b).

Population in low-elevation coastal zones (LECZ) projected for 2030 and 2060

Exposed population: 1 million people – >200 million people

Population growth scenarios:
I = growth at lowest end of forecasts
II = growth at low end of forecasts
III = growth at high end of forecasts
IV = growth towards highest end of forecasts

Low-elevation coastal zones

Figure 9.28: Tens to hundreds of millions of people in Africa are projected to be exposed to sea level rise, with a major risk driver being increased exposure due to population increase in low-lying areas. (a) Population in the low-elevation coastal zone (LECZ) projected for 2030 (+10cm SLR) and 2060 (+21 cm SLR). (b) African countries with highest population in LECZ, and additional population exposed in the 100-year floodplain. Data sourced from (Neumann et al., 2015).

Sea level rise and coastal flooding

Africa's low-lying coastal zone population is expected to grow more than any other region from 2000 to 2060 (see Figure 9.28) (Neumann et al., 2015). Future rapid coastal development is expected to increase existing high vulnerabilities to sea level rise (SLR) and coastal hazards, particularly in East Africa (*high confidence*) (Figure 9.29) (Hinkel et al., 2012; Kulp and Strauss, 2019). By 2100, sea levels are projected to rise at least 40 cm above those in 2000 in a below 2°C scenario, and possibly up to 1 m by the end of the century under a 4°C warming scenario (Serdeczny et al., 2017) (see also Cross-Chapter Box SLR in Chapter 3).

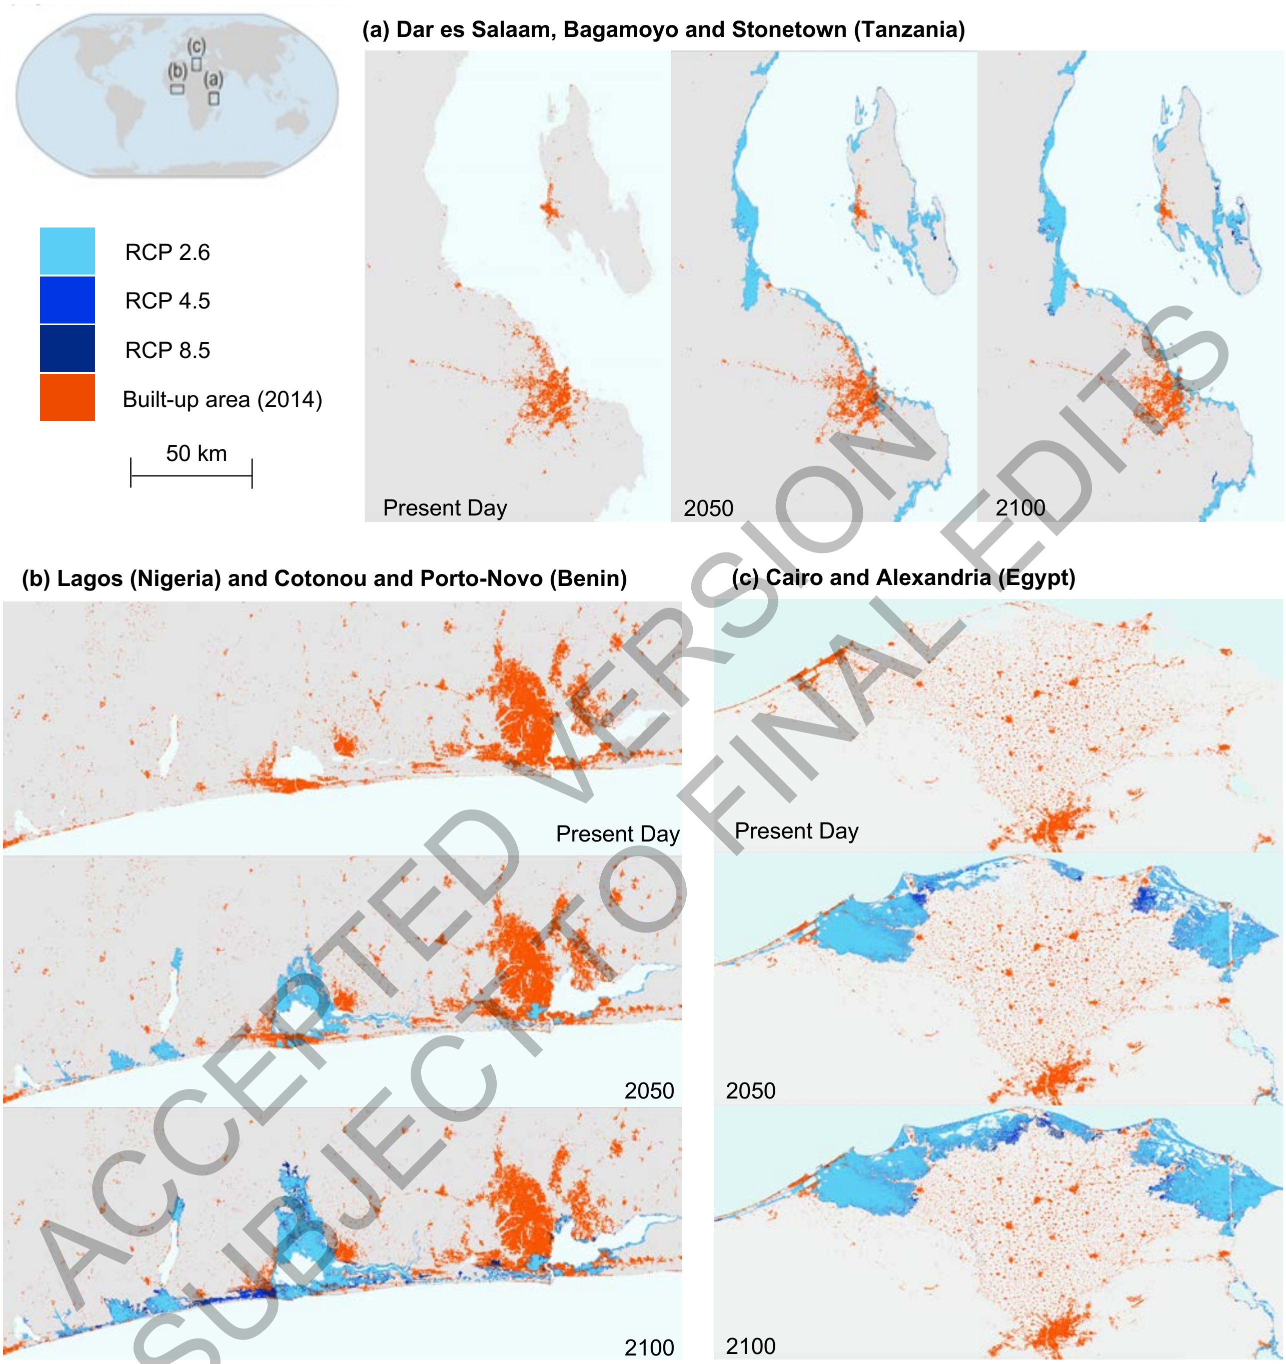

Figure 9.29: Selected African cities exposed to sea level rise include (a) Dar es Salaam, Bagamoyo, and Stone Town in Tanzania (East Africa), (b) Lagos in Nigeria, and Cotonou and Porto-Novo in Benin (West Africa), and (c) Cairo and Alexandria in Egypt (North Africa). Orange shows built-up area in 2014. Shades of blue show permanent flooding due to sea level rise by 2050 and 2100 under low (RCP2.6), medium (RCP4.5) and high (RCP8.5) greenhouse gas emissions scenarios. Darker colours for higher emissions scenarios show areas projected to be flooded in addition to those for lower emissions scenarios. The figure assumes failure of coastal defences in 2050 and 2100. Some areas are already below current sea level rise and coastal defences need to be upgraded as sea level rises (e.g., in Egypt), others are just above mean sea levels and they do not necessarily have high protection levels, so these defences need to be built (e.g., Dar Es Salam and Lagos). Blue shading shows permanent inundation surfaces predicted by Coastal DEM and SRTM given the 95th percentile K14/RCP2.6, RCP4.5, and RCP8.5, for present day, 2050, and 2100 sea level projection for permanent inundation (inundation without a storm surge event), and RL10 (10-year return level storm) (Kulp and Strauss, 2019). Low-lying areas isolated from the ocean are removed from the inundation surface using

connected components analysis. Current water bodies are derived from the SRTM Water Body Dataset. Orange areas represent the extent of coastal human settlements in 2014 (Corbane et al., 2018). See Figure CCP4.7 for projections including subsidence and worst-case scenario projections for 2100.

In the absence of any adaptation, Egypt, Mozambique, and Nigeria are projected to be worst affected by SLR in terms of the number of people at risk of flooding annually in a 4°C warming scenario (Hinkel et al., 2012). Recent estimates have explored the potential damages due to SLR and coastal extreme events in 12 major African cities using a stochastic approach to account for uncertainty (Abadie et al., 2020). Expected aggregate damages to these cities in 2050 are USD 65 billion for RCP4.5 and USD 86.5 billion for RCP8.5, and USD 137.5 billion under a high-end scenario that incorporates expert opinion on additional ice sheet melting (Table 9.8). When considering low-probability, high-damage events, aggregate damage risks can be more than twice as high, reaching USD 187 billion and USD 206 billion under RCP4.5 and RCP8.5 scenarios, respectively, and USD 397 billion under the high-end scenario. City characteristics and exposure play a larger role in expected damages and risk than changes in sea level. The city of Alexandria in North Africa leads the ranking, with aggregate expected damage of USD 36 billion and USD 50 billion under RCP4.5 and RCP8.5 scenarios, respectively, and USD 79.4 billion under the high-end scenario.

Table 9.8: Regional relative sea level rise and associated damage risks in 12 major African coastal cities under four SLR scenarios. Panel (a) Regional relative sea level rise by 2050 and 2100. For SLR, median and 95th percentiles are presented, in centimetres. Panel (b) Probabilistic damage estimations by 2050 include expected average damages (EAD), damages at the 95th percentile (VaR) and the Expected Shortfall (ES), which represents the average damages of the 5% worst cases. Four relative sea level projections were considered under no adaptation: the RCP2.6, 4.5 and 8.5 scenarios from the IPCC AR5, and a high-end RCP8.5 scenario that incorporates expert opinion on additional ice sheet melting. Note that figures are provided in undiscounted millions of US dollars (2005) and have been rounded off to avoid a false sense of precision (Abadie et al., 2020; Abadie et al., 2021).

a) Regional relative sea level rise (cm)

City	Year	RCP2.6		RCP4.5		RCP8.5		High end	
		Median	P95	Median	P95	Median	P95	Median	P95

Sea level rise and associated episodic flooding are identified as key drivers of projected net migration of 750,000 people out of the East African coastal zone between 2020 and 2050 (IPCC, 2019a). These trends, alongside the emergence of 'hotspots' of climate in and out-migration (Box 9.8), will have major implications for climate-sensitive sectors and the adequacy of human settlements, including urban infrastructure and social support systems. Actions which could help reduce the number of people being forced to move in distress, include adoption of inclusive and climate-resilient development policies, together with targeted investments to manage the reality of climate migration; and mainstreaming climate migration in development planning (Box 9.8).

Drought

Although an increase in drought hazard is projected for North and southwest southern Africa with increased global warming (Figure 9.15), Central African countries may have the highest drought risk because of high vulnerability and high population growth (Ahmadalipour et al., 2019). Among continents, Africa contains the second largest population of people living in drylands, which is expected to double by 2050 (IPCC, 2019a). Continuing current population and GDP growth trends, the extent of urban land in arid zones is projected to increase around 180% in Southern Africa, 300% in North Africa, and 700% in mid-latitude Africa by 2030 when compared to 2000, without considering climate change (Güneralp et al., 2015). At 1.5°C warming, urban populations exposed to severe droughts in West Africa are projected to increase (65±34 million) and increase further at 2°C (IPCC, 2018b; Liu et al., 2018b). Risks associated with increases in drought frequency and magnitudes are projected to be substantially larger at 2°C than at 1.5°C for North Africa and Southern Africa (IPCC, 2018b; Oppenheimer et al., 2019). Dryland populations exposed (vulnerable) to water stress, heat stress, and desertification are projected to reach 951 (178) million at 1.5°C, 1,152 (220) million at 2°C, and 1,285 (277) million at 3°C of global warming (IPCC, 2019a). At global warming of 2°C under a scenario of low populaton growth and sustainable development (SSP1), the exposed (vulnerable) dryland population is 974 (35) million and for higher population growth and low environmental protections (SSP3) it is 1.27 billion (522 million), a majority of which is in West Africa (IPCC, 2019a).

Extreme heat

Projections for 173 African cities show that around 25 cities will have over 150 days per year with an apparent temperature above 40.6°C for 1.7°C global warming, increasing to 35 cities for 2.1°C and 65 cities for 4.4°C warming, with West African cities most affected (Rohat et al., 2019). Across Africa, urban population exposure to extreme heat is expected to increase from 2 billion person-days per year for 1985–2005 to 45 billion person-days for 1.7°C global warming with low population growth (SSP1) and to 95 billion person-days for 2.8°C and medium-high population growth (SSP4) by the 2060s, with increases of 20–52 times 1985–2005 levels by 2080–2100, depending on the scenario (Rohat et al., 2019). West Africa (especially Nigeria) has the highest absolute exposure and Southern Africa the least. Considering the urban heat island effect, the more vulnerable populations under 5 and over 64 exposed to heat waves of >15 days over 42°C are projected to increase from 27 million in 2010 to 360 million by 2100 for 1.8°C global warming, increasing to 440 million for >4°C global warming, with West Africa most affected (Marcotullio et al., 2021). This portends increased vulnerability to risk of heat stress in big cities of Central, East and West Africa (*very high confidence*) (Gasparrini et al., 2015; Liu et al., 2017; Rohat et al., 2019). Shifting to a low urban population growth pathway is projected to achieve a greater reduction in aggregate exposure to extreme heat for most cities in West Africa whereas limiting warming through lower emissions pathways achieves greater reductions in exposure in Central and East Africa (Rohat et al., 2019).

The African population exposed to compound climate extremes, such as coincident heat waves and droughts or drought followed immediately by extreme rainfall, is projected to increase 47-fold by 2070–2099 compared to 1981–2010 for a scenario with high population growth and 4°C global warming (SSP3/RCP8.5) and only 12-fold for low population growth and 1.6°C global warming (SSP1/RCP2.6), with West, Central-East, northeastern and southeastern Africa especially exposed (Weber et al., 2020). Coincident heat waves and drought is the compound event to which the most people are projected to be exposed: ~1.9 billion person-events (a 14-fold increase) for SSP1/RCP2.6 and ~7.3 billion person-events (52-fold increase) for SSP3/RCP8.5 (Weber et al., 2020).

9.9.4.2 Projected Risks to Electricity Generation and Transmission

Climate change poses an increased risk to energy security for human settlements in Africa (*high confidence*). With burgeoning urban populations and growing economies, sub-Saharan Africa's electricity needs are growing. The IEA projects total generation capacity in Africa must grow 2.5 times from 244 GW in 2018 to 614 GW by 2040 (IEA, 2019). African nations plan to add significant generation capacity from natural gas, hydropower, wind and solar power. Each of these technologies is associated to a varying degree with climate risk.

The long lifespan of hydropower dams exposes them to decades of climatic variability. There is a wide range of uncertainty around the future climate of Africa's major river basins, but in several basins, there is the likelihood of increased rainfall variability and a drier climate (see Box 9.5). In countries that rely primarily on hydropower, climate change could have considerable impacts on electricity prices and as a result, consumers' expenditure (Sridharan et al., 2019). With increasing societal demands on limited water resources and future climate change, it is expected that there will be an intensification of water-energy-food competition and trade-offs (*high confidence*) (Section 9.7; Box 9.5).

9.9.4.3 Projected Risks to Road Infrastructure

Climate change and sea level rise will result in high economic costs for road infrastructure in sub-Saharan Africa (*medium confidence*) (Chinowsky et al., 2015). Across Africa as a whole, potential cumulative costs estimates through 2100 range from USD 183.6 billion (with adaptation) to USD 248.3 billion (no adaptation) to repair and maintain existing roads damaged by temperature and precipitation changes directly related to projected climate change (see Figure 9.30) (Chinowsky et al., 2013). Climate-related road damage and associated repairs will be a significant financial burden to countries, but to varying degrees according to flood risk, existing road asset liability, topography and rural connectivity, among other factors (Chinowsky et al., 2015; Cervigni et al., 2017; Koks et al., 2019). For example, Mozambique is projected to face estimated annual average costs of USD 123 million for maintaining and repairing roads damaged directly by precipitation and temperature changes from climate change through 2050 in a median climate change scenario for a policy that does not consider climate impacts during road design and construction (Chinowsky et al., 2015). Risk of river flooding to bridges in Mozambique under current conditions is estimated to be USD 200 million, equal to 1.5% of its GDP per year, and could rise to USD 400 million per year in the worst-case climate change scenario by 2050 (Schweikert et al., 2015).

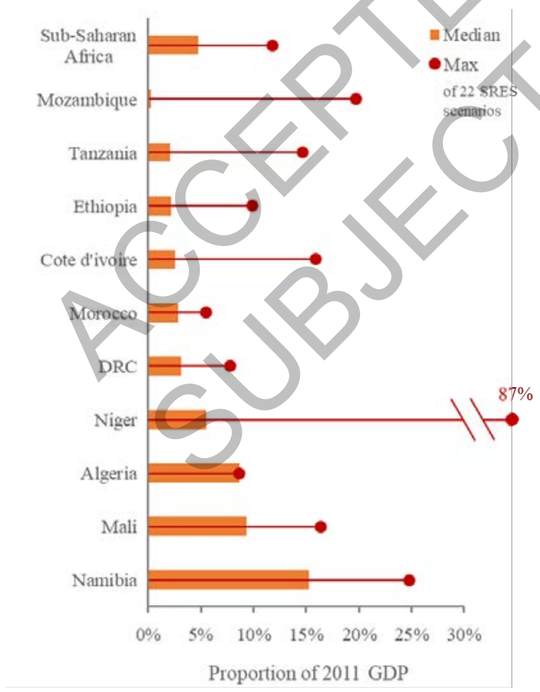

Figure 9.30: Projected costs for repair and maintenance of pre-2011 road infrastructure in selected African countries as a result of projected climate-change-related damages due directly to precipitation and temperature changes through to 2100 (Data sources: (Chinowsky et al., 2013). The analysis was run for 22 SRES climate scenarios and the median, and maximum results of the analyses are represented as proportions of the 2011 GDP of each country.

9.9.5 Adaptation in Human Settlements and for Infrastructure

9.9.5.1 Solutions and Residual Risk Observed in Human Settlements

Autonomous responses to climate impacts in 40 African cities show that excess rainfall is the primary climate driver of adaptation, followed by multi-hazard impacts, with 72% of responses focused on excess rainfall (Hunter et al., 2020). Innovation for adaptation in areas such as home design, social networks, organisations and infrastructure, is evident (Swanepoel and Sauka, 2019). Social learning platforms also increase communities' adaptive capacities and resilience to risk (Thorn et al., 2015).

There is limited evidence of successful, proactively planned climate change adaptation in African cities (Simon and Leck, 2015), particularly for those countries highly vulnerable to climate change (Ford et al., 2014). Planned adaptation initiatives in African cities since 2006 have been predominantly determined at the national level with negligible participation of lower levels of government (Ford et al., 2014). Adaptation action directed at vulnerable populations is also rare (Ford et al., 2014). There are emerging examples of cities planned climate adaptation measures, such as those advanced by Durban (Roberts, 2010), Cape Town (Taylor et al., 2016) and Lagos (Adelekan, 2016). There are also examples of community-led projects such as those in Maputo (Broto et al., 2015), which have seen meaningful help from a range of policy networks, dialogue forums and urban learning labs (Pasquini and Cowling, 2014; Shackleton et al., 2015). These researched cities can be lighthouses for wider exchange and the basis for a deeper synthesis of evidence (Lindley et al., 2019). However, planned adaptation progress is slow, especially in West and Central Africa (Tiepolo, 2014).

Nature-based solutions are also being deployed in mitigating and adapting to climate change, with demonstrated long-term health, ecological and social co-benefits (Swanepoel and Sauka, 2019) (Section 9.6.4). The cost-benefit analysis of nature-based solutions, compared to purely grey infrastructure initiatives, is discussed in Chapter 6 (Section 6.3.3). Nature-based solutions can also lengthen the life of existing built infrastructure (du Toit et al., 2018). Since 2014, an increasing number of ecosystem-based adaptation projects involving the restoration of mangrove, wetland and riparian ecosystems have been initiated across Africa, a majority of which address water-related climate risks (Table 9.9).

Table 9.9: Examples of ecosystem-based solutions to climate impacts in African cities.

Project	City	Solution	Reference
Green Urban Infrastructure (GUI)	Beira (Mozambique)	Mitigating against increased flood risks through restoration of mangrove and other natural habitats along the Chiveve river and the development of urban green spaces.	(IPCC, 2019a; CES Consulting Engineers Salzgitter GmbH and Inros Lackner SE, 2020) .
The Msimbazi Opportunity Plan (MOP) 2019-2024	Dar es Salaam, Tanzania	Enhancing urban resilience to flood risk by reducing flood hazard, and reducing people, properties and critical infrastructure exposed to flood hazard.	(Croitoru et al., 2019)
Tanzania Ecosystem Based Adaptation	Dar es Salaam and five coastal districts, Tanzania	Rehabilitation of over 3,000 hectares of climate-resilient mangrove species.	(UNEP, 2019)
Building Resilience in the Coastal Zone through Ecosystem–based approaches to adaptation	Maputo, Mozambique	Restoration of mangrove and riparian ecosystems for flood control and protection from coastal flooding enhanced water supply.	(GEF, 2019)
Addressing Urgent Coastal Adaptation Needs and Capacity Gaps in Angola	Five coastal communities in Angola	Restoration of 561 hectares of wetland, mangroves and other ecological habitats to promote flood defence and mitigate the threat of drought.	(UNEP, 2020)

Green City Kigali 2016-	Kigali (Rwanda)	600 hectares planned neighbourhood which integrates green building and design, efficient and renewable energy, recycling and inclusive living.	(SWECO, 2019)
Urban Natural Assets for Africa - Rivers for Life	Kampala (Uganda)	Preservation of natural buffers to enhance the protective functions offered by natural ecosystems that support disaster resilience benefit.	(World Bank, 2015)

For green infrastructure to be successful, however, sustainable landscapes and regions require both stewardship and management at multiple levels of governance and social scales (Brink et al., 2016).

Currently planned climate change adaptation to coastal hazards in Africa's large coastal cities has mainly been achieved through expensive coastal engineering efforts such as sea walls, revetments, breakwaters, spillways, dikes and groynes. Examples are found in West Africa (Adelekan, 2016; Alves et al., 2020). Beach nourishment efforts have also been undertaken in Egypt, Banjul and Lagos (Frihy et al., 2016; Alves et al., 2020). However, the use of vegetated coastal ecosystems presents greater opportunities for African cities because of the lower costs (Duarte et al., 2013).

Most (>80%) of Africa's large coastal cities have no adaptation policies and, where available, these are mostly, except for South Africa, dominated by national plans (Olazabal et al., 2019). Coastal adaptation actions minimally consider socioeconomic projections and are not at all aligned with future climate scenarios and risks, which is highly limiting for adaptation planning (Olazabal et al., 2019).

9.9.5.2 Anticipated Adaptation and Residual Risk for Human Settlements

Africa's smaller towns and cities have received far less scholarly and policy development attention for adaptation (Clapp and Pillay, 2017; White and Wahba, 2019). Smaller towns also have less ability to partner effectively with private entities for adaptation initiatives (Wisner et al., 2015). Political will to address climate change and information flows between key stakeholders, professional and political decision-makers may be easier to establish in smaller cities than in the megacity context (Wisner et al., 2015).

Exposure and vulnerability are particularly acute in informal areas, making coordinated adaptation challenging. Yet, there is growing recognition of the potential for bottom-up adaptation that embraces informality in order to more effectively reduce risk (Taylor et al., 2021a) (Figure 9.31). This can provide an opportunity for change towards more risk-sensitive urban development and transformative climate adaptation (Leck et al., 2018). Addressing social vulnerability is particularly important for ensuring the resilience of populations at risk. Improved monitoring, modelling and communication of climate risks is needed to reduce the impacts of climate hazards (Tramblay et al., 2020; Cole et al., 2021a).

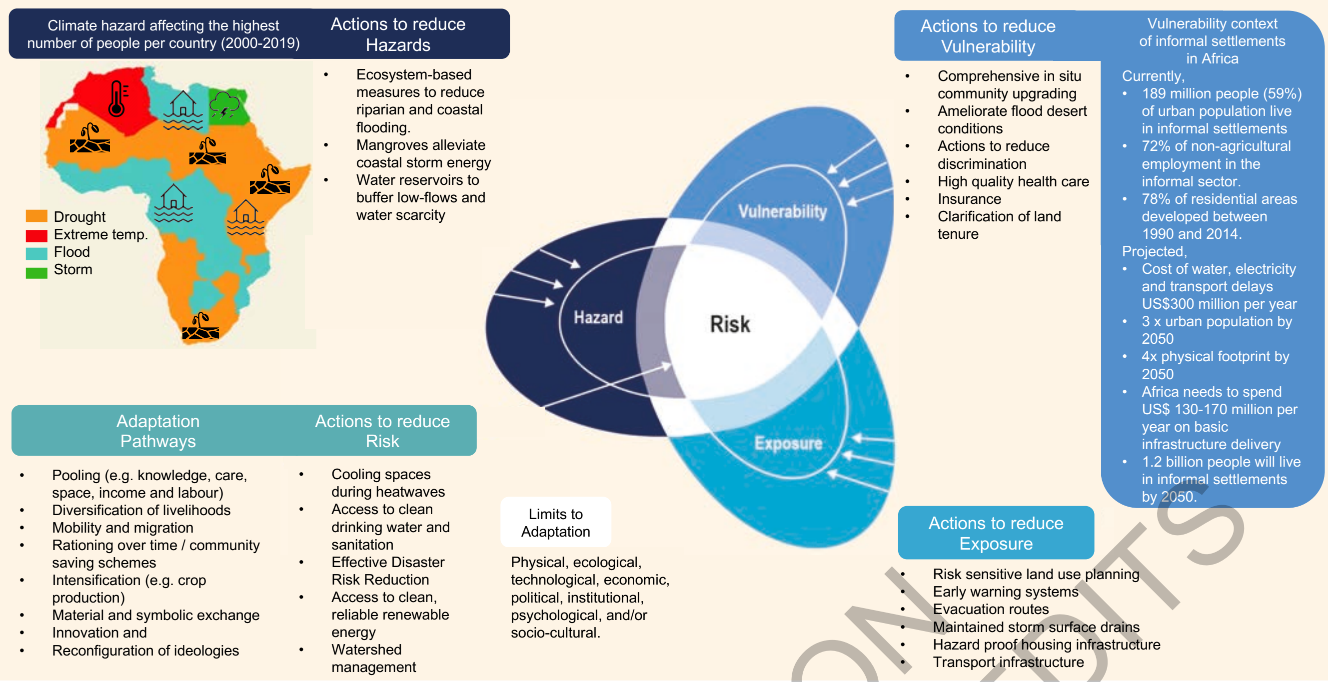

Figure 9.31: Key elements of adaptation in informal settlements in Africa. Adapted from (Thorn et al., 2015; Fedele et al., 2019; Satterthwaite et al., 2020)

9.9.5.3 Anticipated Adaptation for Transport Systems in Africa

Higher costs will be incurred to maintain and repair damages caused to existing roads as a result of climate change for countries with no adaptation policy for transport infrastructure (*very high confidence*) (Chinowsky et al., 2013; Cervigni et al., 2017; Koks et al., 2019). Countries with a greater percentage of unpaved roads will, however, incur higher economic costs through adaptation policy when compared to no adaptation policy (Cervigni et al., 2017).

Adaptation measures in the transport sector have focused on the climate resilience of road infrastructure. Modelling suggests that proactive adaptation of road designs to account for temperature increases is a ‘no regret’ option in all cases, but accounting for precipitation increases should be assessed on a case-by-case basis (*medium confidence*) (Cervigni et al., 2017). African governments will need climate adaptation financing options to meet the higher capital requirements of resilient road infrastructure interventions (Hearn, 2016).

Under the Nationally Appropriate Mitigation Action (NAMA) programme, investments in public transport and transit-oriented development are highlighted as desired mitigation-adaptation interventions within cities of South Africa, Ethiopia and Burkina Faso (UNFCCC, 2020). These interventions simultaneously reduce the vulnerability of low-income residents to climate shocks, prevent lock-ins into carbon-intensive development pathways and reduce poverty (*high confidence*) (Hallegatte et al., 2016; Rozenberg et al., 2019). The combined mitigation-adaptation interventions in the land use transport systems of African cities are also expected to have sufficient short-term co-benefits (reducing air pollution, congestion and traffic fatalities) to be ‘no regret’ investments (*very high confidence*) (Hallegatte et al., 2016; Rozenberg et al., 2019). Only eight African countries have transport-specific adaptation measures in their NDCs (Nwamarah, 2018). Five African countries have submitted National Adaptation Plans (NAPs) (Table 9.10).

Table 9.10: Transport sector references in the National Adaptation Plans of five African countries. Source: (Government of Burkina Faso, 2015; Government of Cameroon, 2015; Government of Togo, 2016; Government of Kenya, 2017; Government of Ethiopia, 2019).

Country	Identify climate change impacts	Promote transport as a disaster risk	Transport-specific adaptation measures			
			Climate resilient	Promote public transport	Promote non-motorized transport	Urban land use planning

		reduction measure	design standards			
Burkina Faso	X		X	X		X
Cameroon			X	X		
Ethiopia	X	X	X	X		
Kenya	X					
Togo				X	X	

9.9.5.4 Projected Adaptation for Electricity Generation and Transmission in Africa

Most electricity infrastructure in Africa has been designed to account for historical climatic patterns. Failure to take into account future climate scenarios in power system planning increases the climate risk facing infrastructure and supplies. Yet, energy demand for cooling over Africa, for example, is expected to increase, with a potential increase in heat stress, population growth and rapid urbanisation to 1.2% of total final energy demand by 2100 compared to 0.4% in 2005 (Parkes et al., 2019). Integrated energy system costs from increased demand for cooling to mitigate heat stress are projected to accumulate from 2005 to USD 51.3 billion by 2035 at 2°C and to USD 486.5 billion by 2076 at 4°C global warming (Parkes et al., 2019).

For hydropower, adaptations to different climate conditions can be made at the level of the power plant, turbine size and reservoir storage capacities, and can be adjusted to projected hydrological patterns (Lempert et al., 2015). At the river basin level, integrated water resource management practices can be implemented across sectors that compete for the same water resources (Howells et al., 2013). At the power system level, the energy mix and the protocol through which different power plants are dispatched can be adapted to different climate scenarios (Spalding-Fecher et al., 2017; Sridharan et al., 2019).

Given the uncertainty around future hydroclimate conditions, hydropower development decisions carry risk of 'regrets' (that is, damages or missed opportunities) when a different climate than was expected materialises. 'Robust adaptation' refers to an adaptation strategy that balances risks across different climate scenarios (Cervigni et al., 2015) (Cross-Chapter Box DEEP in Chapter 17). Development bank lending principles require consideration of the regional picture and interactions with other developments along a river when they determine the social and environmental impacts of the proposed hydropower project. However, these principles often do not explicitly consider climate change, so the risk of reoccurring drought-induced hydropower shortages could be missed (Box 9.5).

Lastly, given the degree to which hydropower competes with other sectors and ecosystems for the same water resources, it is critical that hydropower planning and adaptation does not occur in isolation. As discussed in Section 9.7, it must be part of an integrated water management system that balances the needs of different water-reliant sectors with other societal and ecological demands under increasingly variable climate and hydrological conditions (Section 9.7.3).

9.10 Health

The health section is organised by disease or health outcome, with observed impacts and projected risks described for each condition. All adaptation options are presented at the end of the section, highlighting prevention and preparedness, community engagement and disease-specific adaptation options.

9.10.1 The Influence of Social Determinants of Health on the Impacts of Climate Change

The social determinants of health are 'the conditions in which people are born, grow, live, work and age' as well as the drivers of these, including the social circumstances which profoundly affect health and drive health disparities (Commission of Social Determinants of Health, 2008; Gurewich et al., 2020). Social features (e.g., health-related behaviours), socioeconomic factors (e.g., income, wealth and education) and environmental determinants (e.g., air or water quality) are critical for shaping health outcomes. These factors are inextricably linked (Schulz and Northridge, 2004; Moore and Diaz, 2015) and are largely outside the domain of the health sector. Climate change is already challenging the health and well-being of African communities, compounding the effects of underlying inequalities (*high confidence*). The interlinkage between climate change and social determinants of health are largely discussed at a global level (Commission of Social Determinants of Health, 2008), or for developed countries (Ahdoot et al., 2015; Levy and Patz, 2015; Department of Economic and Social Affairs, 2016), with scant evidence for Africa. Nevertheless, there is robust evidence that the health impacts of climate change disproportionately affect the poorest people and children and, in some situations, can differ by gender and age (St Louis and Hess, 2008; Nyahunda et al., 2020; Ragavan et al., 2020) (see Box 9.1). Unequal access to health care particularly affects rural communities (Falchetta et al., 2020), vulnerable women and children (Wigley et al., 2020a) and challenges the achievement of development priorities such as universal health care access (SDG 3) (Weiss et al., 2020).

9.10.2 Observed Impacts and Projected Risks

Climate change is already impacting certain health outcomes in Africa (e.g. temperature-related mortality) and risks for most (but not all) health outcomes are projected to increase with increasing global warming (Figure 9.32), with young children (<5 years old), the elderly (>65 years old), pregnant women, individuals with pre-existing morbidities, physical labourers and people living in poverty or affected by other socioeconomic determinants of health being the most vulnerable (*high confidence*). Women may be more vulnerable to climate change impacts than men (Chersich et al., 2018; Jaka and Shava, 2018; Adzawla et al., 2019a). Contextualising projected impacts of climate change on health requires an understanding of observed impacts (Figure 9.32). Without management and mitigation, current and projected morbidities and mortalities will put additional strain on health, social and economic systems (Hendrix, 2017; Alonso et al., 2019).

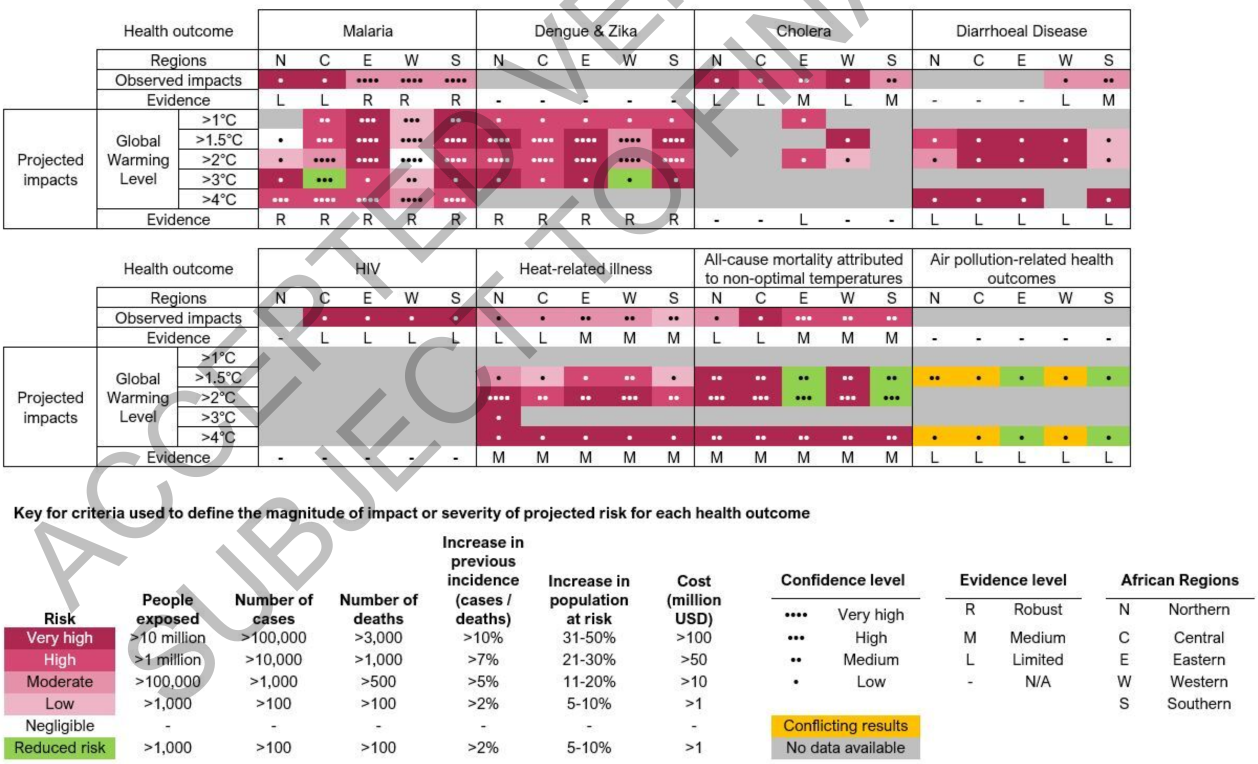

Figure 9.32: Observed climate impacts and projected climate change risks across African regions for eight key health outcomes. Increased global warming levels are shown relative to pre-industrial 1850–1900. This list of health impacts and risks is not intended to be exhaustive, but instead focusses on well-documented conditions. This assessment is a synthesis across 58 studies on observed impacts and 29 studies on projected risks for health (see Supplementary Material Table SM 9.7). The category of air pollution-related health outcomes includes health impacts from changing particulate matter concentrations due to climate change.

9.10.2.1 Vector-Borne Diseases

9.10.2.1.1 Malaria

Observed impacts

Higher temperatures and shifting patterns of rainfall influence the distribution and incidence of malaria in sub-Saharan Africa (*high confidence*) (Agusto et al., 2015; Beck-Johnson et al., 2017). Up to 10.9 million km^2 of sub-Saharan Africa is optimally suitable for year-round malaria transmission (Mordecai et al., 2013; Ryan et al., 2015). Current climate suitability for endemic malaria transmission is concentrated in the central African region, some areas along the Southern coast of West Africa and the East African coast (Ryan et al., 2020).

In East Africa, there has been an expansion of the *Anopheles* vector into higher altitudes (Gone et al., 2014; Carlson et al., 2019) and increasing incidence of infection with *P. falciparum* with higher temperatures (*high confidence*) (Alemu et al., 2014; Lyon et al., 2017). Over Southern Africa, changes in temperature and rainfall are increasing malaria transmission (Abiodun et al., 2018). In West Africa, studies show both positive (Adu-Prah and Kofi Tetteh, 2015; Darkoh et al., 2017) and negative (M'Bra et al., 2018) correlations of malaria incidence with increases in mean monthly temperatures, and an abundance of *Anopheles gambiae s.s.* associated with mean diurnal temperature (Akpan et al., 2018).

Malaria incidence and outbreaks in East Africa were linked with both moderate monthly rainfall and extreme flooding (Boyce et al., 2016; Amadi et al., 2018; Simple et al., 2018), and increase one to two months after periods of rainfall in Southern and West Africa (Diouf et al., 2017; Ferrão et al., 2017; Adeola et al., 2019). The years following La Niña events (Southern Africa) (Adeola et al., 2017)) and high relative humidity (West Africa) (Adu-Prah and Kofi Tetteh, 2015; Darkoh et al., 2017) have been positively linked with malaria incidence.

Projected risks

Since AR5, significant progress has been made in understanding how changes in climate influence the seasonal and geographical range of malaria vectors, transmission intensity and burden of disease of malaria across Africa. Yet projecting changes remains challenging given the range of factors that influence transmission and disease patterns, and model outputs contain high degrees of uncertainty (Zermoglio et al., 2019; Giesen et al., 2020). Models have limited ability to account for population changes and development trends (Kibret et al., 2015; Kibret et al., 2017), investments in health sectors and interventions (McCord, 2016; Colborn et al., 2018; Caminade et al., 2019), and confounders such as age, socioeconomic status, employment and labour migration and climate variability (Bennett et al., 2016; Karuri and Snow, 2016; Byass et al., 2017; Chuang et al., 2017; Colborn et al., 2018). Nevertheless, available models do allow for projections of malaria transmission under different climate change scenarios to be made with high levels of certainty.

In East and southern Africa and the Sahel, malaria vector hotspots and prevalence are projected to increase under RCP4.5 and RCP8.5 by 2030 (1.5°C–1.7°C global warming) (*high confidence*) (Leedale et al., 2016; Semakula et al., 2017b; Zermoglio et al., 2019), becoming more pronounced later in the century (2.4°C–3.9°C global warming) (Ryan et al., 2020). Under RCP4.5, 50.6–62.1 million people in East and Southern Africa will be at risk of malaria by the 2030s (1.5°C global warming), and 196–198 million by the 2080s (2.4°C global warming) (Ryan et al., 2020). Northern Angola, Southern DRC, western Tanzania and central Uganda are predicted to be worst impacted in 2030, extending to western Angola, upper Zambezi River Basin, northeastern Zambia and the East African highlands by 2080 (Ryan et al., 2020). Under rising temperatures, by the 2050s, the greatest shifts in suitability for malaria transmission will be seen in East, Southern and Central Africa (2°C global warming) (Tonnang et al., 2014; Zermoglio et al., 2019; Ryan et al., 2020).

Conversely, in some regions, changing climatic conditions are projected to reduce malaria hotspots and prevalence. With continued greenhouse gas emissions, these include: West Africa by 2030 (1.7°C global warming) (*high confidence*) (Yamana et al., 2016; Semakula et al., 2017b; Ryan et al., 2020), parts of Southern Central Africa and dryland regions in East Africa by 2050 (2.5°C global warming) (*high confidence*) (Semakula et al., 2017b; Ryan et al., 2020), and large areas of southern Central Africa and the western Sahel by 2100 (>4°C global warming) (Yu et al., 2015; Tourre et al., 2019). These reductions in transmission correspond with decreasing environmental suitability for the malaria vector and parasite in these regions (Ryan et al., 2015; Mordecai et al., 2020). Most areas in Burkina Faso, Cameroon, Ivory Coast, Ghana, Sierra Leone, Niger, Nigeria, Zambia and Zimbabwe will have almost zero malaria transmission under RCP8.5 (Semakula et al., 2017b; Tourre et al., 2019).

The El Niño-Southern Oscillation (ENSO) cycle currently contributes to seasonal epidemic malaria in epidemic-prone areas (*high confidence*), and is projected to shift the malaria epidemic fringe southward and into higher altitudes by mid- to end-century (*high confidence*) (Bouma et al., 2016; Semakula et al., 2017b; Caminade et al., 2019). More evidence is needed, however, of climate variability impacts through ENSO cycles in future risk projections, as well as a deeper understanding of how climate change will impact the length of transmission season for mosquitoes, particularly in areas where increases in spring and autumn temperatures may increase suitability for the reproduction of malaria vectors (Ryan et al., 2020). Other gaps in knowledge include a better understanding of mosquito thermal biology and thermal limits for a variety of species, potential adaptations to extreme temperatures and how landscape changes contribute to malaria transmission (Tompkins and Caporaso, 2016).

9.10.2.1.2 Mosquito-borne viruses

Observed impacts

Climate variability has driven a global intensification of mosquito-borne viruses (e.g., dengue, Zika and Rift Valley Fever), including expansion into areas with higher altitudes (Leedale et al., 2016; Mweya et al., 2016; Messina et al., 2019). Concerns centre on diseases vectored by the yellow fever mosquito (*Aedes aegypti*), common throughout most of sub-Saharan Africa, and the tiger mosquito (*Aedes albopictus*), currently largely confined to western Central Africa (Kraemer et al., 2019; Mordecai et al., 2020).

Although warming temperatures are largely responsible for increasing environmental suitability for mosquito vectors (Mordecai et al., 2019), droughts can augment transmission when open water storage provides breeding sites near human settlements, and when flooding enables mosquitoes to proliferate and spread viruses further (Mweya et al., 2017; Bashir and Hassan, 2019). Within Africa's rapidly growing cities, diseases vectored by urban-adapted *Aedes* mosquitoes pose a major threat, especially in West Africa (Zahouli et al., 2017; Weetman et al., 2018; Messina et al., 2019). Dengue virus expansion may cause explosive outbreaks but the burden of dengue haemorrhagic fever and associated mortality is higher in areas where transmission is already endemic (Murray et al., 2013).

Projected risks

Populations of *Aedes aegypti* and *Aedes albopictus* mosquitoes and epidemics of dengue and yellow fever and other *Aedes*-borne viruses are expected to increase, including at high altitudes (Weetman et al., 2018; Messina et al., 2019; Ryan et al., 2019; Gaythorpe et al., 2020; Mordecai et al., 2020). *Aedes albopictus* may expand beyond western Central Africa into Chad, Mali and Burkina Faso by mid-century at >2°C global warming (Kraemer et al., 2019). Shifts projected in *Aedes* range due to changing environmental suitability, combined with rapid urbanisation and population growth, suggest that by 2050 populations exposed to these vectors in Africa may double, and by 2080 nearly triple at >2°C global warming (Kraemer et al., 2019). Southern limits of dengue transmission in Namibia and Botswana, and the western Sahel, may show the greatest expansions in environmental suitability under 1.8°C–2.6°C global warming (Messina et al., 2019). In the warmest scenarios (RCP8.5), however, some parts of Central Africa may become too hot for mosquitoes to transmit dengue, and thus at-risk populations may peak at intermediate warming levels (Ryan et al., 2019). Climatic conditions favourable for mosquitoes, combined with the increase of animal trade, may result in the expansion of the geographic range of zoonotic diseases like Rift Valley fever (Martin et al., 2008), a threat for human and animal health with strong socioeconomic impacts (Peyre, 2015).

9.10.2.2 Diarrhoeal Diseases, HIV and Other Infectious Diseases

9.10.2.2.1 Diarrhoeal diseases

Observed impacts

Africa has the highest rates of death due to diarrhoeal diseases in the world (Havelaar et al., 2015; Troeger et al., 2018) and many children have repeated diarrhoeal episodes with impaired growth, stunting, immune dysfunction and reduced cognitive performance (Squire and Ryan, 2017). High land and sea temperatures (Paz, 2009; Musengimana et al., 2016) and precipitation extremes increase transmission of bacterial and protozoal diarrhoeal disease agents (Boeckmann et al., 2019) through contamination of drinking water and food preparation and preservation practices (Figure 9.33) (Levy et al., 2016; Soneja et al., 2016; Walker, 2018).

Cholera incidence has been shown to increase with temperature (Trærup et al., 2011). Outbreaks, however, are most frequent in East and Southern Africa following tropical cyclones (Moore et al., 2017b; Troeger et al., 2018; Ajayi and Smith, 2019; Cambaza et al., 2019).

Africa's rapidly urbanising population increases the demand for freshwater and is occurring in places that already have stretched water and sanitation infrastructure (Howard et al., 2016). These conditions, especially during periods of water scarcity, can reduce the frequency and adequacy of hand washing and thereby increase disease transmission.

Projected risks

Disruptions in water availability, such as during droughts or infrastructure breakdown, will jeopardise access to safe water and adequate sanitation, undermine hygiene practices and increase environmental contamination with toxins (Howard et al., 2016; WWF-SA, 2016; Miller and Hutchins, 2017).

Climate change is projected to cause 20,000–30,000 additional diarrhoeal deaths in children (<15 years old) by mid-century under 1.5°C–2.1°C global warming (WHO, 2014), with West Africa most affected, followed by East, Central and southern Africa. Cholera outbreaks are anticipated to impact East Africa most severely during and particularly after ENSO events (Moore et al., 2017b).

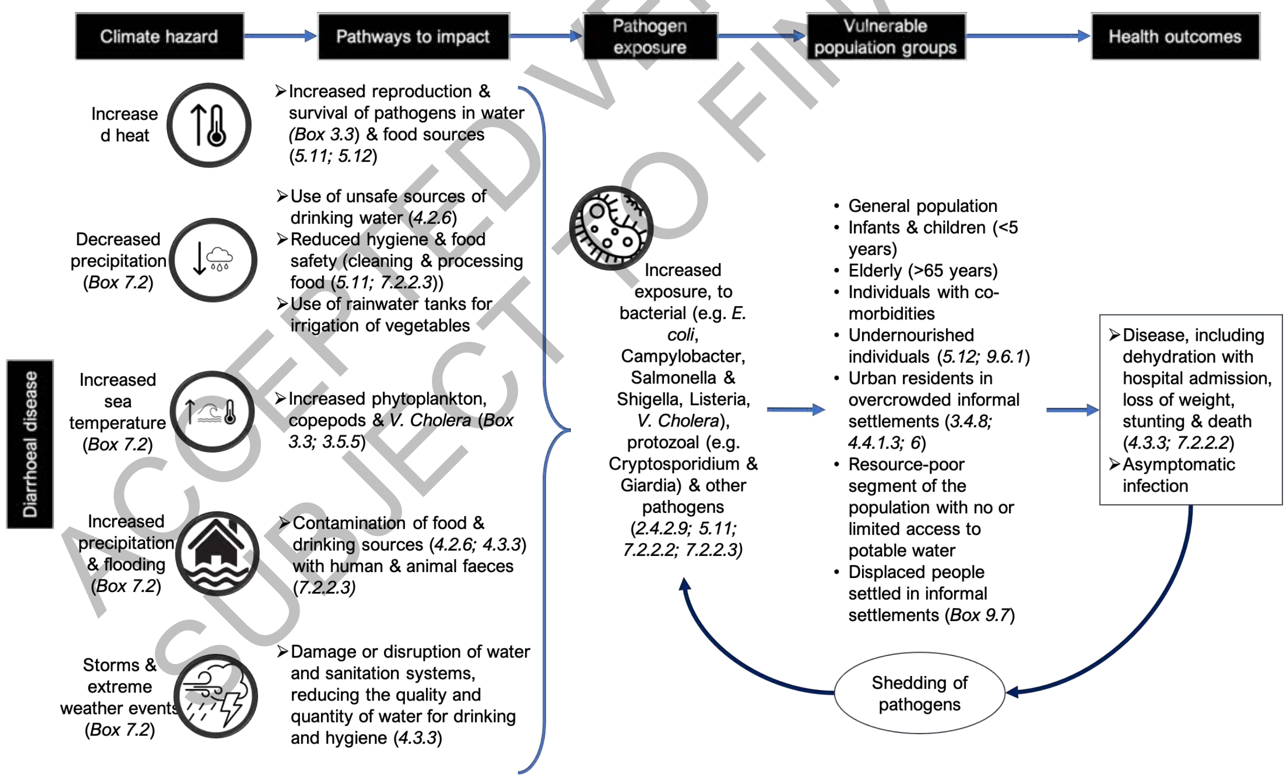

Figure 9.33: Pathways to impact: diarrhoeal disease. Schematic showing the pathways of impact diarrhoeal disease in Africa as a result of exposure to climate hazards.

[START BOX 9.6 HERE]

Box 9.6: Pandemic Risk in Africa: COVID-19 and Future Threats

Rapid advances in vaccination and other control measures in high-income countries means that the burden of COVID-19 is increasingly concentrated in low- and middle-income countries, including those in Africa. The extent to which the COVID-19 pandemic is influenced by weather or by future changes in climate remains contested (WMO, 2021). In time, COVID-19 may develop seasonal dynamics (Baker et al., 2020; Kissler et al., 2020) similar to other respiratory infections (Carlson et al., 2020b).

Early work interpreted low-reported cases of COVID-19 in Africa as suggesting evidence of a protective climatic effect, but increasing evidence indicates the role of climate is secondary to the timing of disease introduction, the pace of implementation of non-pharmaceutical interventions, and surveillance gaps (Evans et al., 2020; WMO, 2021). Going forward, testing coverage, reporting, governance, non-pharmaceutical interventions and vaccine distribution and uptake are *likely* to be far more significant for Africa's COVID-19 trajectory than climate change. Compounding risks, where climate hazards and natural disasters impair outbreak responses, may disrupt interventions or cause additional deaths (Phillips et al., 2020; Salas et al., 2020).

Emerging and future pandemic threats

Future influenza pandemics are highly *likely*, as are regional epidemics and pandemics of novel zoonotic viruses (including coronaviruses and flaviviruses) (*high confidence*). In the next decades, climate change will reshape the risk landscape for emerging zoonotic threats as wildlife-livestock-human interfaces shift, facilitating the emergence of novel zoonotic threats and spillover of known zoonoses into novel geographies (Carlson et al., 2020a; Mordecai et al., 2020). Characteristics of urban development and level of service provision, for example, crowded living spaces and transport facilities, and access to water and sanitation will influence the transmission of COVID-19 and future disease outbreaks (Wilkinson, 2020). Historically, West and Central Africa were considered especially at risk of outbreaks given their high biodiversity, high intensity of human-wildlife contact including wild meat trade, vulnerable health systems and history of Ebola virus disease outbreaks (Paige et al., 2014; Allen et al., 2017; Pigott et al., 2017). However, as the Middle East respiratory syndrome coronavirus (MERS-CoV) and COVID-19 pandemics have shown, there are multiple hotspots of viruses with pandemic potential globally, many of which are not in Africa. Thus, labelling African rainforests as unique 'hotspots' undermines global health work and pandemic preparedness.

[END BOX 9.6 HERE]

9.10.2.2.2 HIV

Observed impacts

Although levels of new HIV infections declined sharply during the last decade, still more than a million adults and children become infected each year (UNAIDS, 2020). Climate influences on HIV are predominately indirect such as through heightened migration due to climate variability, or extreme weather events leading to increased transactional sex to replace lost sources of income. Changes in climate affect each of the main drivers of HIV transmission in women, including poverty, inequity and gender-based violence (Burke et al., 2015a; Loevinsohn, 2015; Fiorella et al., 2019).

Projected risks

'Oscillating' or 'circular' migration for migrant workers in urban and mining centres drove HIV transmission in the 1990s and 2000s (Lurie, 2006), and climate-related displacement may have similar effects (see Box 9.7) (Gray and Mueller, 2012; Loevinsohn, 2015; Low et al., 2019). Food insecurity and nutritional deficiencies, projected to increase with increasingly variable climates, has been shown to increase sexual risk-taking and migration, as well as increase susceptibility to other infections (Lieber et al., 2021). Projected increases in exposure to infectious diseases pose considerable threats to HIV-infected people who may already have compromised immune function. Additionally, reduced lung function in people with HIV from previous tuberculosis infection may put them at high risk for morbidity and death during extreme heat (Abayomi and Cowan, 2014). Moreover, extreme weather events accompanied by damage to health system infrastructure could compromise the continuity of antiretroviral treatment (Weiser et al., 2010; Pozniak et al., 2020).

9.10.2.2.3 Other infectious diseases

Poor populations in the western Sahel have the highest burden of bacterial meningitis worldwide, with seasonal dynamics driven by the dry Harmattan winds that transport dust long distances across the continent (Agier et al., 2013; García-Pando et al., 2014). In Nigeria, rising temperatures are projected to increase meningitis cases by about 50% for 1.8°C global warming (RCP2.6 in 2060–2075), and by almost double for 3.4°C global warming (RCP8.5 in 2060-2075) (Abdussalam et al., 2014). Bilharzia is also highly climate-sensitive, with its distribution influenced by changes in temperature and precipitation, as well as development, such as the introduction of freshwater projects (e.g., canals, hydroelectric dams and irrigation schemes) (Adekiya et al., 2019).

9.10.2.3 Temperature-Related Impacts

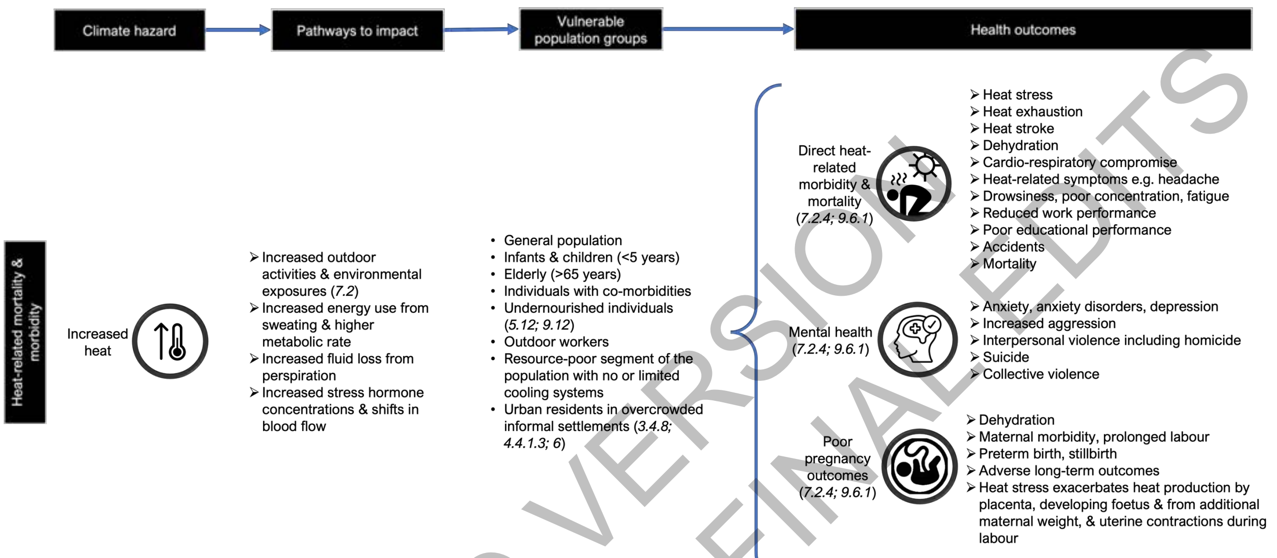

Figure 9.34: Pathways to impact: heat-related morbidities. Schematic showing the pathways of impact for heat-related morbidities in Africa as a result of exposure to climate hazards. Numbers in the figure refer to chapter sections of this report. Indirect health impacts of heat are not shown. For example, risk of malnutrition from reduced crop yields or reduced fisheries catches (see Section 9.8.5).

9.10.2.3.1 Mortality and morbidity

Observed impacts

Emergency department visits and hospital admissions have been shown to increase at moderate to high temperatures (Bishop-Williams et al., 2018; van der Linden et al., 2019), with increased levels of mortality recorded on days with raised temperatures in Burkina Faso (Kynast-Wolf et al., 2010; Diboulo et al., 2012; Bunker et al., 2017), Ghana (Azongo et al., 2012), Kenya (Egondi et al., 2012; Egondi et al., 2015), South Africa (Wichmann, 2017; Scovronick et al., 2018), Tanzania (Mrema et al., 2012) and Tunisia (Bettaieb et al., 2010; Leone et al., 2013). Cause of death most commonly involves cardiovascular diseases (Kynast-Wolf et al., 2010; Scovronick et al., 2018), but increased incidences of respiratory (Scovronick et al., 2018), stroke (Longo-Mbenza et al., 1999) and non-communicable diseases (Bunker et al., 2017) have also been linked with heat.

Excess death rates from non-optimal temperature in sub-Saharan Africa are estimated to be nearly double the global average, with 24% of the more than 5 million annual deaths associated with non-optimal temperature occurring in Africa (Zhao et al., 2021). The region had the world’s highest cold-related excess death ratio and lowest heat-related excess death ratio over the period 2000–2019. However, during this time, cold-related excess deaths declined more rapidly than the increase in heat-related excess deaths, resulting in a net decrease in the excess death ratio from temperature.

Recent estimates of the burden of mortality associated with the additional heat exposure from recent human-induced warming suggest approximately 43.8% of heat-related mortality in South Africa was attributable to anthropogenic climate change from 1991–2018 (Vicedo-Cabrera et al., 2021). In many of South Africa's 52 districts, this equates to dozens of deaths per year. The elderly and children under five years are most vulnerable to heat exposure (Sewe et al., 2015; Scovronick et al., 2018).

Projected risks

Globally, Africa is predicted to suffer disproportionately higher all-cause mortality risk from higher temperature-related all-cause mortality from global warming, compared to temperate, Northern Hemisphere countries (Carleton et al., 2018). The number of days projected to exceed potentially lethal heat thresholds per year reaches 50–150 days in West Africa at 1.6°C global warming, up to 200 days in West Africa and 100–150 days in Central Africa and parts of coastal East Africa at 2.5°C, and over 200 days for parts of West, Central and East Africa for >4°C global warming (Mora et al., 2017) (see Sections 9.5.3–7; Figure 9.15). Projected rates of heat-related mortality among people in the Middle East and North Africa who are older than 65 years increase by 8–20 fold in 2070–2099, compared with 1951–2005, based on RCP4.5 and RCP8.5 (both at >2°C global warming) (Ahmadalipour and Moradkhani, 2018).

Temperature-related mortality across Africa is projected to escalate with global warming, reaching 50–180 additional deaths per 100,000 people annually in regions of North, West, and East Africa for 2.5°C global warming, and increasing to 200-600 per 100,000 people annually for 4.4°C global warming (Carleton et al., 2018) (Figure 9.35). However, some regions that currently experience cold-related mortality (e.g., Lesotho and Ethiopian highlands) are projected to have reduced temperature-related mortality risk from warming. Greenhouse gas mitigation is projected to save tens of thousands of lives: limiting warming to RCP4.5 (2.5°C) rather than RCP8.5 (4.4°C) at the end of the century is projected to avoid on average 71 deaths per 100,000 people annually across Africa with larger reductions in risk in North, West, Central and parts of East Africa (Figure 9.35). The cost of mitigating heat stress using energy-intensive cooling methods is expected to be to be unachievable for many African countries (Parkes et al., 2019) (see Section 9.9.4).

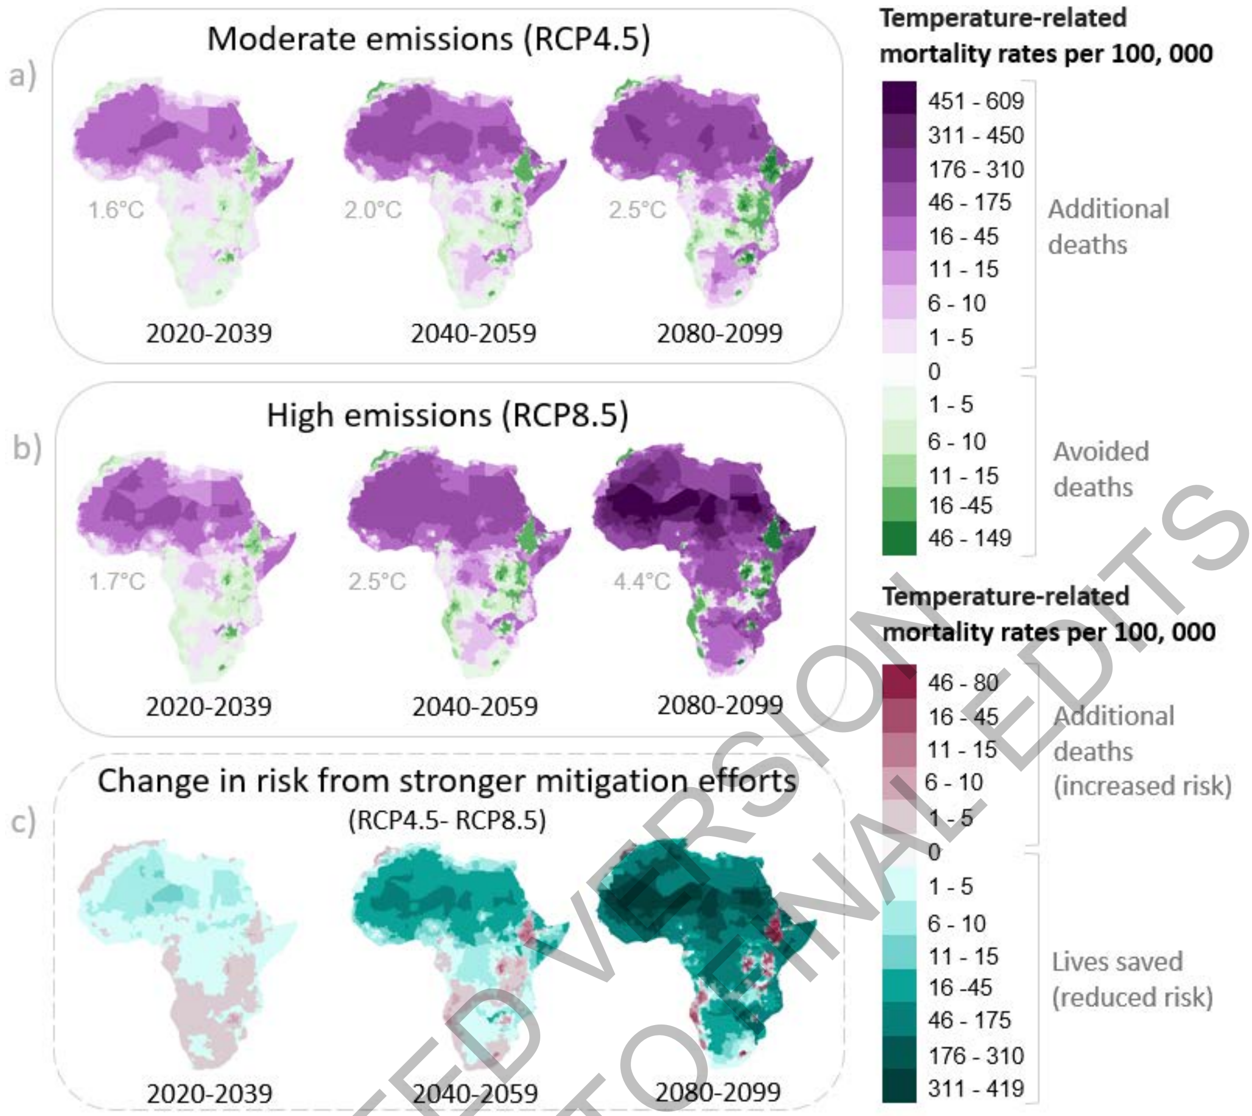

Figure 9.35: Temperature-related mortality risk in Africa with increased global warming. Maps showing changes in mortality rates in deaths per 100 000 for global warming in the years 2020–2039, 2040–2059, and 2080–2099 for (a) medium emissions scenario (RCP 4.5); (b) a high emissions scenario (RCP 8.5); and (c) showing avoidable deaths due to increased emissions mitigation to achieve reduced global warming (RCP4.5–RCP8.5). These estimates of climate change impacts on mortality rates include temperature-related impacts only. They account for the benefits of income growth and incremental adaptation to climate change, both of which reduce mortality sensitivity to extreme temperatures. Projections were based on income and demographics from Shared Socioeconomic Pathway 3 (SSP3), with future adaptation based on adaptation actions observed in the global historical record. The estimates do not include the costs of the behaviours and investments required to achieve such adaptation (Carleton et al., 2018). Areas shown in green in c) have fewer deaths due to temperature under RCP8.5 than RCP4.5. This is because cold is currently the greatest driver of temperature-related deaths in these countries, which will be alleviated with increasing levels of global warming (Zhao et al., 2021).

9.10.2.3.2 Heat stress in specific settings

Heat stress symptoms are prevalent among people in buildings that are poorly ventilated or insulated, or constructed with unsuitable materials (e.g., corrugated metal sheeting). These features are common to many structures in Africa, including in slums, informal and low-income settlements, as well as schools and healthcare facilities (Bidassey-Manilal et al., 2016; Naicker et al., 2017; Wright et al., 2019). Temperatures inside these structures can exceed outdoor temperatures by 4°C or more and have large diurnal fluctuations (Mabuya and Scholes, 2020). Daily wage labourers and residents of urban informal settlements are among the most vulnerable to heat stress because of the urban heat island effect, with congestion, little ventilation, shade, open space and vegetation (Bartlett, 2008) being associated with impacts of both hot and cold conditions on public health (Ramin, 2009), and the number of years lived depending on age, sex and comorbidities (Egondi et al., 2015). Temperature extremes are *likely* to result in relatively more deaths in informal settlements than in other settlement types (Scovronick and Armstrong, 2012).

The urban heat island effect exacerbates current and projected heat stress in Africa's rapidly growing cities (Mitchell, 2016) and is discussed in more detail in Section 9.9.3.

Escalating temperatures and longer-duration heatwaves are *likely* to heavily affect workers already exposed to extreme temperatures, e.g., outdoor workers (Kjellstrom et al., 2018) and miners (El-Shafei et al., 2018; Nunfam et al., 2019a; Nunfam et al., 2019b). Vulnerability may also be high for women who cook food for a living, and children who accompany them, due to prolonged exposure to high temperatures (Parmar et al., 2019). Prisons, commonly poorly ventilated and overcrowded, are also high-risk settings (Van Hout and Mhlanga-Gunda, 2019).

9.10.2.3.3 Maternal and child health

Exposure to high temperatures during pregnancy has been linked with adverse birth outcomes, including stillbirths or miscarriages (Asamoah et al., 2018) and long-term behavioural and developmental deficiencies (Duchoslav, 2017; MacVicar et al., 2017).

9.10.2.4 Impacts of Extreme Weather

During extreme conditions, for example, Cyclone Kenneth (Codjoe et al., 2020) and El Niño 2015-2016 (WHO, 2016; Pozniak et al., 2020), direct physical injury, loss of life, destruction of property and population displacement can occur. Flooding and landslides are common after extreme rainfall and are the most frequently described impact of climate variability in Africa's cities currently, with residents of poorly serviced or informal settlements most vulnerable (Hunter et al., 2020). Post-traumatic stress disorders in affected individuals are common, including in children (Rother, 2020). In rural areas, the resulting damage to health facilities, access routes and transport services can severely compromise health service delivery (WHO, 2016). The effects of extreme weather on urban health infrastructure depends on the characteristics, location and adaptive capacity of cities (see Section 9.9.4).

9.10.2.5 Malnutrition

Observed impacts

Africa has experienced the greatest impacts of climate change on acute food insecurity and malnutrition (FAO and ECA, 2018). Adverse climatic conditions exacerbate the impacts of an unstable global economy, conflict and pandemics on food insecurity (AfDB, 2018b; Food Security Information Network (FSIN), 2019; Fore et al., 2020) (see Chapter 5, Section 5.12.4).

More than 250 million Africans are undernourished, mostly in Central and East Africa (FAO et al., 2020), which increases childhood stunting, affects cognition and has trans-generational sequelae (IFPRI, 2016; UNICEF et al., 2019). Undernutrition is strongly linked with hot climates (Hagos et al., 2014; Tusting et al., 2020). In Burkina Faso, low crop yields resulted in around 110 deaths per 10,000 children under five, with 72% of this impact attributable to adverse climate conditions in the growing season (Belesova et al., 2019).

Increasing incidence and expanded distributions of vector-borne livestock diseases (e.g., bluetongue, trypanosomiasis and Rift Valley Fever) in response to changes in rainfall and increasing temperatures, undermine food security, especially among subsistence farmers (Samy and Peterson, 2016; Caminade et al., 2019). Locust infestations linked with changes in climate (Salih et al., 2020) are a major risk for food security in Africa.

Projected risks

Projected risks for malnutrition in Africa are high (FAO, 2016) (see Section 9.8.1): 433 million people in Africa are anticipated to be undernourished by 2030 (FAO et al., 2020) and, compared to 1961–1990, 1.4 million additional African children will suffer from severe stunting by 2050 under 2.1°C global warming (WHO, 2014). In Burkina Faso, the mortality burden due to low crop yields could double by 2100 with 1.5°C of global warming (Belesova et al., 2019). Drought risks will include crop and livestock failures

(Ahmadalipour et al., 2019). Additionally, increasing concentrations of atmospheric CO_2 will affect the nutritional quality of C_3 plant staples, lowering levels of protein and minerals like zinc and iron (Myers et al., 2014; Weyant et al., 2018). Declining fish catches due to ocean warming, illegal fishing and poor stock management are projected to increase deficiencies of zinc, iron and vitamin A for millions of people across Mozambique, Angola and multiple West African countries (Golden et al., 2016) (see Section 9.8.5).

9.10.2.6 Non-Communicable Diseases and Mental Health

Links between climate change and the environmental risk factors for non-communicable diseases (NCDs) may be direct (e.g., extreme heat exposure in people with cardiovascular disease) or indirect, such as via the global agriculture and food industry (Landrigan et al., 2018). These effects are largely unreported for Africa (Amegah et al., 2016), where the burden of many NCDs is growing rapidly with increasing urbanisation and pollution (Rother, 2020).

Many urban poor populations have unhealthy dietary practices, which present major risks for obesity, type II diabetes and hypertension. Paradoxically, despite growing levels of undernutrition, the incidence of overweight and obesity continues to rise in Africa, particularly in children under five from the northern and southern parts of the continent (FAO and ECA, 2018). Diabetes is increasingly prevalent and outcomes may worsen if climate change undermines health infrastructure and the range of available foods (Keeling et al., 2012; Kula et al., 2013; Chersich and Wright, 2019).

The relationship between cancer and climate change is complex and indirect. Changing temperature and humidity may alter the distribution of Aflatoxin-producing fungi, contaminating food (grains, maize) and causing cancer (see Box 5.9 in Chapter 5) (Sserumaga et al., 2020; Valencia-Quintana et al., 2020). Severe storms and flooding may disrupt wastewater treatment or disposal, potentially contaminating drinking water with carcinogenic substances.

Areas with low service provision (e.g., informal settlements in Africa) suffer from increased infestations of pests such as flies, cockroaches, rats, bedbugs and lice, which may be controlled by chemical pesticides (Rother et al., 2020) and may become more prevalent with a changing climate (Mafongoya et al., 2019). Inappropriate pesticide use and disposal cause endocrine disruption and increased incidences of some cancers (Rother et al., 2020).

9.10.2.6.1 Mental health and well-being
Mental health and well-being are affected by local climate conditions and are therefore sensitive to climate change (Burke et al., 2018b; Obradovich et al., 2018). High temperatures are strongly associated with poor mental health and suicide in South Africa (Kim et al., 2019). Exposure to extreme heat directly influences emotional control, aggression and violent behaviour, escalating rates of interpersonal violence, with homicides rising by as much as 18% in South Africa when temperatures are above 30°C compared with temperatures below 20°C (Burke et al., 2015a; Chersich et al., 2019b; Gates et al., 2019).

Extreme weather events are often severely detrimental to mental health (Scheerens et al., 2020), with elevated rates of anxiety, post-traumatic stress disorder and depression in impacted individuals (Schlenker and Lobell, 2010; Nuvey et al., 2020). Youth may be at especially high risk (Barkin et al., 2021).

Loss of livestock from disease or lack of pastures is strongly linked with poor mental health among farmers (Nuvey et al., 2020). Climate change impacts on mental health among refugees is concerning but remains under-researched (Matlin et al., 2018).

9.10.2.7 Air Quality-Related Health Impacts

Links between air quality and climate change are complex (Smith et al., 2014; Szopa et al., 2021). Increases in particulate matter concentrations are driven more by vehicle emissions, solid waste, biomass burning and development (Abera et al., 2021) than by climate change, and these factors vary widely across regions of the continent (West et al., 2013). Women and children who are exposed to high particulate matter concentrations when cooking indoors and HIV-infected people are more vulnerable to the health impacts of air pollution (Abera et al., 2021). Information on the direction of change of air quality in different African regions attributable to climate change are contradictory (Westervelt et al., 2016; Silva et al., 2017). Additionally, much uncertainty remains about interactions between air quality and climate change and relative impacts of different modes of development and climate change on pollutants. However, increasing temperatures combined with a reduction in rainfall are *likely* to increase particulate matter concentrations (Abera et al., 2021), particularly in North Africa (Westervelt et al., 2016; Silva et al., 2017).

Nevertheless, continued dependence on fossil-fuelled power plants will result in tens of thousands of avoidable deaths due to air pollution by 2030 (Marais and Wiedinmyer, 2016), and accelerate climate change. Actions to reduce air pollution can both mitigate climate change and have major co-benefits for health (West et al., 2013; Rao et al., 2016; Markandya et al., 2018; Rauner et al., 2020a; Rauner et al., 2020b) (see also AR6 WGIII, Chapters 3, 4, 8 and 10). Investing in renewable energy resources rather than reliance on the combustion of fossil fuels would mark an important step forward for African population health (Marais et al., 2019). This is especially important in South Africa which emits approximately half the total carbon emissions for Africa, ranking 12th in the world for carbon emissions (Mohsin et al., 2019).

Dust events in West Africa have severe health impacts (cardiorespiratory and infectious diseases, including meningitis) (Ayanlade et al., 2020) given the proximity of the Sahara, which produces about half of the yearly global mineral dust (de Longueville et al., 2013). Wildfires are projected to become the main source of particulate matter in West, Central and southern Africa under both the lowest and highest future emissions scenarios, whereas, under intermediate scenarios (i.e., SSP3/RCP4.5), anthropogenic sources of particulate matter are projected to exceed that produced by wildfires (Knorr et al., 2017).

[START BOX 9.7 HERE]

Box 9.7: The Health-Climate Change Nexus in Africa

The intersections between climate change and human health are involve interactions of numerous systems and sectors (Lindley et al., 2019; Yokohata et al., 2019). This complexity means that holistic, transdisciplinary and cross-sectoral (systems) approaches like One Health, EcoHealth and Planetary Health can improve the long-term effectiveness of responses to health risks (Zinsstag, 2012; Whitmee et al., 2015; Nantima et al., 2019). More research is needed to identify sustainable solutions (Rother et al., 2020), as recently re-emphasised by the Intergovernmental Panel on Biodiversity in its report on the COVID-19 pandemic (IPBES, 2020). The close dependency of many Africans on their livestock and surrounding ecosystems forms a context where integrated health approaches are especially critical for addressing climate change risks to health (Figure Box 9.7.1) (Watts et al., 2015; Cissé, 2019).

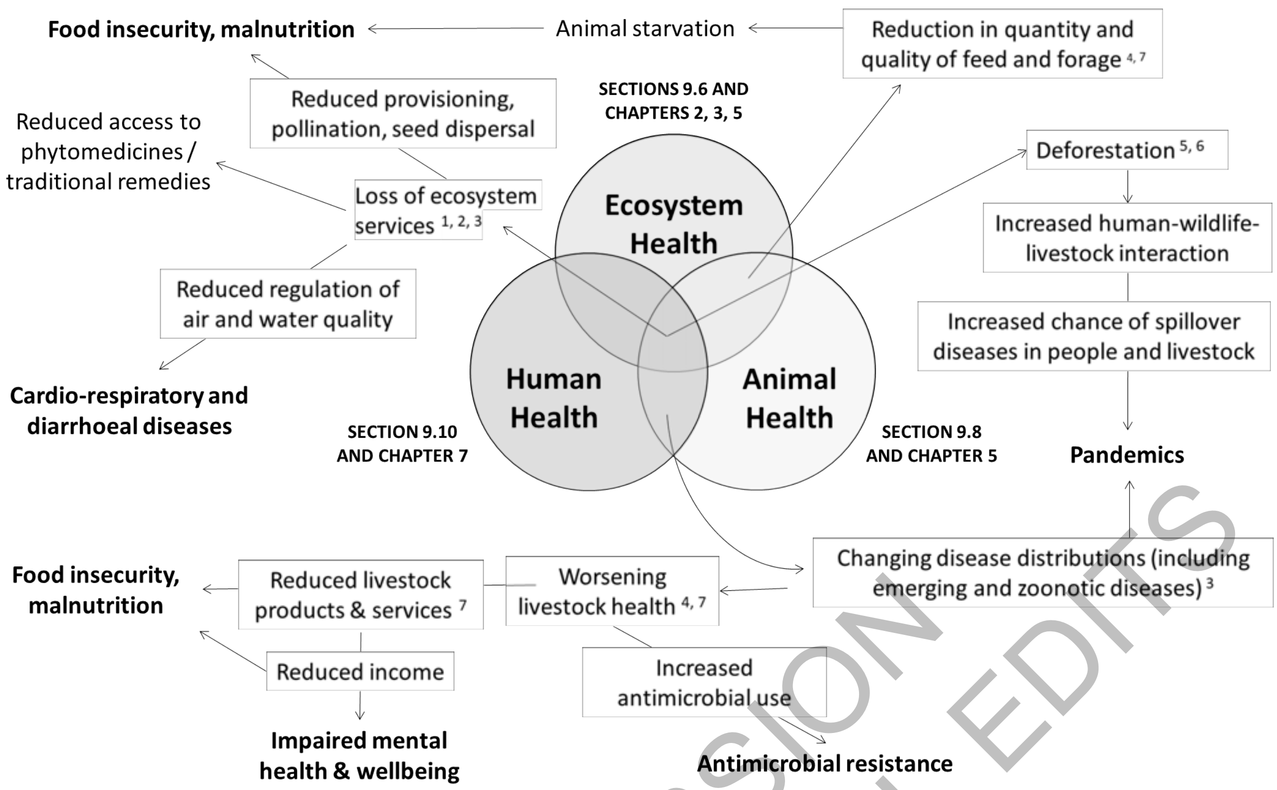

Figure Box 9.7.1: Human, ecosystem and animal health are intimately interlinked, and require transdisciplinary approaches such as One Health, EcoHealth and Planetary Health for effective, sustainable, long-term management. This schematic shows some examples of these interlinkages, and how they impact human health, highlighting the complex interactions and the importance of holistic, systems approaches to health interventions, including for climate change adaptation. Supporting literature: 1 (Egoh et al., 2012); 2 (Wangai et al., 2016); 3 (Failler et al., 2018); 4 (Ifejika Speranza, 2010); 5 (Brancalion et al., 2020); 6 (Bloomfield et al., 2020); 7 (Rojas-Downing et al., 2017).

Integrated approaches to health in Africa can deliver multiple benefits for humans and ecosystems For example, rather than addressing micronutrient deficiencies with supplements, which may not be accepted culturally and can be disrupted by stockouts or similar, addressing nutrient deficiencies in staple crops by selecting or breeding more nutritious varieties (e.g., orange-fleshed sweet potatoes or 'golden rice' for vitamin A deficiency) may prove to be more sustainable options (Datta et al., 2003; Nair et al., 2016; Laurie et al., 2018; Oduor et al., 2019; Stokstad, 2019). Additionally, some micro- or macronutrient deficiencies and food insecurities may be improved by addressing the depletion of soils through better management, including the incorporation of holistic, sustainable principles, such as those promoted by agroforestry or regenerative agriculture (Rhodes, 2017; Elevitch et al., 2018; LaCanne and Lundgren, 2018) (5.12.4).

[END BOX 9.7 HERE]

9.10.3 Adaptation for Health and Well-Being in Africa

In this section, we focus on adaptation actions that are well-documented or shown to have the potential for substantially improving health or well-being. These adaptation options are assessed in Figure 9.36 and Table 9.11.

In Africa, adaptive responses have begun to be implemented by local, national and international entities (Ebi and Otmani Del Barrio, 2017). With strong leadership, these initiatives can be used as an opportunity for comprehensive, transformative change rather than incremental improvements to existing systems. Adaptation responses are necessarily context-specific and can focus on providing services for vulnerable and high-risk populations (Dumenu and Obeng, 2016; Herslund et al., 2016).

Adaptation actions in the health sector range from building resilient health systems to preparing responses to health impacts of extreme weather events to reducing effects of increasing temperatures in residential and occupational settings (Kjellstrom et al., 2016; Chersich and Wright, 2019). A climate-resilient health system involves functional and effective health systems (WHO, 2015), national and local policy plans with resources for implementation, and long- and short-term communication strategies to raise awareness around climate change (Nhamo and Muchuru, 2019).

Many health conditions associated with climate change are not new, and existing evidence-based interventions can be modified to address shifting disease patterns (Ebi and Otmani Del Barrio, 2017). Adaptation options can build on a long tradition of community-based services in Africa (Ebi and Otmani Del Barrio, 2017). Indeed, strengthening many of the services already provided (e.g., childhood vaccinations and vector control) will help curtail emerging burdens of climate-sensitive conditions. However, a disproportionate focus on emerging zoonotic and vector-borne viruses could undermine climate change adaptation efforts in Africa if it shifts the focus away from health system strengthening and leaves few resources for addressing other health impacts of climate change.

Core components of an adaptation response include rapid impact packages (e.g., mass drug administration for schistosomiasis), education of women and direct poverty alleviation (Bailey et al., 2019). Where droughts are more frequent and rainfall patterns have shifted, adaptation support can be provided for strategies developed by communities, including the adaptation of livelihoods and diversification of crops and livestock (Mbereko et al., 2018; Bailey et al., 2019). Continued efforts through partnerships, blending adaptation and disaster risk reduction, and long-term international financing are needed to bridge humanitarian and sustainable development priorities (Lindley et al., 2019) (Cross-Chapter Box HEALTH in Chapter 7).

9.10.3.1 Risk Assessment and Warning Systems

Improved institutional capacity for risk monitoring and early warning systems is key to support emergency preparedness and responsiveness in Africa, as well as shock-responsive and long-term social protection (FAO and ECA, 2018). Climate risk assessments grounded in evidence and locally appropriate technologies are important for identifying priority actions, the scale of intervention needed and high-risk geographical areas and populations. Potential tools include those developed by WHO (Ceccato et al., 2018) and the Strategic Tool for Analysis of Risk (Ario et al., 2019).

Warning systems that predict seasonal to intra-seasonal climate risks could assist in improving response times to extreme weather events (such as droughts, flooding or heat waves) and shifts in infectious diseases. Weather and other types of forecasting provide an advanced warning – a central tenet of disaster risk reduction (Funk et al., 2017; Okpara et al., 2017a; Lumbroso, 2018). Models encompassing each component of the human-animal-environmental interface, including disease surveillance in humans and animals and remote sensing of vegetation indexes, water and soil can be used to project patterns of zoonose outbreaks (UNDP, 2016; Bashir and Hassan, 2019; Durand et al., 2019). Early warning systems may help better prepare for these and other forms of infectious disease outbreaks (Thomson et al., 2006) but adaptation is possible in the absence of statistical tools through vaccination and surveillance, for example.

Surveillance systems for diseases and vectors are well-established in many parts of Africa (Ogden, 2017). However, many data gaps remain, especially in monitoring climate-sensitive conditions such as diarrheal- and arbovirus-related diseases, and morbidity and mortality stemming from heat exposure (Ogden, 2017; Buchwald et al., 2020).

Climate and health adaptation indicators are required for Africa to strengthen institutional capacity for risk monitoring and early warning systems, emergency preparedness and response, vulnerability reduction measures, shock-responsive and long-term social protection and planning and implementing resilience building measures (FAO and ECA, 2018). National-level progress is assessed through the Lancet Countdown indicators (Watts et al., 2018), however, district- and local-level indicators are needed to measure levels of vulnerability and response effectiveness at a local level, and for informing planning local service delivery. Potential indicators include monitoring the number of excess health conditions during extreme heat events. Indoor temperature monitoring in sentinel houses and health facilities is a related indicator (Ebi and Otmani Del Barrio, 2017), linked with threshold temperature levels at which health impacts occur, and the ability of the built environment to protect against these impacts (e.g., for heatwaves).

Measuring climate-health linkages is challenging due to the considerable diversity of the exposures, impacts and outcomes, as well as constraints in key technical areas. Increasing our understanding of this diversity and how this is influenced by adaptative changes is a major knowledge gap. This could be facilitated through a pan-African database of climate and other environmental exposures, together with real-time statistical support for analyses of climate and health associations.

9.10.3.2 Community Engagement

Increased awareness can facilitate community engagement and action (see Section 9.4.3). In Ghana, for example, local communities understand the climate hazards that drive outbreaks of meningitis and adapt accordingly by improving housing to limit heat and exposure, changing funeral practices during outbreaks, increased vaccination uptake and afforestation (Codjoe and Nabie, 2014). Similarly, participation in community organisations improved child nutrition in vulnerable rural households in Eswatini (Anchang et al., 2019). Interventions specifically targeting women are beneficial for food security, although they may be undermined by harmful gender norms in communities that are patriarchal, led by chiefs or have high rates of gender-based violence (Jaka and Shava, 2018; Kita, 2019; Masson et al., 2019). The BRACED project in Burkina Faso and Ethiopia specifically adopted a gender-transformative approach as an integral part of resilience-building (McOmber et al., 2019). Improving 'climate literacy' could empower youth, women and men to be active citizens in promoting adherence of governments to international agreements in climate change (Mudombi et al., 2017; Chersich et al., 2019a).

9.10.3.3 9.10.3.1Health Financing

Poor and low-income households often are not able to afford high out-of-pocket costs for medical care, or it consumes a large portion of their income. As a result, without financial aid, peoples' health needs may not be met after a climate shock (Hallegatte and Rozenberg, 2017). Microfinance (the provision of small-scale financial products to low income and otherwise disadvantaged groups by financial institutions) and disaster contingency funds can serve to reduce health risks of climate change for low-income communities (Agrawala and Carraro, 2010; Ozaki, 2016), as can different forms of insurance and disaster relief (Fenton et al., 2015; Dowla, 2018). Unconditional cash transfers in Kenya, Uganda and Zambia assisted vulnerable groups to absorb the negative impacts of climate-related shocks or stress and to prepare for these (Lawlor et al., 2019; Ulrichs et al., 2019). Based on several case studies in Africa, the Food and Agriculture Organization recommends a 'Cash+' approach which combines cash transfers with productive assets, inputs or technical training to address the needs of vulnerable households in emergency situations, and enhance livelihoods potential, income generation and food security (FAO, 2017). New economic models have been implemented in North Africa, focused on poor households, youth and women that enable access to credit and support the implementation of policies that balance cash and food crops, social safety nets and social protection (Mumtaz and Whiteford, 2017; Narayanan and Gerber, 2017) (see also Sections 9.4, 9.8 and 9.11).

9.10.3.4 Disease-Specific Adaptations

Adaptation to prevent malaria
Increasing distribution and coverage of long-lasting insecticide-treated bed nets, improved diagnostic tests and increasing health service access could mitigate the impacts of climate change on malaria if aligned with the predicted or actual burden of malaria (*medium confidence*) (Kienberger and Hagenlocher, 2014; Thwing et al., 2017). Understanding seasonal shifts in malaria transmission suitability as a result of climate change can guide more targeted seasonal public health responses and better planning for different types of management and control interventions based on the impact. For example, an increase in the number of months where climate conditions are suitable for mosquito survival will require public health responses for an extended period of time (Ryan et al., 2020).

In malaria-endemic areas, repeated malaria infections can provide temporary immunity, which reduces new clinical cases (Laneri et al., 2015; Yamana et al., 2016). Conversely, where people have little or no immunity, exposure to malaria can lead to epidemics (Semakula et al., 2017a; Ryan et al., 2020). Pregnant women and infants remain at risk for severe malaria, regardless of immunity status. Vector control and case management capacity should be rapidly scaled up in newly affected areas where risks for epidemics are high and populations are especially vulnerable. Poverty-alleviation initiatives underpin malaria control as the malaria burden is strongly tied to socioeconomic status (Huldén et al., 2014; Degarege et al., 2019).

Contextualised risk studies on local drivers of transmission are still lacking and present a major gap in developing appropriate adaptation strategies (*high confidence*). Progress has been made identifying and ranking vulnerability and exposure indicators (Protopopoff et al., 2009; Onyango et al., 2016a), however, better linking of biophysical and socioeconomic determinants of risk in integrated assessment models are needed (Caminade et al., 2019; Zermoglio et al., 2019), as are applied approaches to develop adaptation strategies for risk management (Leedale et al., 2016; Onyango et al., 2016b; Sadoine et al., 2018).

Adaptation to reduce diarrhoeal disease

Reducing pathogen concentrations in water and across food chains is fundamental for controlling diarrhoeal diseases (van den Berg et al., 2019). Diarrhoea prevention and treatment post-disaster, encompass social mobilisation campaigns, water treatment, enhanced surveillance and vaccination and treatment centres for cholera (Cambaza et al., 2019) and typhoid (Neuzil et al., 2019).

Improved water, sanitation and hygiene (WASH) requires robust water and sanitation infrastructure (Duncker, 2017; Kohlitz et al., 2017; Venema and Temmer, 2017) and technological adaptations (Gabert, 2016; van Wyk et al., 2017), such as waterless on-site sanitation (Sutherland et al., 2021), diversification of water sources (e.g., rainwater harvesting (Lasage and Verburg, 2015) and groundwater abstraction (MacDonald et al., 2012)), and sharing of best practices across the continent (WASH Alliance International, 2015; Jack et al., 2016) (see also Section 9.7.3; Chapter 4, Section 4.6.4). Hand hygiene can be improved through the creation of handwashing stations, increased access to soap and simple technologies such as the foot-operated Tippy taps (Coultas and Iyer, 2020; Mbakaya et al., 2020).

Adaptation to reduce conditions related to heat exposure

Reducing morbidity and mortality during extreme heat events requires changes in behaviour and health promotion initiatives, health system interventions and modifications to the built and natural environment. Health promotion initiatives include promoting adequate hydration and simple cooling measures such as drinking cold liquids, water sprays and raising awareness of the symptoms and importance of heat stress, including heatstroke (Aljawabra and Nikolopoulou, 2018). Adaptive measures are especially important for high-risk groups such as outdoor workers, the elderly, pregnant women and infants. Health systems interventions may include early warning systems, heat health regulation, and health workers providing cooling interventions, such as supplying cool water or fans, during heat waves. Changes to the built environment include painting the roofs of houses white and improving ventilation during extreme heat (Codjoe et al., 2020), the use of insulation materials or altering the building materials used for the construction of housing to improve their ability to moderate indoor temperatures (Mathews et al., 1995; Makaka and Meyer, 2006).

Adaptation to prevent malnutrition

Transformative adaptation requires integration of resilience and mitigation across all parts of the food system including production, supply chains, social aspects and dietary choices (IPCC, 2019a). Adaptation to prevent malnutrition goes hand-in-hand with adaptation to prevent food insecurity, as is discussed in Section 9.8.3 and Chapter 5, Section 5.12.5.

Urban agriculture and forestry can improve nutrition and food security, household income and mental health of urban farmers while mitigating against some of the impacts of climate change like flooding and landslides (by stabilising the soil and reducing runoff, for example), heat (by providing shade and through evapotranspiration) and diversifying food sources in case of drought (Zezza and Tasciotti, 2010; Lwasa et al., 2014; Battersby and Hunter-Adams, 2020).

The health sector needs to collaborate and coordinate adaptation activities with other sectors, as well as civil society and international agencies, to engage communities in health promotion (Irwin et al., 2006; Commission of Social Determinants of Health, 2008; Braveman and Gottlieb, 2014). The importance of social determinants of health, such as socioeconomic status, education and the physical environment in which people live and work and their consideration during development are highlighted in Chapter 7 (see Sections 7.1.6 and 7.4.2)

Figure 9.36: Adaptation options across multiple sectors have potential for reducing risk across multiple health outcomes, considering their potential to reduce vulnerability, and potential barriers to implementation (e.g., lack of social acceptance). Reduced risk for health may result from targeted actions or as a result of co-benefits (see Supplementary Material Table SM9.8 for a full list of references).

Table 9.11: Co-benefits, barriers and enablers of adaptation responses to climate change impacts on human health in Africa (see Supplementary Material Table SM 9.9 for a full list of references).

Response category	Co-benefits	Inter-sectoral trade-offs and/or drawbacks	Enablers	Barriers
Policy development	Policies and plans that facilitate service delivery and guide national and international funding; decreased number of work hours lost; improved work performance, increased productivity		Willingness of policymakers; political support; politically willing environment; inter-sectoral collaboration	Lack of implementation; poor governance
Education & awareness	Promotion of sustainable living and circular economy		Guarantee to sustained funding; political support; politically willing environment; increased accessibility of learning institutions	Lack of implementation; historical and colonisation-related insensitivities
Health systems & primary healthcare services	Capacity building in communities; buffered economic impact of outbreaks/ disasters; job creation	Increased GHG from building; increased energy demand; decreased productivity and increased work hours lost due to waiting times	Guarantee to sustained funding; political support; politically willing environment	Corruption and fraudulent activities around resource allocation
Surveillance, risk assessments, monitoring, & research	Evidence to improve adaptation response; fast post-disaster recovery; increased awareness and disease prevention; improved health system functioning post-disasters		Requires effective institutional arrangements and inter-sectoral collaboration; guarantee to sustained funding; requires skills development	May be limited by uncertainty in modelled predictions and thresholds
Resource management	Improved health system functioning post-disasters; capacity building in communities; promotes economic growth/stability; increases the tourism potential of the area; increased accessibility/ mobility of the community; reduced land degradation, desertification, and bush encroachment; food security; decreased emissions	Increased GHG from building; increased energy demand; increased crowding/ population density; land use; microclimate and ecosystem disruption	Guarantee to sustained funding; political support; politically willing environment; requires effective institutional arrangements and inter-sectoral collaboration; requires skills development	Corruption and fraudulent activities around resource allocation
Vector control & disease prevention	Decreased mortality; improved work performance; increased productivity; improved mental health	Increased GHG; decreased biodiversity; environmental impacts of production, packaging, and delivery; potentially detrimental to health	Guarantee to sustained funding; funding and resources; future planning or retrofit required	Last-mile access; cost per capita and capacity for service delivery

9.11 Economy, Poverty and Livelihoods

9.11.1 Observed Impacts of Climate Change on African Economies and Livelihoods

9.11.1.1 Economic Output and Growth

Increased average temperatures and lower rainfall have reduced economic output and growth in Africa, with larger negative impacts than other regions of the world (Abidoye and Odusola, 2015; Burke et al., 2015a; Acevedo et al., 2017; Kalkuhl and Wenz, 2020). In one estimate, GDP per capita is on average 13.6% lower for African countries than it would be if anthropogenic warming since 1991 had not occurred (Diffenbaugh and Burke, 2019), although impacts vary substantially across countries (see Figure 9.37). As such, global warming has increased economic inequality between temperate, Northern Hemisphere countries and those in Africa (Diffenbaugh and Burke, 2019). Warming also leads to differential economic damages within Africa (Baarsch et al., 2020). One estimate found a 1°C increase in 20-year average temperature reduced GDP growth by 0.67 percentage points, with the greatest impacts in Central African Republic, Democratic Republic of Congo and Zimbabwe (Abidoye and Odusola, 2015). Changes in rainfall patterns also influence individual and national incomes. Had total rainfall not declined between 1960 and 2000, the gap between African GDP and that of the rest of the developing world would be 15–40% smaller than today, with the largest impacts in countries heavily dependent on agriculture and hydropower (Barrios et al., 2010).

Aggregate macroeconomic impacts manifest through many channels (Carleton et al., 2016). Macroeconomic evidence suggests aggregate impacts occurred largely through losses in agriculture with a smaller role for manufacturing (Barrios et al., 2010; Burke et al., 2015b; Acevedo et al., 2017). Sector-specific analyses confirm that declines in productivity of food crops, commodity crops and overall land productivity contribute to lower macroeconomic performance under rising temperatures (Schlenker and Lobell, 2010; Bezabih et al., 2011; Jaramillo et al., 2011; Lobell et al., 2011; Adhikari et al., 2015). Labour supply and productivity declines in manufacturing, industry, services and daily wage labour have been observed in other regions (Graff Zivin and Neidell, 2014; Somanathan et al., 2015; Day et al., 2019; Nath, 2020) and contribute to aggregate economic declines, countering aggregate poverty reduction strategies and other sustainable development goals (Satterthwaite and Bartlett, 2017; Day et al., 2019). In a case study of a rural town in South Africa, over 80% of businesses (both formal and informal) lost over 50% of employees and revenue due to agricultural drought (Hlalele et al., 2016). Drought and extreme heat events have also reduced tourism revenues in Africa (Section 9.6.3). Infrastructure damage and transport disruptions from adverse climate events reduce access to services and growth opportunities (Chinowsky et al., 2014). In global datasets including Africa, tropical cyclones have been shown to have large and long-lasting negative impacts on GDP growth (Hsiang and Jina, 2014).

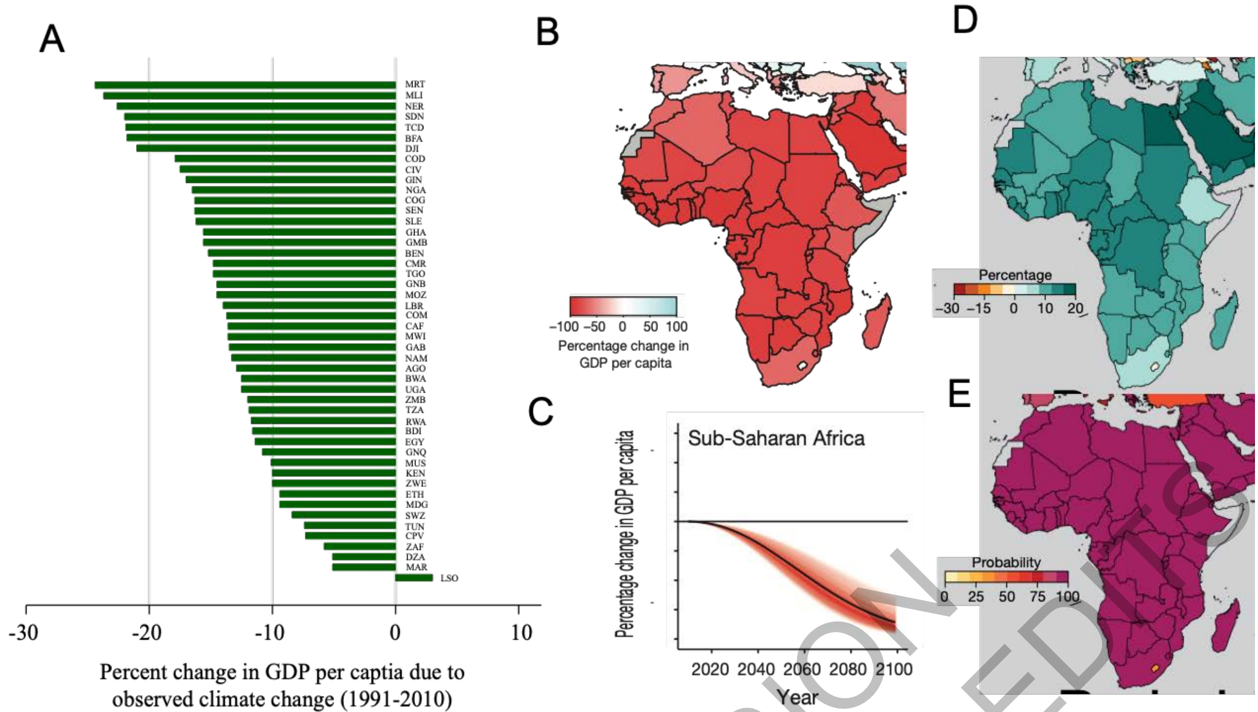

Figure 9.37: Observed aggregate economic impacts and projected risks from climate change in Africa. (A) Estimated effect of anthropogenic climate change on GDP per capita for 48 African countries between 1991 and 2010. (B, C) Projected effect on GDP per capita of global warming of ~4°C by 2100 compared to no global warming after 2010 at country level (B) and averaged across sub-Saharan Africa (C). (D) Benefits to GDP per capita of holding warming to 1.5°C versus 2°C above pre-industrial. (E) Probability of realising any economic benefits by holding warming to 1.5°C versus 2°C. Data sources: (Burke et al., 2015b; Burke et al., 2018a; Diffenbaugh and Burke, 2019).

9.11.1.2 Human Capital Development and Education

Investments in human capital, particularly education, are critical for socioeconomic development and poverty reduction by providing valuable skills and expanding labour market opportunities. Much progress has been made in improving education access, however, in sub-Saharan Africa, 32% of children, adolescents and youth (~97 million people) remain out of school (UNESCO Institute of Statistics, 2018). Climate variability and change can undermine educational attainment with negative impacts on later life earning potential and adaptive capacity to future climate change (Lutz et al., 2014) (Figure 9.11).

Several studies indicate experiencing low rainfall, warming temperatures or extreme events reduce education attainment and that future climate change may reduce children's school participation, particularly for agriculturally-dependent and poor urban households. In West and Central Africa, experiencing lower-than-average rainfall during early life is associated with up to 1.8 fewer years of completed schooling in adolescence while more rainfall and milder temperatures during the main agricultural season were positively associated with educational attainment for boys and girls in rural Ethiopia (Randell and Gray, 2016; Randell and Gray, 2019). In Uganda, low rainfall reduced primary school enrolment by 5% for girls (Björkman-Nyqvist, 2013), and in Malawi, in utero drought exposure was associated with delayed school entry among boys (Abiona, 2017). In rural Zimbabwe, experiencing drought conditions during the first few years of life was associated with fewer grades of completed schooling in adolescence, which translates into a 14% reduction in lifetime earnings (Alderman et al., 2006). In Cameroon, warming temperatures have negatively affected plantain yields, which in turn is linked to lower educational attainment (Fuller et al., 2018). One suggested mechanism underlying the relationship between climate and schooling is that adverse climatic conditions can reduce income among farming households, leading them to pull children out of school (Randell and Gray, 2016; Marchetta et al., 2019). Other potential mechanisms are poor harvests from droughts or supply interruptions from extreme weather events leading to undernutrition among young children, negatively affecting cognitive development and schooling potential (Alderman et al., 2006; Bartlett, 2008).

More research is needed on climate change impacts on education in Africa. This information can help ensure families keep children in school amidst climate-related income shocks. For example, in Mexico, a conditional cash transfer program mitigated the negative effect of natural disasters on school attendance (de Janvry et al., 2006).

9.11.2 Projected Risks of Climate Change for African economies and livelihoods

Future warming will have negative consequences for economic growth in Africa, relative to a future without additional climate change and assuming current levels of adaptation (*high confidence*) (Dell et al., 2012; Burke et al., 2015a; Burke et al., 2015b; Acevedo et al., 2017; Baarsch et al., 2020). Statistically-based empirical analyses project that global warming of 2.3°C by 2050 could lower GDP per capita across sub-Saharan Africa by 12% (SSP2) (Baarsch et al., 2020) and 80% for warming >4°C by 2100 (SSP5, 75% for MENA) (Burke et al., 2015b). Depending on the future socioeconomic scenario, this could increase global inequality and leave some African countries poorer than at present (Burke et al., 2015b). Inequalities between African countries are projected to widen under climate change, with negative impacts estimated to be largest in West and East Africa (Baarsch et al., 2020). While negative impacts across African economies are highly *likely* under climate change, precise magnitudes are debated in the literature. Alternative statistical analyses suggest a 12% reduction of GDP per capita by 2100 under RCP8.5 across African countries relative to a future without climate change (Kahn et al., 2019), while computable general equilibrium models generate smaller damages as well, ranging from 3.8% reduction across sub-Saharan Africa in 2060 under warming of 2.5°C (Dellink et al., 2019) to 12% across all of Africa in 2100 under warming of 5°C (SSP4) (Takakura et al., 2019).

Substantial avoided economic damages to African countries are projected from ambitious, near-term global mitigation limiting global warming well below 2°C above pre-industrial levels (*high confidence*). Increased economic damage forecasts for Africa under high emissions scenarios start diverging rapidly from low emissions scenarios by the 2030s (Baarsch et al., 2020). Across nearly all African countries, GDP per capita is projected to be at least 5% higher by 2050 and 10–20% higher by 2100 if global warming is held to 1.5°C versus 2°C (Burke et al., 2018a; Baarsch et al., 2020) (Figure 9.37). The probability of this positive gain to GDP per capita from achieving 1.5°C versus 2°C is reported as close to 100% (Burke et al., 2018a). While these estimates rely on temperature and rainfall-driven damages, sea level rise also poses a risk for Africa. By 2050, damages from sea level rise across sub-Saharan Africa could reach 2–4% of GDP, depending on the socioeconomic, adaptation and emissions scenario (Parrado et al., 2020).

Heat stress is projected to reduce working hours and work capacity under climate change, with among the largest declines in sub-Saharan Africa and for workers in vulnerable occupation groups, such as those working outdoors (Kjellstrom et al., 2014; Kjellstrom et al., 2016; de Lima et al., 2021) (AR6 WGII, Chapter 5). Global warming of 3°C is projected to reduce labour capacity in agriculture by 30–50% in sub-Saharan Africa (relative to the baseline in 1986–2005) (de Lima et al., 2021). These effects lead to substantial aggregate losses, for example, in West Africa, labour productivity impacts under a 3°C temperature increase are estimated to cost up to 8% of GDP (Roson and Sartori, 2016). Manufacturing productivity across Africa is projected to decline under RCP8.5 by 0–15% by 2080–2099, with the largest effects in the Democratic Republic of Congo, Ethiopia, Somalia, Mozambique and Malawi (Nath, 2020).

Large risks to road, rail and water infrastructure are projected from climate change with substantial economic cost implications (see Section 9.9.3; Box 9.5).

9.11.3 Informality

Aggregate GDP data capture formal economic activity but informal employment is the main source of employment in Africa, accounting for 85.8% of all employment (71.9%, excluding agriculture), which is 21.4% higher than the global average (ILO, 2018b). Estimates of national levels of informal employment range from 30% in South Africa, to 94.6% in Burkina Faso (ILO, 2018b), with high variability within countries such as South Africa and Nigeria (Etim and Daramola, 2020). Informal employment is a greater source of employment for women than for men in sub-Saharan Africa and young and old have especially high rates of informal employment: 94.9% of persons between ages 15 and 24 in employment and 96% of persons aged 65 and older (ILO, 2018b).

Informal sector impacts are omitted from GDP-based impacts projections. Yet informal sector activity and small to medium-sized enterprises can be highly exposed to climate extremes, as they are often located in low-lying areas, coastal areas, sloped or other hazardous zones (Thorn et al., 2015; Satterthwaite et al., 2020). Businesses and individuals in the informal sector, including construction workers, domestic workers, street vendors and transport workers, often cannot operate during climate shocks due to interruptions in transportation and commodity flows and, without the ability to insure against risk, struggle to recover assets from extreme events such as flooding, landslides and waterlogging (Chen, 2014; Thorn et al., 2015; Roy et al., 2018a). Women are overrepresented in the more poorly remunerated sections of the informal economy (Satterthwaite et al., 2020).

There is scope for governments to better harness the role of the informal sector in mitigation and adaptation (Douxchamps et al., 2015; Satterthwaite et al., 2020). Multi-level governance that includes informal service providers, such as informal water and sanitation networks, into planned adaptation programmes can increase climate resilience, in part because these networks can respond with more flexibility than hard infrastructure projects (Satterthwaite et al., 2020; Peirson and Ziervogel, 2021). Climate risk is often concentrated in urban informal settlements (Section 9.9.4). Here, informal land markets influence development patterns and can help ensure adherence to building codes to ensure safety of informally built structures at high risks of landslides and floods and enforce compliance with regulations relating to planning and land use (Thorn et al., 2015; Satterthwaite et al., 2020). Improving land management practices of charcoal producers and artisanal gold miners, combined with appropriate alternative livelihood and energy sources, can reduce emissions and increase resilience (e.g., reduce erosion and sedimentation, increase water infiltration) and benefit health (Atteridge, 2013; Paz et al., 2015; Macháček, 2019; Barenblitt et al., 2021; Eniola, 2021). Providing concessional loans, commercial financing or equity investment to informal brick makers can boost delivery of low emission social housing while the use of crop residues or renewable energy for brick making can replace wood biomass and reduce pressure on forests (Alam, 2006; Paz et al., 2015).

9.11.4 Climate Change Adaptation to Reduce Vulnerability, Poverty and Inequality

High temperature-related income losses have been observed in low- and high-income countries, suggesting optimistic economic development trajectories may not substantially reduce climate change impacts on aggregate economic performance in Africa (*low confidence*) (Burke et al., 2015b; Deryugina and Hsiang, 2017; Henseler and Schumacher, 2019). Nevertheless, climate change impacts on poverty in Africa will depend on how socioeconomic development unfolds over the coming decades (*medium confidence*) (Rozenberg and Hallegatte, 2015; Hallegatte and Rozenberg, 2017; Henseler and Schumacher, 2019). Climate change by 2030 is projected to push 39.7 million Africans into extreme poverty[3] under a baseline scenario of delayed and non-inclusive growth, with food prices acting as the dominant channel of impact, but this number is cut roughly in half under an inclusive economic growth scenario (Rozenberg and Hallegatte, 2015; Hallegatte and Rozenberg, 2017; Jafino et al., 2020).

People in Africa are disproportionately employed in highly climate-sensitive sectors: 55–62% of the sub-Saharan African workforce is employed in agriculture and while between 90–95% of cropland is rainfed (Woodhouse et al., 2017; ILO, 2018a; International Institute of Water Management, 2019; World Bank, 2020c), there has been an expansion of small-scale 'farmer-led irrigation' (Woodhouse et al., 2017). Agricultural GDP also appears more strongly affected by increasing temperatures than non-agricultural GDP, implying livelihood diversification out of agriculture may help minimise future economic damage (Bezabih et al., 2011; Burke et al., 2015b; Acevedo et al., 2017; Deryugina and Hsiang, 2017), although such workforce reallocation requires careful management and planning depending on the overall livelihood portfolios, type of farmer and profitability (Stringer et al., 2020). De-agrarianisation can feed urbanisation, which may exacerbate inequality within and between countries (Stringer et al., 2020).

Changes in trade patterns may help mitigate projected aggregate economic losses by reallocating agricultural production abroad and encouraging economic diversification toward less affected sectors. Temperature increases have been shown to lower agriculture and manufacturing exports with especially large declines in

3 Extreme poverty is defined using a consumption poverty line at US$1.25 per day, using 2005 purchasing power parity exchange rates.

poor countries (Jones and Olken, 2010; Roberts and Schlenker, 2013). Further, imports of agricultural products are projected to rise across most of Africa by 2080-2099 under a high emissions scenario (RCP8.5), with increases ranging from ~30% of GDP in the Central African Republic to ~5% of GDP in South Africa and Nigeria, although some countries will experience increases in net agricultural exports (Nath, 2020). While these reallocation effects may be large, current evidence is mixed regarding whether such adjustment of production will dampen or amplify overall social costs of climate change in Africa (Costinot et al., 2012; Bren d'Amour et al., 2016; Wenz and Levermann, 2016; Nath, 2020), as food prices are projected to rise by 2080-2099 across all African countries under a scenario with high challenges to mitigation and adaptation (SSP3 and RCP8.5), with the largest price effects (up to 120%) experienced in Niger, Chad and Sudan (Nath, 2020). Moreover, reallocating production of agriculture abroad could be maladaptive if it leads to decline or replacement of traditional sectors by industrial and service sectors which could lead to land abandonment, food insecurity and loss of traditional practices and cultural heritage (Thorn et al., 2020; Gebre and Rahut, 2021; Nyiwul, 2021).

African countries have high inequality: the average within-country share of income accruing to the top 10% of households was estimated at 50% for 2019 (Robilliard, 2020). However, analysis of INDCs across 54 African countries suggests current climate policies do not, on average, target social inequality in energy, water and food security; proposed mitigation and adaptation actions fell about 23% for every 1% rise in social inequality across these sectors (Nyiwul, 2021). In contrast, adaptation actions can be designed in ways that actively work towards reducing inequality, whether gender, income, employment, education or otherwise (Andrijevic et al., 2020).

In rural Africa, poor and female-headed households face greater livelihood risks from climate hazards (*high confidence*). Women often constitute a high proportion of the informal workforce and are also more *likely* to be unemployed than men (ILO, 2018a). These factors leave women, and particularly female-headed households, at greater risk of poverty and food insecurity from climate hazards. Controlling for multiple factors, income of female-headed households in agricultural districts in South Africa is more vulnerable to precipitation variability than those headed by men (Davidson, 2016; Flatø et al., 2017). Across nine countries in East and West Africa women tend to control smaller plots of land that is often of poorer quality, have less access to inputs such as fertilizer, tools and improved seeds, have lower educational attainment and benefit less from extension services, government agencies and non-governmental organisations (Perez et al., 2015). Gender assessments prior to adaptation programmes can identify disparities in division of labour and income and socio-cultural norms, hindering women from holding leadership positions or determining livelihood and resource-use activities, thereby helping ensure equitable benefits from livelihood diversification and improving women's working conditions (ILO, 2018a). Gender-responsive policy instruments can measure success using sex-disaggregated data to monitor impact and meaningful participation in decision-making (GCF, 2018b).

Exposure to climate hazards can trap poorer households in a cycle of poverty (Dercon and Christiaensen, 2011; Sesmero et al., 2018) and poor people in Africa are often more exposed to climate hazards than non-poor people. For example, poor people live in hotter areas in Nigeria and in multiple African countries, poor households are more exposed to flooding (Hallegatte et al., 2016) (Section 9.9.2). Daily wage labourers and residents of urban informal settlements are vulnerable to heat stress because of the urban heat-island effect combined with congestion, little shade and ventilation (Bartlett, 2008). Climate change can negatively affect household poverty through price spikes, destroying assets or ability to invest in new assets and reducing productivity (Hallegatte et al., 2016) with important impact pathways operating through agriculture, ecosystem functioning and health (Sections 9.6, 9.8, 9.10; Chapters 5, 7, 8). Non-poor people can lose more in absolute terms from climate shocks because of having more assets and higher incomes, but in relative terms, poor people often lose more than the non-poor. These relative losses matter most for livelihoods and welfare (Hallegatte et al., 2016).

In Malawi, wealthier households were able to maintain more diversified livelihoods, buffering them from extreme weather-related income losses (Sesmero et al., 2018). Poorer households have limited access to resources such as savings, credit, irrigation technologies and insurance, which can lead to larger crop and other income losses from climate hazards, preventing investments to improve resilience to future climate shocks (Castells-Quintana et al., 2018). Poor households may reduce risk or aid recovery by cooperating with other households in their community to adapt collectively to climate change, for example, through informal insurance networks (Paul et al., 2016; Wuepper et al., 2018). Prioritising poor households for interventions including social protection, ecosystem-based adaptation, universal healthcare, climate-smart buildings and agriculture, flexible work hours under extreme heat and early warning systems will increase adaptation to climate shocks (Angula and Menjono, 2014; Moosa and Tuana, 2014; Hallegatte et al., 2016; Day et al., 2019) (Section 9.6.4; Chapter 6). Pro-poor policies that link mitigation and adaptation, such as using renewable energy to increase rural electrification or using revenues from a carbon tax, combined with international financial support to increase social assistance, could support sustainable eradication of poverty under near-term climate change (Hallegatte et al., 2016; Aklin et al., 2018; Simpson et al., 2021c). Integrating urban green infrastructure into adaptation planning in informal settlements can simultaneously unlock pathways for inclusivity and social justice (Tozer et al., 2020; Wijesinghe and Thorn, 2021) (Section 9.9.5).

Social protection has been used for decades, particularly in eastern and southern Africa, to safeguard poor and vulnerable populations from poverty and food insecurity (Niño-Zarazúa et al., 2012). Instruments of social protection include public works programs, cash transfers, in-kind transfers, social insurance and microinsurance schemes that assist individuals and households to cope during times of crisis and minimise social inequality. Evidence from Kenya, Ethiopia and Uganda indicates national social protection programmes are effective in improving individual and household resilience to climate-related shocks, regardless of whether they aim specifically to address climate risks (Ulrichs et al., 2019). Strengthening social protection and better integrating climate risk management into design of social protection programs can help build long-term resilience to climate change (Hallegatte et al., 2016; Agrawal et al., 2019). For example, Public Works programs can build climate resilience by targeting soil, water and ecosystem conservation and carbon sequestration, such as South Africa's Working for Water Programme that restores river catchments to reduce fire risk and increase water supplies (Turpie et al., 2008; Norton et al., 2020).

9.11.4.1 Climate Insurance

African countries and communities are inadequately insured against climate risk. Insurance penetration is less than 2% of GDP (Swis Re, 2019) and 90% of natural catastrophe losses were uninsured in Africa in 2018 (Swis Re, 2019) leaving a large risk protection gap. The cost of reinsurance in Africa's most mature insurance market – South Africa – has increased since 2017 due to climate-related payouts (SAIA, 2018; Simpson, 2020), *likely* to further reduce the extent of insurance coverage. Emerging trends that seek to address this gap include innovative weather and drought index-based insurance schemes to transfer risk, forward-looking climate data and models to manage risk and insurers transitioning from risk transfer providers to proactive risk managers.

The most significant area of climate risk insurance innovation has occurred in weather and drought index-based insurance schemes that pay out fixed amounts based on the occurrence of an event instead of full indemnification against assessed losses (Table 9.12). However, despite the relatively low cost, uptake remains low due to affordability constraints, lack of awareness, access to and trust in products, distribution challenges, basis risk, poor transparency, challenges regarding the integration of complementary interventions (e.g., access to improved inputs or informal savings/credit) and poor perceptions/norms of insurance and risk transfer. Lack of data and models further hinders insurers' ability to price risk correctly, which reduces value to clients (Greatrex et al., 2015; Di Marcantonio and Kayitakire, 2017; WEF, 2021). Impact assessments point to potential but remain context-specific (Awondo, 2019; Hansen et al., 2019b; Noritomo and Takahashi, 2020). In addition, there is no comprehensive overview of the number of people covered by such schemes, nor of the value they provide in terms of actual claims payouts. Lastly, donor and/or public funds still play an outsized role in launching and/or sustaining these schemes and schemes beyond weather and drought remain limited (Table 9.12).

Insurers and their clients are often unaware of their risk exposure, partly due to data and modelling gaps. Climate information services and related collaborations are increasingly helping to address this problem (see Section 9.4.5). Climate change attribution methods to estimate the contribution of anthropogenic climate change to the cost of parametric insurance offers possibilities for a sharing of the premium between the impacted African country and a global climate fund, such as the Green Climate Fund (New et al., 2020). Technology companies and start-ups (including fintechs) are also emerging as solutions to fill risk gaps, leveraging new approaches to data and technology through the use of sensors, drones and satellite imaging to speak to mainly agricultural risks, but also urban risks such as informal settlement fires, exacerbated by heat and drought (Table 9.12).

Ten African insurers formally committed to help manage climate risk on the continent through the Nairobi declaration of the UNEP Principles for Sustainable Insurance (PSI) in 2021 (UNEP PSI, 2021). Some early examples of public-private partnerships with municipalities and governments to better manage climate risk are also emerging (Table 9.12).

Table 9.12: Insurance opportunities to mitigate climate risk.

Initiatives	Drought/ heatwave	Flood	Cyclone	Fire	Example	Policyholders/ beneficiaries	Reference
Index and parametric schemes – smallholder farmer	x	x			ACRE Africa, Pula, R4 Rural Resilience Initiative, KLIP, FISP, Ghana Agricultural Insurance Pool, Oko Crop Assurance	Smallholder farmers	(Greatrex et al., 2015; CTA, 2019; Global Index Insurance Facility, 2019; WFP, 2020; Fava et al., 2021; OKO Finance, 2021; Pula, 2021; Tsan et al., 2021)

[START BOX 9.8 HERE]

Box 9.8: Climate Change, Migration and Displacement in Africa

Climatic conditions are important drivers of migration and displacement with migration responses to climate hazards strongly influenced by economic, social, political and demographic processes (Cross-Chapter Box MIGRATE in Chapter 7).

Most climate-related migration and displacement observed currently is within countries or between neighbouring countries, rather than to more geographically distant high-income countries (Hoffmann et al., 2020; Kaczan and Orgill-Meyer, 2020). Natural-related disaster displacements in sub-Saharan Africa were over 2.6 million in 2018 and 3.4 million in 2019 (13.9% of the global total and one of the highest historical figures for the region), with East (1,437,7000) and West Africa (798,000) being hotspots in 2018 (Mastrorillo et al., 2016; IDMC, 2019; IDMC, 2020) (Table Box 9.8.1). Estimates indicate future climate change effects on internal migration in Africa will be considerable (Rigaud et al., 2018) (Table Box 9.8.2).

Internal migration, displacement and urbanisation

Climate change can have opposing influences on migration flows. Deteriorating economic conditions caused by climate hazards can encourage out-migration (Wiederkehr et al., 2018). However, these same economic losses undermine household resources needed to migrate (Cattaneo and Peri, 2016). The net effect of these two forces leads to mixed results across study methodologies and contexts (Carleton and Hsiang, 2016; Borderon et al., 2019; Cattaneo et al., 2019; Hoffmann et al., 2020).

Urbanisation in Africa is affected by climate conditions in rural agricultural areas (*high confidence*). Urbanisation can increase when reduced moisture availability depresses farm incomes or pastoral livelihoods become unviable (Marchiori et al., 2012; Henderson et al., 2014; Mastrorillo et al., 2016). The influence of rainfall on rural-urban migration increased since decolonisation, possibly due to more lenient legislation on internal mobility, with each 1% reduction in precipitation below a long-term average associated with a 0.45% increase in urbanisation (Barrios et al., 2006). Rate of rural-urban migration is anticipated to increase (Neumann et al., 2015) as a result of increasing vulnerability of agricultural livelihoods to climate change (Serdeczny et al., 2017). Nevertheless, rural-urban migration is not a simple one-way process. Peri-urban and rural areas provide developmental feedback loops, helping create a 'regional agglomeration' effect, for instance, through growing food demand, family and social connections, and flows back to rural areas of goods and services and financial investments (UN-Habitat, 2016; Dodman et al., 2017).

Migration is an important and potentially effective climate change adaptation strategy in Africa and must be considered in adaptation planning (*high confidence)* (Williams et al., 2021). The more agency migrants have (that is, degree of voluntarity and freedom of movement), the greater the potential benefits for sending and receiving areas (*high agreement, medium evidence*) (Cross-Chapter Box MIGRATE in Chapter 7). In a synthesis of 63 studies covering over 9,700 rural households in dryland sub-Saharan Africa, 23% of households employed migration (primarily temporary economic) to adapt to changes in rainfed agriculture (Wiederkehr et al., 2018). Migration responses to climate change tend to be stronger among wealthier households, as poorer households often lack financial resources necessary to migrate (Kaczan and Orgill-Meyer, 2020).

International migration

Studies on propensity to emigrate have uncovered conflicting results. Some findings suggest in low-income countries high temperatures 'trap' people at home and lower migration rates abroad, but in middle-income countries, these same high temperatures encourage emigration (Cattaneo and Peri, 2016). However, other research finds in poor and agriculturally-dependent countries, high temperatures encourage international out-migration, particularly to the OECD (Cai et al., 2016). Some evidence indicates people who leave tend to be more educated, possibly leading to 'brain drain' (Mbaye, 2017). Recent evidence suggests hotter-than-normal temperatures across 103 countries, including many in Africa, increased asylum applications to the European Union (Missirian and Schlenker, 2017). Assuming no change in present-day vulnerability, asylum applications are projected to increase 34% across Africa (relative to 2000–2014) at 2.2°C global warming (Missirian and Schlenker, 2017), although this finding has been challenged in the literature (Abel et al., 2019; Boas et al., 2019).

International remittances are a vital resource for developing countries that can help aid recovery from climate shocks (Hallegatte et al. 2016). Estimated at USD 48 billion in 2019 their importance is expected to grow further due to foreign direct investment declines during the COVID-19 pandemic (World Bank, 2020a). Furthermore, domestic remittances from rural-urban migration can help rural households respond to climate risks (KNOMAD, 2016). However, adequate finance and banking infrastructure are essential for remittances and, on average, cash transfer costs for sub-Saharan African countries remain the highest globally (World Bank, 2020a). Mobile money technologies and regulation that promotes competition in the remittances market can reduce transaction costs (World Bank, 2020a). Governments can further address challenges facing internal and international migrants by including them in health services and other social programmes and protecting them from discrimination (World Bank, 2020a).

Table Box 9.8.1: Reported impacts of climate on migration in Africa (Findings on the linkages between climatic conditions and migration vary greatly across countries in Africa)

Climate driver	Country	Climate - Migration linkages	Reference
Temperature	Kenya	Cool temperatures linked to internal labour migration among males	(Gray and Wise, 2016)
	Uganda	High temperatures linked to increased non-labour migration among females. Short hot spells linked to increased temporary migration. Long-term heat stress linked to permanent migration through an agricultural livelihoods pathway.	(Gray and Wise, 2016; Call and Gray, 2020)
	Tanzania	Temperature-induced income shocks linked to decreased long-term rural-urban migration among men.	(Hirvonen, 2016)
Precipitation	Kenya	Increased precipitation linked to decreased rural-urban migration.	(Mueller et al., 2020)
	Zambia	Increased precipitation linked to increased internal migration.	(Mueller et al., 2020)
	Burkina Faso	Drier regions linked to increased temporary and permanent migrations to other rural areas. Short-term precipitation deficits linked to increased long-term migration to rural areas and decreased risk of short-term migration to distant destinations.	(Henry et al., 2004)
	Ethiopia	Drought linked to men's labour migration from rural to urban areas, especially in land-poor households. Drought linked to decreased marriage-related migration by women. Precipitation variability and drought linked to labour migration from rural to urban areas. Precipitation variability and drought linked to out-migration to communities where precipitation variability and drought probability are lower. High precipitation variability linked to increased migration, either through increased non-farm activities, which enable migration through economic resources or through insufficient agricultural production, which increase migration needs.	(Gray and Mueller, 2012; Morrissey, 2013; Hermans-Neumann et al., 2017; Groth et al., 2021)
	Ghana	Increased severity of drought and household insecurity linked to reduced future migration intentions of households.	(Adger et al., 2021)
	Malawi	Precipitation shocks linked to rural out-migration to communities where precipitation variability and drought probability are lower. Precipitation shocks (flood and droughts) linked to longer-term urban migration and/or reverse (i.e., urban-rural) migration.	(Lewin et al., 2012; Suckall et al., 2015)
	Mali	Decreased precipitation linked to overall increase in out-migration – where farming families or individuals from farming communities will leave their origin community – and some changes in duration and destination of trips. These moves can be either permanent or short-term, domestic or international.	(Grace et al., 2018)

	Niger	Drought linked to economically-induced migration of households from rural areas to cities. Drought also linked to temporary international migration.	(Afifi, 2011)
Temperature and precipitation	Burkina Faso	High temperatures linked to negative effects on all migration streams including international migration, much of which is to neighbouring countries. International migration also declines with precipitation.	(Gray and Wise, 2016)
	Senegal	No detected linkages between climate and migration.	(Gray and Wise, 2016)
	Nigeria	No detected linkages between climate and migration.	(Gray and Wise, 2016)
	Botswana	Increased temperatures and precipitation linked to decreased internal migration.	(Mueller et al., 2020)
	South Africa	Higher temperatures and precipitation extremes linked to increased rural out-migration, especially among black and low-income South Africans.	(Mastrorillo et al., 2016)
	Senegal	Precipitation variability, drought and increased temperatures linked to seasonal migration from rural to urban areas.	(Hummel, 2016)
	Zambia	Hotter and drier climate linked to inter-district migration of wealthy districts. Poor districts characterised by climate-related immobility.	(Nawrotzki and DeWaard, 2018)

Table Box 9.8.2: Projected numbers and shares of internal climate migrants in 2050 by sub-regions of sub-Saharan Africa. Projections are for internal migration driven by three slow-onset climate hazards (water stress, crop failure, and sea level rise), and excluding rapid-onset hazards such as floods and tropical cyclones. As such, they present a lower-bound estimate of potential climate change impacts on internal migration. Projections are for two warming scenarios: low emissions (RCP2.6) and high emissions (RCP8.5), both coupled with a socioeconomic pathway (SSP4) in which low-income countries have high population growth, high rates of urbanisation, and increasing inequality within and among countries. By 2050, between 17.4 million (RCP2.6) and 85 million (RCP8.5) people (up to 4% of the region's total population) could be moving as a consequence of climate impacts on water stress, crop productivity and sea level rise. More inclusive socioeconomic pathways with lower population growth are projected to reduce these risks. West Africa has the highest levels of climate migrants, potentially reaching more than 50 million, suggesting that climate impacts will have a particularly pronounced impact on future migration in the region. In East Africa, out-migration hotspots include coastal regions of Kenya and Tanzania, western Uganda and parts of the northern highlands of Ethiopia. Kampala, Nairobi and Lilongwe may become hotspots of climate in-migration, coupled with existing rural to urban migration trends, and a high likelihood of movement toward non-climate-related sources of income in cities. Source: (Rigaud et al., 2018).

Region		Global warming around 2.5°C above pre-industrial by 2050 (RCP8.5)	Global warming around 1.7°C above pre-industrial by 2050 (RCP2.6)
East Africa	Average number of internal migrants by 2050 (million)	10.1	6.9
	Internal climate migrants as percent of population	1.28%	0.87%
West Africa	Average number of internal migrants by 2050 (million)	54.4	17.9
	Internal climate migrants as percent of population	6.87%	2.27%

Central Africa	Average number of internal migrants by 2050 (million)	5.1			2.6		
	Internal climate migrants as percent of population	1.31%			0.66%		
Southern Africa	Average number of internal migrants by 2050 (million)	1.5			0.9		
	Internal climate migrants as percent of population	2.31%			1.40%		
Sub-Saharan Africa	Average number of internal migrants by 2050 (million)	71.1			28.3		
	Minimum (left) and maximum (right) million	56.6	85.7		17.4	39.9	
	Internal climate migrants as percent of population	3.49%			1.39%		
	Minimum (left) and maximum (right) percent	2.71%		4.03%	0.91%		2.04%

[END BOX 9.8 HERE]

9.11.5 COVID-19 Recovery Stimulus Packages for Climate Action

The COVID-19 pandemic recovery effort includes significant opportunities for African countries to reduce future vulnerability to compound climate, economic and health risks. Fiscal recovery packages could set economies on a pathway towards net-zero emissions, reducing future climate risk or entrench fossil-fuel intensive systems, exacerbating risk (Hepburn et al., 2020; Dibley et al., 2021; IEA, 2021). Investments in renewable energy, building efficiency retrofits, education and training, natural capital (that is, ecosystem restoration and ecosystem-based adaptation), R&D, connectivity infrastructure and sustainable agriculture can help meet both economic recovery and climate goals (Hepburn et al., 2020; Dibley et al., 2021).

The impacts of the COVID-19 pandemic have been substantially worsened by climate hazards in many places. In others, outbreak response has been disrupted (Phillips et al., 2020; Kruczkiewicz et al., 2021). These vulnerabilities are rooted in insufficient disaster preparedness infrastructure but are almost always worsened by social and economic inequality. Ensuring the most vulnerable populations are properly protected from climate change has co-benefits for recovery from the COVID-19 pandemic (Manzanedo and Manning, 2020). In particular, efforts to reduce syndemic vulnerabilities across key sectors (especially health, livelihoods and food security) will lessen climate change impacts and will also reduce the risk and impacts of future epidemics and pandemics, for example, during the pandemic, water scarcity has been a barrier to a key risk mitigation behaviour (handwashing). In the long-term, development efforts focused on water, sanitation and hygiene (WASH) will reduce this vulnerability and also reduce the health toll of diarrheal disease linked to climate change (Anim and Ofori-Asenso, 2020; Zvobgo and Do, 2020). Spending recovery funds on social safety nets will reduce inequality and protect the most vulnerable communities (especially women and low-income and marginalised communities) from the social and economic impacts of disasters. Key among these safety nets is universal health coverage, including low- or no-cost access to essential medicine, high-quality preventative care, financial protections against medical debt and increased geographic and population coverage for all services (Hallegatte et al., 2016). All of these are key components of climate change adaptation for health and will reduce both the rate at which future outbreaks start and their total scope and impact (Carlson et al., 2021). The co-benefits of multilateral cooperation on the attainment of universal health coverage will be a key determinant of success or failure in both climate change adaptation and pandemic preparedness.

[START BOX 9.9 HERE]

Box 9.9: Climate Change and Security: Interpersonal Violence and Large-scale Civil Conflict

There is substantial evidence that climate variability influences human security across Africa (see Chapter 7 WGII Section 7.2.7 and 7.3.3 7). However, the strength and nature of this link depend on socioeconomic and institutional conditions, and climate is just one of many factors influencing violence and civil conflict (Schleussner et al., 2016a; von Uexkull et al., 2016; Linke et al., 2018; Mach et al., 2019; van Weezel, 2019; Ide et al., 2020).

Projections of security implications of long-run climate change in Africa are uncertain, as they rely on extrapolating observed effects of short-run climate variability (Burke et al., 2014). Lack of detection and attribution studies limit assessment of the impacts of observed anthropogenic climate change on security.

Interpersonal violent crime

Evidence from across the globe finds that interpersonal violence, ranging from use of profanity to violent crime, increases with temperature and sometimes low rainfall (Hsiang et al., 2013a; Burke et al., 2014; Gates et al., 2019). The effect of temperature may be driven by a physiological mechanism (Morrison et al., 2008; Seo et al., 2008; Ray et al., 2011), while effects of rainfall may operate through an agricultural yield impacts channel (Burke et al., 2014). While few studies link interpersonal violence to climate in Africa, Gates et al. (2019) documents homicide risks increasing under high temperatures in South Africa, and similarity across diverse study settings suggests temperature-induced violent crime *likely* generalizes to Africa (Burke et al., 2014).

Large-scale intergroup conflict

Climatic conditions also change the risk of large-scale conflicts such as riots, ethnic conflicts and civil war (Burke et al., 2014; Koubi, 2019). The effects of temperature are particularly well-studied in Africa. Risk of violent conflict rises with temperature in Sudan and South Sudan (Maystadt and Ecker, 2014; Maystadt et al., 2014; Scheffran et al., 2014), Kenya (Hsiang et al., 2013b; Scheffran et al., 2014), the East African region (O'Loughlin et al., 2012) and across sub-Saharan Africa (Burke et al., 2009; O'Loughlin et al., 2014; Witmer et al., 2017). Estimates indicate that warming trends since 1980 have elevated conflict risk across sub-Saharan Africa by 11% (Burke et al., 2009; Carleton et al., 2016).

Periods of low rainfall or flooding also contribute to social instability and upheaval across Africa (Miguel et al., 2004; Ralston, 2015; von Uexkull et al., 2016; Harari and Ferrara, 2018; van Weezel, 2019; Ide et al., 2020). The link between rainfall and conflict appears *likely* due to crop losses and declines in economic opportunity. One study finds that dry growing seasons increase conflict incidence across 36 African nations, with spillover effects from the location of climate shock to neighbouring communities (Harari and Ferrara, 2018). Conflict-inducing impacts of drought have also been uncovered in Somalia (Maystadt and Ecker, 2014), Uganda, Sudan, Ethiopia and Kenya (Fjelde and von Uexkull, 2012; Hendrix and Salehyan, 2012; Couttenier and Soubeyran, 2014; Ralston, 2015; Linke et al., 2018; van Weezel, 2019), the Democratic Republic of Congo (von Uexkull et al., 2020) and in a pooled sample of African and Asian countries (von Uexkull et al., 2016). Extremely high rainfall may also incite conflict risk, although results are mixed (Hendrix and Salehyan, 2012; Raleigh and Kniveton, 2012). This uncertainty, combined with large uncertainties in rainfall projections under climate change, render future impacts of anthropogenic emissions on rainfall-induced conflict in Africa highly uncertain.

While conflict-climate links have been repeatedly identified in Africa, climate is one of many interacting conflict risk factors and appears to explain only a small share of total variation in conflict incidence (von Uexkull et al., 2016; Mach et al., 2019; van Weezel, 2019).

Opportunities for adaptation

Adaptive capacity with respect to climate and conflict remains low in Africa (Sitati et al., 2021). For example, one study finds that relative to each country's optimal annual temperature, realized temperatures across sub-Saharan Africa increase the annual incidence of war by 29.3% on average (Carleton et al., 2016). Another finds that rising temperatures due to climate change may lead to higher levels of violence in sub-Saharan Africa if political rights do not improve from current conditions (Witmer et al., 2017). Available studies on adaptation in conflict-affected areas tend to have a narrow focus, particularly on agriculture-related adaptation in rural contexts and adaptation by low-income actors, with little known beyond these contexts (Sitati et al., 2021). Literature on the gender dimension of climate adaptation in conflict-affected countries is also limited (Sitati et al., 2021).

Migration is a common response (Sitati et al., 2021) and may be an effective adaptive response to climate-induced conflict. Bosetti et al. (2018) find that countries with high emigration propensity display lower sensitivity of conflict to temperature, with no evidence of detrimental impacts on the destination countries. Indigenous knowledge has also been applied to enable adaptation amidst conflict, for example, in Libya, to deal with erratic rainfall (Biagetti, 2017).

Other socioeconomic factors have been identified as adaptive opportunities. Rising incomes may mitigate conflict-climate relationships (Carleton et al., 2016), while weak institutions, lack of political freedom, agricultural dependence and exclusion of ethnic groups increase their strength (Schleussner et al., 2016a; von Uexkull et al., 2016; Witmer et al., 2017; Ide et al., 2020). In particular, agriculturally dependent and politically excluded groups in Africa are especially vulnerable to the impact of drought on conflict (von Uexkull et al., 2016; Koubi, 2019). Household-level resilience to economic shocks has been shown to lower support for violence after drought (von Uexkull et al., 2020). Local-level institutions have also been shown to support non-violence under adverse climate conditions (Bogale and Korf, 2007).

These findings suggest that ameliorating ethnic tensions, improving political institutions, and investing in economic diversification and household resilience could mitigate future impacts of climate change on conflict.

[END BOX 9.9 HERE]

9.12 Heritage

Africa is a rich reservoir of heritage resources and indigenous knowledge, showcased by about 96 sites inscribed by UNESCO as World Heritage Sites (UNESCO, 2018b). These include 53 sites specifically denoted as having great cultural importance and 5 sites with mixed heritage values. Unfortunately, valuable cultural heritage in forms of tangible evidence of past human endeavour, and the intangible heritage encapsulated by diverse cultural practices of many communities (Feary et al., 2016), is under great threat from climate change.

9.12.1 Observed Impacts on Cultural Heritage.

For more than 10,000 years, Africans recorded over 8,000 painted and engraved images on rock shelters and rock outcroppings across 800 exceptional rock art sites of incalculable value (Hall et al., 2007; di Lernia and Gallinaro, 2011; di Lernia, 2017; Clarke and Brooks, 2018; Barnett, 2019), but which are exceptionally fragile to the elements. Unfortunately, there has been a poor study of direct climate change impacts on rock art across Africa.

Underwater heritage includes shipwrecks and artefacts lost at sea and extends to prehistoric sites, sunken towns and ancient ports that are now submerged due to climatic or geological changes (Spalding, 2011). Off the shores of Africa, about 111 shipwrecks have been documented, with South Africa having a major share of about 41 sites. The sunken Egyptian city of Thonis-Heracleion and its associated 60+ shipwrecks reflect the richness of Africa's waters. Unfortunately, increased storm surges and violent weather currently threaten the integrity of shipwrecks by accelerating the destruction of wooden parts and other features (Harkin et al., 2020). However, climate change impacts on underwater cultural heritage sites are poorly studied, as it requires specialist assessment techniques (Feary et al., 2016), and marine archaeology studies are not well-established in Africa.

Intangible heritage includes instruments, objects, artefacts and cultural spaces associated with communities, and are almost always held orally (UNESCO, 2003). Loss of heritage assets may be a direct consequence of climate change/variability (Markham et al., 2016), or a consequence of indirect factors resulting from climate change, for example, economic instability and poor decision-making in areas of governance. In northern Nigeria, climate change exacerbates the impact of poor land use decisions, reducing the flow of the Yobe River and negatively impacting the Bade fishing festival because the available fish species continue to decline (Oruonye, 2010). Similarly, Lake Sanké in Mali has been degraded by a combination of urban development and poor rainfall, threatening the Sanké mon collective fishing rite (UNESCO, 2018b).

Migration related to climate change and climatic events could offer openings to women and young people to become de facto family heads (Kaag et al., 2019). However, such societal changes also increase community vulnerability to the loss of cultural knowledge held by village elders. For example, in Mauritius, the Sega tambour Chagos music is at risk, as elders familiar with the landscape pass on (Boswell, 2008).

Case study: Traditional earthen 'green energy' buildings

Historically, Africa has had a unique and sustainable architecture (Diop, 2018) characterised by area-specific, traditional earthen materials and associated indigenous technology. Key examples include Tiébélé in Burkina Faso, Walata in Mauritania, Akan in Ghana, Ghadames in Libya, Old Towns of Djenné in Mali (World Heritage Site) and other diverse earthen architecture across sub-Saharan Africa. Adegun and Adedeji (2017) indicate that earthen materials provide advantages in thermal conductivity, resistivity and diffusivity, indoor and outdoor temperature, as well as cooling and heating capacities. Moreover, earthen materials are recyclable and environmentally 'cleaner' (Sanya, 2012) because of the absence or small quantity of cement in production, thus reducing carbon emissions. Despite these advantages, the expertise and socio-cultural ceremonies that accompany building and renewal of earthen architecture are disappearing fast (Adegun and Adedeji, 2017). Further, earthen construction is being threatened by extreme climatic variability and changing climate that exacerbates decay (Brimblecombe et al., 2011; Bosman and Van der Westhuizen, 2014; Brooks et al., 2020).

9.12.2 Projected Risks

Sea level rise and its associated hazards will present increasing climate risk to African heritage in the coming decades (Marzeion and Levermann, 2014; Reimann et al., 2018; Brito and Naia, 2020) (Figure 9.38). Although no continental assessment has quantified climate risk to African heritage and little is known of near term exposure to hazards such as sea level rise and erosion, for a handful of coastal heritage sites included in global or Mediterranean studies, 10 cultural sites are identified to be physically exposed to sea level rise by 2100 at high emissions scenarios (RCP8.5) (Marzeion and Levermann, 2014; Reimann et al., 2018), of which, 7 World Heritage Sites in the Mediterranean are also projected to face medium or high risk of erosion (Reimann et al., 2018) (Figure 9.38). Further, Brito and Naia (2020) identify natural heritage sites across 27 African countries that will be affected by sea level rise by 2100 (RCP8.5), of which 15 sites covering eight countries demonstrated a high need for proactive management actions because of high levels of biodiversity, international conservation relevance and exposure to sea level rise (Figure 9.38). These nascent studies highlight the potential severity of risk and loss and damage from climate change to African heritage, as well as gaps in knowledge of climate risk to African cultural and natural, particularly concerning bio-cultural heritage.

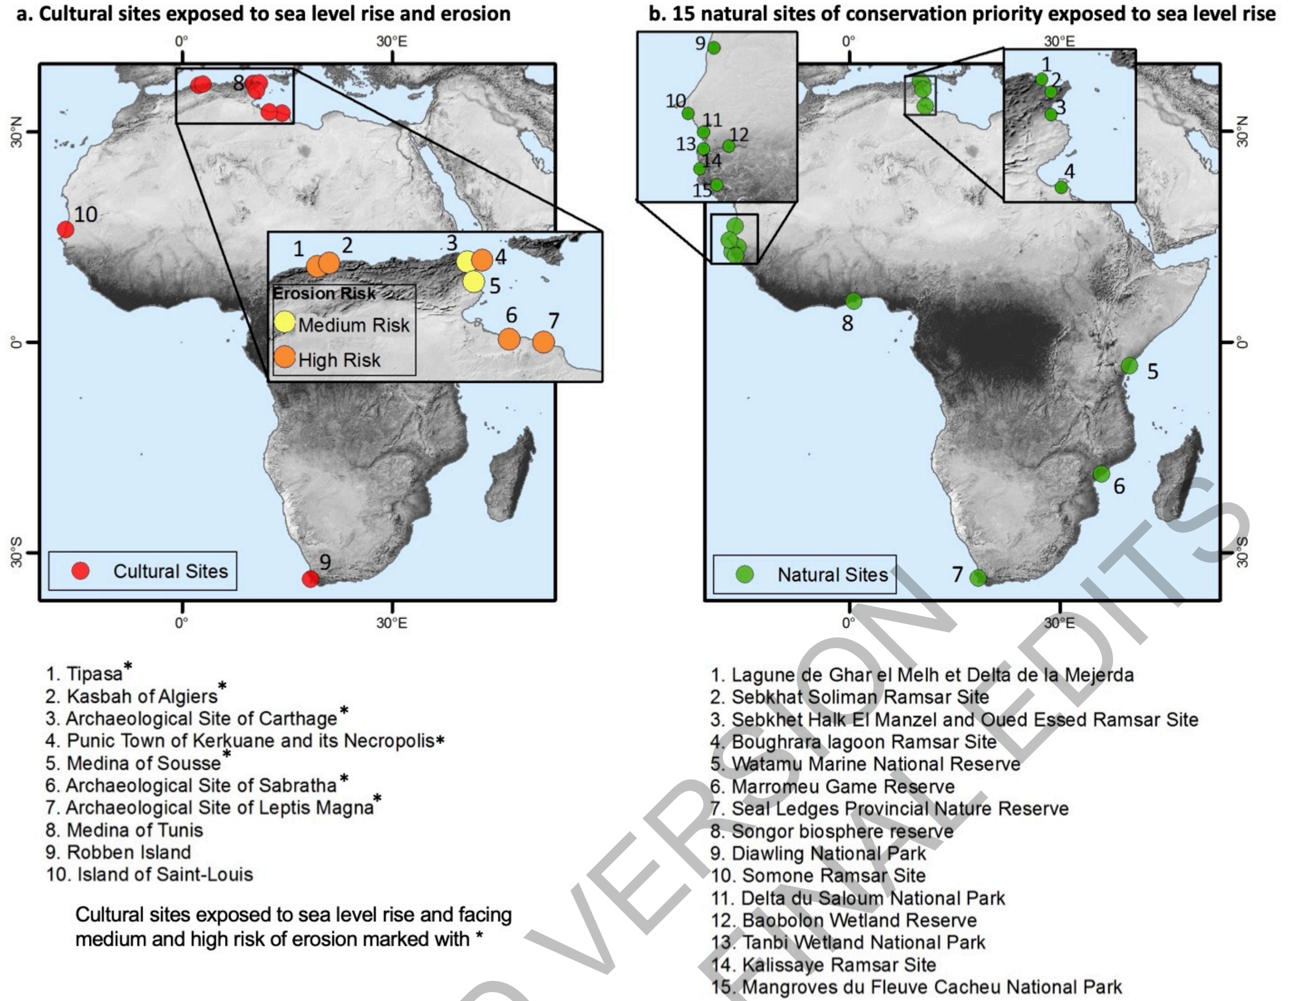

Figure 9.38: Risk to Africa's cultural and natural coastal heritage sites from sea level rise and erosion by 2100 (RCP8.5). Panel (a) Exposed World Heritage sites projected to be affected by sea level rise under a high-end sea level rise scenario (RCP8.5, 2100) (Marzeion and Levermann, 2014; Reimann et al., 2018). Panel a call out) Sites identified to be also exposed to medium and high erosion risk under current and future conditions (2000 and 2100) under a high-end sea level rise scenario (Reimann et al., 2018). Panel (b) The 15 topmost African natural sites (coastal protected areas) identified to be exposed to negative impacts from sea level rise and as priority for conservation (Brito and Naia, 2020).

Although climate change is a significant risk to heritage sites (Brito and Naia, 2020), there is little research on how heritage management is adapting to climate change, and particularly, whether the capacity of current heritage management systems can prepare for and deal with consequences of climate change (Phillips, 2015) (see also Cross-Chapter Box SLR in Chapter 3).

Worsening climate impacts are cumulative and often exacerbate the vulnerability of cultural heritage sites to other existing risks, including conflict, terrorism, poverty, invasive species, competition for natural resources and pollution (Markham et al., 2016). These issues may affect a broad range of tourism segments, including beach vacation sites, safari tourism, cultural tourism and visits to historic cities (UNWTO, 2008). Climate change impacts have the potential to increase tourist safety concerns, especially at sites where increased intensity of extreme weather events or vulnerability to floods and landslides are projected (Markham et al., 2016) (see also Cross-Chapter Box EXTREMES in Chapter 2). There may also be circumstances where interventions required to preserve and protect the resource alter its cultural significance (van Wyk, 2017).

9.12.3 Adaptation

Research highlights potential in integrating indigenous knowledge, land use practices, scientific knowledge and heritage values to co-produce tools that refine our understanding of climate change and variability and develop comprehensive heritage adaptation policy (Ekblom et al., 2019) (Table 9.13).

Table 9.13: Examples of responses to climate change impacts to heritage sites.

Heritage	Type	Example		Type of Climate Impact	Intervention Focus or Activity	Main Intervention Activity	State of Materials	Final State of Heritage	Literature
Tangible	Ancient	Historic buildings	Ounga Byzantine Fort and associated archaeological remains, Tunisia	Coastal erosion	Archaeological conservation of fort	Building repairs to outer walls of fort but other archaeological areas no intervention	Mixed. Fort is in good condition, but other parts of the site are under threat of coastal erosion, particularly lesser archaeological remains of other periods	Some aspects of site well preserved, other parts damaged	(Slim et al., 2004)
		Archaeological sites	Sabratha, Roman City, Libyan coast	Sea level rise, local flooding and coastal erosion	Monitoring of condition	None	Loss of archaeological remains into the sea	Some aspects of site well preserved, other parts damaged	(Abdalahh, 2011)
	Living	Cities / towns	Lamu Old Town and archipelago, Kenya	Sea Level Rise impacting low lying areas and climate variability impacting protective mangroves	Lamu Old Town managed by National Museums of Kenya the mangrove forests by Community Forest Associations and Forest Conservation and Management Act of 2016. Changes in biodiversity and cultural resilience to climate shocks.	Draft for National Policy for Disaster Management in Kenya	Mangrove forests provide protection from storm surges and coastal erosion. Changing biodiversity of mangroves is threatening mangroves which threaten Lamu Old Town	Continuing deterioration	(Wanderi, 2019)
		Mud buildings	Tiébélé, Burkina Faso	Climate variability causing flooding, erosion.	Local community conservation	Improvements to drainage and land security, development of conservation and management plans.	Current and ongoing conservation	Stable	(Birabi and Nawangwe, 2011)
Bio-cultural		Rock art	Golden Gate Highlands, South Africa	Precipitation and atmospheric changes	Monitoring of condition	No known intervention	Biodeterioration of condition of rock surface	Increasing loss of rock surfaces	(Viles and Cutler, 2012)

			causing luxuriant lichen growth				and images on the rock surfaces	
Intangible (indigenous)	Language	!Xun and Khwe Indigenous Youth of South Africa	Climate variability causing drought and loss of plants	Groups (youth)	Documentation	Non-formal, local	Enhancement, promotion	(Bodunrin, 2019)
		Indigenous Language Use in Agricultural Radio Programming in Nigeria	Climate variability increasing frequency of drought	Farmer groups, communities	Research, documentation	Formal, local	Promotion, transmission	(Adeyeye et al., 2020)
	Rituals	Enkipaata, Eunoto and Olng'esherr Maasai male rites of passage	Climate variability causing drought	Maasai community groups	Identification, documentation, research	Formal, non-formal, local, foreign	promotion	(UNESCO, 2018a)
	Customs & beliefs	Sanké mon fishing festival in Mali	Climate variability reducing rainfall	Malinkés, Bambara and Buwa communities	Identification, documentation, preservation	Formal, non-formal, local	promotion	(UNESCO, 2009)
	Indigenous engineering systems	Water measurers of the Foggara irrigation system in Algeria	Increased siltation and sandstorms Climate variability causing flooding	Touat and Tidikelt communities	Research, identification, documentation	Formal, local	transmission	(Mokadem et al., 2018)
	Arts and crafts	Traditional crafts made from various parts of the Date Palm in Egypt, Mauritania, Morocco, Sudan, Tunisia and other countries outside Africa	Climate variability causing shift in plant habitats	Residents of oases, groups, communities, agricultural cooperative societies	Research, identification, documentation, preservation, protection	Formal, non-formal, local, foreign	Transmission, promotion, enhancement, revitalization	(UNESCO, 2003) (Shabani et al., 2012)

Conservation of heritage may require offsetting the impact of loss through partial or total excavation under certain circumstances, like environment instability, or where *in situ* heritage preservation is exorbitant in cost (Maarleveld and Guérin, 2013).

Although many underwater shipwrecks and ruins of cities are currently preserved better *in situ* than similar sites on land (Feary et al., 2016), preserving such heritage is often financially prohibitive with many physical and technical challenges. Further, skill capacities of heritage agencies are limited to a few qualified archaeologists in Africa (Maarleveld and Guérin, 2013).

For centuries, Africans have drawn on intangible heritage to enhance their resilience to climatic variability and support adaptation practices. For example, pastoralist communities have historically translated their experiences into memories that can be 'translated' into diverse adaptive practices (Oba, 2014). In coastal Kenya, Mijikenda communities rely on indigenous knowledge and practices used in the management of the sacred Kaya Forests to adapt their farming to a changing climate (Wekesa et al., 2015).

Hence, preservation measures for transforming oral information into written records should ensure viability of intangible cultural heritage by giving due consideration to the confidentiality of culturally sensitive information and intellectual property rights (Feary et al., 2016).

Inclusion of cultural landscapes and intangible heritage in the landscape approach at the regional scale development planning processes may have significant impacts on protected area management (Feary et al., 2016). For example, at the Domboshava rock art site in Zimbabwe, all management decisions are taken in direct consultation with traditional leaders and other stakeholders from surrounding communities (Chirikure et al., 2010). Such adaptation strategies promote a more open-minded approach to heritage by leveraging local development (UNESCO, 2018b).

Lack of expertise and resources, together with legislation that privileges certain typologies of heritage, seem to limit implementation of approved policies (Ndoro, 2015). Additionally, cultural heritage has least priority in terms of budgetary allocation, capacity building and inclusion into school curricula. Failure to consider the views of people who attach spiritual significance to places is detrimental to the conservation of heritage places (Bwasiri, 2011). In particular, documented cases of local people having to pay an entrance fee, like tourists, to access burial grounds and places of pilgrimage negate local participation in cultural site management (Ndoro, 2015).

In the long term, heritage managers and local authorities could shift from planning primarily for disaster response and recovery to strategies that focus on disaster preparedness, reducing the vulnerability of sites and strengthening resilience of local communities (UNFCCC, 2007; Domke and Pretzsch, 2016). This could evolve into innovative approaches that integrate community, government and the research sector in productive cultural heritage management partnerships.

There is a need for institutions to establish, maintain and update a comprehensive inventory of underwater cultural heritage. This can be done using non-intrusive, detailed mapping of the wreck site and a 3D model from which scientists can reconstruct the site in detail (Maarleveld and Guérin, 2013).

[START FAQ9.1 HERE]

FAQ 9.1: Which climate hazards impact African livelihoods, economies, health and well-being the most?

Climate extremes, particularly extreme heat, drought, and heavy rainfall events, impact the livelihoods, health, and well-being of millions of Africans. They will also continue to impact African economies, limiting adaptation capacity. Interventions based on resilient infrastructure and technologies can achieve numerous developmental and adaptation co-benefits.

Rainfall impacts African livelihoods and well-being primarily through drought and heavy rainfall events. Drought frequency, duration and intensity is projected to increase in most parts of Africa, but particularly in

West Africa and the Sahel. By 2030, about 250 million people may experience high water stress in Africa, with up to 700 million people displaced as a result. In sub-Saharan Africa, floods are expected to displace an average of 2.7 million people in any given year in the future. Changing rainfall distributions together with warming temperatures will alter the distributions of disease vectors like mosquitoes and midges. Malaria vector hotspots and prevalence are projected to increase in East and southern Africa and the Sahel under RCP4.5 by the 2030s, exposing an additional 50.6–62.1 million people to malaria risk.

Increases in the number of hot days and nights, as well as in heatwave intensity and duration, have had negative impacts on agriculture, human health, water availability, energy demand and livelihoods. By some estimates, African countries' GDP per capita is on average 13.6% lower since 1991 than if anthropogenic warming had not occurred. In the future, high temperatures combined with high humidity exceed the threshold for human and livestock tolerance over larger parts of Africa and with greater frequency. Increased average temperatures and lower rainfall will further reduce economic output and growth in Africa, with larger negative impacts than on other regions of the world.

Resilient infrastructure and technologies are required to cope with the increasing climate variability and change (Figure FAQ 9.1). These include improving housing to limit heat and exposure, along with improving water and sanitation infrastructure. Such interventions to ensure that the most vulnerable are properly protected from climate change have many co-benefits, including for pandemic recovery and prevention.

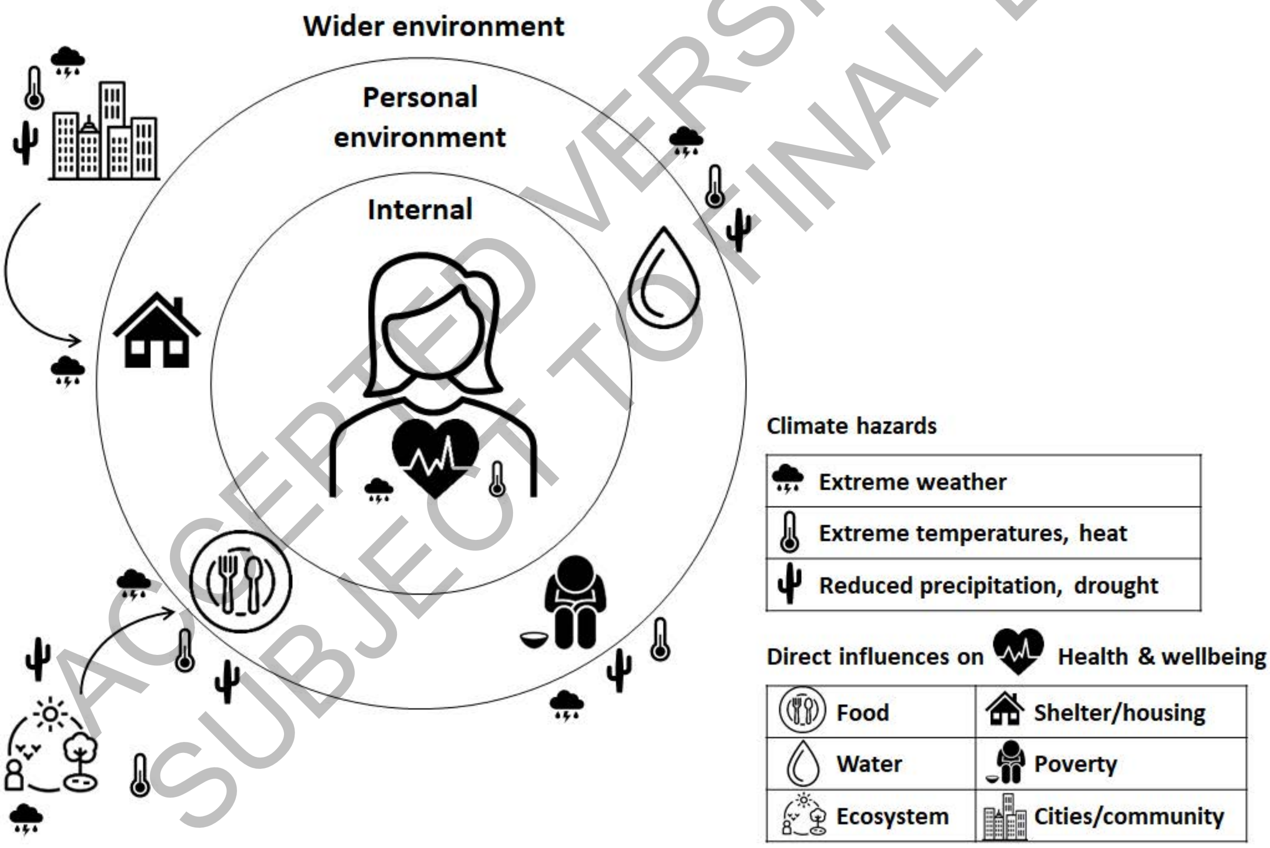

Figure FAQ9.1.1: A schematic illustration of the interconnectedness of different sectors and impacts that spillover to affect the health and well-being of African people.

[END FAQ9.1 HERE]

[START FAQ9.2 HERE]

FAQ9.2: What are the limits and benefits of climate change adaptation in Africa?

The capacity for African ecosystems to adapt to changing environmental conditions is limited by a range of factors, from heat tolerance to land availability. Adaptation across human settlements and food systems are further constrained by insufficient planning and affordability. Integrated development planning and increasing finance flows can improve African climate change adaptation.

Many species will lose all suitable habitats due to increases in temperature by 2100. Coupled with projected losses of Africa's protected areas, higher temperatures will also reduce carbon sinks and other ecosystem services. Many nature-based adaptation measures (e.g., for coral reefs, mangroves, marshes) are no longer effective at 1.5ºC of global warming. Human-based adaptation strategies for ecosystems reach their limits as availability and affordability of land decreases, resulting in migration, displacement and relocation.

The limits to adaptation for human settlements arise largely from developmental challenges associated with Africa's rapid urbanisation, poor development planning, and increasing numbers of urban poor residing in informal settlements. Further limits arise from insufficient consideration of climate change in adaptation planning and infrastructure investment and insufficient financial resources. There are also limits to adaptation for food production strategies. Increasing climate events – droughts and floods – impose specific adaptation responses which poorer households cannot afford. For instance, the use of early-maturing or drought-tolerant crop varieties may increase resilience, but adoption by smallholder farmers is hindered by the unavailability or unaffordability of seed.

Adaptation in Africa can reduce risks at current levels of global warming. However, there is very limited evidence for the effectiveness of current adaptation at increased global warming levels. Ambitious, near-term mitigation would yield the largest single contribution to successful adaptation in Africa.

Current adaptation finance flows are billions of USD less than the needs of African countries and around half of finance commitments to Africa reported by developed countries remain undisbursed. Increasing adaptation finance flows by billions of dollars (including public and private sources), removing barriers to accessing finance and providing targeted country support can improve climate change adaptation across Africa.

[END FAQ9.2 HERE]

[START FAQ9.3 HERE]

FAQ 9.3: How can African countries secure enough food in changing climate conditions for their growing populations?

Climate change is already impacting African food systems and will worsen food insecurity in sub-Saharan Africa in the future. An integrated approach to adaptation planning can serve as a flexible and cost-effective solution for addressing African food security challenges.

Maize and wheat yields have decreased on average 5.8% and 2.3%, respectively, in Sub-Saharan Africa due to climate change. Among the 135 million acutely food-insecure people in crisis globally, more than half (73 million) are in Africa. This is partly due to the growing severity of drought. Adding to these challenges, Africa has the fastest-growing population in the world. Its population is expected to increase by roughly 50% over the next fifteen years, growing from 1.2 billion people to over 1.8 billion by 2035.

Sustainable agricultural development combined with enabling institutional conditions, such as supportive governance systems and policy, can provide farmers with greater yield stability in uncertain climate conditions. It is also widely acknowledged that an integrated approach for adaptation planning that combines (i) emerging Climate Information Services, (ii) capacity building, (iii) local and indigenous knowledge systems and (iv) strategic financial investment can serve as a flexible and cost-effective solution for addressing African food security challenges (Section 9.4.1.2; Box 9.2).

[END FAQ9.3 HERE]

[START FAQ9.4 HERE]

FAQ9.4: How can African local knowledge serve climate adaptation planning more effectively?

A strong relationship between scientific knowledge and local knowledge is desirable, especially in developing contexts where technology for prediction and modelling is least accessible.

In many African settings, farmers use the local knowledge gained over time – through experience and passed on orally from generation to generation – to cope with climate challenges. Indigenous knowledge systems of weather and climate patterns include early warning systems, agroecological farming systems and observation of natural or non-natural climate indicators. For instance, biodiversity and crop diversification are used as a buffer against environmental challenges: if one crop fails, another will survive. Local knowledge of seasons, storms, and wind patterns is used to guide and plan farming and other activities.

Collaborative partnerships between research, agricultural extension services and local communities would create new avenues for the co-production of knowledge in climate change adaptation to better inform adaptation policies and practices across Africa (Section 9.4.3; Box 9.2).
