However, biodiversity observations remain sparse, and statistical and modelling tools can provide conflicting diversity information (e.g., Righetti et al., 2019; Dutkiewicz et al., 2020) because correlative approaches assume that the modern-day relationship between marine species distribution and environmental conditions remains the same into the future, whereas mechanistic models permit marine species to respond dynamically to changing environmental forcing. Moreover, existing global projections of future biodiversity disproportionately focus on the effects sea surface temperature (Thomas et al., 2012), typically overlooking other factors such as ocean acidification, deoxygenation and nutrient availability (Section 3.2.3), and often failing to account for natural adaptation (e.g., Section 3.3.4, Box 3.1, Barton et al., 2016; Henson et al., 2021).

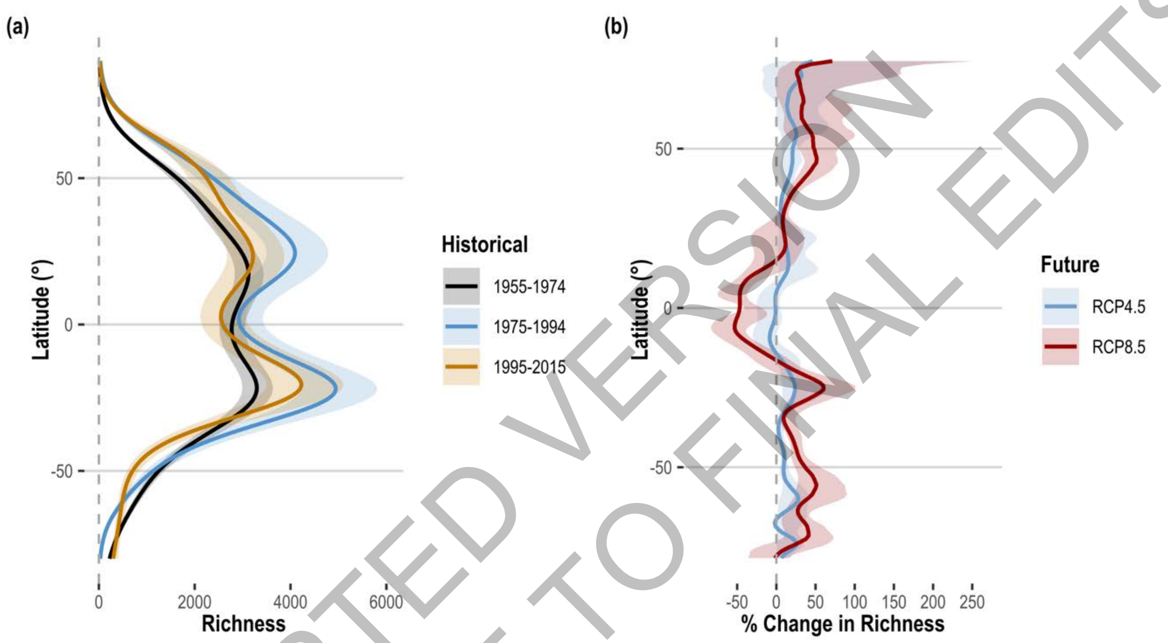

Figure 3.18: Changes in latitudinal marine species richness latitudinal distribution. (a) Observed species richness for three historical periods. The observed latitudinal patterns in species richness, are for a suite of taxonomic groups based on 48,661 marine species (Chaudhary et al., 2021). (b) Projected changes in species richness under RCP4.5 and RCP8.5 calculated as differences by grid cell by 2100 relative to 2006. Latitudinal global median (5° moving average) (based on Figure 1b,c in García Molinos et al., 2016). The projected latitudinal patterns in changes in species richness under climate change are based on a numerical model that includes species-specific information across a suite of taxonomic groups, based on 12,796 marine species (García Molinos et al., 2016).

[START BOX 3.2 HERE]

Box 3.2: Marine Birds and Mammals

Marine birds (seabirds and shorebirds) and mammals include charismatic species and species that are economically, culturally and ecologically important (Sydeman et al., 2015; Albouy et al., 2020; Pimiento et al., 2020). Their long generation times and slow population growth suggests limited evolutionary resilience to rapid climate change (Section 3.3.4, Sydeman et al., 2015; Miller et al., 2018). According to the Red List Species Assessments of the International Union for Conservation of Nature (IUCN, 2020), the greatest current hazards to these groups include human use of biological resources and areas, invasive species and pollution (Figure Box3.2.1, Dias et al., 2019; Lusseau et al., 2021). Impacts of climate change and severe weather are ranked among the five most-important hazards, influencing 131 and 45 bird and mammal species, respectively (see Figure Box 3.2.1 for selection of species), including 24 bird and seven mammal species that are currently listed as endangered, critically endangered or threatened. Furthermore, according to these IUCN assessments, climate change and severe weather are expected to impact an additional 122 and 18 marine bird and mammal species over the next 50–100 years, respectively (Figure Box 3.2.1 Dias et al., 2019).

Marine birds and mammals are vulnerable to climate-induced loss of breeding and foraging habitats such as sea ice (Section 3.4.2.12), sandy beaches (Section 3.4.2.6), salt marshes (Section 3.4.2.5) and seagrass beds (*high confidence*) (Section 3.4.2.5, Sydeman et al., 2015; Bindoff et al., 2019; Ropert-Coudert et al., 2019; Von Holle et al., 2019; Albouy et al., 2020; Amano et al., 2020; Bestley et al., 2020; Grose et al., 2020). With warming, shorebird population abundances decline in the tropics, *likely* due to heat stress and habitat loss, and increase at higher latitudes (Amano et al., 2020). Marine mammals dependent on sea-ice habitat are particularly vulnerable to warming (*medium confidence*) (Albouy et al., 2020; Bestley et al., 2020; Lefort et al., 2020), yet vulnerability can differ between populations. Ongoing sea-ice loss is decreasing some polar bear populations while others remain stable, *likely* related to past harvesting history, regional differences in sea-ice phenology and ecosystem productivity (Hamilton and Derocher, 2019; Molnár et al., 2020). Nevertheless, even under an intermediate emission scenario RCP4.5, increasing ice-free periods will *likely* reduce both recruitment and adult survival across most polar bear populations over the next four decades, threatening their existence (*medium confidence*) (Figure Box3.2.2, Molnár et al., 2020).

Climate change is affecting marine food-web dynamics (*high confidence*) (Sections 3.4.2, 3.4.3), and the vulnerability and adaptive capacity of marine birds and mammals to such changes is linked to the species' breeding and feeding ecology. Higher-vulnerability species include central-place foragers (confined to, for example, breeding colonies fixed in space), diet and habitat specialists, and species with restricted distributions such as marine mammal populations in SES (*medium confidence*) (McMahon et al., 2019; Ropert-Coudert et al., 2019; Albouy et al., 2020; Grose et al., 2020; Sydeman et al., 2021). Surface-feeding and piscivorous marine birds appear to be more vulnerable to food-web changes than diving seabirds and planktivorous seabirds (*medium confidence*) (Sydeman et al., 2021). During the 2014–2015 Pacific heatwave, around one million piscivorous common murres died along a 1500 km coastal stretch in the Pacific USA due to reduced prey availability (Jones et al., 2018b; Piatt et al., 2020). Marine birds are vulnerable to phenological shifts in food-web dynamics, as they have limited phenotypic plasticity of reproductive timing, with potentially little scope for evolutionary adaptation (*medium confidence*) (Keogan et al., 2018), although changes in reproduction timing are observed in several species (Section 3.4.4.1, Sydeman et al., 2015; Descamps et al., 2019; Sauve et al., 2019). There is *limited evidence* of marine mammals' capacity to adapt to shifting phenologies, but observed responses include changes in the onset of migrations, moulting and breeding (Section 3.4.4.1, Ramp et al., 2015; Hauser et al., 2017; Beltran et al., 2019; Bowen et al., 2020; Szesciorka et al., 2020).

Increased emergence of infectious disease in mammals and birds is expected with ocean warming, due to new transmission pathways from changing species distributions, higher species densities caused by habitat loss, and increased vulnerability due to environmental stress on individuals (*limited evidence*) (Sydeman et al., 2015; VanWormer et al., 2019; Sanderson and Alexander, 2020). Marine birds and mammals are *likely* to suffer from increased mortalities due to increasing frequencies of HABs, and of extreme weather, at sea, on sea ice, and in terrestrial breeding habitats (Broadwater et al., 2018; Gibble and Hoover, 2018; Ropert-Coudert et al., 2019; Grose et al., 2020). Also, climate-change driven distributional shifts have strengthened interactions with other anthropogenic impacts, through, for example, increasing risks of ship strikes and bycatch (*medium confidence*) (e.g., Hauser et al., 2018; Krüger et al., 2018; Record et al., 2019; Santora et al., 2020).

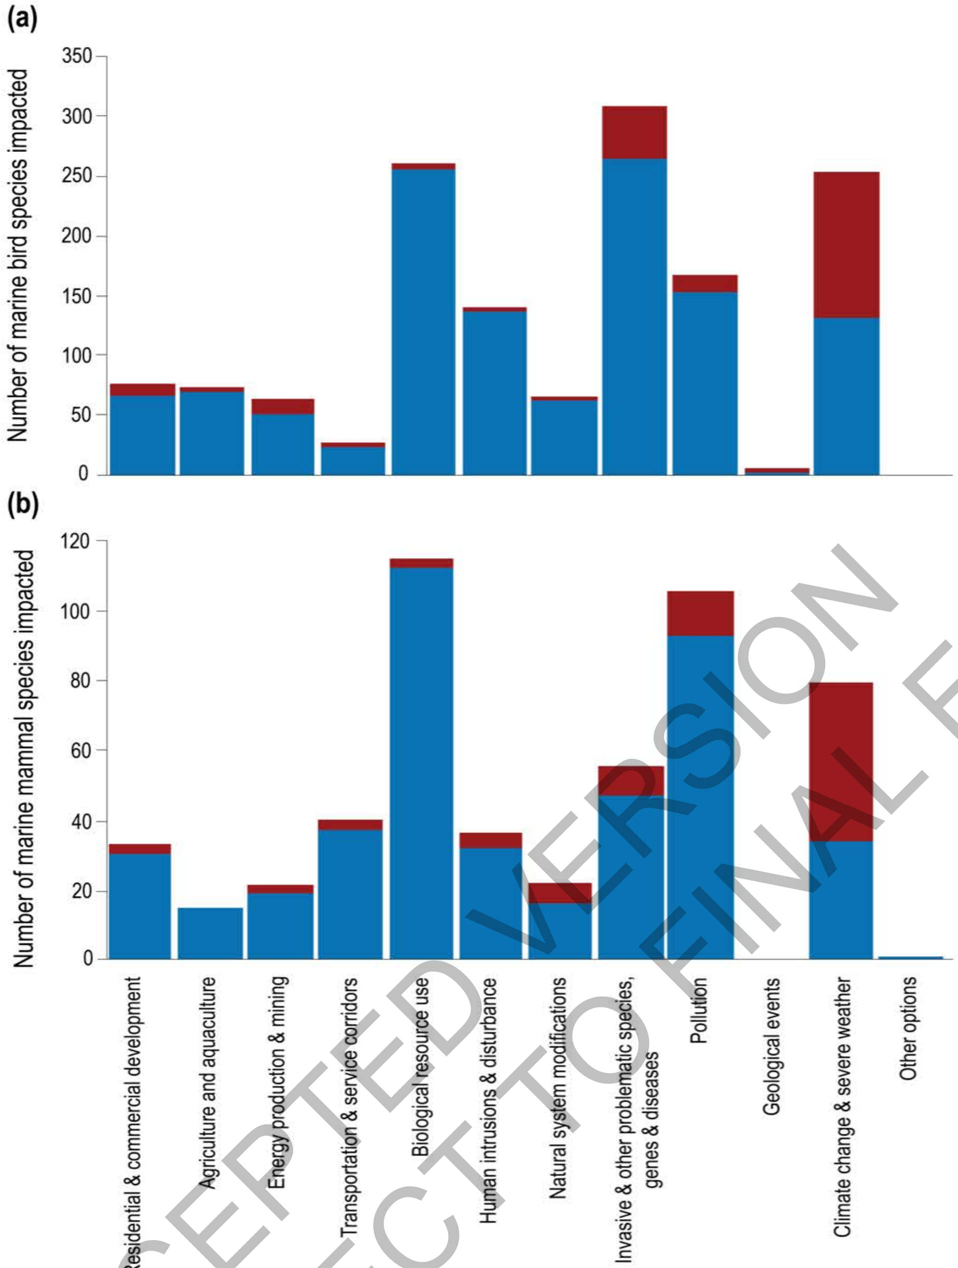

Figure Box 3.2.1: Hazard assessment for marine birds and mammals. Number of (a) marine birds and (b) mammals currently impacted by different hazards (blue), and numbers of additional species expected to be exposed to these threats over the next 50–100 years (red), as assessed in the International Union for Conservation of Nature Red List (IUCN, 2020). Seabird species include species in the key orders *Sphenisciformes*, *Pelecaniformes, Suliformes, Anseriformes, Procellariiformes* and *Charadriiformes* categorised as inhabitants of marine ecosystems (n = 483 species, assessed in the period 2016–2019). Marine mammal species include the species reviewed by Lusseau et al. (2021) (n = 136 species, assessed in the period 2008–2019).

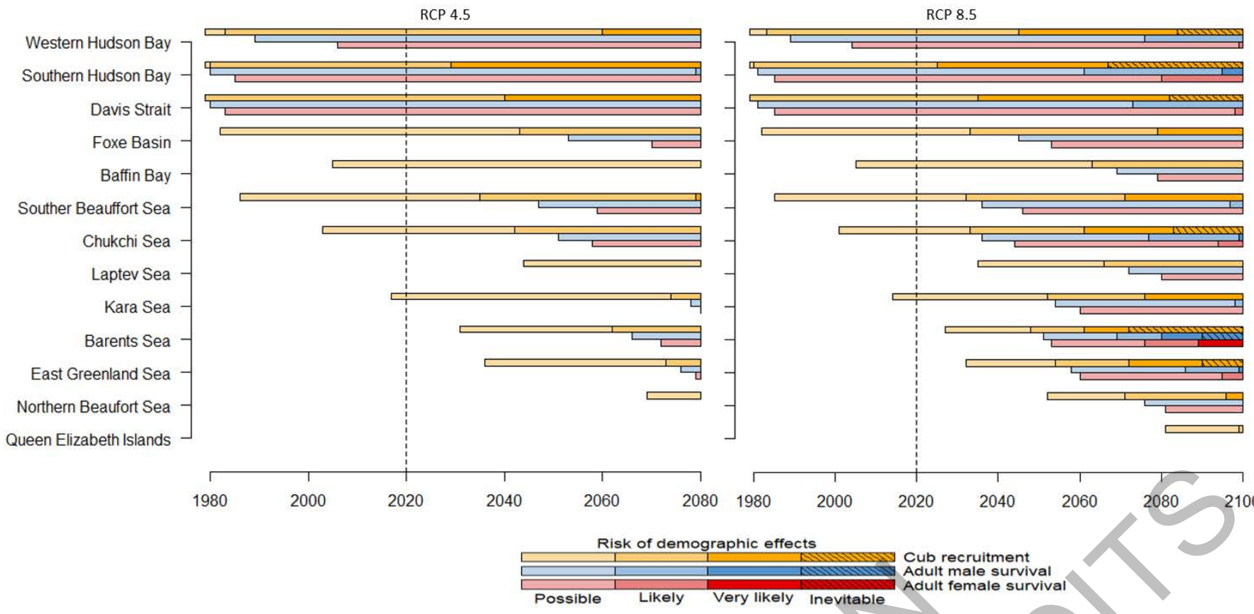

Figure Box 3.2.2: Modelled risk timelines for demographic impacts on circumpolar polar bear subpopulations, and associated confidence assessments, due to extended fasting periods with loss of sea ice. Years of first impact on cub recruitment (yellow), adult male survival (blue) and adult female survival (red) are shown for the (a) RCP4.5 and (b) RCP8.5. Data from Molnár et al. (2020).

[END BOX 3.2 HERE]

3.4.3.3.3 Abrupt ecosystem shifts and extreme events

Climate-change driven changes in ocean characteristics and the frequency and intensity of extreme events (Section 3.2) increase the risk of persistent, rapid and abrupt ecosystem change (*very high confidence*), often referred to as ecosystem collapses or regime shifts (AR6 WGI Chapter 9, Collins et al., 2019a; Canadell and Jackson, 2021; Ma et al., 2021). Such abrupt changes include altering ecosystem structure, function and biodiversity outside the range of natural fluctuations (Collins et al., 2019a; Canadell and Jackson, 2021). They can involve mass mortality events and 'tipping points' or 'critical transitions,' where strong positive feedbacks within an ecosystem lead to self-sustaining change (Figure 3.19a, Scheffer et al., 2012; Möllmann et al., 2015; Biggs et al., 2018). Abrupt ecosystem shifts have been observed in both large open-ocean ecosystems and coastal ecosystems (Section 3.4.2) with dramatic social consequences through significant loss of diverse ecosystem services (*high confidence*) (Section 3.5, Biggs et al., 2018; Pinsky et al., 2018; Beaugrand et al., 2019; Collins et al., 2019a; Filbee-Dexter et al., 2020b; Huntington et al., 2020; Trisos et al., 2020; Turner et al., 2020b; Canadell and Jackson, 2021; Ma et al., 2021; Ruthrof et al., 2021). A summary of previous assessments of abrupt ecosystem shifts and extreme events are provided in Table 3.21.

Table 3.21: Summary of previous IPCC assessments of observed and projected abrupt ecosystem shifts and extreme events.

Observations	Projections
AR5 (Wong et al., 2014)	
Observations of abrupt ecosystem shifts and extreme events were not assessed in this report.	Warming and acidification will lead to coral bleaching, mortality, and decreased constructional ability (*high confidence*), making coral reefs the most vulnerable marine ecosystem with little scope for adaptation. Temperate seagrass and kelp ecosystems will decline with the increased frequency of heatwaves and sea temperature extremes as well as through the impact of invasive subtropical species (*high confidence*).

SROCC (Collins et al., 2019a)	
Marine heatwaves (MHWs), periods of extremely high ocean temperatures, have negatively impacted marine organisms and ecosystems in all ocean basins over the last two decades, including critical foundation species such as corals, seagrasses and kelps (*very high confidence*)	Marine heatwaves are projected to further increase in frequency, duration, spatial extent and intensity (maximum temperature) (*very high confidence*). Climate models project increases in the frequency of marine heatwaves by 2081–2100, relative to 1850–1900, by approximately 50 times under RCP8.5 and 20 times under RCP2.6 (*medium confidence*). Extreme El Niño and La Niña events are projected to *likely* increase in frequency in the 21st century and to *likely* intensify existing hazards, with drier or wetter responses in several regions across the globe. Extreme El Niño events are projected to occur about as twice as often under both RCP2.6 and RCP8.5 in the 21st century when compared to the 20th century (*medium confidence*). Limiting global warming would reduce the risk of impacts of MHWs, but critical thresholds for some ecosystems (e.g., kelp forests, coral reefs) will be reached at relatively low levels of future global warming (*high confidence*)

Abrupt ecosystem shifts are associated with large-scale patterns of climate variability (Alheit et al., 2019; Beaugrand et al., 2019; Lehodey et al., 2020), some of which are projected to intensify with climate change (*medium confidence*) (WGI AR6 Chapter 1, Wang et al., 2017a; Collins et al., 2019a; Chen et al., 2021). Over the past 60 years, abrupt ecosystem shifts have generally followed El Niño/Southern Oscillation events of any strength, but some periods had geographically limited ecological shifts (~0.25% of the global ocean in 1984–1987) and others more extensive shifts (14% of the global ocean in 2012–2015) (*medium confidence*) (Figure 3.19b, Beaugrand et al., 2019). Typically, interacting drivers, such as eutrophication and overharvest, reduce ecosystem resilience to climate extremes (e.g., MHW, cyclones) or gradual warming, and hence promote ecosystem shifts (*high confidence*) (Figure 3.19a, Rocha et al., 2015; Biggs et al., 2018; Babcock et al., 2019; Turner et al., 2020b; Bergstrom et al., 2021; Canadell and Jackson, 2021; Tait et al., 2021). Also, shifts in different ecosystems may be connected through common drivers or through cascading effects (*medium confidence*) (Rocha et al., 2018a).

Recent MHWs (Section 3.2.2.1) have caused major ecosystem shifts and mass mortality in oceanic and coastal ecosystems, including corals, kelp forests and seagrass meadows (Sections 3.4.2.1, 3.4.2.3, 3.4.2.5, 3.4.2.6, 3.4.2.10, Cross-Chapter Box MOVING SPECIES in Chapter 5 and Cross-Chapter Box EXTREMES in Chapter 2), with dramatic declines in species foundational for habitat formation or trophic flow, biodiversity declines, and biogeographic shifts in fish stocks (*very high confidence*) (Table 3.15, Cross-Chapter Box MOVING SPECIES in Chapter 5, Canadell and Jackson, 2021). Three major bleaching episodes on Australia's Great Barrier Reef in 5 years corresponded with extreme temperatures in 2016, 2017 and 2020 (Pratchett et al., 2021). Between 1981 and 2017, marine heatwaves have increased more than 20-fold due to anthropogenic climate change (Section 3.2.2.1, WGI AR6 Chapter 9, Laufkötter et al., 2020; Fox-Kemper et al., 2021), increasing the risk of abrupt ecosystem shifts (*high confidence*) (Figure 3.19a, Cross-Chapter Box EXTREMES in Chapter 2, van der Bolt et al., 2018; Garrabou et al., 2021; Wernberg, 2021).

Ecosystems can recover from abrupt shifts (e.g., Babcock et al., 2019; Christie et al., 2019; Medrano et al., 2020). However, where climate change is a dominant driver, ecosystem collapses increasingly cause permanent transitions (*high confidence*), although the extents of such transitions depend on emission scenario (Trisos et al., 2020; Garrabou et al., 2021; Klein et al., 2021; Pratchett et al., 2021; Wernberg, 2021). Over the coming decades, MHW are projected to *very likely* become more frequent under all emission scenarios (Section 3.2, WGI AR6 Chapter 9, Fox-Kemper et al., 2021), with intensities and rates too high for recovery of degraded foundational species, habitats, or biodiversity (*medium confidence*) (Babcock et al., 2019; Garrabou et al., 2021; Klein et al., 2021; Serrano et al., 2021; Wernberg, 2021). Emission pathways that result in temperature overshoot above 1.5ºC will increase the risks of abrupt and irreversible shifts in coral reefs and other vulnerable ecosystems (Section 3.4.4).

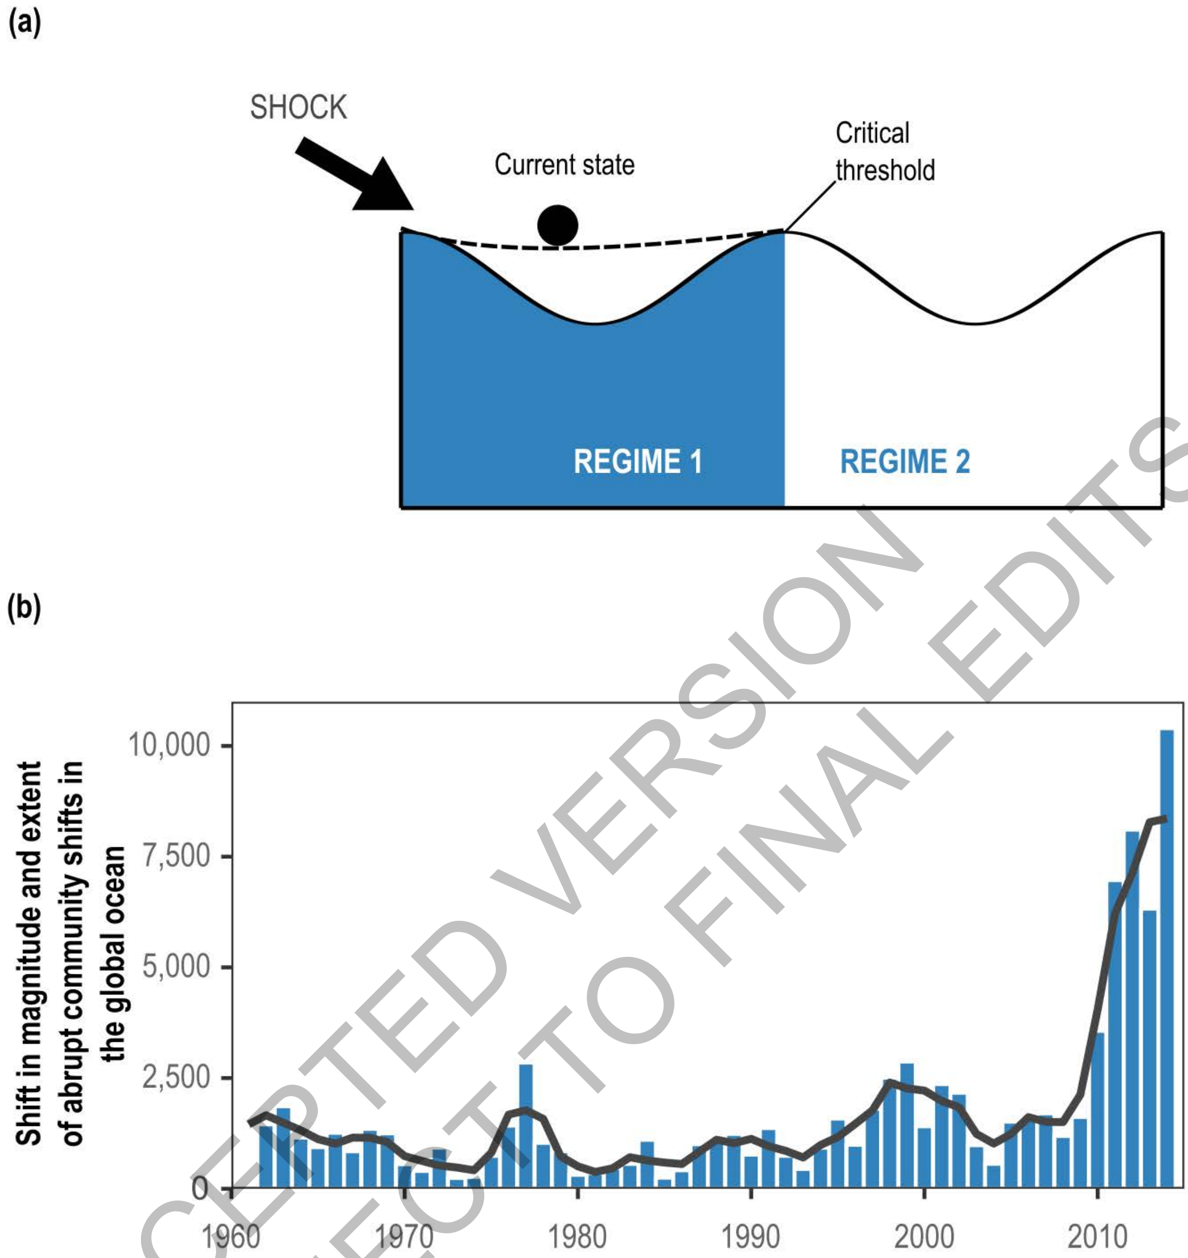

Figure 3.19: Observed ecological regime shifts and their drivers in the oceans. (a) A conceptual representation of ecosystem resilience and regime shifts. Shift from Regime 1 to Regime 2 can be triggered by either a large shock (i.e., an abrupt environmental transition) or gradual internal or external change that erodes the dominant balancing feedbacks, reducing ecosystem resilience (indicated by the shallower dotted line, relative to the deeper 'valley' reflecting higher resilience). Figure based on Biggs et al. (2018). (b) The sum of the magnitude and extent of the abrupt community shifts that has been estimated at each geographic cell in the global ocean during 1960–2014, calculated as the ratio of the amplitude of the change in a particular year to the average magnitude of the change over the entire time series (thus is dimensionless). Figure based on Beaugrand et al. (2019).

3.4.3.3.4 Time of emergence – species exposure to altered environments

Since SROCC, more studies have assessed the time of emergence for climate-impact drivers (Section 3.2.3), and the ecosystem attributes through which the impacts manifest. However, as in previous assessments (Table 3.22), the time of emergence for a given driver or ecosystem attribute depends on the reference period, the definition of the signal emergence threshold and the spatial and temporal scales considered (Box 5.1 in SROCC, Kirtman et al., 2013; Bindoff et al., 2019).

Table 3.22: Summary of previous IPCC assessments of projected time of emergence.

System	Projections
Coastal	Multiple climate-impact drivers will emerge in the 21st century under RCP8.5, while the time of emergence will be later and with few climatic hazards under RCP2.6. Non-climate impacts such as eutrophication add to, and in some cases, exacerbate these large-scale slow climate drivers beyond biological thresholds at local scale (e.g., deoxygenation).
Epipelagic	Observed range shifts in response to climate change in some regions such as the north Atlantic are strongly influenced by warming due to both multi-decadal climate change and variability, suggesting that there is a longer time-of-emergence of range shifts from natural variability and a need for longer biological time series for robust attribution.
Open Ocean	The timing for five primary drivers of marine ecosystem change (surface warming and acidification, oxygen loss, nitrate concentration and net primary production change) are all prior to 2100 for >60% of the ocean area under RCP8.5 and over 30% under RCP2.6 (*very likely*). Anthropogenic signals are expected to remain detectable over large parts of the ocean even under the RCP2.6 scenario for pH and SST but are *likely* to be less conspicuous for nutrients and NPP in the 21st century. For example, for the open ocean, the anthropogenic pH signal in Earth System Models (ESM) historical simulations is *very likely* to have emerged for three-quarters of the ocean prior to 1950 and it is *very likely* over 95% of the ocean has already been affected, with little discernible difference between scenarios. The climate signal of oxygen loss will *very likely* emerge by 2050 with a *very likely* range of 59–80% by 2031–2050 and increasing with a *very likely* range of 79–91% of the ocean area by 2081–2100 (RCP8.5 emissions scenario). The emergence of oxygen loss is smaller in area under RCP2.6 scenario in the 21st century and by 2090 the area where emergence is evident is declining. It has also been shown that signatures of altered oxygen solubility or utilisation may emerge earlier than for oxygen levels.
Deep sea	Emergence of risk is expected to occur later at around the mid-21st century under RCP8.5 for abyssal plain and chemosynthetic ecosystems (vents and seeps). All deep seafloor ecosystems are expected to be subject to at least moderate risk under RCP8.5 by the end of the 21st century, with cold water corals undergoing a transition from moderate to high risk below 3ºC.

Anthropogenically driven changes in chlorophyll-a concentrations across an ensemble of 30 ESMs are expected to exceed natural variability under RCP8.5 by 2100 in ~65–80% of the global oceans, when the natural variability is calculated using the ensemble's standard deviation (Schlunegger et al., 2020). However, if two standard deviations are used, then significant trends in chlorophyll-a concentration are expected under RCP8.5 across ~31% of the global oceans by 2100 (Dutkiewicz et al., 2019). In contrast, the anthropogenic signal in phytoplankton community structure, which has a lower natural variability, will emerge under RCP8.5 across 63% of the ocean by 2100 when two standard deviations are used (*limited evidence*) (Dutkiewicz et al., 2019).

The time of emergence of climate impacts on ecosystems will be modulated jointly by species-specific adaptation potential (Section 3.3.4, Jones and Cheung, 2018; Collins et al., 2020; Gamliel et al., 2020; Miller et al., 2020a), speed of range shifts and spatial reorganisation (*high confidence*) (Sections 3.3, 3.4.2,3.4.3). These ecosystem responses complicate projections of the time of emergence of environmental properties that impact biogeochemical cycling (Schlunegger et al., 2019; Schlunegger et al., 2020; Wrightson and Tagliabue, 2020), ecosystem structure and biodiversity (Figure 3.20a,c, Dutkiewicz et al., 2019; Trisos et al., 2020), and higher trophic levels, including fisheries targets (Cheung and Frölicher, 2020). Better accounting for multiple interacting factors in ESMs (Box 3.1), which will provide insight into how marine ecosystems will respond to future climate (*high confidence*).

The time of emergence of ecosystem responses supports planning for specific time-bound actions to reduce risks to ecosystems (Sections 3.6.3.2.1 Bruno et al., 2018; Trisos et al., 2020). Although under RCP 8.5, climate refugia from SST after 2050 are primarily in the Southern Ocean in tropical waters, these refugia are mainly from deoxygenation (Bruno et al., 2018). Marine assemblages in these places will be exposed to unprecedented temperatures after 2050, peaking in 2075 (Figure 3.20a,b, Trisos et al., 2020)(). In contrast, changes in phytoplankton community structure will emerge earlier, and primarily in the Pacific Ocean subtropics, and through much of the North Atlantic Ocean (Figure 3.20c,d, Dutkiewicz et al., 2019). Under RCP8.5, changes in phytoplankton community structure and, to a lesser extent, exposure of marine species to unprecedented temperatures, will emerge earlier in MPAs, covering ~7.7% of the global oceans, (Section 3.6.2.3.2.1, UNEP-WCMC and IUCN, 2020; UNEP-WCMC and IUCN, 2021) compared to non-MPAs (Figure 3.20b,d). Such assessment can support planning for future MPA placement and extent. Because MPAs can serve as refugia from non-climate drivers (Sections 3.6.2.3, 3.6.3.2.1), they facilitate opportunities for adaptation among marine species and communities in coastal oceans (Section 3.4.2).

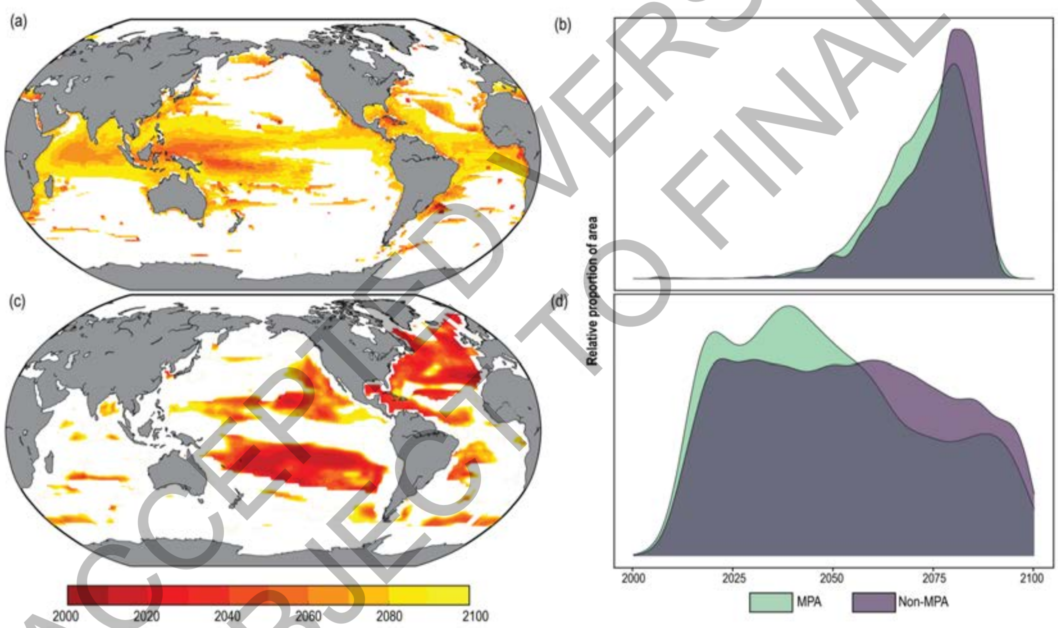

Figure 3.20: Time of exposure to altered environments. (a) Simulated spatial variation in the time of exposure of marine species to unprecedented temperatures under RCP8.5. Time of exposure is quantified as the median year after which local species are projected to encounter temperatures warmer than the historical maximum within their full geographic range for a period of at least five years. This estimate is based on 22 Coupled Model Intercomparison Project 5 (CMIP5) models, and is drawn from data presented by Trisos et al. (2020). Only regions that have times of emergence by 2100 are shown. (b) The distribution in the time of exposure to unprecedented temperatures within marine assemblages (Trisos et al., 2020) under RCP8.5 in marine protected areas (in turquoise) and in non-marine protected areas (in purple). Values were calculated after regridding to equal-area 0.5° hexagons. (c) Time of emergence for phytoplankton community structure changes (based on a proxy – ecosystem-model reflectance at 500 nm) under RCP8.5. Only regions with statistically significant ($p < 0.05$) trends, that are presently largely ice-free and that have times of emergence by 2100 are shown. Figure based on the results of one model numerical model from Dutkiewicz et al. (2019). (d) The distribution in the time of emergence for changes in phytoplankton community structure (same proxy as in Panel c) (Dutkiewicz et al., 2019) under RCP8.5 in marine protected areas (in turquoise) and in non-marine protected areas (in purple). Values were calculated after regridding to equal-area 0.5° hexagons.

3.4.3.4 Biomass

3.4.3.4.1 Observed changes

Observed changes in biomass in the global ocean, beyond those for phytoplankton (Table 3.23), have not routinely been attributed to climate-impact drivers, but rather to the compound effects of multiple drivers, especially fishing (Christensen et al., 2014; Palomares et al., 2020). We therefore do not assess observed changes in ocean biomass here.

3.4.3.4.2 Projected changes

Zooplankton biomass

Based on an ensemble of CMIP5 ESMs, SROCC projected declines in global zooplankton biomass by 2100 dependent on emission scenario (*low confidence*) (Table 3.23). The new CMIP6 ESM ensemble projects a decline in global zooplankton biomass by –3.9% ± 8.2%, (*very likely range*) and –9.0% ± 8.9% in the period 2081–2100 relative to 1995–2014 under SSP1-2.6 and SSP5-8.5, respectively (Figure 3.21d, Kwiatkowski et al., 2020), thus reinforcing the SROCC assessment albeit with greater inter-model uncertainties.

Table 3.23: Summary of previous IPCC assessments of changes in open ocean and deep sea biomass.

Measure	Observations	Projections
AR5 WGII: (Hoegh-Guldberg et al., 2014; Pörtner et al., 2014)		
Chlorophyll-*a*/phytoplankton biomass	Phytoplankton biomass: The approximately 15-year archived time series of satellite-chlorophyll (as a proxy of phytoplankton biomass) is too short to reveal trends over time and their causes (WGII AR5 Section 6.1.2, Pörtner et al., 2014). Chlorophyll concentrations measured by satellites have decreased in the subtropical gyres of the North Pacific, Indian, and North Atlantic Oceans by 9%, 12%, and 11%, respectively, over and above the inherent seasonal and interannual variability from 1998 to 2010 (*high confidence*; p-value ≤ 0.05). Significant warming over this period has resulted in increased water column stratification, reduced mixed layer depth, and possibly decreases in nutrient availability and ecosystem productivity (*limited evidence, medium agreement*). The short time frame of these studies against well-established patterns of long-term variability leads to the conclusion that these changes are about as *likely* as not due to climate change (WGII AR5 Chapter 30 Hoegh-Guldberg et al., 2014).	Owing to contradictory observations there is currently uncertainty about the future trends of major upwelling systems and how their drivers (enhanced productivity, acidification, and hypoxia) will shape ecosystem characteristics (*low confidence*) (WGII AR5 Chapter 6 Executive Summary, Pörtner et al., 2014).
Animal biomass	The climate-change-induced intensification of ocean upwelling in some eastern boundary systems, as observed in the last decades, may lead to regional cooling rather than warming of surface waters and cause enhanced productivity (*medium confidence*), but also enhanced hypoxia, acidification, and associated	

	biomass reduction in fish and invertebrate stocks.	
SROCC (Bindoff et al., 2019)		
Chlorophyll-*a*/phytoplankton biomass	Changes reported in overall open ocean chlorophyll levels (a proxy of phytoplankton biomass) of <±1% yr^{-1} for individual time periods. Regionally, trends of ±4% between 2002–2015 for different regions are found when different satellite products are merged, with increases at high latitudes and moderate decreases at low latitudes (SROCC Section 5.2.2.6, Bindoff et al., 2019).	
Animal biomass	Observed changes in open ocean and deep sea biomass were not assessed in this report.	There is *high agreement* in model projections that global zooplankton biomass will *very likely* reduce in the 21st century, with projected decline under RCP8.5 almost doubled that of RCP2.6 (*very likely*). However, the strong dependence of the projected declines on phytoplankton production (*low confidence*) and simplification in representation of the zooplankton communities and foodweb render their projections having *low confidence*. The global biomass of marine animals, including those that contribute to fisheries, is projected to decrease by 4.3 ± 2.0% (95% confidence intervals) and 15.0 ± 5.9% under RCP2.6 and RCP8.5, respectively, by 2080–2099 relative to 1986–2005, while the decrease is around 4.9% by 2031–2050 across all RCP2.6 and RCP8.5 (*very likely*). Regionally, total animal biomass decreases largely in tropical and mid-latitude oceans (*very likely*). Projected decrease in upper ocean export of organic carbon to the deep seafloor is expected to result in a loss of animal biomass on the deep seafloor by 5.2–17.6% by 2090–2100 compared to the present (2006–2015) under RCP8.5 with regional variations (*medium confidence*). Some increases are projected in the polar regions, due to enhanced stratification in the surface ocean, reduced primary production and shifts towards small phytoplankton (*medium confidence*). The projected impacts on biomass in the abyssal seafloor are larger under RCP8.5 than RCP4.5 (*very likely*).
WGI AR6 Chapter 2 (Gulev et al., 2021)		

Chlorophyll-*a*/phytoplankton biomass	The multi-sensor time series of chlorophyll-*a* concentration has been updated to cover two decades (1998–2018). Global trends in chlorophyll-*a* for the last two decades are insignificant over large areas of the global oceans, but some regions exhibit significant trends, with positive trends in parts of the Arctic and the Antarctic waters (>3% yr^{-1}), and both negative and positive trends (within ±3% yr^{-1}), in parts of the tropics, subtropics and temperate waters. In the last two decades, the concentration of phytoplankton at the base of the marine food web, as indexed by chlorophyll concentration, has shown weak and variable trends in low and mid-latitudes and an increase in high latitudes (*medium confidence*).	Projected changes in open ocean and deep sea biomass were not assessed in this report.

Marine animal biomass

Using an ensemble of global-scale marine ecosystem and fisheries models (Fish-MIP, Tittensor et al., 2018) with the CMIP5 ESM ensemble, SROCC concludes that projected ocean warming and decreased phytoplankton production and biomass will reduce global marine animal biomass during the 21st century (*medium confidence*). The simulated declines (with *very likely range*) are –3.5 ± 4.8% and –14.0 ± 14.6% under RCP2.6 and RCP8.5, respectively, by 2080–2099 relative to 1995–2014 (SROCC Section 5.2.3, Bindoff et al., 2019; Lotze et al., 2019)[1]. Updated Fish-MIP simulations with CMIP6 (Figure 3.21g,h,i) confirm the projected decline in total marine animal biomass in the 21st century (Tittensor et al., 2021). The simulated declines (with *very likely range*) are –5.7% ± 4.1% and –15.5% ± 8.5% under SSP1-2.6 and SSP5-8.5, respectively, by 2080–2099 relative to 1995–2014 (Figure 3.21g), showing greater declines and lower inter-model uncertainties (Tittensor et al., 2021). These declines result from combined warming and decreased primary production (with *low confidence* in future changes in primary production, Section 3.4.3.5) and are amplified at each trophic level within all ESM and marine ecosystem model projections across all scenarios (*medium confidence*) (Kwiatkowski et al., 2019; Lotze et al., 2019; Tittensor et al., 2021). However, there is *limited evidence* about how underlying food-web mechanisms amplify the climate signal from primary producers to higher trophic levels, and several putative mechanisms have been proposed (Section 3.4.4.2.2, Chust et al., 2014a; Stock et al., 2014; Kwiatkowski et al., 2019; Lotze et al., 2019; Heneghan et al., 2021). As assessed in SROCC, the biomass projections contain considerable regional variation, with declines in tropical to temperate regions and strong increases in total animal biomass are projected in polar regions under high-emission scenarios, with climate-change effects that are spatially similar but less pronounced under lower-emission scenarios (Figure 3.21b,c,e,f,h,i; Tai et al., 2019; Tittensor et al., 2021).

Benthic biomass

SROCC assessed that reduced food supply to the deep sea will drive a reduction in abyssal seafloor biota by 2100 for RCP8.5 (Table 3.23). Simulations from one size-resolved benthic biomass model coupled to an ocean-biogeochemistry model forced with the CMIP5 ESM HadGEM2-ES (Yool et al., 2017) project a decline in the globally integrated total seafloor biomass of –1.1% and –17.6% by 2100 under RCP2.6 and RCP8.5, respectively (*limited evidence, high agreement*). In waters shallower than 100 m, total benthic biomass is projected to increase by 3.2% on average by 2100 under RCP8.5, primarily driven warming-

[1] SROCC reported declines in total marine animal biomass have been recomputed using 1995–2014 as the baseline period and the *very likely* ranges (5–95%) are now computed from the model ensemble ranges assuming a normal distribution.

increased growth rates (Yool et al., 2013), while at depths >2000 m (representing 83% of the ocean seafloor), declines of –32% arise from climate-driven decreases in surface primary production and particulate organic carbon (POC) flux to the seafloor (Yool et al., 2013; Kelly-Gerreyn et al., 2014; Yool et al., 2015; Yool et al., 2017). These patterns are qualitatively similar under RCP2.6, except in the Pacific and Indian Ocean basins, where some increased total seafloor biomass is projected (Yool et al., 2013). Updated simulations with the same benthic biomass model (Kelly-Gerreyn et al., 2014) forced with the CMIP6 ESM UKESM-1 project declines in total seafloor biomass of –9.8% and –13.0% by 2081–2100 relative to 1995–2014 for SSP1-2.6 and SSP5-8.5, respectively (Figure 3.21j,k,l, updated from Yool et al., 2017). These projected changes in benthic biomass are based on *limited evidence*. Development of ensemble projections forced with a range of ESMs and a benthic model that considers the ecological roles of temperature (Hunt and Roy, 2006; Reuman et al., 2014), oxygen (Mosch et al., 2012) and ocean acidification (Andersson et al., 2011) will provide opportunities to better quantify uncertainty in projected declines in total seafloor biomass under climate change.

Conclusions

Overall, ocean warming and decreased phytoplankton production and biomass will drive a global decline in biomass for zooplankton (*low confidence*), marine animals (*medium confidence*) and seafloor benthos (*low confidence*), with regional differences in the direction and magnitude of changes (*high confidence*). There is increasing evidence that responses will amplify throughout the food web and at ocean depths, with relatively modest changes in surface primary producers translating into substantial changes at higher trophic levels and for deep-water benthic communities (*medium confidence*).

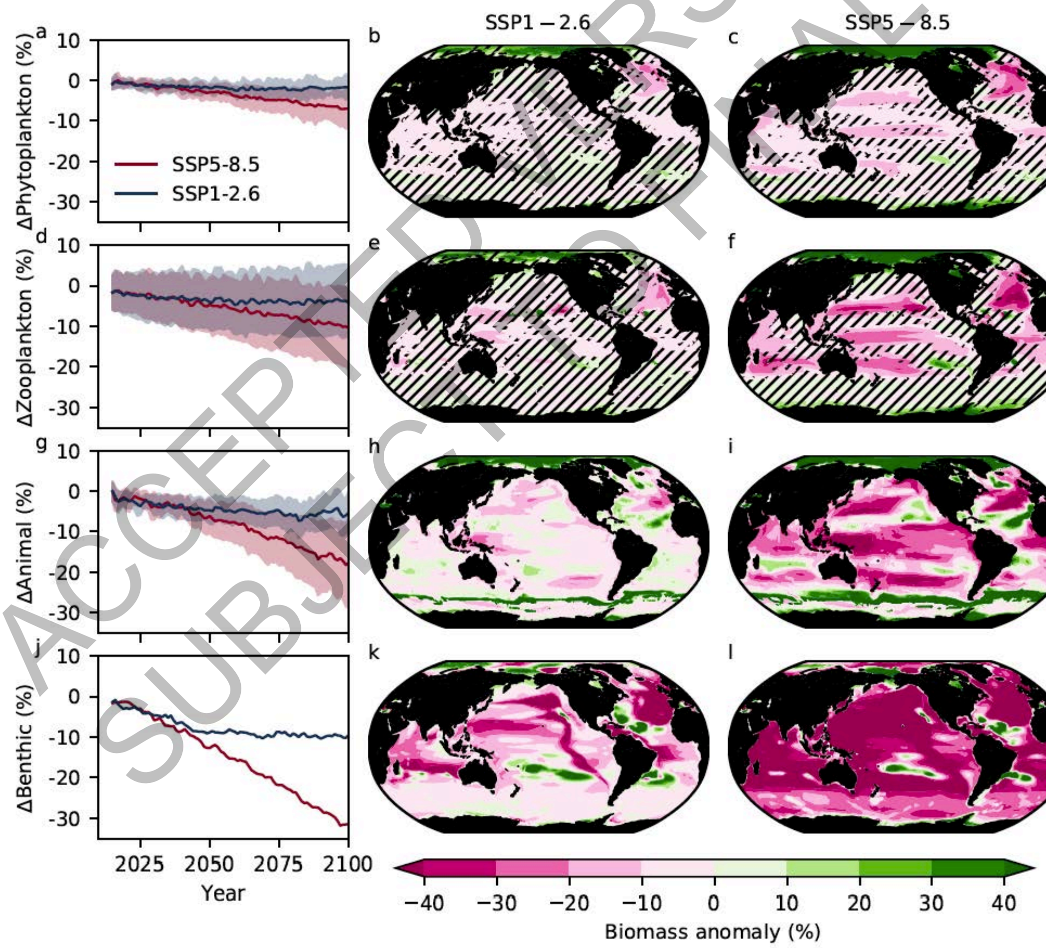

Figure 3.21: Projected change in marine biomass. Simulated global biomass changes of (a,b,c) surface phytoplankton, (d,e,f) zooplankton, (g,h,i) animals and (j,k,l) seafloor benthos. In (a,d,g,j), the multi-model mean (solid lines) and *very likely range* (envelope) over 2000–2100 relative to 1995–2014, for SSP1-2.6 and SSP5-8.5. Spatial patterns of simulated change by 2090–2099 are calculated relative to 1995–2014 for (b,e,h,k) SSP1-2.6 and (c,f,i,l) SSP5-8.5. Confidence intervals can be affected by the number of models available for the Coupled Model Intercomparison Project 6 (CMIP6) scenarios and for different variables. Only one model was available for panel (j), so no confidence interval is

calculated. For panels (a–f), the ensemble projections of global changes in phytoplankton and zooplankton biomasses updated based on Kwiatkowski et al. (2019) include, under SSP1-2.6 and SSP5-8.5, respectively, a total of nine and 10 CMIP6 Earth System Models (ESMs). For panels (g,h,i), the ensemble projections of global changes in total animal biomass updated based on Tittensor et al. (2021) include 6–9 published global fisheries and marine ecosystem models from the Fisheries and Marine Ecosystem Model Intercomparison Project (Fish-MIP, Tittensor et al., 2018; Tittensor et al., 2021), forced with standardised outputs from two CMIP6 ESMs. For panels (j,k,l), globally integrated changes in total seafloor biomass have been updated based on Yool et al. (2017) with one benthic model (Kelly-Gerreyn et al., 2014) forced with the CMIP6 ESM HadGEM2-ES.

3.4.3.5 Changes in Primary Production and Biological Carbon Export Flux

3.4.3.5.1 Observed changes in primary production

Analyses of satellite-derived primary production over the past two decades (1998–2018) showed generally weak and negative trends (up to −3.0%) at low and mid latitudes (Kulk et al., 2020). In contrast, positive trends occurred in large areas of the South Atlantic and South Pacific Oceans, as well as in polar and coastal (upwelling) regions (up to +4.5%, Cross-Chapter Paper 6, Kulk et al., 2020). Data-assimilating ocean biogeochemical models estimate a global decline in primary production of 2.1% per decade in the period 1998–2015, driven by the shoaling mixed layer and decreasing nitrate concentrations (Gregg and Rousseaux, 2019). This is consistent with previous assessments that identified ocean warming and increased stratification as the main drivers (*high confidence*) affecting the regional variability in primary production Bindoff et al. (2019). However, as noted in SROCC and WGI AR6 Chapter 2 (Table 3.24, Gulev et al., 2021), observed inter-annual changes in primary production on global and regional scales are nonlinear and largely influenced by natural temporal variability, providing *low confidence* in the trends.

Table 3.24: Summary of previous IPCC assessments of ocean primary production and carbon export flux.

Process	Observed Impacts	Projected Impacts
SROCC (Bindoff et al., 2019)		
Open ocean primary production	Past open ocean productivity trends, including those determined by satellites, are appraised with *low confidence*, due to newly identified region-specific drivers of microbial growth and the lack of corroborating in situ time series datasets.	Net primary productivity is *very likely* to decline by 4–11% by 2081–2100, relative to 2006–2015, across CMIP5 models for RCP8.5, but there is *low confidence* for this estimate due to the *medium agreement* among models and the *limited evidence* from observations. The tropical ocean net primary productivity is *very likely* to decline by 7–16% for RCP8.5, with *medium confidence* as there are improved constraints from historical variability in this region.
Open ocean carbon export	Analyses of long-term trends in primary production and particle export production, as well as model simulations, reveal that increasing temperatures, leading to enhanced stratification and nutrient limitation, will have the greatest influence on decreasing the flux of particulate organic carbon (POC) to the deep ocean. However, different lines of evidence (including observation, modeling and experimental studies) provide *low confidence* on the mechanistic understanding of how climate-impact drivers affect different components of the biological pump in the epipelagic ocean, as well as	The projected changes in export production can be larger than global primary production because they are affected by both the net primary production changes, but also how shifts in food web structure modulates the 'transfer efficiency' of particulate organic material, which then affects the sinking speed and lability of exported particles through the ocean interior to the sea floor. As export production is a much better understood net integral of changing net nutrient supply and can be constrained by interior ocean nutrient and oxygen levels, there is *medium confidence* in

	changes in the efficiency and magnitude of carbon export in the deep ocean.	projections for global export production changes based on CMIP5 model runs.
WGI AR6 Chapters 2 and 5 (Canadell et al., 2021; Gulev et al., 2021)		
Open ocean primary production	Global ocean marine primary production is estimated to be 47 ± 7.8 PgC yr^{-1} with *low confidence* because of the small number of recent studies and the insufficient length of the time series analysed. A small decrease in productivity is evident globally for the period 1998–2015, but regional changes are larger and of opposing signs (*low confidence*) (WGI AR6 Section 2.3.4.2.2, Gulev et al., 2021).	In CMIP5 models run under RCP8.5, particulate organic carbon (POC) export flux is projected to decline by 1–12% by 2100 (Taucher and Oschlies, 2011; Laufkötter et al., 2015). Similar values are predicted in 18 CMIP6 models, with declines of 2.5–21.5% (median –14%) between 1900 and 2100 under the SSP5-8.5 scenario. The mechanisms driving these changes vary widely between models due to differences in parameterisation of particle formation, remineralisation and plankton community structure (WGI AR6 Section 5.4.4.2, Canadell et al., 2021).

3.4.3.5.2 Projected changes in primary production

Across 10 CMIP5 and 13 CMIP6 ESM ensembles, global mean net primary production is projected to decline by 2080–2099 relative to 2006–2015, under all RCPs and SSPs (Kwiatkowski et al., 2020). However, under comparable radiative forcing, the CMIP6 multi-model mean projections of primary production declines (mean ± SD: –0.56 ± 4.12% under SSP1-2.6, and –3.00 ± 9.10% under SSP5-8.5) are less than those of previous CMIP5 models (3.42 ± 2.47% under RCP2.6, and 8.54 ± 5.88% under RCP8.5) (WGI AR6 Section 5.4.4.2, Kwiatkowski et al., 2020; Canadell et al., 2021). The inter-model uncertainty associated with CMIP6 net primary production projections is larger than in CMIP5, and it is consistently larger than the scenario uncertainty. For each SSP across the CMIP6 ensemble, individual models project both increases and decreases in global primary production, reflecting a diverse suite of bottom-up and top-down ecological processes, which are variously parameterised across models (Laufkötter et al., 2015; Bindoff et al., 2019). Further, accurate simulation of many of the biogeochemical tracers upon which net primary production depends (e.g., the distribution of iron, Tagliabue et al., 2016; Bindoff et al., 2019) remains a significant and ongoing challenge to ESMs (*high confidence*) (Séférian et al., 2020).

Regionally, multi-model mean changes in primary production show generally similar patterns of large declines in the North Atlantic and the western equatorial Pacific, while in the high latitudes, primary production consistently increases in CMIP5 and CMIP6 by 2100 (Kwiatkowski et al., 2020, Cross-Chapter Paper 6). In the Indian Ocean and sub-tropical North Pacific, which were regions of consistent net primary production decline in CMIP5 projections (Bopp et al., 2013), the regional declines are reduced in magnitude, less spatially extensive, and are typically less robust in CMIP6. Further assessment of simultaneous changes in processes such as nutrient advection, nitrogen fixation, the microbial loop, and top-down grazing pressure (WGI AR6 Section 5.4.4.2, Laufkötter et al., 2015; Bindoff et al., 2019; Canadell et al., 2021) are required to fully understand the regional primary production response in CMIP6 (Kwiatkowski et al., 2020). Given the regional variations in the estimates of primary production changes and the uncertainty in the representation of the dominant drivers, there remains *low confidence* in the projected global decline in net primary production.

3.4.3.5.3 Observed processes driving changes in global export flux

The SROCC *medium confidence* assessment that warming, stratification, declines in productivity and changes in plankton community in the epipelagic zone result in reduced export of primary production to deeper layers (Table 3.24) is supported by subsequent literature (Bach et al., 2019; Leung et al., 2021). POC export efficiency is constrained by altered mixing and nutrient availability (Boyd et al., 2019; Lundgreen et al., 2019), particle fragmentation (Briggs et al., 2020), as well as viral, microbial, and planktonic community structure (Fu et al., 2016; Guidi et al., 2016; Flombaum et al., 2020; Kaneko et al., 2021) and metabolic rates

(Cavan et al., 2019). These processes are strongly interlinked and their net effect on primary production export from the upper ocean remain difficult to quantify observationally (Boyd et al., 2019). Since SROCC, there is increasing evidence that ocean deoxygenation can alter zooplankton community structure (Wishner et al., 2018), zooplankton respiration rates (Cass and Daly, 2014; Cavan et al., 2017) and patterns of diel vertical migration (Aumont et al., 2018), which may focus remineralisation of organic carbon at the upper margins of OMZs (Section 3.4.3.4 on depth shifts due to OMZ, Bianchi et al., 2013; Archibald et al., 2019).

Data on export flux from the upper ocean are limited either in coverage and consistency (ship-board sampling) or duration (sediment traps) and are subject to considerable spatial variability (as shown in satellite observations, Boyd et al., 2019). As a result, trends are weak, inconsistent and often not statistically significant (Lomas et al., 2010; Cael et al., 2017; Muller-Karger et al., 2019; Xie et al., 2019). Deep-ocean fluxes are similarly equivocal (Smith et al., 2018; Fischer et al., 2019; Fischer et al., 2020). In coming years, an increasing number of Argo floats equipped with bio-optical sensors should help improve estimates of particle flux spatial and temporal variability (e.g., Dall'Olmo et al., 2016).

Projected changes

SROCC and WGI AR6 reported global declines in POC export flux, between –8.9 to –15.8% by 2100 relative to 2000 under RCP8.5 in CMIP5 models, and –2.5 to –21.5% (median value –14%) between 1900 and 2100 under SSP5-8.5 in CMIP6 models (WGI AR6 5.4.4.2, Table 3.24, Bindoff et al., 2019; Canadell et al., 2021). In CMIP5 model runs, the decrease in the sinking flux of organic matter from the upper ocean into the ocean interior was strongly related to the changes in stratification that reduce net nutrient supply (Fu et al., 2016; Bindoff et al., 2019), especially in tropical regions, and the projections for global export production changes are reported with *medium confidence*. Increasing model complexity with more widespread representation of ocean biogeochemical processes between CMIP5 and CMIP6, and inclusion of more than one or two classes of phyto- and zooplankton will provide opportunities to improve assessments of how climate-impact drivers affect different components of biological carbon pump in the epipelagic ocean, as well as changes in the efficiency and magnitude of carbon export in the deep ocean (*high confidence*) (Box 3.3, Le Quéré et al., 2016; Séférian et al., 2020; Wright et al., 2021).

[START BOX 3.3 HERE]

Box 3.3: Deep Sea Ecosystems

Deep-sea ecosystems include all waters below the 200 m isobath as well as the underlying benthos, and they provide habitats for highly diversified and specialised biota, which play a key role in the cycling of carbon and other nutrients (Figure Box3.3.1, Thurber et al., 2014; Middelburg, 2018; Snelgrove et al., 2018). The deep sea covers >63% of Earth's surface (Costello and Cheung, 2010) and is exposed to climate-driven changes in abyssal, intermediate, and surface waters that influence sinking fluxes of particulate organic matter (*high confidence*) (Figure Box3.3.1, Sections 3.1, 3.2.1, 3.2.2, 3.4.3.4, WGII AR5 Section 30.5.7, SROCC Sections 5.2.3, 5.2.4, Hoegh-Guldberg et al., 2014; Bindoff et al., 2019). These ecosystems are also influenced by non-climate drivers, especially fisheries, oil and gas extraction (Thurber et al., 2014; Cordes et al., 2016; Zhang et al., 2019a); cable laying (United Nations, 2021); and mineral resource exploration (Hein et al., 2021); with proposed large-scale deep-sea mining a potential future source of impacts (Danovaro, 2018; Levin et al., 2020).

Ocean warming alters biological processes in deep-sea ecosystems in ways that affect deep-sea habitat, biodiversity, and material processing. Enhancement of microbial respiration by warming attenuates sinking POC, which has been associated with the globally projected declines in total seafloor biomass of –9.8% and –13.0% by 2081–2100 relative to 1995–2014 under SSP1-2.6 and SSP5-8.5, respectively (*limited evidence*) (Section 3.4.3.4). Additionally, climate-change-driven oxygen loss (Section 3.2.3.2, Luna et al., 2012; Belley et al., 2016), and geographic shifts in predator distributions (Section 3.4.3.1) are anticipated to affect deep-sea biodiversity (*limited evidence, high agreement*) (Smith et al., 2012; Morato et al., 2020). Complex responses of some bathyal crustacean assemblages to environmental change suggest an increase in phylogenetic diversity but limited decreases in abundances with temperature (Ashford et al., 2019). Acute mortality of some reef-forming cold-water corals to laboratory-simulated warming (Lunden et al., 2014) suggests that both long-term warming and the increase of MHWs in intermediate and deep waters (Elzahaby and Schaeffer, 2019) could pose significant risk to associated ecosystems (*high confidence*). Thermal tolerance thresholds (lethal and sub-lethal) of scleractinians in laboratory settings depend on their geographic position and capacity for thermal adaptation, as well as other factors including food, oxygen and pH (*medium to high confidence*) (Naumann et al., 2013; Hennige et al., 2014; Lunden et al., 2014; Naumann et al., 2014; Georgian et al., 2016; Gori et al., 2016; Maier et al., 2016; Büscher et al., 2017).

The extension and intensification of deep-water acidification (Section 3.2.3.1) has been identified as a further key risk to deep-water coral ecosystems (*medium confidence*) (Bindoff et al., 2019). Literature since SROCC supports this assessment (Morato et al., 2020; Puerta et al., 2020), although scleractinians and gorgonians are found in regions undersaturated with respect to aragonite (Thresher et al., 2011; Fillinger and Richter, 2013; Baco et al., 2017). Laboratory experiments on reef-forming scleractinians show variable results, with regional acclimation potential and population-genetic adaptations (Georgian et al., 2016; Kurman et al., 2017). *Desmophyllum pertusum*[6] and *M. oculata* maintain calcification in moderately low pH (7.75) and near-saturation of aragonite (Hennige et al., 2014; Maier et al., 2016; Büscher et al., 2017), but lower pH (7.6) and corrosive conditions lead to net dissolution of *D. pertusum* skeletons (*high confidence*) (Lunden et al., 2014; Kurman et al., 2017; Gómez et al., 2018). Experiments suggest that *D. dianthus* is more sensitive to warming than acidification and when both are high, as projected under climate change. Warming appears to compensate for declines in calcification, with fitness also sensitive to food availability (Bramanti et al., 2013; Movilla et al., 2014; Gori et al., 2016; Baussant et al., 2017; Büscher et al., 2017; Schönberg et al., 2017; Höfer et al., 2018; Maier et al., 2019).

In OMZ regions (Section 3.2.3.2), benthic species distributions (Sperling et al., 2016; Levin, 2018; Gallo et al., 2020), abundance and composition of demersal fishes in canyons (De Leo et al., 2012) and deep-pelagic zooplankton (Wishner et al., 2018) follow oxygen gradients, indicating that deep-sea biodiversity and ecosystem structure will be impacted by extension of hypoxic areas (*medium confidence*). Fossil records show benthic population collapse and turnover when oxygen ranged from oxic to mildly or severely hypoxic (Cross-Chapter Box PALEO in Chapter 1, Moffitt et al., 2015). Regional extirpations among cold-water corals in the paleorecord were associated with substantial declines in oxygen, coincident with abrupt warming and altered intermediate water masses properties (Wienberg et al., 2018; Hebbeln et al., 2019). Despite mortality and functional impacts from low oxygen concentrations observed in aquaria (Lunden et al., 2014), recent observations of the deep-water coral *D. pertusum* suggest adaptive capacity to hypoxia among specimens from OMZ regions that are highly productive (*low confidence*) (Hanz et al., 2019; Hebbeln et al., 2020).

Chemosynthetic ecosystems could be particularly prone to oxygen decline (*low to medium confidence*). Projected OMZ expansion in the vicinity of seep communities could favour sulphide-tolerant species, as suggested from fossil records (Moffitt et al., 2015), but this will exclude large symbiont-bearing foundation species of methane seep ecosystems (Fischer et al., 2012; Sweetman et al., 2017). Projected warming, or shifts in warm-current circulation along continental margins, could enhance dissociation of buried methane hydrates (Phrampus and Hornbach, 2012; Phrampus et al., 2014), either increasing anaerobic methane oxidation (Boetius and Wenzhöfer, 2013), which benefit seep communities, or increasing gas fluxes, which would decrease anaerobic methane oxidation rates and exclude chemosynthetic fauna.

Environmental niche models (FAO, 2019; Morato et al., 2020; Puerta et al., 2020) project that under RCP8.5, >50% of present-day scleractinian habitats in the North Atlantic Ocean, will become unsuitable by 2100, with greater impacts on *D. pertusum* than on *D. dianthus* or *Madrepora oculata*. For gorgonians, corresponding habitat loss is *likely* >80%. Much less is known about the environmental niches of deep-sea sponges, preventing a similar assessment (Kazanidis et al., 2019; Puerta et al., 2020).

Climate-driven impacts further limit the resilience of deep-sea ecosystems to impacts from human activities (*high confidence*) (Levin and Le Bris, 2015; Rogers, 2015; Sweetman et al., 2017). However, assessing cumulative climatic and non-climatic impacts is challenging for these data-poor environments (Ashford et al., 2018; Levin, 2018; Armstrong et al., 2019; Heffernan, 2019; Kazanidis et al., 2020; Orejas et al., 2020), where lack of knowledge increases the possibility of overlooking ecosystem vulnerabilities and risks (Levin, 2021). A paucity of information about the natural variability and historical trends of these habitats prevents

[6] Previously named *Lophelia pertusa*

robust assessment of adaptive capacities and potential vulnerabilities to extreme events (Aguzzi et al., 2019; Levin et al., 2019; Chapron et al., 2020; Danovaro et al., 2020; Le Bris and Levin, 2020; Levin, 2021). The spatial resolution of CMIP5 models is too coarse to robustly project changes in mesoscale circulation at the seafloor (Sulpis et al., 2019), on which deep-sea ecosystems depend for organic material supplies and dispersal of planktonic and planktotrophic larvae (*high confidence*) (Fox et al., 2016; Mitarai et al., 2016; Dunn et al., 2018). Higher-resolution modelling from CMIP6 (Orr et al., 2017), multiannual and high-frequency records of ocean bottom-water properties (Meinen et al., 2020), and better understanding and accounting of biogeochemical mechanisms of organic carbon transport to the ocean interior is expected to improve this capacity (Boyd et al., 2019; Séférian et al., 2020).

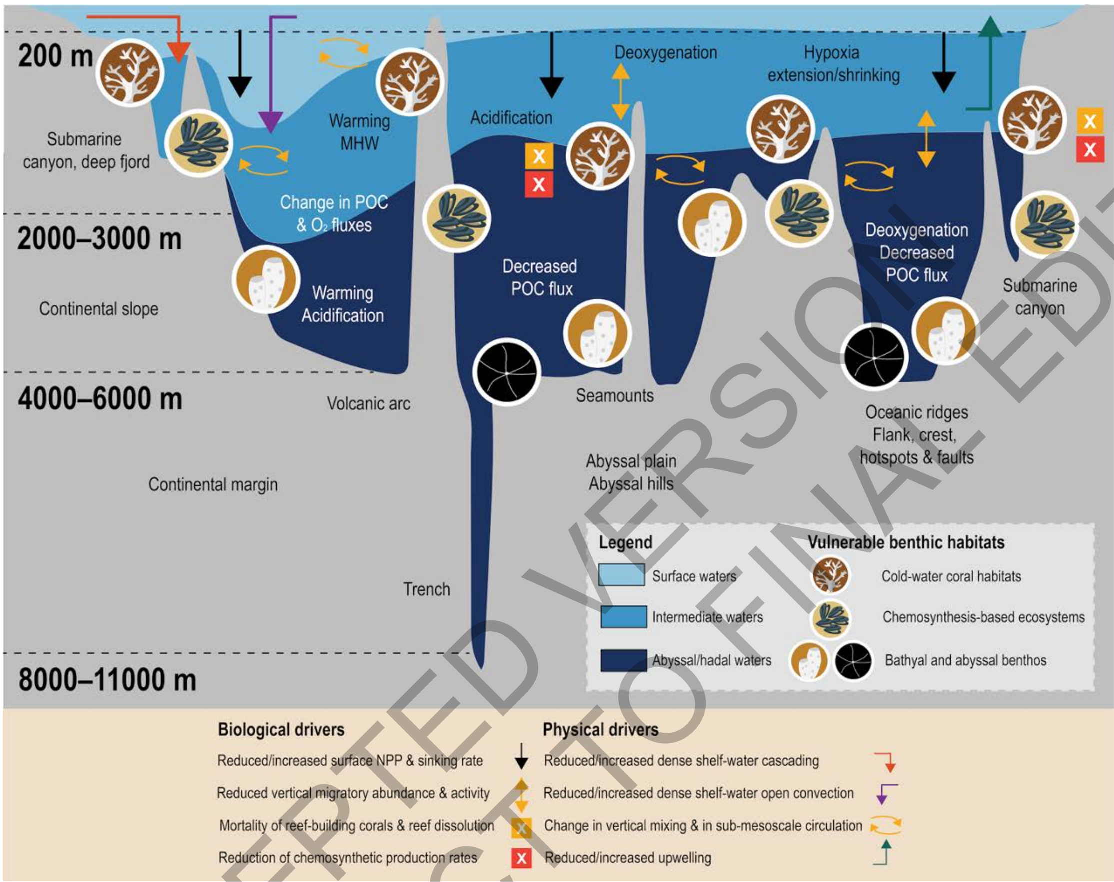

Figure Box3.3.1: Schematic of the combination of climate-impact drivers in different deep-ocean ecosystems. Key physical and biological drivers of change in the deep-sea and benthic habitats with specific vulnerabilities are discussed in Section 3.4.3.3.

[END BOX 3.3 HERE]

3.4.4 Reversibility and Impacts of Temporary Overshoot of 1.5°C or 2°C Warming

Scenarios limiting warming to the 1.5°C and 2°C limits in the Paris Agreement can involve temporarily exceeding those warming levels before declining again (WGI AR6 Section 4.6.2.1, Lee et al., 2021). The effect of such "overshoot" on marine and coastal ecosystems depends on the reversibility of both the response of climate-impact drivers, and the response of organisms and ecosystems to the climate-impact drivers, during the overshoot period. WGI AR6 assessed that temporary overshoot of a 2°C warming threshold has irreversible effects on global mean sea-level and also effects on ocean heat content that persist beyond 2100 (WGI AR6 Section 4.6.2.1, Lee et al., 2021). Model results indicate that sea surface temperatures (*high confidence*), Arctic sea ice (*high confidence*), surface ocean acidification (*very high confidence*) and surface ocean deoxygenation (*very high confidence*) are reversible within years to decades if net emissions reach zero or below (WGI AR6 Table 4.10, Lee et al., 2021). Although changes in these surface ocean variables are reversible, habitat-forming ecosystems including coral reefs and kelp forests may undergo irreversible phase shifts with >1.5°C warming (Section 3.4.2.1, 3.4.2.3), and are thus at high risk this century in 1.5°C or 2°C scenarios involving overshoot (Tachiiri et al., 2019). In an overshoot scenario in which CO_2 returns to 2040 levels by 2100 (SSP5-3.4-OS, O'Neill et al., 2016), SST and Arctic sea ice do not fully return by 2100 to levels prior to the CO_2 peak (*medium confidence*) (WGI AR6 Section 4.6.2.1, Lee et al., 2021), suggesting that reversal of marine ecological impacts from 21st century climate impacts would extend into the 22nd century or beyond (McManus et al., 2021). Models also indicate that global sea level rise, as well as warming, ocean acidification and deoxygenation at depth, are irreversible for centuries or longer (*very high confidence*) (WGI AR6 Section 4.6.2.1 and Table 4.10, Palter et al., 2018; Li et al., 2020c; Lee et al., 2021).

3.5 Vulnerability, Resilience and Adaptive Capacity in Marine Social-Ecological Systems, including Impacts to Ecosystem Services

3.5.1 Introduction

This Section assesses the impacts of climate change on ecosystem services (Table 3.25, Chapter 1) and the outcomes on social-ecological systems, building on previous assessments (Table 3.26). Section 3.5.2 assesses how changes in biodiversity influence ecosystem services. Then Sections 3.5.3 and 3.5.4 assess provisioning services (food and non-food), Section 3.5.5 assesses supporting and regulating services, and Section 3.5.6, cultural services. Where evidence exists, the section evaluates how the vulnerability and adaptive capacity of social-ecological systems govern the manifestation of impacts on each ecosystem service.

Table 3.25: Ocean and coastal ecosystem services. Adapted from IPBES (2017), with examples made specific to ocean and coastal ecosystems by Chapter 3 authors.

Ecosystem Service Category	Components	Ocean and Coastal Examples
Provisioning	Food and feed	Status of harvested marine fish, invertebrates, mammals, and plants.
	Medicinal, biochemical and genetic resources	Existence of and access to biological resources that could offer future prospects for development, including marine fish, invertebrates, mammals, plants, microbes, viruses.
	Materials and assistance	Existence of and access to minerals, shells, stones, coral branches, dyes used to create other goods; availability of marine organisms to exhibit in zoos, aquariums, and as pets.
	Energy	Existence of and access to sources of energy, including oil and gas reserves; solar, tidal, and thermal ocean energy; and biofuels from marine plants.
Supporting and Regulating	Habitat creation and maintenance	Status of nesting, feeding, nursery, and mating sites for birds, mammals, and other marine life, and of resting and overwintering places for migratory marine life or insects. Connectivity of ocean habitats.
	Dispersal and other propagules	Ability of marine life to spread gametes and larvae successfully by broadcast spawning reproduction, and ability of adults to disperse widely.
	Regulation of climate	Status of carbon storage and sequestration, methane cycling in

		wetlands, and dimethyl sulfide creation and destruction.
	Regulation of air quality	Status of aquatic processes that maintain and balance CO_2, oxygen, nitrogen oxides, sulfur oxides, volatile organic compounds, particulates, and aerosols.
	Regulation of ocean acidification (Section 3.2.3.1)	Status of chemical and biological aquatic processes that maintain and balance CO_2 and other acids/bases.
	Regulation of freshwater quantity, location and timing	Status of water storage by coastal systems, including groundwater flow; aquifer recharge; and flooding responses of wetlands, coastal water bodies, and developed spaces.
	Regulation of freshwater and coastal water quality	Status of chemical and biological aquatic processes that retain and filter coastal waters, capture pollutants and particles, and oxygenate water (e.g., natural filtration by sediments including adsorbent minerals and microbes).
	Regulation of organisms detrimental to humans and marine life	Status of grazing that controls harmful algal blooms and algal overgrowth of key ecosystems. Environmental conditions that suppress marine pathogens.
	Formation, protection and decontamination of soils and sediments	Status of chemical and biological aquatic processes that capture pollutants and particles (e.g., adsorption by minerals, microbial breakdown of pollutants).
	Regulation of hazards and extreme events	Ability of coastal environments to serve as wave energy dissipators, barriers, and wave breaks.
	Regulation of key elements	Status of aquatic processes that maintain and balance stocks of carbon, nitrogen, phosphorus, and other elements critical for life.
Cultural	Physical and psychological experiences	Existence of and access to recreational opportunities including visiting beaches and coastal environments; and aquatic activities such as fishing, boating, swimming, and diving.
	Supporting identities	Existence of and access to cultural, heritage, and religious activities, and opportunities for intergenerational knowledge transfer. Sense of place.
	Learning and inspiration	Existence of educational opportunities and characteristics to be emulated, as in biomimicry.
	Maintenance of options	Existence of opportunities to develop new medicines, materials, foods, and resources, or to adapt to a warmer climate and emergent diseases.

Table 3.26: Conclusions from previous IPCC assessments about observed and projected climate impacts to ocean and coastal biodiversity and ecosystem services.

Ecosystem service and chapter subsection	Observed Impacts	Projected Impacts
All (Section 3.5)	Climate change has affected marine "ecosystem services with regionally diverse outcomes, challenging their governance (*high confidence*). Both positive and negative impacts result for food security through fisheries (*medium confidence*), local cultures and livelihoods (*medium confidence*), and tourism and recreation (*medium confidence*). The impacts on ecosystem services have negative consequences for health and well-being (*medium confidence*), and for Indigenous Peoples and local communities dependent on fisheries (*high confidence*) (1.1, 1.5, 3.2.1, 5.4.1, 5.4.2, Figure SPM.2)" (SROCC SPM A.8, IPCC, 2019c).	"Long-term loss and degradation of marine ecosystems compromises the ocean's role in cultural, recreational, and intrinsic values important for human identity and well-being (*medium confidence*) (3.2.4, 3.4.3, 5.4.1, 5.4.2, 6.4)" (SROCC SPM B.8, IPCC, 2019c).
Biodiversity (Section 3.5.2)	"[Climate] Impacts are already observed on [coastal ecosystem] habitat area and biodiversity, as well as ecosystem functioning and services (*high confidence*) (4.3.2, 4.3.3, 5.3, 5.4.1, 6.4.2, Figure SPM.2)" (SROCC SPM A.6, IPCC, 2019c).	"Risks of severe impacts on biodiversity, structure and function of coastal ecosystems are projected to be higher for elevated temperatures under high compared to low emissions scenarios in the 21st century and beyond." (SROCC SPM B.6, IPCC, 2019c).
Food provision (Section 3.5.3)	"Warming-induced changes in the spatial distribution and abundance of some fish and shellfish stocks have had positive and negative impacts on catches, economic benefits, livelihoods, and local culture (*high confidence*). There are negative consequences for Indigenous Peoples and local communities that are dependent on fisheries (*high confidence*). Shifts in species distributions and abundance has challenged international and national ocean and fisheries governance, including in the Arctic, North Atlantic and Pacific, in terms of regulating fishing to secure ecosystem integrity and sharing of resources between fishing entities (*high confidence*) (3.2.4, 3.5.3, 5.4.2, 5.5.2, Figure SPM.2)". (SROCC SPM A.8.1 IPCC, 2019c).	"Future shifts in fish distribution and decreases in their abundance and fisheries catch potential due to climate change are projected to affect income, livelihoods, and food security of marine resource-dependent communities (*medium confidence*). Long-term loss and degradation of marine ecosystems compromises the ocean's role in cultural, recreational, and intrinsic values important for human identity and well-being (*medium confidence*) (3.2.4, 3.4.3, 5.4.1, 5.4.2, 6.4)" (SROCC SPM B.8,IPCC, 2019c).
Non-food consumable provisioning services (Section 3.5.4.1)	*Observed impacts on non-food provisioning services not previously assessed.*	"Reductions in marine biodiversity due to climate change and other anthropogenic stressors (Tittensor et al., 2010), such as ocean acidification (CBD, 2009) and pollution, might reduce the discovery of genetic resources from marine species useful in pharmaceutical, aquaculture, agriculture, and other industries (Arrieta et al., 2010), leading to a loss

		of option value from marine ecosystems.” (WGII AR5 Section 6.4.1.2, Pörtner et al., 2014)
Renewable energy (Section 3.5.4.2)	*Observed impacts on ocean renewable energy not previously assessed.*	“Ocean renewable energy can support climate change mitigation, and can comprise energy extraction from offshore winds, tides, waves, thermal and salinity gradient and algal biofuels. The emerging demand for alternative energy sources is expected to generate economic opportunities for the ocean renewable energy sector (*high confidence*), although their potential may also be affected by climate change (*low confidence*) (5.4.2, 5.5.1, Figure 5.23)”. (SROCC SPM C.2.5, IPCC, 2019c).
Habitat creation and maintenance (Section 3.5.5.1)	“[Climate] Impacts are already observed on [coastal ecosystem] habitat area and biodiversity, as well as ecosystem functioning and services (*high confidence*) (4.3.2, 4.3.3, 5.3, 5.4.1, 6.4.2, Figure SPM.2)” (SROCC SPM A.6, IPCC, 2019c). “In polar regions, ice associated marine mammals and seabirds have experienced habitat contraction linked to sea ice changes (*high confidence*).” (SROCC SPM A.5.2, IPCC, 2019c).	“In the Southern Ocean, the habitat of Antarctic krill, a key prey species for penguins, seals and whales, is projected to contract southwards under both RCP2.6 and RCP8.5 (*medium confidence*) (3.2.2, 3.2.3, 5.2.3)” (SROCC SPM B5.3, IPCC, 2019c). “Ocean warming, oxygen loss, acidification and a decrease in flux of organic carbon from the surface to the deep ocean are projected to harm habitat-forming cold-water corals, which support high biodiversity, partly through decreased calcification, increased dissolution of skeletons, and bioerosion (*medium confidence*).” (SROCC SPM B5.4, IPCC, 2019c).
Climate regulation and air quality (Section 3.5.5.2)	“Global ocean heat content continued to increase throughout [the 1951-present] period, indicating continuous warming of the entire climate system (*very high confidence*)” (WGI AR6 TS1.2.3, Arias et al., 2021).	“The increase in global ocean heat content (TS2.4) will *likely* continue until at least 2300 even for low-emission scenarios.” (WGI AR6 Box TS.9, Arias et al., 2021).
	“Land and ocean have taken up a near-constant proportion (globally about 56% year^{-1}) of CO_2 emissions from human activities over the past six decades, with regional differences (*high confidence*)” (WGI AR6 SPM A1.1, IPCC, 2021b).	“While natural land and ocean carbon sinks are projected to take up, in absolute terms, a progressively larger amount of CO_2 under higher compared to lower CO_2 emissions scenarios, they become less effective, that is, the proportion of emissions taken up by land and ocean decrease with increasing cumulative CO_2 emissions. This is projected to result in a higher proportion of emitted CO_2 remaining in the atmosphere (*high confidence*)” (WGI AR6 SPM B4.1, IPCC, 2021b).
	Observed impacts on marine organisms’ contribution to climate regulation not previously assessed.	“The effect of climate change on marine biota will alter their contribution to climate regulation, that is, the maintenance of the chemical composition and physical processes in the atmosphere and oceans (*high confidence*) (Beaumont et al., 2007)”

		(WGII AR5 Section 6.4.1.3, Pörtner et al., 2014).
Provision of fresh water, maintenance of water quality, regulation of pathogens (Section 3.5.5.3)	*Observed climate impacts on salinisation of coastal soil and groundwater not previously assessed.*	"In the absence of more ambitious adaptation efforts compared to today, and under current trends of increasing exposure and vulnerability of coastal communities, risks, such as erosion and land loss, flooding, salinisation, and cascading impacts due to mean sea level rise and extreme events are projected to significantly increase throughout this century under all greenhouse gas emissions scenarios (*very high confidence*)." (SROCC SPM B9.1, IPCC, 2019c)
	"Global warming compromises seafood safety (*medium confidence*) through human exposure to elevated bioaccumulation of persistent organic pollutants and mercury in marine plants and animals (*medium confidence*), increasing prevalence of waterborne *Vibrio* sp. pathogens (*medium confidence*), and heightened likelihood of harmful algal blooms (*medium confidence*)." (SROCC SPM B.8.3, IPCC, 2019c).	"[Risks from marine-borne pollutants and pathogens] are projected to be particularly large for human communities with high consumption of seafood, including coastal Indigenous communities (*medium confidence*), and for economic sectors such as fisheries, aquaculture, and tourism (*high confidence*) (3.4.3, 5.4.2, Box 5.3)" (SROCC SPM B.8.3, IPCC, 2019c).
	"Since the early 1980s, the occurrence of harmful algal blooms (HABs) and pathogenic organisms (e.g., *Vibrio*) has increased in coastal areas in response to warming, deoxygenation and eutrophication, with negative impacts on food provisioning, tourism, the economy and human health (*high confidence*)." (SROCC Chapter 5 Executive Summary, Bindoff et al., 2019).	"Overall, the occurrence of HABs, their toxicity and risk on natural and human systems are projected to continue to increase with warming and rising CO_2 in the 21st century (Glibert et al., 2014; Martín-García et al., 2014; McCabe et al., 2016; Paerl et al., 2016; Gobler et al., 2017; McKibben et al., 2017; Rodríguez et al., 2017; Paerl et al., 2018; Riebesell et al., 2018) (*high confidence*)." (SROCC Box 5.4, Bindoff et al., 2019).
Regulation of physical hazards (Section 3.5.5.4)	"Coastal ecosystems are already impacted by the combination of sea level rise, other climate-related ocean changes, and adverse effects from human activities on ocean and land (*high confidence*)... Coastal and near-shore ecosystems including saltmarshes, mangroves, and vegetated dunes in sandy beaches, ... provide important services including coastal protection... (*high confidence*)" (SROCC Chapter 4 Executive Summary, Oppenheimer et al., 2019).	"The decline in warm water coral reefs is projected to greatly compromise the services they provide to society, such as...coastal protection (*high confidence*)..." (SROCC SPM B.8.2, IPCC, 2019c).
Ocean and coastal carbon storage (Section 3.5.5.5)	"Recent observations show that ocean carbon processes are starting to change in response to the growing ocean sink, and these changes are expected to contribute significantly to future weakening of the ocean sink under medium- to high-emission scenarios. However, the effects of these changes is not yet reflected in a weakening	"Emission scenarios SSP4-6.0 and SSP5-8.5 lead to warming of the surface ocean and large reductions of the buffering capacity, which will slow the growth of the ocean sink after 2050. Scenario SSP1-2.6 limits further reductions in buffering capacity and warming, and the ocean sink weakens in response to the declining rate of

	trend of the contemporary (1960–2019) ocean sink (*high confidence*)" (WGI AR6 Chapter 5 Executive Summary, Canadell et al., 2021).	increasing atmospheric CO_2. There is *low confidence* in how changes in the biological pump will influence the magnitude and direction of the ocean carbon feedback" (WGI AR6 Chapter 5 Executive Summary, Canadell et al., 2021).
	"Mangrove, seagrass, and salt marsh ecosystems offer important carbon storage and sequestration opportunities (*limited evidence, medium agreement*), in addition to ecosystem goods and services such as protection against coastal erosion and storm damage and maintenance of habitats for fisheries species." (WGII AR5 Technical Summary).	"…under high emission scenarios, sea level rise and warming are expected to reduce carbon sequestration by vegetated coastal ecosystems (*medium confidence*); however, under conditions of slow sea level rise, there may be net increase in carbon uptake by some coastal wetlands (*medium confidence*)" (SROCC Chapter 5, Bindoff et al., 2019).
Cultural Services (Section 3.5.6)	"Climate change impacts on marine ecosystems and their services put key cultural dimensions of lives and livelihoods at risk (*medium confidence*), including through shifts in the distribution or abundance of harvested species and diminished access to fishing or hunting areas. This includes potentially rapid and irreversible loss of culture and local knowledge and Indigenous knowledge, and negative impacts on traditional diets and food security, aesthetic aspects, and marine recreational activities (*medium confidence*)" (SROCC SPM B.8.4, IPCC, 2019c).	"Future shifts in fish distribution and decreases in their abundance and fisheries catch potential due to climate change are projected to affect income, livelihoods, and food security of marine resource-dependent communities (*medium confidence*). Long-term loss and degradation of marine ecosystems compromises the ocean's role in cultural, recreational, and intrinsic values important for human identity and well-being (*medium confidence*)" (SROCC SPM B.8, IPCC, 2019c).

3.5.2 Biodiversity

Climate change is a key agent of biodiversity change in numerous ocean and coastal ecosystems (*very high confidence*) (Table 3.26, Worm and Lotze, 2021), and climate change and biodiversity loss reinforce each other (Pörtner et al., 2021b). Biodiversity has changed in association with ocean warming and loss of sea ice (Sections 3.4.2.10, 3.4.3.3.3; Section CCP6 2.4.2), SLR (Section 3.4.2; Cross-Chapter Box SLR in Chapter 3), coral bleaching (Section 3.4.2.1), MHWs (Sections 3.4.2.1-3.4.2.5), and upwelling changes (*high confidence*) (Section 3.4.2.9). Overlapping non-climate drivers (Section 3.1) also decrease ocean and coastal ecosystem biodiversity (*very high confidence*) (O'Hara et al., 2021; Pörtner et al., 2021b). There is *medium confidence* that local and regional marine biodiversity losses from climate disrupt ecosystem services provided by specific ocean and coastal species or places (Sections 3.5.3–3.5.6, Figure 3.23, Table 3.26, Box 3.3, Dee et al., 2019a; Hossain, 2019; Smale et al., 2019; Teixeira et al., 2019; Martin et al., 2020; Pathak, 2020; Weiskopf et al., 2020; Zunino et al., 2020; Archer et al., 2021). However, adaptive capacity varies greatly among ecosystems, and ecological functions sometimes remain, despite changes in species assemblages, as in certain coral reef communities (Richardson et al., 2020). Projected changes in biodiversity due to climate change (Section 3.4.3.3.3) are expected to alter the flow and array of ocean and coastal ecosystem services (*high confidence*) (Smale et al., 2019; Cavanagh et al., 2021; Ruthrof et al., 2021; Worm and Lotze, 2021), but data gaps hinder developing projections of ecosystem service changes detailed enough to support decision making (Rosa et al., 2020).

Non-indigenous marine species are major agents of ocean and coastal biodiversity change, and climate and non-climate drivers interact to support their movement and success (*high confidence*) (Iacarella et al., 2020). At times, non-indigenous species act invasively and outcompete indigenous species, causing regional biodiversity shifts and altering ecosystem function, as seen in the Mediterranean region (*high confidence*) (e.g., Mannino et al., 2017; Bianchi et al., 2019; Hall-Spencer and Harvey, 2019; Verdura et al., 2019; García-Gómez et al., 2020; Dimitriadis et al., 2021). Warming-related range expansions of non-indigenous species have directly or indirectly decreased commercially important fishery species and nursery habitat (Booth et al., 2018). Non-indigenous species outperform indigenous species in coastal zones experiencing warming and freshening (McKnight et al., 2021). Non-climate drivers, especially marine shipping in newly ice-free locations (Chan et al., 2019), fishing pressure (Last et al., 2011), aquaculture of non-indigenous species (Mach et al., 2017; Ruby and Ahilan, 2018), and marine pollution and debris (Gall and Thompson, 2015; Carlton et al., 2018; Carlton and Fowler, 2018; Lasut et al., 2018; Miralles et al., 2018; Rech et al., 2018; Therriault et al., 2018), promote range shifts and movement of non-indigenous species (*high confidence*). Non-climate drivers can also intensify the ecological effects of non-indigenous species (Geraldi et al., 2020). Invasive marine species can alter species behaviour, reduce indigenous species abundance, reduce water clarity, bioaccumulate more heavy metals than indigenous species, and inhibit ecosystem resilience in the face of extreme events (*medium confidence*) (McDowell et al., 2017; Geburzi and McCarthy, 2018; Anton et al., 2019; Ruthrof et al., 2021). Risks from invasive species to the sources of other ecosystem services or aquatic goods, including valuable materials, mining activities, shipping, or ocean energy installations, have not been evaluated.

Reducing risk to ecosystem functions and services that depend on biodiversity requires an integrated approach that acknowledges the close linkages between the climate and biodiversity crises and common governance challenges (Pörtner et al., 2021b). Climate-focused solutions that employ nature-based solutions (NbS), technological interventions, and socio-institutional interventions (Section 3.6.2) can also safeguard biodiversity (Pörtner et al., 2021b), which in turn will help ocean and coastal ecosystems adapt to climate impacts as well as help sustain the services they provide to people (Sections 3.5.3–3.5.6).

3.5.3 Food Provision

Globally, about 17% of humans' average per capita intake of animal protein in 2017 came from marine and freshwater wild-caught and aquacultured aquatic animals (Costello et al., 2020; FAO, 2020a). Per capita intake of seafood is 50% or more in some Small Island Developing States (SIDS) (Vannuccini et al., 2018), and consumption per capita is 15 times higher in Indigenous Peoples than non-Indigenous Peoples (Cisneros-Montemayor et al., 2016). Fishery products also supply critical dietary micronutrients worldwide (Section 3.5.4.1, Hicks et al., 2019; Vianna et al., 2020). Marine and freshwater fisheries and aquaculture provide livelihoods for an estimated 10–12% of the world's population (Barange et al., 2018). Fishing and aquaculture provide women and their families with substantial amounts of food and income (Harper et al., 2020b), because at least 11% of small-scale fishers (Harper et al., 2020b) and up to half of all fishery and aquaculture workers (FAO, 2018) are women. This section assesses how climate-driven alterations of the abundance or nutritional quality of food from the sea could affect humans. Aquaculture, catch potential changes, and human adaptations to changes in wild and cultured harvests, are assessed in Section 5.9.

Ocean and coastal fauna are moving towards higher latitudes globally due to warming (*high confidence*) (Section 3.4.3.1, Table 3.26), challenging fishers and fisheries management (*high confidence*) as fishers also move poleward and diversify harvests (*medium evidence, high agreement*) (Table 3.26, Sections 3.4.3.3.3, 5.8.4, Leitão et al., 2018; Liang et al., 2018; Ottosen et al., 2018; Peck and Pinnegar, 2018; Pinsky et al., 2018; Erauskin-Extramiana et al., 2019; Free et al., 2019; Gianelli et al., 2019; Scott et al., 2019; Smith et al., 2019; Gervais et al., 2021). Model hindcasts have identified temperature-associated fisheries reductions worldwide (Free et al., 2019), and they have implicated overfishing as the primary non-climate driver increasing fishery vulnerability (Section 5.8.4, Peck and Pinnegar, 2018; Das et al., 2020). Catch composition is changing in many locations fished by smaller-scale, less mobile commercial, artisanal, and recreational fisheries (*high confidence*) (Booth et al., 2018; Townhill et al., 2019; Young et al., 2019b; Robinson et al., 2020; Champion et al., 2021). Limited exceptions have been noted, with wild harvests in some places remaining stable or increasing (e.g., Arreguín-Sánchez, 2019; Robinson et al., 2019b; Kainge et al., 2020). Where possible, fishers are maintaining harvests by broadening catch diversity, traveling poleward, and changing gear and strategies (*high confidence*) (Section 3.6.3.1.2, Barange et al., 2018; Dubik et al., 2019; Townhill et al., 2019). Fisheries and aquaculture adaptations, including management, are comprehensively assessed in Sections 3.6.3.1.2, 5.8.4, and 5.9.4.

Ocean acidification and deoxygenation caused by climate change are thought to influence fishing and aquaculture harvests, but *limited evidence* prevents assessing their present global impact on harvests. Substantial economic losses in the North American Pacific Coast shellfish aquaculture industry in the 2000s assessed in SROCC (Bindoff et al., 2019) and WGII AR5 (Pörtner et al., 2014) remain the clearest example of human harm from ocean acidification. Technology-based adaptations (Section 3.6.3) have minimised aquaculture losses from ocean acidification, including early warning systems to guide hatchery operations and culturing resilient shellfish strains (Section 5.9.4, Barton et al., 2015a). Laboratory studies show that ocean acidification decreases the fitness, growth, or survival of many economically and culturally important larval or juvenile shelled mollusks (*high confidence*) (Cao et al., 2018; Onitsuka et al., 2018; Stevens and Gobler, 2018; Griffith et al., 2019a; Mellado et al., 2019), and of several valuable wild-harvest crab species (Barton et al., 2015a; Punt et al., 2015; Miller et al., 2016; Swiney et al., 2017; Gravinese et al., 2018; Tomasetti et al., 2018; Long et al., 2019; Trigg et al., 2019). Ocean acidification alters larval settlement and metamorphosis of fish in laboratory studies (*high confidence*) (Cattano et al., 2018; Espinel-Velasco et al., 2018), suggesting possible changes in fish survival and thus fishery characteristics. Deoxygenation can decrease size and abundance of marine species and suppress trophic interactions (Levin, 2003), decrease the diversity within marine ecosystems (Sperling et al., 2016) while temporarily increasing catchability and increasing the risk of overfishing (Breitburg et al., 2018), and decrease the ecosystem services provided by specific fisheries (Orio et al., 2021). The chronic effects of deoxygenation on wild fisheries are complex and highly interactive with co-occurring drivers and overall ecosystem responses (*medium evidence, high agreement*) (Townhill et al., 2017; Rose et al., 2019). Detecting and attributing marine ecosystem responses to ocean acidification and deoxygenation outside of laboratory studies remains challenging because of the strong influence of co-occurring environmental changes on natural systems (Section 3.3.5, Rose et al., 2019; Doo et al., 2020).

Ocean and coastal organisms will continue moving poleward under RCP8.5 (*high confidence*) (Section 3.4.3.1.3, Figure 3.18), and this is expected to decrease fisheries harvests in low latitudes and alter species composition and abundance in higher latitudes (*high confidence*) (Table 3.26, Figure 3.23, Asch et al., 2018; Morley et al., 2018; Tai et al., 2019; Erauskin-Extramiana et al., 2020; Shelton et al., 2021). Species that succeed in new ranges or conditions may offer opportunities to diversify regional fisheries or aquaculture (Sections 3.6.3.1.2, 5.8.4, 5.9.4, Bindoff et al., 2019), or they may outcompete indigenous species and act as invasive species (Sections 3.4.2.10, 3.5.2).

Temperature will continue to be a major driver of fisheries changes globally, but other non-climate factors like organism physiology and ecosystem response (Section 3.3) and fishing pressure (Chapter 5), as well as other climate-impact drivers like acidification, deoxygenation, and sea-ice loss (Section 3.2), will play critical roles in future global and local fisheries changes (*high confidence*). Warming, acidification, and business-as-usual fishing policy under RCP8.5 are projected to place around 60% of global fisheries at very high risk (*medium confidence*) (Cheung et al., 2018). Model intercomparison showed that ocean acidification and protection affect ecosystems more than fishing pressure, and ecological adaptation greatly determines impacts on fishery biomass, catch and value until approximately 2050 (*medium confidence*) (Olsen et al., 2018). Ecosystem responses to warming water, fishing pressure, food-web changes, MHWs, and sea ice algal populations have been responsible for highly variable or collapsing populations of Northern Hemisphere high-latitude forage fish species including sand lances (*Ammodytes* spp.), Arctic cod (*Boreogadus saida*), capelin (*Mallotus catervarius*), and herring (*Clupea* spp.) (Lindegren et al., 2018; Steiner et al., 2019; Arimitsu et al., 2021; Suca et al., 2021). Declining stocks of forage fish are expected to have detrimental effects on seabirds, pelagic fish, and marine mammals (*medium confidence*) (Lindegren et al., 2018; Steiner et al., 2019), which may harm dependent human communities, including Arctic Indigenous Peoples (*low confidence*) (Arctic Monitoring and Assessment Programme, 2018; Steiner et al., 2019). Modelled fishery futures and revenue depend on environmental scenario, fishing fleet composition and management, and ocean acidification and temperature responses of harvested species (*high confidence*) (Punt et al., 2014; Punt et al., 2015; Seung et al., 2015; Fernandes et al., 2017; Rheuban et al., 2018; Tai et al., 2019; Punt et al., 2020). Detrimental effects of ocean acidification are projected to begin emerging in specific fisheries by 2030 (*limited evidence, high agreement*) [(southern Tanner crab (*Chionoecetes bairdi*) (Punt et al., 2015); sea scallop (*Placopecten magellanicus*) (Rheuban et al., 2018); Northeast Arctic cod (*Gadus morhua*) (Hänsel et al., 2020); Arctic fisheries (Lam et al., 2016)]. At the same time, projected hypoxic conditions of ~2 mg l^{-1} of oxygen will be consistently detrimental across taxonomic groups, developmental stages, and climate regions (*high confidence*) (Sampaio et al., 2021). Ecosystem-based management (Section 3.6.3.1.2) shows promise for decreasing risk from interacting climate and non-climate drivers to forage species and fished species.

3.5.4 Other Provisioning Services

3.5.4.1 Non-Food Consumable Products

The interaction of climate and non-climate drivers endangers the supply of non-food consumable products developed from marine organisms (*limited evidence, high agreement*). This broad class includes nutraceuticals (derived from fish, krill, shellfish, seaweeds, microbes), food preservatives or additives (derived from crustaceans, fish, microalgae and seaweeds, cyanobacteria), pharmaceuticals (derived from fish, shellfish, microbes, cyanobacteria, corals, sponges), or cosmetic products (derived from sponges, phytoplankton and seaweeds, fish, etc.) (Freitas et al., 2012; Dewapriya and Kim, 2014; Leal and Calado, 2015; Stengel and Connan, 2015; Greene et al., 2016; Ciavatta et al., 2017; Gutiérrez-Rodríguez et al., 2018). But biodiversity changes, warming, acidification, and non-climate drivers (especially fishing pressure) may decrease the availability of these organisms or the potency of the compounds they produce (Section 5.7.5.1, Table 3.26, Figure 3.23, Webster and Taylor, 2012; Mehbub et al., 2014; Kotta et al., 2018; Martins et al., 2018; Conrad et al., 2021). Observed and projected declines and movement of fish stocks due to fishing pressure and climate change impacts (IPCC, 2019b) have generated concerns that the supply and safety of fish and krill oil for human dietary supplements may decline (Section 5.7.5.1, Gribble et al., 2016; Lloret et al., 2016). This risk can be lowered by technological adaptations (Section 3.6.2.2) such as increasing the use of alternative sources, like marine phytoplankton, macroalgae, marine microbes (Dewapriya and Kim, 2014; Greene et al., 2016; Dave and Routray, 2018; Nguyen et al., 2020) and underutilised resources such as fish, seal, crab and shrimp byproducts (Dave and Routray, 2018), and by improving extraction and processing efficiency(Cashion et al., 2017). Climate effects on non-food consumable products could be widespread yet poorly detected, complicating assessment of impacts, risks, and vulnerability reduction.

There is *insufficient evidence* to develop global projections of future climate impacts on humans through changes in non-food consumable marine products, but specific local examples have been investigated, such as the Arctic ooligan (eulachon) (*Thaleichthys pacificus*), a small smelt fish. Ooligan grease has been used by Indigenous Peoples of the North Pacific coast (Phinney et al., 2009) for at least 5000 years to treat stomach aches, colds and skin conditions and as a traditional food source high in omega-3 fatty acids (Byram and Lewis, 2001; Cranmer, 2016; Patton et al., 2019). Analysis of remains have shown that ooligan could comprise up to 67% of traditional historical fisheries catches (Patton et al., 2019). Because ooligan spawning relies on the timing of the spring freshet, and because the species has declined in the last 25 years due to fishing pressure and predation, the species may be at risk from combined climate and non-climate drivers (*medium confidence*) (Talloni-Álvarez et al., 2019). Projections under RCP2.6 or RCP8.5 estimate reductions by 21% or 31% by 2050 in essential nutrients from traditional seafood for Indigenous Peoples in Canada, relative to 2000, with a modelled nutritional deficit that includes non-traditional dietary substitutions (Marushka et al., 2019).

3.5.4.2 Non-Consumable Goods

Limited evidence about climate impacts exists for valuable non-food aquatic materials. Ocean warming and acidification harm red coral (*Corallium rubrum*) (Bramanti et al., 2013) and communities hosting black coral (*Antipatharian* spp.), both used for jewellery (Ross et al., 2020). While no-take MPAs (Section 3.6.3.2) enhance red coral structural complexity, they only weakly compensate for warming effects (Cerrano et al., 2013; Montero-Serra et al., 2019). *Antipatharian* spp. are not well studied or monitored (Gress and Andradi-Brown, 2018). Acidification and warming negatively impact pearl oysters (Welladsen et al., 2010; Liu and He, 2012; Liu et al., 2012; Hoegh-Guldberg et al., 2014; Zhang et al., 2019b). Projected climate impacts for 2035 would decrease the average net present value of French Polynesia's pearl aquaculture industry by 29.1% compared to the present (Hilsenroth et al., 2021). Climate impacts on ornamental species sought by aquarists have not been well studied (Dee et al., 2019b).

Decreasing the vulnerability of renewable energy installations, particularly wind turbines, to climate risks (Table 3.26, Bindoff et al., 2019) could include technological adaptations (Section 3.6.2.2) such as storm "survival mode" settings (Penalba et al., 2018); preparation for hazards such as icing, SLR, drifting sea ice, and wave activity (Neill et al., 2018; Goodale and Milman, 2019; Solaun and Cerdá, 2019), and biofouling (*medium confidence*) (Want and Porter, 2018; Joyce et al., 2019; Vinagre et al., 2020), which is expected to increase in response to warming and acidification (*medium confidence*) (Dobretsov et al., 2019; Khosravi et al., 2019; Liu et al., 2020d; Lamim and Procópio, 2021). Macroalgae and fish processing byproducts are being tested for biofuel use (Greene et al., 2016; Alamsjah et al., 2017; Saifuddin and Boyce, 2017; Sakthivel et al., 2018; Sudhakar et al., 2019; Nguyen et al., 2020; Ramachandra and Hebbale, 2020; Tan et al., 2020), but weather variability could pose financial risk to this sector (Kleiman et al., 2021).

3.5.5 Supporting and Regulating Services

Ocean and coastal regulating services are detailed in Table 3.25. The economic value of all regulating ecosystem services in 2015 was estimated at 29.1 trillion USD, with water- and climate-regulating services contributing the most (Balasubramanian, 2019).

3.5.5.1 Habitat Creation and Maintenance and Larval Dispersal

Climate impacts have already altered ocean and coastal habitats (Section 3.4.2, Table 3.26, Gissi et al., 2021) in ways that have led to species range shifts, biodiversity changes, phenology changes, and regime shifts (Section 3.4.3) from the surface ocean to the seafloor (*very high confidence*) (Box 3.3, Figure 3.22). Continued ocean and coastal habitat impacts are projected, and their severities will depend on emissions scenario and co-occurring drivers (Section 3.4.3, Qiu et al., 2019) or extremes (e.g., Babcock et al., 2019). Warming and physical circulation are projected to change larval dispersal, a habitat-related service (Bashevkin et al., 2020), but identifying probable outcomes remains challenging owing to the high variability among species, locations, and recruitment (Schilling et al., 2020; King et al., 2021; Le Corre et al., 2021; Raventos et al., 2021). Climate risks to habitat can be decreased by reducing non-climate drivers, preserving ecosystems, or restoring habitat (Sections 3.6.2, 3.6.3.2). Risk to larval dispersal cannot be meaningfully addressed at scale by human-implemented adaptations; instead, declines in this service will pressure natural systems to adapt via physiological plasticity or evolution (Section 3.3, Bashevkin et al., 2020).

3.5.5.2 Climate Regulation and Air Quality

Climate regulation by the ocean depends on physical and biogeochemical processes (Sections 3.2–3.4) that create, move, and store heat, water vapor and other climate-active compounds including CO_2, methane, and dimethyl sulfide and methane (WGI AR6 Chapter 6, Naik et al., 2021). Over the 21st century, ocean heat and CO_2 uptake will continue (WGI AR6 SPMB4.1, B5.1, IPCC, 2021b) and sea ice loss from warming will allow some additional CO_2 uptake (Armstrong et al., 2019), but the ocean will take up a smaller fraction of CO_2 emissions as atmospheric CO_2 concentrations rise (*high confidence*) (Table 3.26, WGI AR6 SPM B4.1, IPCC, 2021b).

There is *very limited evidence* on climate-driven air-quality changes in the coastal zone. Increased humidity decreases the lifetime of ozone and increases particulate matter and indoor mold levels (USGCRP, 2016), potentially affecting near-shore air quality. However, coastal zone air pollution can enhance coastal climate impacts by increasing risk of acid rain, which worsens ocean acidification (nitrogen oxides, sulphur oxides, and mercury, Doney, 2010; Northcott et al., 2019).

3.5.5.3 Provision of Fresh Water, Maintenance of Water Quality, and Regulation of Pathogens

The salinities of many estuaries, deltas, coastal fresh water aquifers, and soils around the world are increasing, and this decrease in water quality is endangering human health and agricultural yields (*very high confidence*) (Table 3.26, Section 3.4.2.4, Bindoff et al., 2019; Bouderbala, 2019; Rahman et al., 2019; Naser et al., 2020; Rakib et al., 2020; Mastrocicco and Colombani, 2021). Coastal salinisation is attributed to regionally varying combinations of climate-impact drivers, like SLR and storm-related flooding by seawater, and non-climate drivers, like water withdrawal and land use changes (*very high confidence*) (Islam et al., 2019; Rahman et al., 2019; Paldor and Michael, 2021). Monitoring-related adaptations (Section 3.6.2.2.2) including advances in modeling and monitoring are providing decision-relevant, regional-scale information

(Colombani et al., 2016; Mukhopadhyay et al., 2019; Slama et al., 2020; Corwin, 2021). For example, new projections indicate which drinking water intake stations on China's Pearl River Estuary will be unable to meet demands by 2100 due to SLR and drought (Wang and Hong, 2021), while others show that SLR effects on seawater intrusion into the coastal aquifer in Kerala, India under both RCP4.5 and RCP8.5 scenarios are negligible (Sithara et al., 2020). Salinisation-associated changes may disproportionately burden women responsible for securing drinking water and fuel, such as in the Indian Sundarbans (Mukhopadhyay et al., 2019). Salinisation will continue to endanger coastal water and soil quality in the future (*high confidence*) (Islam et al., 2019; Paldor and Michael, 2021), but the evidence assessed above shows that subsequent impacts to human health and agriculture will depend heavily on regional variations in environment and human behaviour (*medium confidence*).

Together, climate and non-climate drivers can mobilise toxins and contaminants in ways that harm human and marine species health (*very high confidence*) (Box 3.2), and climate change is altering these relationships (*high confidence*) (Table 3.26, Bindoff et al., 2019). Under warming or ocean acidification, marine molluscs exposed to pharmaceuticals via wastewater experience more detrimental biological consequences or greater bioaccumulation (*limited evidence, high agreement*) (Costa et al., 2020a; Costa et al., 2020b; Dionísio et al., 2020; Freitas et al., 2020; Kibria et al., 2021). Physical circulation, temperature, and biogeochemical characteristics (Bowman et al., 2020; Liu et al., 2020a; Liu et al., 2020b; Sun et al., 2020; Zhang et al., 2020b) control the ubiquitous oceanic distribution of methylmercury, and ocean acidification- and warming-driven changes in planktonic speciation and interactions can promote additional food-web bioaccumulation of methylmercury (Tada and Marumoto, 2020; Wu et al., 2020b; Zhang et al., 2020b; Zhang et al., 2021a). Interactions among drivers also matter: temperature plus overfishing increased tissue methylmercury concentrations in Atlantic bluefin tuna from the 1970s to the 2000s more than the decreases in the late 1990s and 2000s from lower environmental mercury levels (Schartup et al., 2019). This appears true for persistent organic pollutants as well, but their bioaccumulation is related more to temperature effects on animal behaviour than on pollutant dynamics (Houde et al., 2019; Wagner et al., 2019; Kalia et al., 2021). By 2100 under RCP8.5, productivity changes and community structure shifts are expected to increase methylmercury concentrations in polar oceans and high-latitude phytoplankton and decrease it in low latitudes (Zhang et al., 2021a). The estimated average global cost of mercury-related health effects by 2050, mainly from seafood consumption during 2010–2050, will be 19 trillion USD (2020), assuming a 3% discount rate, if methylmercury emissions are not reduced (Zhang et al., 2021b).

Since previous assessments, evidence has increased that climate impacts such as warming, extreme weather, and SLR are increasing the geographic spread and risk of marine-borne human pathogen outbreaks, including *Vibrio* spp. (*very high confidence*) (Table 3.26, Bindoff et al., 2019; Logar-Henderson et al., 2019; Froelich and Daines, 2020; Montánchez and Kaberdin, 2020; Semenza, 2020; Ferchichi et al., 2021). Climate change affects at least 30 human pathogens with aquatic-system infection routes (e.g., ingestion of contaminated water or seafood, or contact with wounds, see Table SM3.2, Cross-Chapter Box ILLNESS in Chapter 2, Nichols et al., 2018). Conditions favourable for *Vibrio cholerae* are increasing globally, which raises risk to humans (Cross-Chapter Box ILLNESS in Chapter 2). Increased storm-related flooding and SLR further increase human encounters with *Vibrio* spp. (Froelich and Daines, 2020). Aquatic diseases, particularly *Vibrio* spp., have caused large economic losses in aquaculture by decreasing the quality or survival of cultured species (Lafferty et al., 2015; Novriadi, 2016). Temperature-based model projections show that all Canadian shellfish beds will experience conditions that promote high risk of *Vibrio* spp. growth by 2100 for both RCP4.5 and RCP8.5 scenarios (Ferchichi et al., 2021). Climate-impact drivers may increase *Vibrio* spp. loads in seafood species: laboratory-simulated heatwaves increase *Vibrio* spp. abundance in Pacific oyster (*Crassostrea gigas*) (Green et al., 2019) and simulated ocean acidification increases hard clam (*Mercenaria mercenaria*) susceptibility to *Vibrio* spp. infection (Schwaner et al., 2020). Projected increases in temperature, extreme and variable rainfall conditions, coastal flooding, and SLR (Section 3.2, Cross-Chapter Box SLR in Chapter 3) strongly increase the risk of frequent and severe aquatic human pathogen outbreaks in ocean and coastal areas that will continue to harm human health and cause economic losses (*high confidence*) (Cross-Chapter Box ILLNESS in Chapter 2, Froelich and Daines, 2020; Semenza, 2020; Ferchichi et al., 2021). Section 3.6.3.1.5 assesses human adaptations to increasing risk of marine-borne pathogens.

Climate-driven changes in temperature, salinity (from ice melt and precipitation changes), deoxygenation, and ocean acidification can alter dynamics of infectious diseases that target ocean and coastal species by increasing hosts' susceptibility or pathogens' abundance or virulence (*high confidence*) (Burge and Hershberger, 2020; Byers, 2021). Coral and urchin diseases have increased over time driven by warming-related declines in organism recovery and survival or immunity (*medium confidence*) (Cohen et al., 2018; Tracy et al., 2019). Seagrass and sea star wasting disease outbreaks have occurred under combinations of ocean warming or MHWs and non-climate drivers (e.g., eutrophication, bottom trawling), but attribution of these outbreaks to specific drivers is still not resolved (Harvell et al., 2019; Jakobsson-Thor et al., 2020; Krause-Jensen et al., 2021). Disease outbreaks threaten marine biodiversity, species that create habitat or dampen wave action, and keystone species (Harvell and Lamb, 2020). Attributing observed changes in marine disease patterns to climate remains extremely difficult owing to interacting climate and non-climate drivers (Burge and Hershberger, 2020) and lack of baseline data (Tracy et al., 2019). Projected increases in the frequency, duration, and intensity of warming events would reduce survival and recovery of some species from hot events, reduce immunity of other species to pathogens, extend poleward ranges of some pathogens, and increase infection risk when host species congregate in scarce habitat (Cohen et al., 2018). Pathogens that target ocean and coastal organisms may themselves be sensitive to future climate conditions or subsequent ecosystem changes, which challenges development of projections (Cohen et al., 2018; Burge and Hershberger, 2020).

Following the *high confidence* assessment of SROCC Table 3.26, Bindoff et al. (2019) that risks associated with HABs will continue to increase with warming and rising CO_2 in the 21st century, new examples have illustrated how toxic HABs interfere with regulating, provisioning (Section 3.5.3), and cultural ecosystem services (Section 3.5.6) in interconnected ways (*limited evidence, high agreement*). A massive toxic *Pseudo-nitzschia* spp. bloom in 2013–2016 along the United States (US) West Coast triggered Dungeness crab, rock crab, and razor clam fishery closures to protect human consumers (Sections 3.6.2, 3.6.3.1.5, McCabe et al., 2016), and this disproportionately harmed fishers, especially small-vessel owners, and fishing-support service industries, primarily through lost revenue (Ritzman et al., 2018; Moore et al., 2019; Trainer et al., 2019; Jardine et al., 2020; Moore et al., 2020a). Toxic *Alexandrium* spp. blooms promoted by climate-driven coastal extremes (e.g., MHWs, stratification, runoff) in Tasmania, Australia, in 2012 and Chile in 2016 caused fish kills, shellfish product recalls, substantial economic losses, and human sickness and death (Trainer et al., 2019). The Chile event caused an estimated loss of 800 million USD in the farmed salmon industry (Díaz et al., 2019) and resulted in a series of large, long-lasting regional protests calling for national aid (Delgado et al., 2019). New evidence, however, suggests that the perceived global increase in harmful algal blooms results from better monitoring and more detrimental bloom impacts rather than a climate-linked mechanism (Hallegraeff et al., 2021).

Natural and engineered systems have long been used effectively to manage precipitation and wastewater safely (Chapter 4, Box 4.5), and maintaining and enhancing them is a key nature-based adaptation strategy for coastal communities (Section 3.6.2.3, Cross-Chapter Paper 2). Estimated values of water purification and stormwater management provided by coastal ecosystems are in the hundreds to thousands of USD per hectare [e.g., 272 Euro per 0.01 $km^2\ yr^{-1}$ from the Mediterranean's sandy coastline (Hérivaux et al., 2018); 1100–2800 USD per 0.01 $km^2\ yr^{-1}$ from the state of Maryland, USA (Campbell et al., 2020b); 600 USD per 0.01 $km^2\ yr^{-1}$ in Zhuzhou City, China (Zhan et al., 2020)]. Both wild and cultured organisms also provide filtration services. Seagrasses' ability to purify water is well recognised by coastal residents and ocean resource users in tropical and temperate locations (Ambo-Rappe et al., 2019; Quevedo et al., 2020; Heckwolf et al., 2021; McKenzie et al., 2021a). Globally, aquacultured shellfish remove an estimated 49,000 tonnes of nitrogen and 6000 tonnes of phosphorus from coastal waters, worth a potential 1.20 billion USD, and they may help improve existing engineered wastewater treatment systems (van der Schatte Olivier et al., 2020). Climate change, especially episodic extreme rains and RSLR (Romero-Lankao et al., 2014), is challenging management and design of wastewater and stormwater systems (*high confidence*) (Flood and Cahoon, 2011; Trtanj et al., 2016; Hummel et al., 2018; Kirshen et al., 2018; Nazarnia et al., 2020; Reznik et al., 2020; McKenzie et al., 2021b) and integrity of coastal landfills (Beaven et al., 2020). Without substantial adaptation that addresses projected wastewater management challenges and community needs (Section 4.2.6.1, Kirshen et al., 2018; Kirchhoff and Watson, 2019; Kool et al., 2020; Nazarnia et al., 2020; Hughes et al., 2021), coastal water quality in many areas will decrease because of more frequent or severe releases of untreated wastes (*high confidence*) (Flood and Cahoon, 2011; Hummel et al., 2018; Hughes et al., 2021; McKenzie et al., 2021b), and this will have harmful consequences for human and coastal ecosystem health (*high confidence*) (Cross-Chapter Box ILLNESS in Chapter 2, Section 4.2.6.1, Bindoff et al., 2019).

3.5.5.4 Regulation of Physical Hazards

Coastal ecosystems physically protect people and property from storms and flooding, and climate change threatens this protection function (Table 3.26, Figure 3.22). Increasingly detailed models show how warm-water coral reefs (Reguero et al., 2019; Storlazzi et al., 2019; Reguero et al., 2021) mangroves (Blankespoor et al., 2017; Menéndez et al., 2020; Trégarot et al., 2021) and wetlands (Sun and Carson, 2020) prevent billions of USD of direct and indirect damage to private and public property and shield millions of people from flooding each year. Protection by mangroves provides more economic benefits in higher-income nations and shields more people in lower-income nations (Menéndez et al., 2020). Seagrasses (James et al., 2020; James et al., 2021), kelp (Morris et al., 2020b; Zhu, 2020), suspended shellfish aquaculture (Gentry et al., 2020; Zhu et al., 2020a), oyster reefs (Chowdhury et al., 2019) coastal wetlands (Möller, 2019; Keimer et al., 2021), and sandy coastlines (Section 3.4.2.6, Hérivaux et al., 2018) also measurably decrease wave energy. Non-climate drivers (e.g., invasive species (James et al., 2020), sediment supply changes (Ganju, 2019; Ladd et al., 2019; Ilia, 2020), erosion and storm damage (Mehvar et al., 2019; Bacopoulos and Clark, 2021)], acting together with climate-impact drivers and impacts (e.g., sea level rise (Cross-Chapter Box SLR in Chapter 3), changes in plant biodiversity (Section 3.5.2, Lee Smee, 2019; Silliman et al., 2019; Schoutens et al., 2020), MHWs (Section 3.4.3.7), and acidification (Section 3.4.2.1)) compromise physical protection by coastal ecosystems (*very high confidence*). See Cross-Chapter Box SLR in Chapter 3 and Sections 3.6.3.1 and 3.6.3.2.2 for assessment of adaptations that address this ecosystem service.

3.5.5.5 Regulation of Carbon Cycling in Ocean and Coastal Ecosystems

Current and future total carbon storage and cycling in the ocean are governed by past and future CO_2 emissions trajectories (Table 3.26), but regional ocean and coastal carbon stocks and cycling vary over time and space due to processes being altered by climate, including ocean circulation, sea-ice cover, coastal upwelling, and thermal stratification (Section 3.2.2.3); ocean primary production and export (Sections 3.2.3, 3.4.4); and marine ecosystem biodiversity (*high confidence*) (Figure 3.22, Section 3.5.2). Quantifying regional carbon fluxes and stocks is still challenging and relies on indirect measures (e.g., Fennel et al., 2019; Clay et al., 2020), especially in coastal ecosystems where drivers interact. Carbon cycling and storage co-occurs with other regulating services such as habitat provision, water quality maintenance, and coastal protection (Ouyang et al., 2018), particularly in vegetated coastal ecosystems (Box 3.4). Adaptations to support regional carbon cycling and storage generally focus on area-based management and conservation (Section 3.6.3.2), but interventions to enhance ocean carbon storage are being explored for mitigation (WGIII AR6 Chapter 7).

[START BOX 3.4 HERE]

Box 3.4: Blue Carbon Ecosystems

Climate change and other anthropogenic drivers, including eutrophication, land-use changes, and overexploitation, directly and indirectly threaten blue carbon ecosystems (Annex II: Glossary). Commonly considered blue carbon ecosystems include vegetated coastal ecosystems (Sections 3.4.2.3–3.4.2.5), whose mangroves, saltmarshes and seagrass beds host rooted, vascular plants known to store large amounts of carbon for long periods and to be amenable to management (Lovelock and Duarte, 2019). Other ocean and coastal taxa including rooted or floating macroalgae (e.g., non-vascular multicellular kelp or seaweed genera such as Macrocystis spp., Sargassum spp., or Laminaria spp., Filbee-Dexter and Wernberg, 2020), phytoplankton, and even pelagic fauna (e.g., finfish or whales, Chami et al., 2019) have also been proposed as blue carbon ecosystems. Terrestrial vascular-plant-derived material can also carry and store significant amounts of carbon in marine environments (Cragg et al., 2020). There is increasing evidence about the coverage and carbon content of macroalgal, planktonic, and faunal taxa, but *low agreement* about their long-term carbon storage potential and manageability (Alongi, 2018b; Wernberg and Filbee-Dexter, 2018; Lovelock and Duarte, 2019; Ortega et al., 2019; Pfister et al., 2019; Queirós et al., 2019; Filbee-Dexter et al., 2020a; Gallagher, 2020; Mariani et al., 2020; Thorhaug et al., 2020; van Son et al., 2020; Bach et al., 2021; Bayley et al., 2021; Cavanagh et al., 2021; Frontier et al., 2021; Martin et al., 2021; Pedersen et al., 2021; Weigel and Pfister, 2021). This section focuses on the array of ecosystem services and adaptation opportunities provided by vegetated coastal blue carbon ecosystems, where consensus and evidence are most abundant. Mitigation potential of blue carbon ecosystems is assessed with land-based mitigation options in WGIII AR6 Section 7.4.

Carbon storage and burial in mangroves, saltmarshes and seagrass meadows (Table Box3.4.1) help regulate ocean and coastal carbon cycling and may contribute to nature-based mitigation, although regional estimates vary widely based on climatic and edaphic conditions (WGIII AR6 Section 7.4). In addition, coastal vegetated ecosystems provide substantial and interdependent regulating, provisioning and cultural ecosystem services. These include disproportionately high biodiversity per unit area (Pörtner et al., 2021a); abundant habitat (Section 3.5.5.1) and nurseries for aquatic, terrestrial, aerial, and microbial species; natural filtration of waste and stormwater runoff into the coastal ocean (Sections 3.5.5.3, 4.2.7, Cross-Chapter Box ILLNESS in Chapter 2); coastal protection (Section 3.5.5.4, Ouyang et al., 2018; Quevedo et al., 2020); food and natural materials (Sections 3.5.3, 3.5.4); and support for tourism, livelihoods, and cultural activities (Section 3.5.6). Global estimates of services provided by coastal blue carbon ecosystems depend on the quality of available mapping, which is currently best developed for mangroves (Macreadie et al., 2019), and improving for saltmarshes and seagrasses (McOwen et al., 2017; McKenzie et al., 2020; Young et al., 2021).

Table Box3.4.1: Estimates of organic carbon storage and burial rates in mangroves, saltmarshes, and seagrass meadows. Estimates are the mean ± 95% confidence interval, where available (indicating the *extremely likely* range) and range. Carbon stocks for mangroves include above- and below-ground storage up to 3 m depth (sampling period 2007–2017). The estimates for saltmarsh and seagrass stocks are soil stocks up to 1 m depth (observations spanning 1983–2016 for saltmarshes and until 2016 for seagrass meadows). Date ranges for the burial rates are: 1989–2020, 1975–2020 and 1956–2016 for mangroves, saltmarshes and seagrass meadows, respectively.

	Mangroves	Saltmarshes	Seagrass meadows
Carbon stocks (MgC ha^{-1})	856 ± 64.2 (79–2208) (Kauffman et al., 2020)	317.2 ± 38.2 (27–1900) (Alongi, 2018c)	139.7 (9.1–628) (Fourqurean et al., 2012; Alongi, 2018d)
Carbon burial rate (g C m^{-2} yr^{-1})	194 ± 30 (6.2–1722) (Wang et al., 2020)	168 ± 14 (1.2–1167.5) (Wang et al., 2020)	220.7 ± 40.2 (-2094–2124) (Alongi, 2018d)
Global Carbon burial rate (TgC yr^{-1})	41 (Wang et al., 2020)	12.63 (Wang et al., 2020)	35.31 (Alongi, 2020)
Global areal coverage (Mha)	13.7 (Richards et al., 2020)	5.5 (McOwen et al., 2017)	16 (McKenzie et al., 2020)

Coastal vegetated ecosystems are vulnerable to harm from multiple climate and non-climate drivers, and together these have reduced wetland area globally (*high confidence*) (Section 3.4.2.5) and endangered the services provided by these ecosystems (*high confidence*). Loss of coastal vegetated ecosystems changes biodiversity (Sections 3.5.2, 3.4.2.3–3.4.2.5) (Numbere, 2019; Parreira et al., 2021), increases risk of damage and erosion from SLR and storms (Sections 3.4.2.3–3.4.2.5, Cross-Chapter Box SLR in Chapter 3, Galeano et al., 2017), and impacts provisioning (Sections 3.5.3–3.5.4, Li et al., 2018b; Maina et al., 2021). These changes also strongly determine the quantity and longevity of blue carbon storage (*high confidence*) (Macreadie et al., 2019; Lovelock and Reef, 2020). Specific site characteristics and ecosystem responses to climate change will determine future local blue carbon storage or loss (*high confidence*) (Table Box3.4.2). For instance, poleward migration of mangroves to areas dominated by salt marshes is expected to increase carbon storage (Kelleway et al., 2016); however, this change in the dominant vegetation and associated faunal changes can modify carbon stocks and sequestration, as well as other ecosystem services (Martinetto et al., 2016; Kelleway et al., 2017; Smee et al., 2017; Macreadie et al., 2019; Macy et al., 2019). Landward range expansion of mangroves, marshes, and seagrass in response to gradual RSLR can enhance carbon sequestration (Cross-Chapter Box SLR in Chapter 3, Section 3.4.2.5, Macreadie et al., 2019), but coastal squeeze can limit this (Phan et al., 2015; Schuerch et al., 2018) and RSLR can either submerge and bury or erode and release stored blue carbon (Section 3.4.2.5, Macreadie et al., 2019; Lovelock and Reef, 2020). Gains and losses of mangrove habitat area (and therefore carbon storage) projected for nations under RCP4.5 and RCP8.5 depend primarily on the combination of SLR rate, adaptation scenario (including coastal development), and island or continental status (Lovelock and Reef, 2020). The influence of warming, MHWs, and acidification on seagrass meadows (Kendrick et al., 2019; Strydom et al., 2020) and associated coralligenous reefs (Zunino et al., 2019) suggests that future warming and especially MHWs will cause more widespread loss of services from these ecosystems (Section 3.4.2.5). Loss of blue carbon ecosystems will not only halt carbon storage, but also release stored carbon: emissions after 2000 due to global mangrove deforestation have been estimated at 23.5–38.7 Tg Cyr^{-1} (Ouyang and Lee, 2020). Mitigation estimates for avoided conversion and restoration of coastal wetlands and the implications of the impacts of climate change are assessed in WGIII AR6 Section 7.4.

To date, initiatives aiming to restore coastal wetland ecosystems primarily address ecosystem characteristics other than carbon storage (Herr et al., 2017; de los Santos et al., 2019; Lovelock and Duarte, 2019; Friess et al., 2020a). But recovery of coastal vegetated ecosystems is expected to bring back the full suite of ecosystem services they provide, not just carbon storage (*medium confidence*) (Marbà et al., 2015a; Burden et al., 2019; Friess et al., 2020a), making coastal restoration a low-risk action that offers both adaptation and mitigation benefits (Steven et al., 2020; Gattuso et al., 2021). Successful restoration requires using appropriate plant species in suitable environmental settings (Wodehouse and Rayment, 2019; Friess et al., 2020a) with favourable geomorphology and biophysical conditions (Cameron et al., 2019; Ochoa-Gómez et al., 2019) and considering social, economic, policy, and operational constraints (Section 3.6.3.2.2, Cross-Chapter Box NATURAL in Chapter 2), now and in the future (*high confidence*) (Duarte et al., 2020; Lovelock and Reef, 2020). Nevertheless, restored spaces may not store carbon at rates equal to those of undisturbed spaces (Yang et al., 2020), and it may take decades to determine or achieve carbon storage outcomes of restoration (Sasmito et al., 2019; Duarte et al., 2020; Oreska et al., 2020). Integration improves efforts to restore or conserve coastal wetland ecosystems to accomplish both adaptation and mitigation outcomes (Steven et al., 2020). Government-led conservation of blue carbon ecosystems as part of national and subnational climate strategies (e.g., Friess et al., 2020a; Kelleway et al., 2020; Wedding et al., 2021) benefits from coordination with private activities, such as incentivising conservation with payments for ecosystem services (Muenzel and Martino, 2018; Friess et al., 2020a). Moreover, successful area-based protection measures consider both environmental and social issues (Section 3.6.3.2). Continued integration and alignment of policies at international to local levels (Section 3.6.5) will also support achieving the adaptation and mitigation benefit of blue carbon spaces (Friess et al., 2020a; Steven et al., 2020; Wu et al., 2020a).

Table Box 3.4.2: Examples of vegetated blue carbon ecosystem carbon storage gains and losses in response to climate-impact drivers, and key actions contributing to maintained or and increased carbon storage. "+C" indicates potential positive effects on blue carbon stocks, "–C" indicates negative effects, "0" indicates no effects, and "ΔC" indicates positive or negative effects. Effects on carbon stocks from 3.4.2.5, Macreadie et al. (2019); Lovelock and Reef (2020); Wang et al. (2020). Key actions to sustain blue carbon storage from Duarte et al. (2020); Wedding et al. (2021).

[END BOX 3.4 HERE]

3.5.6 Cultural Services

Cultural services provided by ocean and coastal ecosystems help maintain psychological well-being, cultural development, human identities, educational opportunities, and reserves that could support development of future goods or activities (Table 3.25). Most recent studies of ocean and coastal cultural services simply detail local benefits using replicable methods (e.g., Drakou et al., 2018; Folkersen, 2018; Förster et al., 2019; Lau et al., 2019; Pouso et al., 2019; Weitzman, 2019; Yang et al., 2019), focusing on diverse ocean and coastal environments and ecosystems (Jobstvogt et al., 2014; Balzan et al., 2018; Drakou et al., 2018; Ingram et al., 2018; Pouso et al., 2018; Zapata et al., 2018; Ghermandi et al., 2019; Pouso et al., 2019; Tanner et al., 2019; Turner et al., 2019; Ortíz Liñán and Vázquez Solís, 2021). Cultural ecosystem services may directly benefit from marine development activities, such as marine aquaculture (e.g., Alleway et al., 2018), and indirectly benefit from marine activities that increase biodiversity (e.g., Causon and Gill, 2018). Cultural services are generally quantified using interviews and revealed-preference or stated-preference valuation (National Research Council, 2005; Sangha et al., 2019), but people often are especially reluctant to evaluate cultural ecosystem services in monetary terms, given the spiritual and community linkages to these services (Oleson et al., 2018).

Additional evidence since previous assessments (Table 3.26) confirms that climate-change impacts on ocean and coastal cultural ecosystem services have already disrupted people's place-based emotional attachments and cultural activities (*limited evidence, high agreement*) (Figure 3.22). Bleaching and mortality of corals in the Great Barrier Reef have induced measurable "reef grief," a type of solastalgia, among reef visitors and researchers (Conroy, 2019; Curnock et al., 2019; Marshall et al., 2019). The mental health of people in Tuvalu (Gibson et al., 2020), Alaska (Allen, 2020), and Honduras (Kent and Brondo, 2020) have suffered from both the experience of climate impacts on ocean and coastal ecosystems (e.g., SLR and changes in fisheries and wildlife), and the anticipation of more in the future. The climate-associated MHWs and harmful algal bloom events in 2014–2016 in the US Pacific Northwest (Moore et al., 2019) prevented seasonal razor clam harvests culturally important to Indigenous Peoples and the local community (Section 3.5.5.3, Crosman et al., 2019). SLR and storm-driven coastal erosion endanger coastal archaeological and heritage sites around the world (*very high confidence*) (Hoque and Hoque, 2008; Carmichael et al., 2018; Reimann et al., 2018; Elliott and Williams, 2019; Ravanelli et al., 2019; Anzidei et al., 2020; Chemeli et al., 2020; García Sánchez et al., 2020; Harkin et al., 2020; Hil, 2020; Rivera-Collazo, 2020).

Disruptions in ocean and coastal ecosystem services partly attributable to climate change have also caused economic losses (*limited evidence, high agreement*). Water quality deterioration over 24 years in a US temperate bay due to nutrient enrichment and warming caused 0.08–0.67 million USD per decade in lost recreational shellfish revenues (Luk et al., 2019). In southwestern Florida, USA, where nutrient enrichment, lake hydrology, and rainfall conditions control cyanobacterial HAB formation (Havens et al., 2019), toxic HAB events deterred visitors and recreation, leading to lodging and restaurant revenue losses (Bechard, 2020), decreased domestic and international arrivals and overall visitor spending (a 99 million USD loss from August to October 2018, Scanlon, 2019), and lost recreational spending from loss of boat-ramp access (a 3 million USD economic loss from June to September 2018, Alvarez et al., 2019). In Cornwall, England, HABs from 2009–2016 disrupted residents' sense of place, identity, and well-being by interrupting recreational and economic activities, and by creating feelings of uncertainty and unease around the safety or dependability of future ocean-related activities (Willis et al., 2018). Increasingly abundant *Sargassum* spp. floating macroalgae from the central Atlantic Ocean and Caribbean Sea, whose proliferation has been attributed to high sea surface temperatures and nutrient enrichment (Wang et al., 2019a), has substantially disrupted beach tourism in the Caribbean and Mexico and imposes millions of dollars of clean-up costs annually on affected beaches (Milledge and Harvey, 2016).

Observed disruption of ocean and coastal cultural services by climate impacts, plus increasingly severe and widespread projected climate change impacts on ocean and coastal ecosystems, imply that risk to cultural ecosystem services will remain constant or grow (*medium confidence*) (Figure 3.22, Table 3.26). Recent studies assert that cultural ecosystem services are at risk from climate change (*high confidence*) (Singh et al., 2019a; Koenigstein, 2020). However, *limited evidence* and complex social-ecological interactions (e.g., Ingram et al., 2018) challenge development of specific projections. For instance, the little auk (*Alle alle*) in the North Water Polynya is traditionally harvested by Indigenous Inughuit for food and community-wide celebrations and seasonal activities, but harvests are threatened to an undetermined degree as the seabird competes for food with recovering bowhead whale (*Balaena mysticetus*) populations and northward range shifts of capelin (*Mallotus villosus*) due to warming (Mosbech et al., 2018). Section 3.6 assesses the cultural implications of implemented human adaptations.

Figure 3.22: Observed global influence of climate-impact drivers on ecosystem services. (Coloured cells) The "observed impact" indicates the total effect of all climate-impact drivers on a specific ecosystem service, using expert judgement based on summary statements throughout Section 3.5. (Grey cells) Co-occurring non-climate drivers that affect the service. Cell colour shows whether the observed impact of the climate-impact driver on a group of ecosystem services is positive (beneficial), negative (detrimental) or mixed (usually resulting from location, the presence of interacting drivers, or changing effects over time). No assessment indicates that not enough evidence is available to assess the direction of impact.

3.6 Planned Adaptation and Governance to Achieve the Sustainable Development Goals (SDGs)

3.6.1 Point of Departure

Human adaptation comprises an array of measures (adaptation options, IPCC, 2014a) that modulate harm or exploit opportunities from climate change (Section 1.2.1.3). Adaptation options that respond to key ocean and coastal risks (Section 3.4) focus on individuals, livelihoods, and economic sectors that benefit from ocean and coastal ecosystem services (Section 3.5). AR5 concluded that local adaptation measures would not alone be enough to offset global effects of increased climate change on marine and coastal ecosystems, and that mitigation of emissions would also be necessary (*high confidence*) (Pörtner et al., 2014; Oppenheimer et al., 2019, Table 3.27). SROCC assessed that ecosystem-based adaptation, including MPAs (*high confidence*) (Bindoff et al., 2019) and adaptive management are effective to reduce climate change impacts (IPCC, 2018; IPCC, 2019b), but that existing marine governance is insufficient to provide an effective adaptation response in the marine ecosystem (*high confidence*) (IPCC, 2019c).

Table 3.27: Conclusions from previous IPCC assessments about implemented adaptation, enablers and limits and contribution to SDGs.

	AR5	SR15	SROCC
Degree of Implementation (Section 3.6.3.1)	The analysis and implementation of coastal adaptation toward climate-resilient and sustainable coasts has progressed more significantly in developed countries than in developing countries (*high confidence*) (Wong et al., 2014).	Adaptation (to SLR) is already happening (*high confidence*) and will remain important over multi-centennial time scales (Hoegh-Guldberg et al., 2018a).	A diversity of adaptation responses to coastal impacts and risks have been implemented around the world, but mostly as a reaction to current coastal risk or experienced disasters (*high confidence*) (Oppenheimer et al., 2019).
Conservation and Restoration (Section 3.6.3.2)	With continuing climate change, local adaptation measures (such as conservation) or a reduction in human activities (such as fishing) may not sufficiently offset global-scale effects on marine ecosystems (*high confidence*) (Pörtner et al., 2014).	Existing and restored natural coastal ecosystems may be effective in reducing the adverse impacts of rising sea levels and intensifying storms by protecting coastal and deltaic regions (*medium confidence*) (Hoegh-Guldberg et al., 2018a).	Ecosystem restoration may be able to locally reduce climate risks (*medium confidence*) but at relatively high cost and effectiveness limited to low emissions scenarios and to less sensitive ecosystems (*high confidence*) (Bindoff et al., 2019).
Enablers, Barriers and Limits of Adaptation (Section 3.6.3.3)	Adaptation strategies for ocean regions beyond coastal waters are generally poorly developed but will benefit from international legislation and expert networks, as well as marine spatial planning (*high agreement*) (Hoegh-Guldberg et al., 2014).	Lower rates of change [associated with a 1.5ºC temperature increase] enhance the ability of natural and human systems to adapt, with substantial benefits for a wide range of terrestrial, freshwater, wetland, coastal and ocean ecosystems (including coral reefs) (*high confidence*) (Hoegh-Guldberg et al., 2018a).	There are a broad range of identified barriers and limits for adaptation to climate change in ecosystems and human systems (*high confidence*). Limitations include […] availability of technology, knowledge and financial support and existing governance structures (*medium confidence*). (Bindoff et al., 2019). Existing ocean governance structures are already facing multi-dimensional, scale-related challenges because of climate change [...] (*high confidence*) (Bindoff et al., 2019).
SDGs and Other Policy Frameworks (Section 3.6.4)	Overall, there is a strong need to develop ecosystem-based monitoring and adaptation strategies to mitigate rapidly growing risks and uncertainties to the coastal and oceanic industries, communities, and nations (*high agreement*) (Hoegh-Guldberg et al., 2014).	Adaptation strategies can result in trade-offs with and among the SDGs (*medium evidence, high agreement*) (Roy et al., 2018).	Achieving [the SDGs] and charting Climate Resilient Development Pathways depends in part on ambitious and sustained mitigation efforts to contain SLR coupled with effective adaptation actions to reduce SLR impacts and risk (*medium evidence, high agreement*) (Oppenheimer et al., 2019).

This section builds on the SROCC assessment of the portfolio of available solutions, their applicability, and their effectiveness in reducing climate change-induced risks to ocean and coastal ecosystems. Section 3.6.2 assesses the set of planned adaptation measures. Section 3.6.3 assesses implementation of adaptation solutions and the enablers, barriers, and limitations that affect their feasibility. Section 3.6.4 evaluates the contribution of planned adaptation to the Sustainable Development Goals (SDGs) and other policy-relevant frameworks, and Section 3.6.5 synthesises emerging evidence about best practices.

3.6.2 Adaptation Solutions

Adaptation in ocean and coastal ecosystems continues to be informed primarily by theory, as there is still *limited evidence* about implemented solutions (*high agreement*) (Seddon et al., 2020) and their success across regions, especially in low-income nations (Chausson et al., 2020). Adapting to climate change depends on society's ability and willingness to anticipate the change, recognise its effects, plan to accommodate its consequences (Ling and Hobday, 2019; Wilson et al., 2020b), and implement a coordinated portfolio of informed solutions. Here, the complete portfolio of adaptation solutions is assessed using the taxonomy of Abram et al. (2019): (1) socio-institutional adaptation, (2) built infrastructure and technology, and (3) marine and coastal nature-based solutions (NbS) (Figure 3.23).

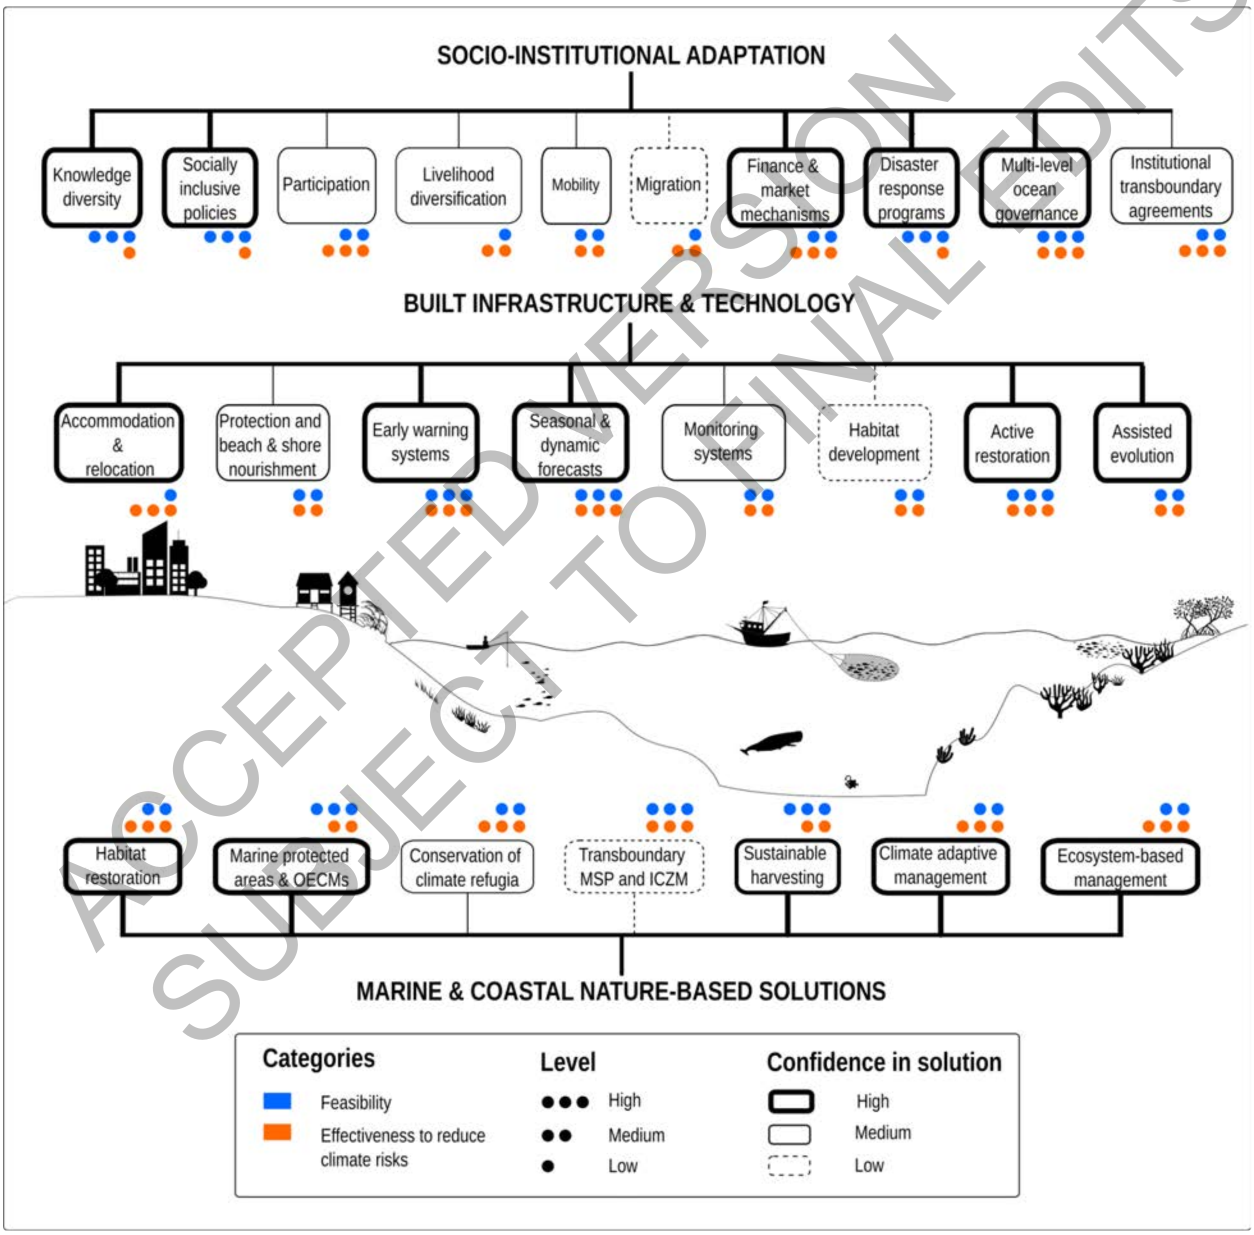

Figure 3.23: Adaptation solutions for ocean and coastal ecosystems that address climate-change risk in different ocean ecosystems, communities and economic sectors. Box-outline weights indicate confidence in the solution's potential to reduce mid-term risks (based on the amount of evidence and agreement supporting the solutions, see SM3.5.1 for full assessment). The feasibility and effectiveness of each solution (low, medium or high) indicates its ability to support ecosystems and societies as they adapt to climate change impacts, based on Table SM3.3.

3.6.2.1 Socio-Institutional Adaptation

Increasing evidence shows that an effective solution portfolio includes social and institutional adaptation (Figure 3.23, top; Table 3.28). Social adaptation to climate change is already occurring, as people use strategies ranging from accommodating change, to coping, adapting and transforming their livelihoods (Béné and Doyen, 2018; Fedele et al., 2019; Galappaththi et al., 2019; Barnes et al., 2020; Ojea et al., 2020; Green et al., 2021c). Although management and institutions have major roles in adaptation (Gaines et al., 2018; Barange, 2019), marine governance is impeded by increasing numbers of often-competing users and uses (Boyes and Elliott, 2014); sector-led, fragmented, efforts (Nunan et al., 2020); and a legal framework less clear than those on land (Crespo et al., 2019; Guggisberg, 2019). Future social responses depend on warming levels and on the institutional, socio-economic and cultural constructs that allow or limit livelihood changes (*medium confidence*) (Chapter 18, Galappaththi et al., 2019; Ford et al., 2020; Green et al., 2021c). Both social and institutional transformations are needed to change the structures of power, culture, politics and/or identity associated with marine ecosystems (Section 1.5.2, Wilson et al., 2020b). Ideally, institutional and social adaptation will work together to sustain knowledge systems and education, enhance participation and social inclusion, facilitate livelihood support and transformational change of dependent coastal communities, provide economic and financial instruments, and include polycentric and multi-level governance of transboundary management (Fedele et al., 2019; Fulton et al., 2019).

Table 3.28: Assessment of socio-institutional adaptation solutions to reduce mid-term climate impacts in oceans and coastal ecosystems. Confidence is assessed in SM3.5.1. Feasibility and effectiveness are assessed in Figure 3.24.

Solution	Confidence in solution *(mid-term potential)*	Contribution to adaptation	Selected references	Examples of implementation
Knowledge diversity	*High confidence*	Consideration of IK and LK systems is beneficial to communities, increases their resilience, and is relevant and transferable beyond the local scale.	(Norström et al., 2020; Petzold et al., 2020; Gianelli et al., 2021; Schlingmann et al., 2021)	Ecotourism (Section 3.6.3.1.3), conservation (Section 3.6.3.2.1)
Socially inclusive policies	*High confidence*	Policies that promote participation of a diversity of groups are able to address existing vulnerabilities in coastal communities, and promote adaptation and transformational change.	(Brodie Rudolph et al., 2020; Ford et al., 2020; Friedman et al., 2020)	Finance (Section 3.6.3.4.2)
Participation	*Medium confidence*	Participation in decision making and adaptation processes is recommended across a range of different hazards and contexts and has the potential to improve adaptation outcomes.	(Brodie Rudolph et al., 2020; Claudet et al., 2020a; Hügel and Davies, 2020; Sumaila et al., 2021)	Fisheries and mariculture (Section 3.6.3.1.2), Indigenous Peoples (Section 3.6.3.4.1).
Livelihood diversification	*Medium confidence*	Livelihood diversification in communities dependent on marine and coastal ecosystems reduces climate risks and confers flexibility	(Blanchard et al., 2017; Cinner and Barnes, 2019; Mohamed Shaffril et al., 2020; Owen, 2020; Pinsky, 2021; Taylor et al., 2021)	Fisheries and mariculture (Section 3.6.3.1.2), coastal communities (Cross-Chapter Box SLR in Chapter 3), tourism (Section 3.6.3.1.3)

		to individuals, which is key to adaptive capacity.		
Mobility	*Medium confidence*	When individuals are given the choice about mobility, they may elect to use this response to minimise climate risks and benefit their livelihoods.	(Barnett and McMichael, 2018)	Fisheries and mariculture (Section 3.6.3.1.2)
Migration	*Low confidence*	Migration often involves different spatio-temporal scales than mobility. Migration could be considered an adaptation solution for some coastal and island populations in the cases of extreme events, but also as a response to more gradual changes (e.g., coastal erosion from sea-level rise (SLR)).	(Maharjan et al., 2020; Biswas and Mallick, 2021; Zickgraf, 2021)	Coastal livelihoods (Section 3.6.3.1.1)
Finance and market mechanisms	*High confidence*	Financial mechanisms and credit provision for marine-dependent livelihoods are effective for overcoming impacts from SLR, extreme events and other climate-impact drivers.	(Shaffril et al., 2017; Dunstan et al., 2018; Hinkel et al., 2018; Moser et al., 2019; Sainz et al., 2019; Woodruff et al., 2020)	Economic dimensions (Section 3.6.3.4.2)
Disaster response programs	*High confidence*	Disaster response programs confer resilience to communities and contribute to adaptation, when designed to be inclusive, participatory and adaptive.	(Nurhidayah and McIlgorm, 2019)	Climate services (Section 3.6.3.4.3), tourism cruise ship sector (Section 3.6.3.1.3)
Multi-level ocean governance	*High confidence*	The multi-scale nature of ocean and coastal climate-change risk demands adaptation solutions at multiple levels of governance that consider the objectives and perceptions of all stakeholders to support local implementation of broad strategies.	(Miller et al., 2018; Gilfillan, 2019; Holsman et al., 2019; Obura et al., 2021).	Policy frameworks (Section 3.6.4.3)
Institutional transboundary agreements	*Medium confidence*	Institutional agreements for the management of transboundary marine resources are key for a	(Engler, 2020; Mason et al., 2020; Oremus et al., 2020; Melbourne-Thomas et al., 2021)	Fisheries (Section 3.6.3.1.2, Cross-Chapter Box MOVING SPECIES in Chapter 5)

		sustainable future given current impacts on marine species distribution due to climate change		

3.6.2.2 *Built Infrastructure and Technology*

Engineering and technology support marine and coastal adaptation (Table 3.29). Built infrastructure includes engineered solutions that protect, accommodate or relocate coastal assets using hard engineering, like seawalls, and soft engineering, such as beach and shore nourishment (Cross-Chapter Box SLR in Chapter 3). Technological tools include early-warning systems for extreme events (Bindoff et al., 2019; Collins et al., 2019a), improved forecast and hindcast models (Winter et al., 2020; Davidson et al., 2021; Spillman and Smith, 2021) and environmental monitoring (Claudet et al., 2020a; Wilson et al., 2020a; Melbourne-Thomas et al., 2021) that support informed decision making (Tommasi et al., 2017; Rilov et al., 2020; A. Maureaud et al., 2021). Emerging adaptation technologies, such as habitat development, active restoration and assisted evolution (Boström-Einarsson et al., 2020; Kleypas et al., 2021), intend to accelerate recovery of damaged ecosystems and promote ecological adaptation to climate change (Jones et al., 2018a; Boström-Einarsson et al., 2020; Kleypas et al., 2021).

Table 3.29: Assessment of built infrastructure and technology solutions to reduce mid-term climate impacts in oceans and coastal ecosystems. Confidence is assessed in SM3.5.1. Feasibility and effectiveness are assessed in Figure 3.24.

Solution	Confidence in solution *(mid-term potential)*	Contribution to adaptation	Selected references	Examples of implementation
Accommodation and relocation	*High confidence*	Asset modification and relocation of livelihoods to adapt to sea-level rise (SLR), extreme events and coastal erosion.	(Hanson and Nicholls, 2020; Monios and Wilmsmeier, 2020; Zickgraf, 2021)	Cross-Chapter Box SLR in Chapter 3, coastal development (Section 3.6.3.1.1).
Protection and beach and shore nourishment	*Medium confidence*	Protection of coastal ecosystems with interventions such as beach and shore nourishment is a common response to beach erosion around the world, and an alternative to hard protection structures such as seawalls.	(Pinto et al., 2020; de Schipper et al., 2021; Elko et al., 2021)	Cross-Chapter Box SLR in Chapter 3, coastal development (Section 3.6.3.1.1).
Early-warning systems	*High confidence*	Early-warning systems can support decision-making, limit economic losses from extreme events, and aid in the enterprise and development of adaptive management systems.	(Bindoff et al., 2019; Collins et al., 2019a; Winter et al., 2020; Neußner, 2021)	Coastal development (Section 3.6.3.1.1), human health (Section 3.6.3.1.5).
Seasonal and dynamic forecasts	*High confidence*	The proliferation of real-time and seasonal forecasts of temperature extremes, marine heatwaves (MHWs), storm surges, harmful algal blooms (HABs), and	(Payne et al., 2017; Hazen et al., 2018; Fernández-Montblanc et al., 2019; Holbrook et al., 2020; Winter et al., 2020; Bever et al., 2021; Davidson et al.,	Fisheries and mariculture (Section 3.6.3.1.2), MPAs (Section 3.6.3.2.1), climate services (Section 3.6.3.2.4).

		the distribution of living marine resources greatly contribute to adaptation through monitoring, early-warning systems, adaptive management and ecosystem-based management.	2021; Spillman and Smith, 2021)	
Monitoring systems	*Medium confidence*	Monitoring systems that address climate-impact drivers, ecosystem impacts and social vulnerabilities in marine social-ecological systems are key for adaptation.	(Nichols et al., 2019; Claudet et al., 2020a; Wilson et al., 2020a)	MPAs (Section 3.6.3.2.1), climate services (Section 3.6.3.2.4), fisheries (Section 3.6.3.1.2).
Habitat development	*Low confidence*	Accelerates the recovery of damaged ecosystems and promotes ecological or biological adaptation to future climate change.	(Jones et al., 2018a; Boström-Einarsson et al., 2020; Kleypas et al., 2021)	Restoration (Section 3.6.3.2.2).
Active restoration	*High confidence*	Reintroduces species or augments existing populations. For example, propagating and transplanting heat-tolerant coral species.	(Boström-Einarsson et al., 2020; Rinkevich, 2021)	Restoration (3.6.3.2.2).
Assisted evolution	*High confidence*	Manipulates species' genes to accelerate natural selection.	(Bulleri et al., 2018; National Academies of Sciences, 2019; Morris et al., 2020c)	Restoration (Section 3.6.3.2.2).

3.6.2.3 Marine and Coastal Nature-Based Solutions (NbS)

The ocean and coastal adaptation portfolio (Figure 3.23) also includes marine and coastal NbS (Table 3.30). NbS that contribute to climate adaptation, also known as ecosystem-based adaptations (EBA), are cross-cutting actions that harness ecosystem functions to restore, protect, and sustainably manage marine ecosystems facing climate change impacts, while also benefiting social systems and human security (Abelson et al., 2015; Barkdull and Harris, 2019) and supporting biodiversity (*high confidence*) (Annex II: Glossary, Cross-Chapter Box NATURAL in Chapter 2, Seddon et al., 2021). NbS are expected to contribute to global adaptation and mitigation goals (*high confidence*) (Beck et al., 2018; Cooley et al., 2019; Hoegh-Guldberg et al., 2019b; Menéndez et al., 2020; Morris et al., 2020a) by protecting coastal environments from SLR and storms (Cross-Chapter Box SLR, Reguero et al., 2018), and by storing substantial quantities of carbon (Sections 3.4.2.5, 3.6.3.1.5, WGIII AR6 Chapter 7, Howard et al., 2017; Chow, 2018; Smale et al., 2018; Singh et al., 2019b; Soper et al., 2019). Marine NbS are cost-effective, can generate social, economic and cultural co-benefits and can contribute to the conservation of biodiversity in the near- to mid-term (*high confidence*) (Secretariat of the Convention on Biological Diversity, 2009; Gattuso et al., 2018; Barkdull and Harris, 2019; McLeod et al., 2019).

Table 3.30: Assessment of marine and coastal nature-based solutions to reduce mid-term climate impacts in oceans and coastal ecosystems. Confidence is assessed in SM3.5.1. Feasibility and effectiveness are assessed in Figure 3.24.

Solution	Confidence in solution *(mid-term potential)*	Contribution to adaptation	Selected references	Examples of implementation

Habitat restoration	*High confidence*	Marine habitat restoration increases biodiversity and protects shorelines and coastal livelihoods from climate oceanic hazards.	(Colls et al., 2009; Arkema et al., 2017; Espeland and Kettenring, 2018; McLeod et al., 2019)	Restoration (Section 3.6.3.2.2)
Marine protected areas (MPAs) and other effective area-based conservation measures (OECMs)	*High confidence*	MPAs and MPA networks that are carefully designed to address climate change, strategically placed, and well enforced, hold great potential to deliver adaptation outcomes. OECMs can confer climate resilience to dependent communities outside of MPAs.	(Section 3.4.3.3.4, Queirós et al., 2016; Roberts et al., 2017; Maxwell et al., 2020a; Arafeh-Dalmau et al., 2021; Gurney et al., 2021; Sala et al., 2021)	Conservation (Section 3.6.3.2.1)
Conservation of climate refugia	*Medium confidence*	Protecting areas that retain climate and biodiversity conditions for longer durations under climate-change can increase the resilience of marine ecosystems to warming and marine heatwaves (MHWs) and facilitate marine species range shifts.	(Section 3.4.3.3.4, Cross-Chapter Box MOVING SPECIES in Chapter 5, Rilov et al., 2020; Wilson et al., 2020a; Arafeh-Dalmau et al., 2021)	Conservation (Section 3.6.3.2.1)
Transboundary marine spatial planning (MSP) and integrated coastal zone management (ICZM)	*Low confidence*	Transboundary MSP and ICZM that incorporate climate-change impacts and adaptation in their design can support climate adaptation and to foster international ocean cooperation.	(Rosendo et al., 2018; Tittensor et al., 2019; Frazão Santos et al., 2020; Rilov et al., 2020; Pinsky et al., 2021)	Tourism (Section 3.6.3.1.3), conservation, (Section 3.6.3.2.1.)
Sustainable harvesting	*High confidence*	Sustainable harvesting is a nature-based solution (NbS) that contributes to adaptation by safeguarding the provision of marine food and cultural services, while reducing the ecological vulnerability of marine ecosystems.	(Gattuso et al., 2018; Burden and Fujita, 2019; Duarte et al., 2020)	Fisheries and mariculture (Section 3.6.3.1.2)
Climate-adaptive management	*High confidence*	Incorporating climate-adaptive management allows climate knowledge and information available for the system to be iteratively updated in	(Cross-Chapter Box MOVING SPECIES in Chapter 5, Rilov et al., 2019; Free et al., 2020; Wilson et al., 2020a; Melbourne-Thomas et al., 2021)	Fisheries and mariculture (Section 3.6.3.1.2), conservation, (Section 3.6.3.2.1), restoration (Section 3.6.3.2.2)

		the management plan. It also facilitates consideration of species distribution shifts and other climate-change responses.		
Ecosystem-based management (EbM)	*High confidence*	EbM focuses on ecosystems. By incorporating many of the above tools, ecosystem-based adaptation (EbA) benefits adaptation of marine ecosystems and supports provision of ecosystem services to people.	(Fernandino et al., 2018; Lowerre-Barbieri et al., 2019)	Fisheries and mariculture (Section 3.6.3.1.2)

3.6.3 Implementation and Effectiveness of Adaptation and Mitigation Measures

This section assesses implemented adaptations introduced in Section 3.6.2 for selected marine sectors (Section 3.6.3.1) and ecosystems (Section 3.6.3.2), using case studies to emphasise characteristics that enable or inhibit adaptation (Section 3.6.3.3). The feasibility and effectiveness of these adaptations is assessed in Figure 3.24.

3.6.3.1 Degree of Implementation and Evidence of Effectiveness Across Sectors

3.6.3.1.1 Coastal community development and settlement

Coastal adaptation often addresses the risk of flooding and erosion from SLR, changes in storm activity and degradation of coastal ecosystems and their services (*high confidence*) (Sections 3.4.2, 3.5, Oppenheimer et al., 2019). Without coastal protection, people and property will be increasingly exposed to coastal flooding after 2050, especially under RCP8.5 (Cross-Chapter Box SLR in Chapter 3, Bevacqua et al., 2020; Kirezci et al., 2020). This section assesses adaptation responses for coastal ecosystems, addressing loss of natural coastal protection (Sections 3.4.2.1, 3.4.2.4–3.4.2.6), and the need for relocation (Section 3.6.2.1.2). Adaptation responses specific to SLR are assessed in detail in Cross-Chapter Box SLR in Chapter 3, while adaptation in coastal cities and settlements is assessed in Chapter 6.

Coastal conservation tends to involve cost-effective, low-impact actions that aim to support both adaptation and mitigation by conserving a wide array of ecosystem functions and services (Gattuso et al., 2018; Gattuso et al., 2021), and that are achievable by nations with extensive coastlines or low-income status (Herr et al., 2017; Taillardat et al., 2018). Where coastlines are undeveloped, the lowest-risk option is to avoid new development, but elsewhere, coastal conservation includes protection of key assets, accommodation of SLR, advancing defences seawards or upwards, or planned retreat from the coast (Cross-Chapter Box SLR in Chapter 3).

Hard engineered structures like seawalls are generally more costly than nature-based adaptations (*high confidence*) (Hérivaux et al., 2018; Haasnoot et al., 2019; Nicholls et al., 2019; Oppenheimer et al., 2019) and can lock communities into engineered responses in the future (Cross-Chapter Box SLR in Chapter 3), creating trade-offs with mitigation goals, which constitutes maladaptation (Nunn et al., 2021) that carries ecological and cultural costs (Sections 3.4.2.4, 3.4.2.6, 3.5.6). As a result there is *high agreement* on the importance of shifting from hard infrastructure to soft infrastructure for coastal defence (Toimil et al., 2020; Nunn et al., 2021). The common remedy for beach erosion is beach nourishment (Oppenheimer et al., 2019; Pinto et al., 2020; Elko et al., 2021), which provides rapid results but poorly quantified trade-offs between efficacy, long-term cost, utility to beach users and ecological damage (de Schipper et al., 2021).

Since SROCC, coastal adaptation using NbS, like restoration of coastal vegetation, has advanced substantially (Cohen-Shacham et al., 2019; Kuhl et al., 2020; Kumar et al., 2020; Morris et al., 2020a). Field and modelling studies confirm that wetland restoration and preservation are key actions to restore coastal protection and reduce community vulnerability to flooding (*very high confidenc*e) (see also Section 3.6, Chapter 15, Cross-Chapter Box SLR in Chapter 3, Jones et al., 2020; Menéndez et al., 2020; Van Coppenolle and Temmerman, 2020), while maintaining coastal ecosystem services (Section 3.5). Restoring coral reefs, oyster reefs and mangroves (Section 3.6.2.1), and protecting macrophyte meadows, dissipate wave energy (Section 3.4.2.1, Yates et al., 2017; Beck et al., 2018; Wiberg et al., 2019; Menéndez et al., 2020), accrete sediment, and elevate shorelines, which reduces exposure to waves and storm surges, and offsets erosional losses (*medium confidence*) (Kench and Mann, 2017; Pomeroy et al., 2018; Dasgupta et al., 2019; James et al., 2019; Morris et al., 2019; David and Schlurmann, 2020; Masselink et al., 2020). However, irreversible regime shifts in ocean ecosystems due to SLR and extreme events such as MHW can limit or compromise restoration in the long term (*high confidence*) (Section 3.4.3.3.3, Cross-Chapter Box SLR in Chapter 3, Marzloff et al., 2016; Johnson et al., 2017a). Under all warming scenarios, coastal wetlands will be impacted by warming and MHWs (Sections 3.2.2.1, 3.2.4.5, Cross-Chapter Box 9.1 in WGI Chapter 9, Fox-Kemper et al., 2021), while also being pressed inland by RSLR (Section 3.4.2.5, Cross-Chapter Box SLR in Chapter 3). Therefore, restoration and conservation are more successful when non-climate drivers are also minimised (*high confidence*) (Brodie et al., 2020; Duarte et al., 2020; Liu et al., 2021).

For highly exposed human settlements, migration is an adaptation option (e.g., for some island populations under extreme circumstances), but there are important uncertainties (Section 15.3.4.6), as international regimes develop around human rights, migration (Scobie, 2019a), displacement (George Puthucherril, 2012) and the implications for national sovereignty (Yamamoto and Esteban, 2014) of disappearing land spaces caused by climate change. Colonial power dynamics can influence climate change responses (Chapter 18), for example when external funders favour migration over local desires to adapt in place to preserve national identity and sovereignty (Bordner et al., 2020). Examples of relocation within livelihoods' customary land show some successes (Section 15.3.4.6).

Evidence since SROCC (Section, 5.5.2.3.3, Bindoff et al., 2019) continues to show that built infrastructure cannot address all of the adaptation challenges that coastal communities face. Coastal squeeze creates tensions between coastal development, armouring, and habitat management (Sections 3.4.2.4–3.4.2.6). Managed realignment is the best option to reduce risks from SLR (*high confidence*) (Cross-Chapter Box SLR in Chapter 3) but requires transformative changes in coastal development and settlement (Felipe Pérez and Tomaselli, 2021; Fitton et al., 2021; Mach and Siders, 2021; Siders et al., 2021). Implementation of protective measures varies among nations and lack of financial resources limits the options available (*very high confidence*) (Cross-Chapter Box SLR in Chapter 3, Hinkel et al., 2018; Klöck and Nunn, 2019).

[START CROSS-CHAPTER BOX SLR HERE]

Cross-Chapter Box SLR: Sea Level Rise

Authors: Gonéri Le Cozannet (France, Chapter 13, CCP4), Judy Lawrence (New Zealand, Chapter 11), David Schoeman (Australia, Chapter 3), Ibidun Adelekan (Nigeria, Chapter 9), Sarah Cooley (USA, Chapter 3), Bruce Glavovic (New Zealand/South Africa, Chapter 18, CCP2), Marjolijn Haasnoot (The Netherlands, Chapter 13, CCP2), Rebecca Harris (Australia, Chapter 2), Wolfgang Kiessling (Germany, Chapter 3), Robert E. Kopp (USA, WGI), Aditi Mukherji (Nepal, Chapter 4), Patrick Nunn (Australia, Chapter 15), Dieter Piepenburg (Germany, Chapter 13), Daniela Schmidt (UK/Germany, Chapter 13), Craig T. Simmons (Australia), Chandni Singh (India, Chapter 10, CCP2), Aimée Slangen (The Netherlands, WGI), Seree Supratid (Thailand, Chapter 4).

Sea-level rise (SLR) is already impacting ecosystems, human livelihoods, infrastructure, food security and climate mitigation at the coast and beyond. Ultimately, it threatens the existence of cities and settlements in low lying areas, and some island nations and their cultural heritage (Chapters 9– 15, Cross-Chapter Paper 2 and 4 Oppenheimer et al., 2019). The challenge can be addressed by mitigation of climate change and coastal adaptation.

Current impacts of sea level rise

The rate of global mean SLR was 1.35 mm yr^{-1} (0.78–1.92 mm yr^{-1}, *very likely* range) during 1901–1990, faster than during any century in at least 3000 years (*high confidence*) (WGI AR6 Chapter 9, Stanley and Warne, 1994; Woodroffe et al., 2016; Fox-Kemper et al., 2021). Global mean SLR has accelerated to 3.25 mm yr^{-1} (2.88–3.61 mm yr^{-1}, *very likely* range) during 1993–2018 (*high confidence*). Extreme sea levels have increased consistently across most regions (WGI AR6 Chapter 9, Fox-Kemper et al., 2021). The largest observed changes in coastal ecosystems are being caused by the concurrence of human activities, waves, current-induced sediment transport, and extreme storm events (*medium confidence*) (Chapters 3, 15 and 16, Takayabu et al., 2015; Mentaschi et al., 2018; Duvat, 2019; Murray et al., 2019; Oppenheimer et al., 2019). Early impacts of accelerating SLR detected at sheltered or subsiding coasts include chronic flooding at high tides, wetland salinisation and ecosystem transitions, increased erosion and coastal flood damage (Chapters 3, 11 and 13–16, WGI AR6 Chapter 9, Sweet and Park, 2014; Moftakhari et al., 2015; Nunn et al., 2017; Oppenheimer et al., 2019; Sharples et al., 2020; Fox-Kemper et al., 2021; Strauss et al., 2021). The exposure of many coastal populations and ecosystems to SLR is high: economic development is disproportionately concentrated in and around coastal cities and settlements (*virtually certain*) (Chapters 3 and 9–15, Cross-Chapter Papers 2 and 4).

Projected risks to coastal communities, infrastructure and ecosystems

Risks from SLR are *very likely* to increase by one order of magnitude well before 2100 without adaptation and mitigation action as agreed by parties to the Paris Agreement (*very high confidence*). Global mean SLR is *likely* to continue accelerating under SSP1-2.6 and more strongly forced scenarios (Figure SLR1, WGI AR6 Chapter 9, Oppenheimer et al., 2019; Fox-Kemper et al., 2021), increasing the risk of chronic coastal flooding at high-tide, extreme flooding during extreme events such as swells, storms and hurricanes, and erosion, and coastal ecosystem losses across many low-lying and erodible coasts (*very high confidence*) (Chapters 3 and 9–15, Cross-Chapter Paper 2, Hinkel et al., 2014; McLachlan and Defeo, 2018; Kulp and Strauss, 2019; Vousdoukas et al., 2020b). The compounding of rainfall, river flooding, rising water tables, coastal surges, and waves are projected to exacerbate SLR impacts on low-lying areas and rivers further inland (Chapters 4 and 11–15) (Bevacqua et al., 2020).

There is *high confidence* that coastal risks will increase by at least one order of magnitude over the 21st century due to committed SLR (Hinkel et al., 2013; Hinkel et al., 2014; IPCC, 2019b). Exposure of population and economic assets to coastal hazards is projected to increase over the next decades, particularly in coastal regions with fast-growing populations in Africa, Southeast Asia, and Small Islands (*medium evidence*) (Chapters 9–15, Cross-Chapter Papers 2 and 4, Neumann et al., 2015; Jones and O'Neill, 2016; Merkens et al., 2016; Merkens et al., 2018; Rasmussen et al., 2020). For RCP8.5, 2.5–9% of the global population and 12–20% of the global gross domestic product (GDP) is projected to be exposed to coastal flooding by 2100 (Kulp and Strauss, 2019; Kirezci et al., 2020; Rohmer et al., 2021). Above 3°C global warming levels (GWL) and with low adaptation, SLR may cause disruptions to ports and coastal infrastructure (Camus et al., 2019; Christodoulou et al., 2019; Verschuur et al., 2020; Yesudian and Dawson, 2021), which in turn may cascade and amplify across sectors and regions, generating impacts to financial systems (Chapters 11, 13, Mandel et al., 2021). Depending on the hydrogeological context, SLR causes salinisation of groundwater, estuaries, wetlands and soils, adding constraints to water management and livelihoods in agriculture sectors, for example, in deltas (Chapters 9, 15, Cross-Chapter Paper 4, Oppenheimer et al., 2019; Nicholls et al., 2020).

Coastal ecosystems can migrate landward or grow vertically in response to SLR, but their resilience and capacity to keep up with SLR will be compromised by ocean warming and other drivers, depending on regions and species, e.g., above 1.5°C for coral reefs (*high confidence*) (Chapter 3, 16, IPCC, 2018; Melbourne et al., 2018; Perry et al., 2018; IPCC, 2019b; Cornwall et al., 2021). Sediments and space for landward retreat are crucial for mangroves, saltmarshes and beach ecosystems (*high confidence*) (Chapter 3, Peteet et al., 2018; Schuerch et al., 2018; FitzGerald and Hughes, 2019; Friess et al., 2019; Leo et al., 2019; Schuerch et al., 2019). Loss of habitat is accompanied by loss of associated ecosystem services, including wave-energy attenuation, habitat provision for biodiversity, food production and carbon storage (Chapter 3, Cross-Chapter Box NATURAL in Chapter 2).

Under a high-emissions, low-likelihood/high-impact scenario, where *low confidence* ice-sheet mass loss occurs, global mean SLR could exceed the *likely* range by more than one additional metre in 2100 (Figure SLR1b, Cross-Chapter Box DEEP in Chapter 17, WGI AR6 Technical Summary and Chapter 9, Arias et al., 2021; Fox-Kemper et al., 2021). This is a reason for concern given that rapid SLR after the last glacial-interglacial transition caused a drowning of coral reefs (*high confidence*) (Camoin and Webster, 2015; Sanborn et al., 2017; Webster et al., 2018), extensive loss of coastal land and islands, habitats and associated biodiversity (*high confidence*) (AR6 WGI Chapter 9, Fruergaard et al., 2015; Fernández-Palacios et al., 2016; Hamilton et al., 2019; Helfensdorfer et al., 2019; Kane and Fletcher, 2020; Fox-Kemper et al., 2021) and triggered Neolithic migrations in Europe and Australia (*medium confidence*) (Cross-Chapter Box PALEO in Chapter 1, Turney and Brown, 2007; Brisset et al., 2018; Williams et al., 2018).

At centennial timescales, projected SLR represents an existential threat for island nations, low-lying coastal zones, and the communities, infrastructure, and cultural heritage therein (Chapters 9–15, Cross-Chapter Paper 4). Even if climate warming is stabilised at 2°C to 2.5°C GWL, coastlines will continue to reshape over millennia, affecting at least 25 megacities and drowning low-lying areas where 0.6–1.3 billion people lived in 2010 (*medium confidence*) (WGI AR6 Chapter 9 Marzeion and Levermann, 2014; Clark et al., 2016; Kulp and Strauss, 2019; Fox-Kemper et al., 2021; Strauss et al., 2021).

Solutions, opportunities and limits to adaptation

The ability to adapt to current coastal impacts, to cope with future coastal risks, and to prevent further acceleration of SLR beyond 2050 depends on immediate mitigation and adaptation actions (*very high confidence*). The most urgent adaptation challenge is chronic flooding at high tide (Chapters 10, 11, and 13–15). Reducing the acceleration of SLR beyond 2050 will only be achieved with fast and profound mitigation of climate change (Nicholls et al., 2018; Oppenheimer et al., 2019). Until 2050, adaptation planning and implementation needs are projected to increase significantly in most inhabited coastal regions (Figure SLR1, WGI AR6 Chapter 9, IPCC, 2019b; Fox-Kemper et al., 2021). For SSP1-2.6 and more strongly forced scenarios, SLR rates continue to increase (WGI AR6 Chapter 9, Fox-Kemper et al., 2021), and so do the scale and the frequency of adaptation interventions needed in coastal zones (Figure SLR1, Haasnoot et al., 2020).

Risks can be anticipated, planned, and decided upon, and adaptation interventions can be implemented over the coming decades, considering their often long lead- and life-times, irrespective of the large uncertainty about SLR beyond 2050 (*high confidence*) (Figure SLR1, Cross-Chapter Box DEEP in Chapter 17, Cross-Chapter Paper 2, Chapters 11, 13, Haasnoot et al., 2018; Stephens et al., 2018; Stammer et al., 2019). Adaptation capacity and governance to manage risks from projected SLR typically require decades to implement and institutionalise (*high confidence*) (Chapters 11,13, Haasnoot et al., 2021). Without considering both short- and long-term adaptation needs, including beyond 2100, communities are increasingly confronted with a shrinking solution space, and adverse consequences are disproportionately borne by exposed and socially vulnerable people (Chapters 1, 8). SLR is *likely* to compound social conflict in some settings (*high confidence*) (Oppenheimer et al., 2019).

Coastal impacts of SLR can be avoided by preventing new development in exposed coastal locations (Chapters 3, 9–15, Cross-Chapter Paper 2, Doberstein et al., 2019; Oppenheimer et al., 2019). For existing developments, a range of near-term adaptation options exists, including (1) engineered, sediment or ecosystem-based protection; (2) accommodation and land use planning, to reduce the vulnerability of people and infrastructure; (3) advance through, e.g., land reclamation; and (4) retreat through planned relocation or displacements and migrations due to SLR (Chapters 9–15, Cross-Chapter Paper 2, Oppenheimer et al., 2019). Only avoidance and relocation can remove coastal risks for the coming decades, while other measures only delay impacts for a time, have increasing residual risk or perpetuate risk and create ongoing legacy effects and *virtually certain* property and ecosystem losses (*high confidence*) (Cross-Chapter Paper 2, Siders et al., 2019). Large-scale relocation has immense cultural, political, social and economic costs, and equity implications, which can be reduced by fast implementation of climate mitigation and adaptation policies (Chapter 8, Cross-Chapter Paper 2, Gibbs, 2015; Haasnoot et al., 2021). While relocation may currently appear socially unacceptable, economically inefficient, or technically infeasible today (Lincke and Hinkel, 2021), it becomes the only feasible option as protection costs become unaffordable and the limits to accommodation become obvious (Chapters 11, 13, 15, Hino et al., 2017; Siders et al., 2019; Strauss et al., 2021). Effective responses to rising sea level involve locally applicable combinations of decision analysis, land use planning, public participation and conflict resolution approaches; together these can anticipate change and help to chart adaptation pathways, over time addressing the governance challenges due to rising sea level (*high confidence*) (Oppenheimer et al., 2019).

Ecosystem-based adaptation can reduce impacts on human settlements and bring substantial co-benefits such as ecosystem services restoration and carbon storage, but they require space for sediment and ecosystems and have site-specific physical limits, at least above 1.5°C GWL (*high confidence*) (Cross-Chapter Box NATURAL in Chapter 2, Chapters 3, 9, 11, 15, Herbert et al., 2015; Brown et al., 2019; Van Coppenolle and Temmerman, 2019; Watanabe et al., 2019; Neijnens et al., 2021). For example, planting and conserving vegetation helps sediment accumulation by dissipating wave energy and reducing impacts of storms, at least at present-day sea levels (*high confidence*) (Temmerman et al., 2013; Narayan et al., 2016; Romañach et al., 2018; Laengner et al., 2019; Leo et al., 2019). Coastal wetlands and ecosystems can be preserved by landward migration (Schuerch et al., 2018; Schuerch et al., 2019) or sediment supply (VanZomeren et al., 2018), but they can be seriously damaged by coastal defences designed to protect infrastructure (Chapters 3, 13, Cooper et al., 2020b). Sediment nourishment can prevent erosion, but it can also negatively impact beach amenities and ecosystems through ongoing dredging, pumping and deposition of sand and silts (VanZomeren et al., 2018; de Schipper et al., 2021; Harris et al., 2021).

There is increasing evidence that current governance and institutional arrangements are unable to address the escalating risks in low-lying coastal areas worldwide (*high confidence*). Barriers to adaptation such as decision-making driven by short-term thinking or vested interests, funding limitations, and inadequate financial policies and insurance can be addressed equitably and sustainably through implementation of suites of adaptation options and pathways, (Chapters 11, 13, 17–18, Cross-Chapter Paper 2). Improved coastal adaptation governance can be supported by approaches that consider changing risks over time, such as "dynamic adaptation pathways" planning (Chapters 11, 13, 18, Cross-Chapter Box DEEP in Chapter 17). Integrated Coastal Zone Management and land-use and infrastructure planning are starting to consider SLR by, for example, monitoring early signals (Haasnoot et al., 2018; Stephens et al., 2018; Kool et al., 2020), updating sea-level projections (Stephens et al., 2017; Hinkel et al., 2019; Kopp et al., 2019; Stammer et al., 2019), considering uncertainties of sea-level projections and coastal impacts (e.g., Stephens et al., 2017; Jevrejeva et al., 2019; Rohmer et al., 2019), as well as engaging with communities, practitioners and scientists, recognising the values of current and future generations (e.g., Nicholls et al., 2014; Buchanan et al., 2016b). While there is *high agreement* that the majority of adaptation needs are not met yet, there is *robust evidence* of sea level rise increasingly being considered in coastal adaptation decision making and being embedded in national and local guidance and regulations (Nicholls et al., 2014; Le Cozannet et al., 2017; Lawrence et al., 2018; Kopp et al., 2019; McEvoy et al., 2021).

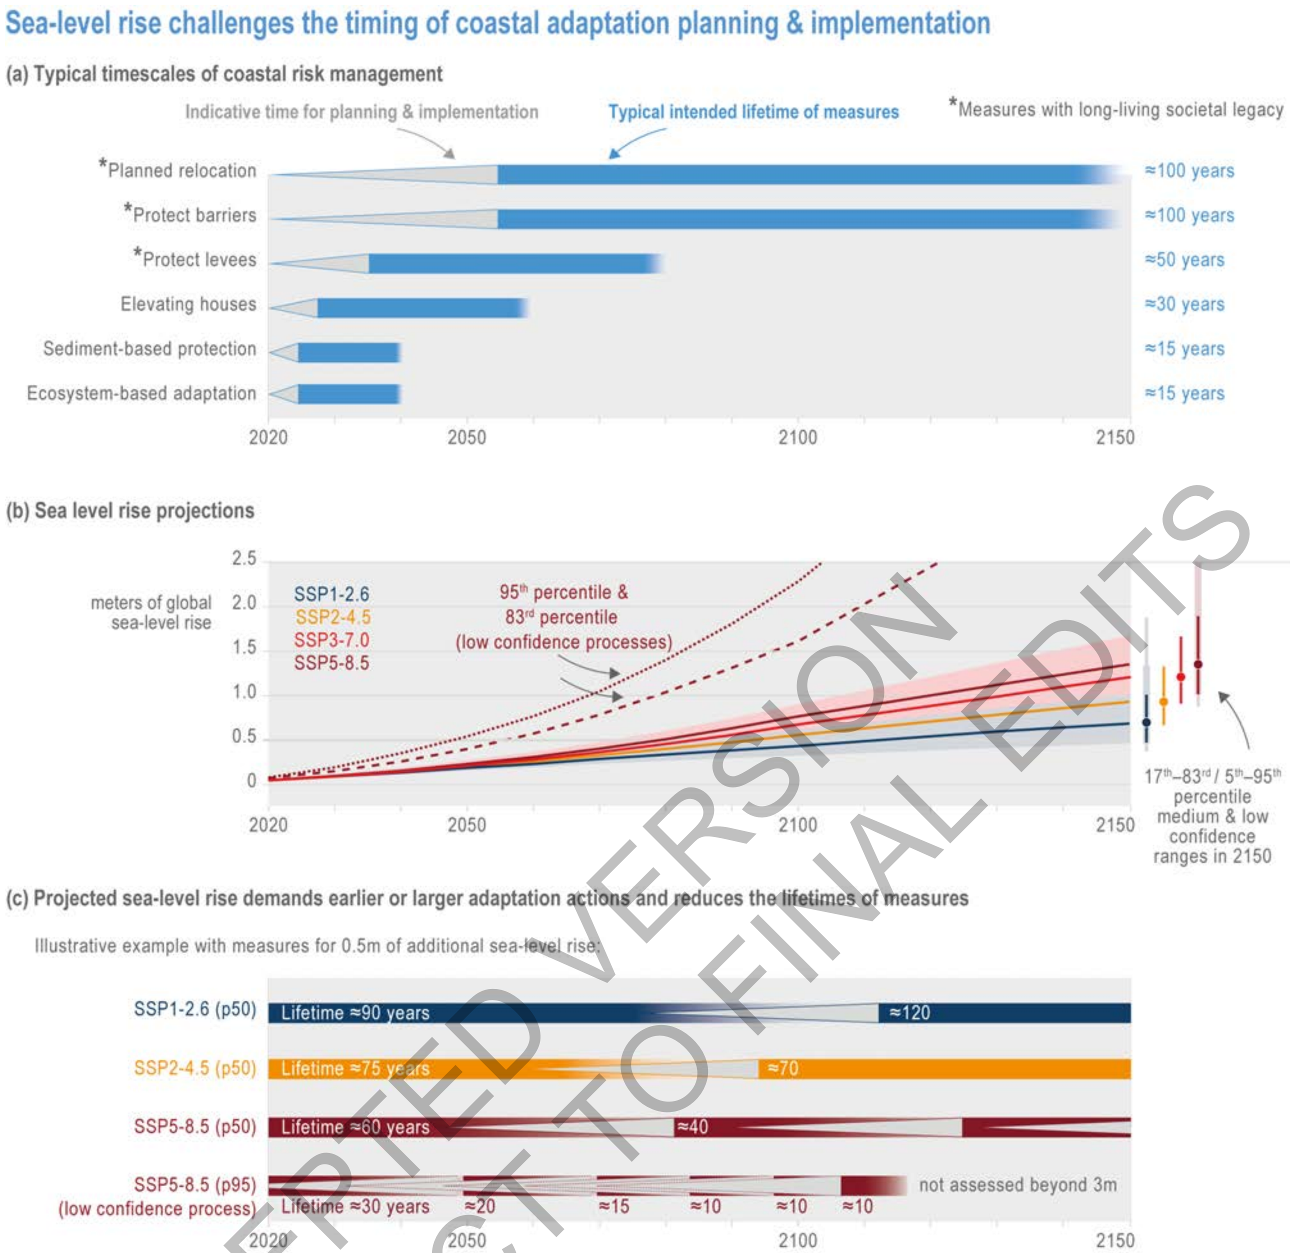

Figure Cross-Chapter Box SLR.1: The challenge of coastal adaptation in the era of sea-level rise (SLR): (a): typical timescales for the planning, implementation (grey triangles) and operational lifetime of current coastal risk-management measures (blue bars); (b): global sea-level projections, which are representative of relative SLR projected for 60 to 70% of global shorelines, within ±20% errors (WGI AR6 Chapter 9, Fox-Kemper et al., 2021); (c): Frequency of illustrative adaptation decisions to +0.5 m of SLR under different SSP-RCP scenarios. In response to accelerated SLR, adaptation either occurs earlier and faster, or accounts for higher amounts of SLR (e.g., to +1 m instead of to +0.5 m). Adaptation to +0.5 m from today's sea-levels have a lifetime of 90 years for SSP1-2.6, but lifetime is reduced to 60 years for SSP5-8.5 and 30 years for a high-end scenario involving *low confidence* processes. Adaptations to +0.5 m are comparable to e.g., the Thames Barrier in the United Kingdom, or the Delta Works in the Netherlands, which primarily had an intended lifetime of 100–200 years. Adaptation measures to +0.2 m may include nourishment or wetland or setback zones.

[END CROSS-CHAPTER BOX SLR HERE]

3.6.3.1.2 Fisheries and mariculture

SROCC (Bindoff et al., 2019) assessed adaptation in fisheries and mariculture (marine aquaculture), and socioeconomically focused updates are provided in Section 5.8.4 and Cross-Chapter Box MOVING SPECIES in Chapter 5. Here, we present a brief synthesis of how fisheries and mariculture adaptations interact with the natural environment, with further detail and supporting material in SM3.5.2.

Mobility allows fishing fleets and fishers to adapt to shifts in marine species distributions (*high agreement*) (Sections 3.4.3.1, 3.5.3, Peck and Pinnegar, 2018; Pinsky et al., 2018; Frazão Santos et al., 2020), but with limits and unintended consequences (Pinsky and Fogarty, 2012; Bell et al., 2021). Diversification of target species, harvest tactics and employment sectors, including transitions from fisheries to mariculture and ecotourism, allows some fishers to accommodate some impacts on their livelihoods (Miller et al., 2018; Robinson et al., 2020; Gonzalez-Mon et al., 2021). Technology and infrastructure adaptations can improve marine harvest efficiency, reduce risk, and support resource management goals (Friedman et al., 2020; Bell et al., 2021; Melbourne-Thomas et al., 2021), but their ability to overcome climate-change impacts remains uncertain (Bell et al., 2020). Improving capacity to predict anomalous conditions in coastal and marine ecosystems (Jacox et al., 2019; Holbrook et al., 2020; Jacox et al., 2020), storm-driven flooding in reef-lined coasts (Scott et al., 2020; Winter et al., 2020) and fisheries stocks (Payne et al., 2017; Tommasi et al., 2017; Muhling et al., 2018) can improve forecasts of coastal and marine resources. These can enhance sustainability of wild-capture fisheries under climate change (*high confidence*) (Blanchard et al., 2017; Tommasi et al., 2017; Pinsky et al., 2020a; Bell et al., 2021). Limiting overexploitation is the central goal of fishery management, and it *very likely* benefits fisheries adaptation to climate change (Burden and Fujita, 2019; Free et al., 2019; Sumaila and Tai, 2020). Conventional tools include catch and size limits, spatial management and adaptive management. Ecosystem-based fisheries management outperforms single-species management (Fulton et al., 2019), is widely legislated (Bryndum-Buchholz et al., 2021), and can reduce climate impacts in fisheries in the near-term, especially under low-emission scenarios (Karp et al., 2019; Holsman et al., 2020). Transboundary agreements on shifting fisheries will reduce the risk of overharvesting (*medium confidence*) (Gaines et al., 2018). Permits tradable across political boundaries could also address this challenge, but *limited evidence* is available regarding their efficacy (Cross-Chapter Box MOVING SPECIES in Chapter 5, Pinsky et al., 2018). Climate-smart conservation (Section 3.6.32.1) under the negotiations on areas beyond national jurisdiction (ABNJ) (Pinsky et al., 2018; Tittensor et al., 2019; Frazão Santos et al., 2020), and in the Convention on Biological Diversity (CBD) areas designed as other effective area-based conservation measures (OECMs, Tittensor et al., 2019) provide further benefits. Despite the potential for of adaptive management to achieve sustainable fisheries, outcomes will *very likely* be inequitable (Gaines et al., 2018; Lam et al., 2020) with lower-income countries suffering the greater biomass and economic losses, increasing inequalities especially under higher emission scenarios (*high confidence*) (Boyce et al., 2020). Flexible and polycentric governance approaches have facilitated some short-term successes in achieving equitable, sustainable fisheries practices, but these may be challenging to implement where other governance systems, especially hierarchical systems, are well-established (Cvitanovic et al., 2018; Bell et al., 2020).

3.6.3.1.3 Tourism

Coastal areas, coastal infrastructure and beaches, sustaining tourism that contributes significantly to local economies (James et al., 2019; Ruiz-Ramírez et al., 2019), are under threat from development, SLR and increased wave energy during storms and (*high confidence*) (Sections 3.4.2.6, 3.4.4–3.4.6, 3.5.6, Lithgow et al., 2019; Ruiz-Ramírez et al., 2019). Engineered solutions like seawalls and revetments have traditionally been used to address coastal erosion (Section 3.6.3.1.1), but soft infrastructure approaches, including beach nourishment, submerged breakwaters and groins, and NbS (Section 3.6.2.1), are becoming more common, partly due to demand from the tourism industry (*medium confidence*) (Pranzini, 2018; Pranzini et al., 2018).

Elsewhere, interactions between tourism and climate impacts worsen outcomes for coastal and ocean environments (Section 3.6.3.1.4). Climate change is opening up new cruise-ship routes in the Arctic (Sun et al., 2018), increasing number of visitors and associated stressors, such as litter, to previously undisturbed areas (Anfuso et al., 2020; Hovelsrud et al., 2020; Suaria et al., 2020). Risk reduction for cruise-ship tourism includes disaster response management, improved mapping, and passenger codes of conduct ensuring social, cultural and ecological sustainability (Stewart et al., 2015; Dawson et al., 2016).

Marine ecotourism, integrating conservation, education and provision of benefits to local communities (Donohoe and Needham, 2006), can provide significant economic benefits (Wabnitz, 2019), and is among the most common livelihood alternatives to support both marine conservation and climate change adaptation (Kutzner, 2019; Pham, 2020; Prasetyo et al., 2020). Ecotourism can enhance social and political will for marine conservation (Cisneros-Montemayor and Sumaila, 2014), and facilitates integration of local and Indigenous Peoples in employment, ownership, and industry governance. The community of Cabo Pulmo, Mexico, self-imposed an MPA and replaced fishing with ecotourism, which now generates millions of USD yr^{-1}, sustains locally owned and operated tour companies, and has increased some fish populations ten-fold (Knowlton, 2020). In Misool, Indonesia, local ecotourism incorporates IK by including local communities' preferences and sustainable resource use (Prasetyo et al., 2020).

Unintended consequences of ecotourism, such as detrimental ecological impacts on reefs (Giglio et al., 2020), sharks, marine birds (Monti et al., 2018), and whales (Higham et al., 2016; Barra et al., 2020; Hoarau et al., 2020), can be minimised by relying on evidence-based management of associated activities (Blumstein et al., 2017). Public perception of climate change connections to tourism can create obstacles (Meynecke et al., 2017; Atzori et al., 2018) such as deterring long-term investment in SIDS tourism initiatives (Santos-Lacueva et al., 2017), or benefits like inclining tourists to participate in conservation projects (Curnock et al., 2019; Miller et al., 2020b; Ziegler et al., 2021). Social and cultural networks may decrease climate vulnerability, as with Indigenous tourism operators in SIDS (Parsons et al., 2018). Tourism-based adaptation can also be improved by equitable access to resources, and recognition and inclusion of all stakeholders during policy planning and implementation. The principles of marine spatial planning (Papageorgiou, 2016) provide for effectively incorporating stakeholders and could inform development of activities to assess climate-associated risks (e.g., Tzoraki et al., 2018; Loehr, 2020). The recent decrease in global tourism due to the COVID-19 pandemic may offer opportunities to transform existing practices to more sustainable approaches (Cross-Chapter Box COVID in Chapter 7, Gössling et al., 2021).

3.6.3.1.4 Maritime transport

Increased maritime transport and cruise-ship tourism in the Arctic are already impacting local and Indigenous Peoples, revealing conflicts over the uses of the ocean and the governance needed to support local people and a sustainable blue economy (*high confidence*) (Debortoli et al., 2019; Palma et al., 2019; Berman et al., 2020; Dundas et al., 2020). While shipping and its associated environmental impacts are projected to grow (Palma et al., 2019; Dawson et al., 2020), adaptation efforts are only at the planning stage (Debortoli et al., 2019). Increased Arctic traffic due to ice loss can benefit trade, transportation and tourism (*medium confidence*), but will also affect Arctic marine ecosystems and livelihoods (*high confidence*) (Palma et al., 2019; Dawson et al., 2020). Increasing search-and-rescue activities (Ford and Clark, 2019) reveal capacity gaps to support future demands (Ford and Clark, 2019; Palma et al., 2019). The Low-Impact Shipping Corridors initiative has been developed as an adaptation strategy in the Arctic, although with limited inclusion of IK and LK (Dawson et al., 2020).

RSLR and the increased frequency and severity of storms are already affecting port activity, infrastructure, and supply chains, sometimes disrupting trade and transport (Monios and Wilmsmeier, 2020), but these hazards are not systematically incorporated into adaptation planning (*medium evidence*) (Monios and Wilmsmeier, 2020; O'Keeffe et al., 2020). Climate-change impacts that increase food insecurity, income loss, and poverty can exacerbate maritime criminal activity including illegal fishing, drug trafficking or piracy (*medium evidence*) (Germond and Mazaris, 2019). A transformational adaptation approach to address climate impacts on maritime activities and increase security (Germond and Mazaris, 2019) would relocate ports, change centers of demand, reduce shipping distances, or shorten supply chains (*medium agreement*) (Walsh et al., 2019; Monios and Wilmsmeier, 2020) as well as decrease marginalization of vulnerable groups, develop polycentric governance systems and eliminate maladaptive environmental policies and resource loss (Belhabib et al., 2020; O'Keeffe et al., 2020).

3.6.3.1.5 Human Health

Health-focused adaptations to climate-driven changes in ocean and coastal water quality (Section 3.5.5.3) mainly leverage technology and infrastructure (Section 3.6.2.2) to improve water-quality monitoring and forecasting to inform socio-institutional adaptation (Section 3.6.2.1) and NbS (Section 3.6.2.3). Seafood quality and safety are decreasing due to climate-driven increases in marine-borne diseases (Cross-Chapter Box ILLNESS in Chapter 2), toxic HABs, or toxin bioaccumulation (*high agreement*) (Karagas et al., 2012; Krabbenhoft and Sunderland, 2013; Rafaj et al., 2013; Curtis et al., 2019; Schartup et al., 2019; Thackray and Sunderland, 2019). Future exposure to seafood-borne contaminants also depends partly on consumers' seafood preferences (Elsayed et al., 2020) and seafood supply (Sunderland et al., 2018). Reducing this risk by decreasing seafood consumption increases risk of eating less nutritious foods, and loss of cultural practices (Chapter 5, Cross-Chapter Box MOVING SPECIES in Chapter 5, Donatuto et al., 2011; Bindoff et al., 2019). Models incorporating high-resolution satellite images, field survey data, meteorological observations and historical records can provide early-warning forecasts of HABs or conditions that favour microbial pathogen outbreaks (Cross-Chapter Box ILLNESS in Chapter 2, Semenza et al., 2017; Franks, 2018; Hattenrath-Lehmann et al., 2018; Borbor-Cordova et al., 2019; Davis et al., 2019; Campbell et al., 2020a; Davidson et al., 2021). Forecasts facilitate preventive public health measures (World Health Organisation and United Nations Children's Fund, 2017), or seafood harvest guidance (Maguire et al., 2016; Leadbetter et al., 2018; Anderson et al., 2019; Bolin et al., 2021), reducing risks of disease outbreaks, waste, and contaminated seafood entering the market (*medium confidence*) (Cross-Chapter Box ILLNESS in Chapter 2, Nichols et al., 2018). Monitoring of water quality and seafood safety (Cross-Chapter Box ILLNESS in Chapter 2), paired with effective public communication and education (Ekstrom et al., 2020) inform individual and local adaptations, including use of personal protective equipment, seafood selection and preparation (Elsayed et al., 2020; Froelich and Daines, 2020; Fielding et al., 2021), income diversification (Section 3.6.2.1, Moore et al., 2020b), public education (Borbor-Cordova et al., 2019), or community-level actions to decrease risk from coastal aquifer and soil salinisation (Slama et al., 2020; Mastrocicco and Colombani, 2021), HAB toxins (Ekstrom et al., 2020) and other contaminants (e.g., methylmercury, metals, persistent organic pollutants) in seafood (Chan et al., 2021). A full assessment of climate-change impacts on human health is found in Chapter 7 and Cross-Chapter Box ILLNESS in Chapter 2.

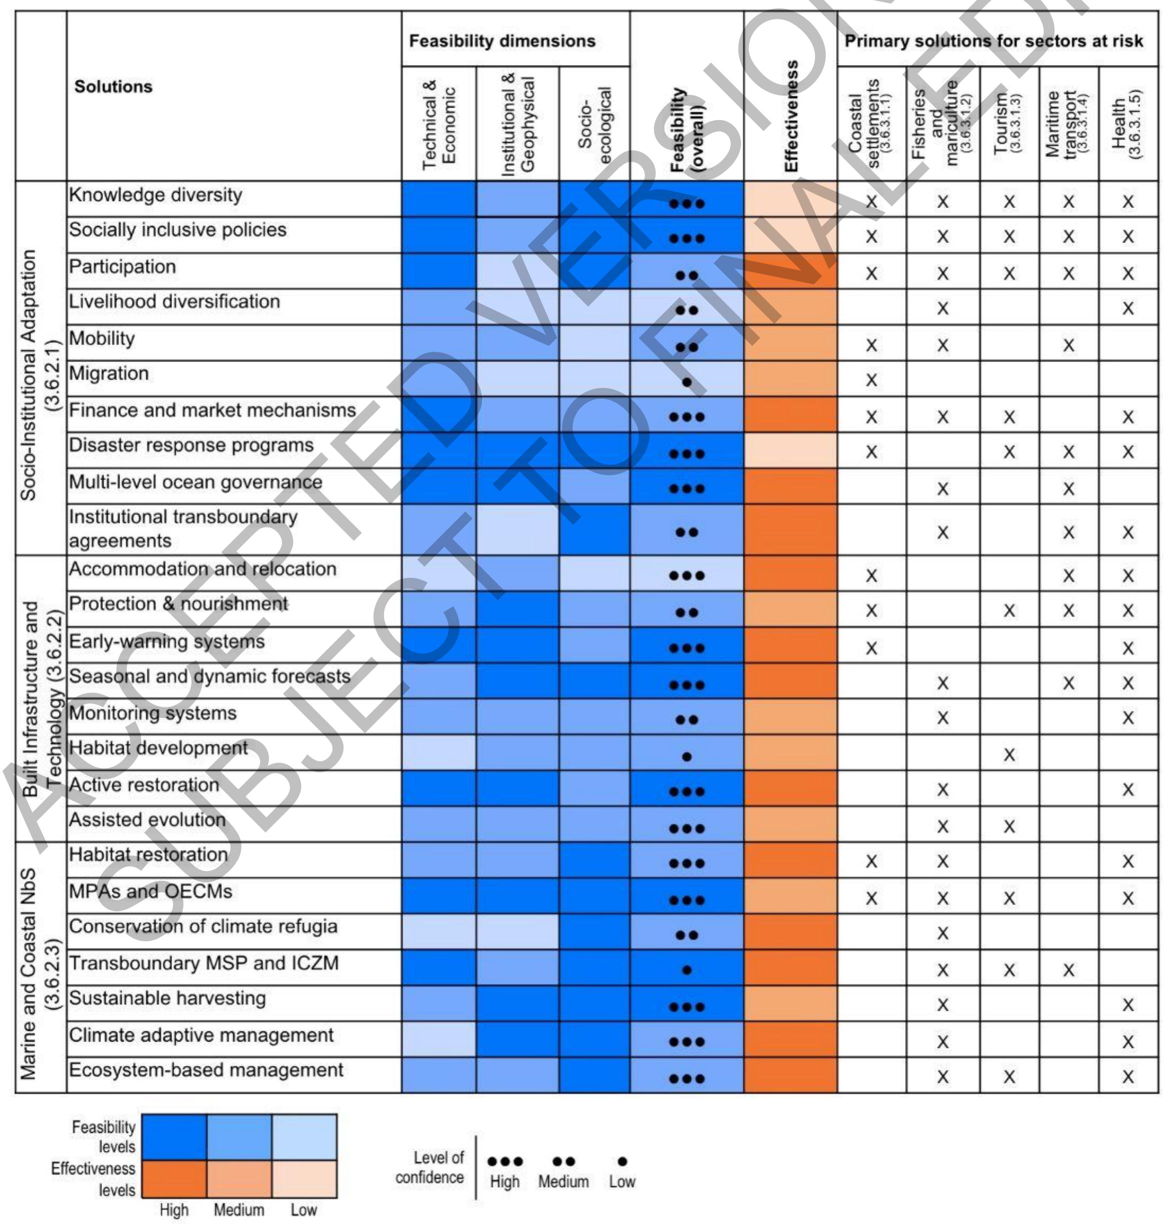

Figure 3.24: Assessment of feasibility and effectiveness of adaptation solutions for ocean and coastal ecosystems. Feasibility dimensions assessed include: technical and economic capacity to deliver and implement the solution, the

institutional and geophysical capacity to implement a solution; and associated social and ecological implications that make a solution more feasible. The general feasibility level is obtained from assessment of the three dimensions together. Note that feasibility is assessed for marine and coastal ecosystems as a whole and not by ecosystem type or region. Feasibility dimensions and assessment are updated and adapted from IPCC (2018) and Singh et al. (2020). Effectiveness: ability of the adaptation solution to reduce climate change mid-term risks. Main solutions are assessed per sector. Underlying data are available in Table SM3.3.

3.6.3.2 Cross-Cutting Solutions for Coastal and Ocean Ecosystems

SROCC concluded that protection, restoration and pollution reduction can support ocean and coastal ecosystems (*high confidence*), and that EbA lowers climate risks locally and provides multiple societal benefits (*high confidence*) (IPCC, 2019c). This section updates the assessment of the effectiveness of these strategies for addressing climate impacts.

3.6.3.2.1 Area-based protection: MPAs for adapting to climate change

Marine protected areas (MPAs) are the most widely implemented area-based management approach (Section 3.6.2.3.2), commonly intended to conserve, preserve, or restore biodiversity and habitats, protect species, or manage resources (especially fisheries) (National Research Council, 2001). By August 2021, 7.74% of the ocean was protected (in both MPAs and other effective conservation measures, OECMs) (UNEP-WCMC and IUCN, 2021), primarily within nations' Exclusive Economic Zones (EEZs). These MPAs support adaptation by sustaining nearshore ecosystems that provide natural erosion barriers (Sections 3.4.2.–3.4.2.5, Cross-Chapter Box SLR in Chapter 3), ecosystem function (Cheng et al., 2019), habitat, natural filtration, carbon storage, livelihoods, and cultural opportunities (Sections 3.5.5, 3.5.6, Erskine et al., 2021) and help ecosystems and livelihoods recover after extreme events (Roberts et al., 2017; Aalto et al., 2019; Wilson et al., 2020a). However, in 2021 only 2.7% of the ocean was in fully or highly protected MPAs (Marine Conservation Institute, 2021), the hard-to-achieve states that most effectively rebuild biomass and fish community structure (Sala and Giakoumi, 2017; Bergseth, 2018; Zupan et al., 2018; Ohayon et al., 2021). Only 1.18% of ABNJ is protected (UNEP-WCMC and IUCN, 2021), mostly due to governance limitations (O'Leary and Roberts, 2017; Vijayaraghavan, 2021), but calls to protect more ABNJ emphasise the need to protect habitat of long-range pelagic fish and marine mammals, maintain the ocean's regulating functions, and minimise impacts from uses such as maritime shipping or deep-sea mining (Table 3.30).

MPAs are theorised to facilitate ecological climate adaptation and contribute to SDG14 ("Life below water", Table 3.30, Figure 3.26, Bates et al., 2014; Lubchenco and Grorud-Colvert, 2015; Gattuso et al., 2018) because they alleviate non-climate drivers and promote biodiversity (i.e., "managed resilience hypothesis", Bruno et al., 2019; Maestro et al., 2019; Cinner et al., 2020). Current MPAs offer conservation benefits such as increases in biomass and diversity of habitats, populations, and communities (*high confidence*) (Pendleton et al., 2018; Bates et al., 2019; Stevenson et al., 2020; Lenihan et al., 2021; Ohayon et al., 2021), and these benefits may last after some (possibly climate-enhanced) disturbances (e.g., tropical cyclones, McClure et al., 2020). But current MPAs do not provide resilience against observed warming and heatwaves in tropical to temperate ecosystems (*medium confidence*) (Bates et al., 2019; Bruno et al., 2019; Freedman et al., 2020; Graham et al., 2020; Rilov et al., 2020). There is *robust evidence* that processes around MPA design and implementation strongly influence whether outcomes are beneficial or harmful for adjacent human communities (McNeill et al., 2018; Zupan et al., 2018; Ban et al., 2019).

Current placement and extent of MPAs will not provide substantial protections against projected climate change past 2050 (*high confidence*), as the placement of MPAs has been driven more often by political expediency (e.g., Leenhardt et al., 2013) than by managing key drivers of biodiversity loss (Cockerell et al., 2020; Stevenson et al., 2020) or climate-impact drivers (Bruno et al., 2018). Only 3.5% of the area currently protected will provide refuges from both SST and deoxygenation by 2050 under both RCP4.5 and RCP8.5 (Bruno et al., 2018) and MPAs are more exposed to climate change under RCP8.5 than non-MPAs (Section 3.4.3.3.4, Figure 3.20d). Community thermal tolerances will be exceeded by 2050 in the tropics and by 2150 for many higher-latitude MPAs (Bruno et al., 2018). Most MPA design has focused on the surface ocean, but MPAs are assumed to protect the entire water column and benthos. Climate-impact drivers (Section 3.2) throughout the water column and rapidly accelerating climate velocities at depths below 200 m (Johnson et al., 2018; Brito-Morales et al., 2020), are projected to affect virtually all North Atlantic deep-water and open ocean area-based management zones in the next 20–50 years (Johnson et al., 2018) and the conservation goals of benthic MPAs in the North Sea are not expected to be fulfilled (Weinert et al., 2021). Heightened risk of non-indigenous species immigration from vessel traffic plus climate change further endangers MPA success (Iacarella et al., 2020), a particular concern in the Mediterranean (D'Amen and Azzurro, 2020; Mannino and Balistreri, 2021), where the current MPA network is already highly vulnerable to climate change (Kyprioti et al., 2021). This new evidence supports SROCC's *high confidence* assessment that present governance arrangements including MPAs are too fragmented to provide integrated responses to the increasing and cascading risks from climate change in the ocean (SROCC SPMC1.2, IPCC, 2019c).

Strategic conservation planning can yield future MPA networks substantially more ready for climate change (e.g., Section 3.6.3.1.5, SROCC SPM C2.1, IPCC, 2019c; Frazão Santos et al., 2020; Rassweiler et al., 2020). Global protection is increasing (Worm, 2017; Claudet et al., 2020b) as nations pursue international targets (e.g., SDG14, "Life below water" aimed to conserve 10% of the ocean by 2020), and the UN CBD proposes to protect 30% by 2030 (Section 3.6.4, SM3.5.3, CBD, 2020). A growing body of evidence (Tittensor et al., 2019; Cabral et al., 2020; Zhao et al., 2020a; Pörtner et al., 2021b; Sala et al., 2021) underscores the urgent need to pursue biodiversity, ecosystem-service provision, and climate-adaptation goals simultaneously, while acknowledging inherent tradeoffs (Claudet et al., 2020a; Sala et al., 2021). Frameworks to create "climate-smart" MPAs (Tittensor et al., 2019) generally include: defining conservation goals that embrace resource vulnerabilities and co-occurring hazards; carefully selecting adaptation strategies that include LK and IK while respecting Indigenous rights and accommodating human behaviour (Kikiloi et al., 2017; Thomas, 2018; Yates et al., 2019; Failler et al., 2020; Wilson et al., 2020a; Croke, 2021; Reimer et al., 2021; Vijayaraghavan, 2021); developing protection that is appropriate for all ocean depths (Brito-Morales et al., 2018; Frazão Santos et al., 2020; Wilson et al., 2020a), especially considering climate velocity (Arafeh-Dalmau et al., 2021); using dynamic national and international management tools to accommodate extreme events or species distribution shifts (Gaines et al., 2018; Pinsky et al., 2018; Bindoff et al., 2019; Scheffers and Pecl, 2019; Tittensor et al., 2019; Cashion et al., 2020; Crespo et al., 2020; Frazão Santos et al., 2020; Maxwell et al., 2020b), which could build on dynamic regulations already in place for fishing or ship strikes (Maxwell et al., 2020b); and seeking to increase connectivity (Wilson et al., 2020a), using genomic or multispecies model insights (Xuereb et al., 2020; Friesen et al., 2021; Lima et al., 2021).

There is growing international support for a 30% conservation target for 2030 (Gurney et al., 2021), that will need efforts beyond protected areas. For example, Other Effective area-based Conservation Measures (OECMs) recognise management interventions that sustain biodiversity, irrespective of their main objective (Maxwell et al., 2020b; Gurney et al., 2021). There is *high agreement* on the potential of OECMs to contribute to conservation and equity, for example by recognising Indigenous territories as OECMs (Maxwell et al., 2020b; Gurney et al., 2021). However, the capacity of these conservation tools to provide adaptation outcomes remains unexplored.

In summary, MPAs and other marine spatial planning tools have great potential to address climate change mitigation and adaptation in ocean and coastal ecosystems, if they are designed and implemented in a coordinated way that takes into account ecosystem vulnerability and responses to projected climate conditions, considers existing and future ecosystem uses and non-climate drivers, and supports effective governance (*high confidence*).

3.6.3.2.2 Ecological restoration, interventions and their limitations

Restoration of degraded ecosystems is a common NbS increasingly deployed at local scales in response to climate change (Cross-Chapter Box NATURAL in Chapter 2, Duarte et al., 2020; Bertolini and da Mosto, 2021; Braun de Torrez et al., 2021). Despite covering limited areas and having uncertain efficacy under future climate change (Gordon et al., 2020), these actions have successfully restored marine populations and ecosystems at regional to global scales (Duarte et al., 2020), and enhanced livelihoods and wellbeing of coastal peoples as well as biodiversity and resilience of ecological communities (Silver et al., 2019; Gordon et al., 2020; Braun de Torrez et al., 2021). Technology-based approaches like active restoration, assisted evolution, and ecological forecasting can aid in moving beyond restoring ecosystems (Section 3.6.2.3) towards enhancing resilience, reviving biodiversity and guarding against loss of foundational, ornamental or iconic species (Bulleri et al., 2018; Collins et al., 2019a; da Silva et al., 2019; National Academies of Sciences, 2019; Boström-Einarsson et al., 2020; Fredriksen et al., 2020; Morris et al., 2020c; Kleypas et al., 2021).

Local restoration projects often target vegetated ecosystems like mangroves, seagrasses and saltmarshes that are valued and used by coastal communities (Veettil et al., 2019; Duarte et al., 2020; Wu et al., 2020a; Bertolini and da Mosto, 2021) Detail on mangroves and corals as EbA and protection/restoration hotspots is provided in SuppMat 3.8. Common and effective actions (Sasmito et al., 2019; Duarte et al., 2020; Oreska et al., 2020) include securing accommodation space (Sections 3.4.2.4–3.4.2.5), restoring hydrological (Kroeger et al., 2017; Al-Haj and Fulweiler, 2020) and sediment dynamics; managing harvesting (particularly in mangroves); reducing pollution (especially in seagrasses, de los Santos et al., 2019); and replanting appropriate species in suitable environmental settings (Wodehouse and Rayment, 2019; Friess et al., 2020a). Although efficacy is context dependent (Zeng et al., 2020; Krause-Jensen et al., 2021), and implementation is most often local (Alongi, 2018a), such projects allow tangible community engagement in climate action. Moreover, because these ecosystems sequester disproportionate amounts of carbon (blue carbon, Annex II: Glossary, Box 3.4), restoration supports climate-change mitigation (Lovelock and Reef, 2020; Gattuso et al., 2021). Yet, constraints remain. For instance, Southeast Asia has 1.21 million km^2 of terrestrial, freshwater and mangrove area biophysically suitable for reforestation, which could mitigate 3.43 ± 1.29 Pg CO_2e yr^{-1} through 2030; however, reforestation is only feasible in a small fraction of this area (0.3–18%) given financial, land-use and operational constraints (Zeng et al., 2020). Nevertheless, the multiple benefits offered by ecosystem restoration will *likely* outweigh competing costs, and increase its relevance as part of adaptation strategy portfolios (Silver et al., 2019; Wedding et al., 2021), national carbon-accounting systems, and NDCs (Friess et al., 2020a; Wu et al., 2020a).

Restoration efficacy of coral reefs, kelp forests and other habitat-forming coastal ecosystems (Section 3.4.2.2–3.4.2.6) are jeopardised by the near-term nature of climate-driven risks (McLeod et al., 2019; National Academies of Sciences, 2019; Coleman et al., 2020b). Modelling studies indicate that available practices will not prevent degradation of coral reefs from >1.5°C of global average surface warming (Figure 3.25, National Academies of Sciences Engineering and Medicine, 2019; Condie et al., 2021; Hafezi et al., 2021). Proposed interventions, not yet implemented, include assisted migration (Boström-Einarsson et al., 2020; Fredriksen et al., 2020; Morris et al., 2020c), assisted evolution (Bay et al., 2019; National Academies of Sciences, 2019) and other engineering solutions like artificial shading and enhanced upwelling (Condie et al., 2021; Kleypas et al., 2021).

Transplanting heat-tolerant coral colonies can increase reef resistance to bleaching (Morikawa and Palumbi, 2019; Howells et al., 2021), but potentially lowering species diversity and altering ecosystem function (Section 3.4.2.1). Genetic manipulation or assisted evolution that propagates genes from heat-tolerant populations could enhance restoration of corals (Anthony et al., 2017; Epstein et al., 2019) and kelp (*medium agreement, limited evidence*) (Coleman and Goold, 2019; Coleman et al., 2020b; Fredriksen et al., 2020; Wade et al., 2020). Managed breeding of corals has also had limited success in the laboratory and at small local scales (National Academies of Sciences, 2019). There is also *limited evidence* that physiological interventions like algal-symbiont or microbiome manipulation could increase coral thermal tolerance in the field (National Academies of Sciences, 2019). Employing the natural adaptive capacity of species or individuals in active restoration for corals and kelps with current technology involves fewer risks than assisted evolution or long-distance relocation (*high confidence*) (Filbee-Dexter and Smajdor, 2019; National Academies of Sciences, 2019). More ambitious engineered interventions like reef shading remain theoretical and not scalable to the reef level (Condie et al., 2021). Debate continues on how to apply planned adaptation in cost-effective ways that will accomplish the intended goals (National Academies of Sciences, 2019; Duarte et al., 2020; Kleypas et al., 2021).

Models show that a combination of available management approaches (restoration, reducing non-climate drivers) and speculative interventions (enhanced corals, reef shading) can contribute to sustaining some coral reefs beyond 1.5°C of global warming with declining effectiveness beyond 2°C of global warming (*medium confidence*) (Figure 3.25, WGII Chapter 17). These proposed interventions are also currently theoretical and impractical over large scales; for example, engineered solutions like reef shading are untested and not scalable at the reef level (Condie et al., 2021). Existing projects suggest that restoration and ecological interventions to habitat-forming ecosystems have additional benefits of raising local awareness, promoting tourism, and creating jobs and economic benefits (Fadli et al., 2012; Boström-Einarsson et al., 2020; Hafezi et al., 2021), provided communities are involved in planning, operation and monitoring (Boström-Einarsson et al., 2020).

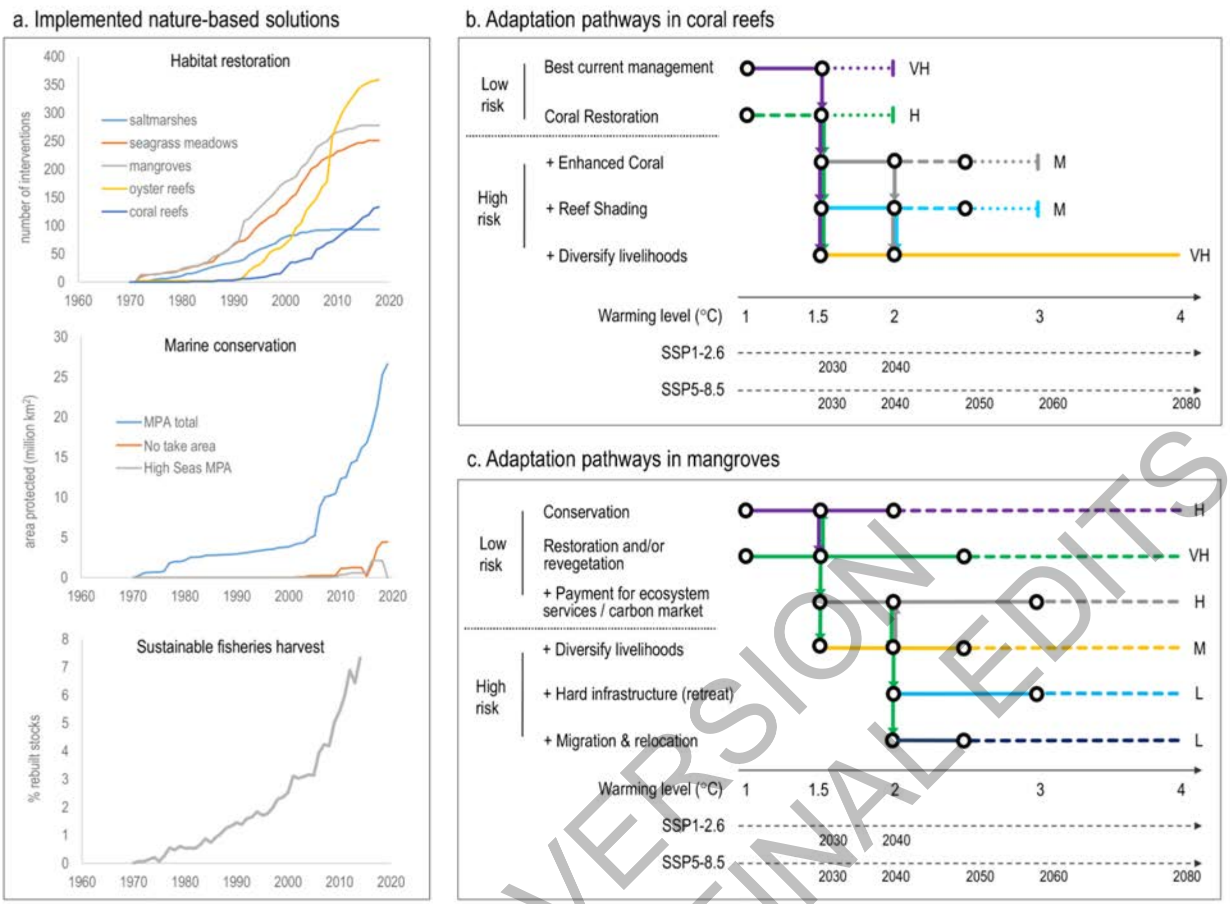

Figure 3.25: Implemented and potential future adaptations in ocean and coastal ecosystems. (a) Global implementation since 1970 of (top) cumulative habitat-restoration projects (Duarte et al., 2020), (middle) cumulative area-based conservation protected area (MPA total, Boonzaier and Pauly, 2016), no-take areas (UN Environment World Conservation Monitoring Centre et al., 2018; UNEP-WCMC, 2019), and (bottom) percentage of total fish stocks rebuilt (Kleisner et al., 2013). (b) Adaptation pathways for coral reefs to maintain healthy cover (line weight: solid lines, *likely* effectiveness; dashed lines, *more likely* than not to *likely;* dotted lines = *unlikely to more likely than not*), with confidence noted for each intervention (VH = *Very High*, H = *High*, M = *Medium*) (Section 3.4.2.1, 3.6.3.2, Anthony et al., 2019; National Academies of Sciences Engineering and Medicine, 2019). Circles denote when other measures must also be implemented. (c) As in (b), but for mangrove ecosystems. Underlying data are available in Tables SM3.4–3.6.

3.6.3.3 Enablers, Barriers and Limitations of Adaptation and Mitigation

Not only is mitigation necessary to support ocean and coastal adaptation (Pörtner et al., 2014; Oppenheimer et al., 2019), but the global emission pathways also impose limits to ocean and coastal adaptation, with lower warming levels enabling greater effectiveness of adaptations (*high confidence*) (Figure 3.25). Chapter 17 broadly assesses the limits to adaptation, while this section focuses on barriers and limits to adaptation imposed by cultural (Section 3.6.3.3.1), economic (Section 3.6.3.3.2) and governance (Section 3.6.3.3.3) dimensions (Hinkel et al., 2018). Globally, these factors more strongly influence ocean development than does local natural resource availability (Cisneros-Montemayor et al., 2021), and are key to avoiding maladaptation. This section also assesses enablers and limits to mitigation (Section 3.6.3.3.4).

3.6.3.3.1 Sociocultural dimensions (culture, ethics, identity, behaviour)

Every coastal community values marine ecosystems for more than the material and intangible resources they deliver, or the physical protection they offer (Díaz et al., 2018). Cultural services that provide identity, spiritual and cultural continuity, religious meaning, or options for the future (e.g., genetic or mineral resources, Bindoff et al., 2019), are not substitutable. Furthermore, interactions between climate impacts and existing inequalities can threaten the human rights of already-marginalised peoples by disrupting livelihoods and food security, which further erodes people's social, economic, and cultural rights (Finkbeiner et al., 2018). For instance, European colonisation and ongoing development blocked the Cucapá Indigenous People's access and rights to resources in the Colorado River Delta, USA, over the 20th century. Recent reallocation of water rights and fishing access is allowing the Cucapá people to reconstruct their cultural identity (Sangha et al., 2019), but future climate change impacts could reverse the community's recovery of their cultural heritage. Adaptations that consider local needs may help sustain cultural services (Ortíz Liñán and Vázquez Solís, 2021).

Interactions with oceans are fundamental to the identities of many coastal Indigenous Peoples (Norman, 2017) and this influences Indigenous responses to climate hazards and adaptation. Around 30 million Indigenous Peoples live along coasts (Cisneros-Montemayor et al., 2016). Seafood consumption among Indigenous Peoples is much higher than for non-Indigenous populations, and marine species support many cultural, medicinal and traditional activities contributing to public health (Section 3.5.3.1, Kenny et al., 2018). Perpetuation of Indigenous cultures depends on protecting marine ecosystems and on adapting to changes in self-led ways (see Section 3.5.6, Sangha et al., 2019) that promote self-determination (von der Porten et al., 2019). Indigenous resurgence, or reinvigorating Indigenous ways of life and traditional management, can include marine resource protection and ocean-sector development founded on culturally appropriate strategies and partnerships, that are consistent with traditional norms and beneficial to local communities (von der Porten et al., 2019). Successful adaptation would simultaneously improve ecosystem health and address current and historical inequities (Bennett, 2018). Examples include practicing traditional resource management, protecting traditional territories, engaging with monitoring, collaborations with non-Indigenous partners, and reinvesting benefits into capacity-building within communities (von der Porten et al., 2019; Equator Initiative, 2020). The legitimacy of different adaptation strategies depends on local and Indigenous Peoples' acceptance, which is based on cultural values (Adger et al., 2017); financial gain cannot compensate for loss of IK or LK (Wilson et al., 2020b). Palau's recent goal of shifting seafood consumption away from reef fishes (Remengesau Jr., 2019) and limiting and closely monitoring the expansion of ecotourism was prompted by the cultural importance of protecting these reefs and associated traditional fisheries for local consumption, a recognition of the importance of tourism, and the hazard of climate change (Wabnitz et al., 2018a).

Adaptations implemented at the local level that consider IK and LK systems are beneficial (*high confidence*) (Nalau et al., 2018; Sultana et al., 2019). Studies in SIDS and the Arctic have shown how IK and LK facilitate the success of EbA (Nalau et al., 2018; Peñaherrera-Palma et al., 2018; Raymond-Yakoubian and Daniel, 2018), reinforce and improve institutional approaches and enhance the provision of ecosystem services (Ross et al., 2019; Terra Stori et al., 2019). Perspectives on adaptation also vary among groups of age, race, (dis)ability, class, caste, and gender (Wilson et al., 2020b), so engaging different groups results in more robust and equitable adaptation to climate change (Cross-Chapter Box GENDER in Chapter 18, McLeod et al., 2018). Some coastal communities have developed substantial social capital and dense local networks based on trust and reciprocity (Petzold and Ratter, 2015), with individual and community flexibility to learn, adapt, and organise themselves to help local adaptation governance (Silva et al., 2020). Recent evidence suggests that policies supporting local institutions can improve adaptation outcomes (*medium confidence*) (Berman et al., 2020). Coastal communities can be engaged using novel approaches to co-generate adaptation solutions (van der Voorn et al., 2017; Flood et al., 2018) that benefit education (Koenigstein et al., 2020) and engagement in adaptation processes (Rumore et al., 2016). Successful adaptation implementation in line with climate-resilient development pathways (WGII Chapter 18) depends on bottom-up, participatory and inclusive processes (Section 3.6.1.2.1) that engage diverse stakeholders (Basel et al., 2020; McNamara et al., 2020; Ogier et al., 2020; Williams et al., 2020), and that protect Indigenous customary rights (Farbotko and McMichael, 2019; Ford et al., 2020), empower women, and give rights to climate refugees (McLeod et al., 2018).

3.6.3.3.2 Economic dimensions (planning, finance, costs)

Finance is a key barrier globally for ocean health, governance and adaptation to climate change (*high agreement*) (Annex II: Glossary, Cross-Chapter Box FINANCE in Chapter 17, Hinkel et al., 2018; Miller et al., 2018; Wabnitz and Blasiak, 2019; Woodruff et al., 2020; Sumaila et al., 2021). Global adaptation finance was estimated to total 30 billion USD yr^{-1} in 2017–2018, or 5% of all climate finance (CPI, 2019), with no tracking specifically for coastal or marine adaptation in low- to middle-income countries. Marine-focused adaptation finance is difficult to trace and label due to the cross-sectoral nature of many projects (Blasiak and Wabnitz, 2018) and the lack of clear definitions about what qualifies as adaptation or as new and additional finance (Donner et al., 2016; Weikmans and Roberts, 2019). Finance for marine conservation from Overseas Development Assistance doubled between 2003 and 2016, reaching 634 million USD in 2016, similar to the level provided by philanthropic foundations (Berger et al., 2019). Yet coastal adaptation to SLR alone is projected to cost hundreds of billions of USD yr^{-1}, depending on the model and emission scenario (e.g., Wong et al., 2014; Nicholls et al., 2019). Economic and financing barriers to marine adaptation are often higher in low- to middle-income countries, where resources influence governance and constrain options for implementation and maintenance (*high confidence*) (Hinkel et al., 2018; Klöck and Nunn, 2019; Tompkins et al., 2020) and impacts on their coastal and marine ecosystems could total several percentage points of their gross domestic product (Wong et al., 2014). Current financial flows are insufficient to meet the costs of coastal and marine impacts of climate change (*very high confidence*) and ocean-focused finance is unevenly distributed, with higher flows within and to developed countries (*very high confidence*).

Development assistance can help resolve resource constraints, but additional governance and coordination challenges can arise from short-term, project-based funding, shifting priorities of donor institutions, and pressures placed on human resources in the receiving nation (Parsons and Nalau, 2019; Nunn et al., 2020). Innovative policy instruments like concessional loans, tax-policy reforms, climate bonds and public-debt forgiveness can supplement traditional financial instruments (Bisaro and Hinkel, 2018; McGowan et al., 2020). Mechanisms for solving the persistent problem of securing upfront investments for coastal protection and other adaptation measures (Bisaro and Hinkel, 2018; Moser et al., 2019; Kok et al., 2021) include integrating adaptation investments into insurance schemes (Reguero et al., 2020) and using debt financing to bridge the time until benefits are realised (Ware and Banhalmi-Zakar, 2020). Insurance mechanisms that link payments to losses from a trigger event (e.g., MHW) can confer resilience to marine-dependent communities (Sumaila et al., 2021). All innovative financial instruments are most effective when they are inclusive and reach vulnerable groups and marginalised communities (*low evidence, high agreement*) (Claudet et al., 2020a; Sumaila et al., 2021).

Countries with large ocean areas within their EEZs have opportunities to develop “blue-green economies” to reduce emissions and finance adaptation pathways (Chen et al., 2018a; Lee et al., 2020). Shifting from grants to results-based financing can help attract more private capital to ocean adaptation (Lubchenco et al., 2016; Claudet et al., 2020a). Public-private partnerships can also increase ocean adaptation finance (Goldstein et al., 2019; Sumaila et al., 2021). For example, the financial benefits that biodiversity conservation confers to seafood harvest resilience could be used to leverage industry participation in adaptation and conservation finance (Barbier et al., 2018). Connecting restoration of blue carbon ecosystems with offset markets (e.g., Vanderklift et al., 2019) shows potential, but uncertainties remain about the international emissions trading under the UN Framework Convention on Climate Change and climate impacts on blue-carbon ecosystems (Section 3.6.3.1.6, Lovelock et al., 2017a; Macreadie et al., 2019).

Transparency, coherence between different actors and initiatives, and project monitoring and evaluation enhance success in adapting and achieving SDG14 (Life below water) (Blasiak et al., 2019). Maladaptation (WGII Chapter 16, Magnan et al., 2016), is a common risk of current project-based funding due to the pressure to produce concrete results (*medium confidence*) (Parsons and Nalau, 2019; Nunn et al., 2020; Nunn et al., 2021). Maladaptation can be avoided through a focus on building adaptive capacity, community-based management, drivers of vulnerability and site-specific measures (*low confidence*) (Magnan and Duvat, 2018; Piggott-McKellar et al., 2020; Schipper, 2020). More research is needed to identify ways that governance and financing agreements can help overcome financial barriers and socio-cultural constraints to avoid maladaptation in coastal ecosystems (*high confidence*) (Hinkel et al., 2018; Miller et al., 2018; Piggott-McKellar et al., 2020; Schipper, 2020).

3.6.3.3.3 Governance dimension (institutional settings, decision making)

Ocean governance has become increasingly complex as new initiatives, new international agreements, institutions, and scientific evidence arise at global, national, and sub-national scales (*high agreement*) (Bindoff et al., 2019; Scobie, 2019b), limiting the present effectiveness of adaptation (IPCC, 2019c). Marine climate governance is within the normatively contested marine governance space (Frazão Santos et al., 2020), which is influenced by geopolitics (Gray et al., 2020) and profit maximisation (Flannery et al., 2016; Haas et al., 2021) in ways that can entrench exclusionary processes in decision making, science management and funding (Levin et al., 2018). This limits just and inclusive ocean governance (Bennett, 2018), perpetuates historical and cultural extractive practices and climate inaction, and leaves little space for Indigenous-led adaptation frameworks and approaches (Nursey-Bray et al., 2019). At the national level, ocean governance for climate-change adaptation is often transversal, requiring consideration of biophysical and environmental conditions (Furlan et al., 2020), while fitting into existing economic (Kim, 2020) and political processes. Adaptation governance that couples existing top-down structures with decentralised and participatory approaches generates shared goals and unlocks required resources and monitoring (Gupta et al., 2016; Haas et al., 2021).

Communities and governments at all levels increasingly use decision-making frameworks (e.g., structured decision making) or decision-analysis tools to evaluate trade-offs between different responses, rather than applying generic best practices to different physical, technical or cultural contexts (*high confidence*) (Watkiss et al., 2015; Haasnoot et al., 2019; Palutikof et al., 2019). Increased effort has also been devoted to developing climate services (actionable information and data products) that bridge the gap between climate prediction and decision-making (Hewitt et al., 2020). Climate services have the potential to inform decision making related to disaster-risk reduction, adaptation responses, marine environmental management (e.g., fisheries management and MPA management) and ocean-based climate mitigation (e.g., renewable energy installations, Le Cozannet et al., 2017; Gattuso et al., 2019; Gattuso et al., 2021). Although improving observational and modelling capacity is important to developing ocean-focused services, particularly in high-risk regions like SIDS where regional climate projections are scarce (WGI AR6 Chapter 9, Morim et al., 2019; Fox-Kemper et al., 2021), data is not the only limiting factor in decision-making (Weichselgartner and Arheimer, 2019). Focusing on user engagement, relationship-building and the decision-making context ensures that climate services are useful to and used by different stakeholders (*high confidence*) (Soares et al., 2018; Mackenzie et al., 2019; Weichselgartner and Arheimer, 2019; Findlater et al., 2021; West et al., 2021).

3.6.3.3.4 Mitigation

Ocean and coastal NbS can contribute to global mitigation efforts, especially with ocean renewable energy and restoration and preservation of carbon ecosystems (Box 3.4, Section 3.6.2.3). Technological, economic and financing barriers presently hamper development of renewable ocean energy (AR6 WGIII Chapter 6). Such development could help small nations reliant on imported fuel meet their climate-mitigation goals and decrease risk from global fuel supply dynamics (Millar et al., 2017; Chen et al., 2018a), but progress is limited by lack of investment (Millar et al., 2017; Lee et al., 2020) or equipment (Aderinto and Li, 2018; Rusu and Onea, 2018). Wave-energy installations, possibly co-located with wind turbines(Perez-Collazo et al., 2018), are promising for both low- to middle-income nations and areas with significant island or remote coastal geographies (Lavidas and Venugopal, 2016; Bergillos et al., 2018; Jakimavičius et al., 2018; Kompor et al., 2018; Penalba et al., 2018; Saprykina and Kuznetsov, 2018; Lavidas, 2019). Wave-energy capture may also diminish storm-induced coastal erosion (Abanades et al., 2018; Bergillos et al., 2018). Tidal energy is a relatively new technology (Haslett et al., 2018; Liu et al., 2018; Neill et al., 2018) with limiting siting requirements (Mofor et al., 2013). Ocean renewable energy expansion faces other technological obstacles including lack of implementable or scalable energy-capture devices, access to offshore sites, competing coastal uses, potential environmental impacts, and lack of power-grid infrastructure at the coast (Aderinto and Li, 2018; Neill et al., 2018).

3.6.4 Contribution to the Sustainable Development Goals and Other Relevant Policy Frameworks

The impacts of climate change on ocean and coastal ecosystems and their services threaten achievement of the UN SDGs by 2030 (*high confidence*), particularly ocean targets (Table 3.31, Nilsson et al., 2016; Pecl et al., 2017; IPCC, 2018; Singh et al., 2019a; Claudet et al., 2020a). Nevertheless, local to international decision-making bodies have assigned the lowest priority to SDG14, Life Below Water (Nash et al., 2020).

Table 3.31: Sustainable Development Goals, grouped into broader categories as discussed in this section (http://sdgs.un.org/goals).

Category	Goal
Society	SDG1: No Poverty
	SDG2: Zero Hunger
	SDG3: Good Health & Well-Being
	SDG4: Quality Education
	SDG5: Gender Equality

Economy	SDG6: Clean Water & Sanitation SDG7: Affordable & Clean Energy SDG8: Decent Work & Economic Growth SDG9: Industry, Innovation & Infrastructure SDG10: Reduced Inequality
Environment	SDG11: Sustainable Cities & Communities SDG12: Responsible Consumption & Production SDG13: Climate Action SDG14: Life Below Water SDG15: Life on Land
Governance	SDG16: Peace and Justice Strong Institutions SDG17: Partnerships to achieve the Goals

3.6.4.1 Climate Mitigation Effects on Ocean-Related SDGs

SROCC underscored the need for ambitious mitigation to control climate hazards in the ocean to achieve SDGs (*medium evidence, high agreement*) (Bindoff et al., 2019; Oppenheimer et al., 2019). Delays in achieving ocean-dependent SDGs observed in SROCC and SR15 can be addressed with ambitious planned adaptation and mitigation action (*high agreement*) (Hoegh-Guldberg et al., 2019b). Since the ocean can contribute substantially to the attainment of mitigation targets aiming to limit warming to 1.5ºC above pre-industrial (Hoegh-Guldberg et al., 2019b), and to adaptation solutions facilitating attainment of social and economic SDGs, climate policy is treating the ocean less as a victim of climate change and more as a central participant in solving the global climate challenge (Cooley et al., 2019; Hoegh-Guldberg et al., 2019a; Dundas et al., 2020).

Relationships between Climate Action (SDG13) targets and SDG14 targets are mostly synergistic (Figure 3.26, Fuso Nerini et al., 2019). Responding to climate-change impacts requires transformative governance (*high confidence*) (Chapters 1 and 18, Collins et al., 2019a; Brodie Rudolph et al., 2020; Claudet et al., 2020a), especially for extreme events and higher-impact scenarios (e.g., higher emissions) (Fedele et al., 2019), and for achieving SDGs through one of the global ecosystems transitions (Chapter 18, Sachs et al., 2019; Brodie Rudolph et al., 2020). Opportunities to transform ocean governance exist in developing new international and local agreements, regulations and policies that reduce the risks of relocating ocean and coastal activities (Section 3.6.3.1.1) or in reinventing established practices (Section 3.6.3.3.3). Policy transformations improving ocean sustainability under SDG14 also help address SDG13 (Brodie Rudolph et al., 2020; Dundas et al., 2020; Claudet, 2021; Sumaila et al., 2021). Emergent situations such as the COVID-19 pandemic may provide opportunities to implement transformative "green recovery plans" that support achievement of the SDGs and NDCs (Cross-Chapter Box COVID in Chapter 7).

3.6.4.2 Contribution of Ocean Adaptation to SDGs

Marine-focused adaptations show promise in helping achieve social SDGs, especially when they are designed to achieve multiple benefits (*medium confidence*) (Figure 3.26, Ntona and Morgera, 2018; Claudet et al., 2020a). Technology- and infrastructure-focused adaptations (Section 3.6.2.2) can help relieve coastal communities from risks associated with poverty (SDG1), hunger (SDG2), health and water sanitation (SDG3 and SDG6), and inequality (SDG10) by supporting aquaculture (Sections 3.5.3, 3.6.3.1), alerting the public about poor water quality (Sections 3.5.5.3, 3.6.3.1), and empowering marginalised groups, such as women and Indigenous Peoples, with decision-relevant information (*medium evidence, high agreement*) (Sections 3.5.5.3, 3.6.3.1). Effectively implemented and managed marine NbS (Section 3.6.2.3) contribute to attainment of social SDGs by preserving biodiversity (Carlton and Fowler, 2018; Warner, 2018; Scheffers and Pecl, 2019), which benefits most ocean and coastal ecosystem services (Section 3.5.3, Figure 3.22), by increasing marine fishery and aquaculture sustainability (Section 3.6.3), by including vulnerable people and communities in management (Section 3.6.3.2.1), by lowering risk of flooding from storms and SLR (Cross-Chapter Box SLR in Chapter 3, Sections 3.6.3.1.1), and by implementing spatial management tools that make room for new uses like renewable energy development (Section 3.6.3.3.4). NbS can therefore help support achievement of No Poverty (SDG1) (Ntona and Morgera, 2018), Zero Hunger (SDG2), Good Health and Well-Being (SDG3) (Duarte et al., 2020), Affordable and Clean Energy (SDG7) (Fuso Nerini et al., 2019; Levin et al., 2020), and Reduced Inequality (SDG10). Socio-institutional marine adaptations (Section

3.6.2.2) that support current livelihoods and help develop alternatives can contribute to attainment of social SDGs by enhancing social equity and supporting societal transformation (*medium confidence*) (Cisneros-Montemayor et al., 2019; Pelling and Garschagen, 2019; Nash et al., 2021). Even societal changes that are not directly marine-related can decrease human vulnerability to ocean and coastal climate risks by improving overall human adaptive capacity (Section 1.2).

Marine adaptation also shows promise for helping support achievement of economic SDGs (*medium confidence*) (Figure 3.26). Marine NbS could help blue economy frameworks achieve Decent Work and Economic Growth (SDG8) (Lee et al., 2020), by sustainably and equitably incorporating ecosystem-based fisheries management, restoration or conservation (Sections 3.6.3.1.2, 3.6.3.2.1 and 3.6.3.2.2) (Voyer et al., 2018; Cisneros-Montemayor et al., 2019; Cohen et al., 2019; Okafor-Yarwood et al., 2020). NbS that involve active restoration or accommodation can contribute to Sustainable Cities and Communities (SDG11) and Infrastructure (SDG9) (Section 3.6.3.1.1). Newly developed marine industries and livelihoods associated with NbS might support attainment of Sustainable Communities (SDG11) (Cisneros-Montemayor et al., 2019). Finance and market mechanisms to support disaster relief or ocean ecosystem services, such as blue carbon or food provisioning, and innovations (SDG9) including new technologies like vessel-monitoring systems (Kroodsma et al., 2018), can contribute to Responsible Consumption and Production (SDG12) (Sumaila and Tai, 2020). Blue economy growth that includes sustainable shipping, tourism, renewable ocean energy, and transboundary fisheries management (Pinsky et al., 2018) have the potential to contribute to Economic Development (SDG8), affordable and clean energy (SDG7) (as well as global mitigation efforts, SDG13, (Hoegh-Guldberg et al., 2019b; Duarte et al., 2020)). Participatory approaches and co-management systems (Section 3.6.2.1) in many maritime sectors can contribute to SDG11 and SDG12 while helping align the blue economy and the SDGs (*high agreement*) (Lee et al., 2020; Okafor-Yarwood et al., 2020).

Developing marine adaptation pathways that offer multiple benefits requires transformational adaptation (*high confidence*) (Claudet et al., 2020a; Friedman et al., 2020; Wilson et al., 2020b; Nash et al., 2021) that avoids risky and maladaptive actions (Magnan and Duvat, 2018; Ojea et al., 2020). Ocean and coastal extreme events and other hazards disproportionately harm the most vulnerable communities in SIDS, tropical and Arctic regions, and Indigenous Peoples (Chapter 8.2.1.2). Presently implemented adaptation activity, at the aggregate level, adversely affects multiple gender targets under SDG5 (*high confidence*) (Cross-Chapter Box GENDER in Chapter 18). Although women make up over half of the global seafood production workforce (fishing and processing sectors), provide more than half the artisanal landings in Pacific region (Harper et al., 2013), dominate some seafood sectors such as seaweed (Howard and Pecl, 2019) and shellfish harvesting (Turner et al., 2020a), and account for 11% of global artisanal fisheries participants (Harper et al., 2020b), they are often not specifically counted in datasets and excluded from decision-making and support programs (Cross-Chapter Box GENDER in Chapter 18, Harper et al., 2020b; Michalena et al., 2020). Targeted efforts to incorporate knowledge diversity, and include artisanal fishers, women and Indigenous Peoples within international, regional, and local policy planning promote marine adaptation that supports achievement of gender equality (SDG5) and reduces inequalities (SDG10) (*limited evidence, high agreement*) (FAO, 2015). Integrated planning, financing, and implementation can help overcome these limitations (Section 3.6.3.3.2, Cross-Chapter Box FINANCE in Chapter 17), ensuring that marine adaptations do not compromise overall human equity or specific SDGs (Österblom et al., 2020; Nash et al., 2021), but are in fact fully synergistic with these goals (Bennett et al., 2021).

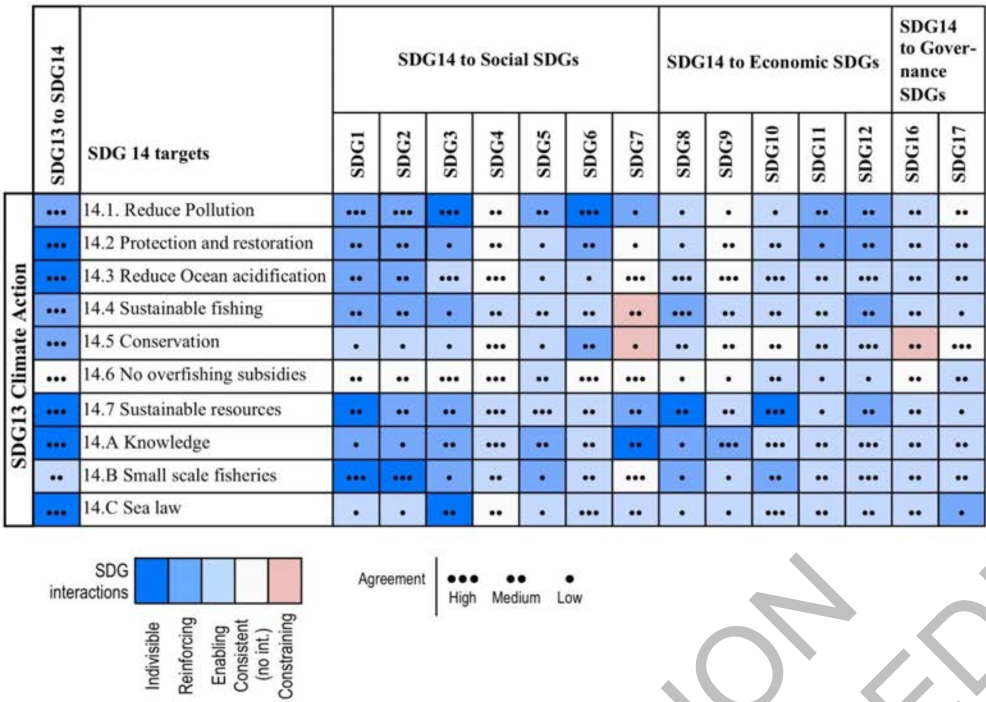

Figure 3.26: Synergies and trade-offs between SDG13 Climate Action, SDG14 Life Below Water and social, economic and governance SDGs. Achieving SDG13 provides positive outcomes and supports the achievement of all SDG14 targets. In turn, meeting SDG14 drives mostly positive interactions with social, economic and governance SDGs. The interaction types, 'Indivisible' (inextricably linked to the achievement of another goal), 'Reinforcing' (aids the achievement of another goal), 'Enabling' (creates conditions that further another goal), 'Consistent' (no significant positive or negative interactions), 'Constraining' (limits options on another goal), follows Nilsson et al. (2016)'s scoring system based on authors' assessment, and agreement denotes consistency across author ratings. Full data available in Table SM3.7.

3.6.4.3 Relevant Policy Frameworks for Ocean Adaptation

The intricacy, scope, timescales, and uncertainties associated with climate change challenge ocean governance, which already is extremely complex because it encompasses a variety of overlapping spatial scales, concerns, and governance structures (Figure CB3.1 in SROCC Chapter 1, Prakash et al., 2019). Assessment of how established global agreements and regional, sectoral, or scientific bodies address climate adaptation and resilience, and how current practices can be improved, is found in SM3.5.3.

There is growing momentum to include the ocean in international climate policy (*robust evidence*), paving the way for a more integrated approach to both mitigation and adaptation. Following adoption of the Paris Agreement in 2015, the UN SDGs (Table 3.31) came into force in 2016, including SDG14 specifically dedicated to life below water (Table 3.31). In 2017, the first UN Ocean Conference was held (United Nations, 2017), the UNFCCC adopted the Ocean Pathway to increase ocean-targeted multilateral climate action (COP23, 2017), and the UN Assembly declared 2021–2030 the Decade for Ocean Science for Sustainable Development (Visbeck, 2018; Lee et al., 2020). Next, 14 world leaders formed the High-Level Panel for a Sustainable Ocean Economy to produce the New Ocean Action Agenda, founded on 100% sustainable management of national ocean spaces by 2025 (Ocean Panel, 2020). All of these initiatives position oceans centrally within the climate-policy and biodiversity-conservation landscapes and seek to develop a coherent effort and common frameworks to achieve marine sustainability (Visbeck, 2018; Lee et al., 2020), new economic opportunities (Konar and Ding, 2020; Lee et al., 2020), more equitable outcomes (Österblom et al., 2020), and decisive climate mitigation and adaptation (Hoegh-Guldberg et al., 2019a), to achieve truly transformative change (Claudet et al., 2020a).

There is *high confidence* in the literature that multilateral environmental agreements need better alignment and integration to support achievement of ambitious international development, climate mitigation, and adaptation goals (Swilling et al., 202; Duarte et al., 2020; Friedman et al., 2020; Conservation International and IUCN, 2021; Pörtner et al., 2021b; Sumaila et al., 2021). The ocean targets of the CBD (e.g., the Post-2020 Global Biodiversity Framework), the SDGs (Agenda 2030) and the Paris Agreement are already inclusive and synergistic (Duarte et al., 2020). However, specific policy instruments and sectors within them could be additionally integrated, especially to address such cross-cutting impacts as ocean acidification and deoxygenation (Gallo et al., 2017; Bindoff et al., 2019), increasing plastic pollution (Ostle et al., 2019; Duarte et al., 2020), high-seas governance (Johnson et al., 2019; Leary, 2019), or deep sea uses (Wright et al., 2019; Levin et al., 2020; Orejas et al., 2020). National adaptation plans present opportunities to synergistically build on mitigation to support equitable development (Morioka et al., 2020), economic planning (Dundas et al., 2020; Lee et al., 2020), and ocean stewardship (von Schuckmann et al., 2020). Alignment of multilateral agreements is expected to increase mitigation impact as well as increase adaptation options (Section 3.6.3, Figure 3.25, Roberts et al., 2020). Opportunities to improve multilateral environmental agreements and policies beyond UNFCCC and CBD processes are discussed in SM3.5.3, and an assessment of commercial species management initiatives and needs is in Chapter 5.

3.6.5 Emerging Best Practices for Ocean and Coastal Climate Adaptation

There is *robust evidence* that a combination of global and local solutions offers the greatest benefit in reducing climate risk (Gattuso et al., 2018; Hoegh-Guldberg et al., 2019a; Hoegh-Guldberg et al., 2019b). Ambitious and swift global mitigation offers more adaptation options and pathways to sustain ecosystems and their services (Figure 3.25). Some solutions target both mitigation and adaptation (e.g., blue carbon conservation, Cross-Chapter Box NATURAL in Chapter 2, Box 3.4), and cross-cutting solutions simultaneously support several ocean-related sectors (e.g., area-based measures support fishing, tourism; Section 3.6.3.2.1) or ecosystem functions (e.g., NbS support coastal protection, biodiversity, habitat, etc., Section 3.6.3.2.2, Sala et al., 2021). Combined solutions also leverage a variety of existing policies and governance systems (Section 3.6.4.3, Duarte et al., 2020) to advance climate mitigation and adaptation. Even communities that face the limits of adaptation, like those who must relocate to cope with rising seas (McMichael et al., 2019; Bronen et al., 2020), urgently require solutions that combine scientific projections, IK and LK, cultural and community values, and ways to preserve cultural identity to support planning and implementation of relocation (McMichael and Katonivualiku, 2020).

NbS are showing promising results in achieving adaptation and mitigation outcomes across marine and coastal ecosystems (Sections 3.6.3.2.1–3.6.3.2.2), but NbS have different degrees of readiness in marine ecosystems (Duarte et al., 2020). Habitat restoration and recovery are highly effective in specific settings and conditions (McLeod et al., 2019). Restoring and conserving vegetated coastal habitats (Sections 3.4.2.4–3.4.2.5) represent robust NbS, especially in the tropics, and particularly when paired with restoration and conservation of terrestrial ecosystems (*robust evidence*) (e.g., peatlands and forests, WGIII AR6 Chapter 7, Hoegh-Guldberg et al., 2019b; Duarte et al., 2020; Griscom et al., 2020). Although most of the focus on NbS efficacy has been on coastal and shelf ecosystems (Section 3.6.3.2), recent advances point to an emerging role of NbS beyond coastal waters in the form of area-based management tools in marine areas beyond national jurisdiction (Section 3.6.2.3, Gaines et al., 2018; Pinsky et al., 2018; Crespo et al., 2020; O'Leary et al., 2020; Visalli et al., 2020; Wagner et al., 2020), because sustainable fisheries and aquaculture and climate-responsive MPAs have high potential to adapt (Tittensor et al., 2019).

Adaptation efforts (Sections 3.6.3.1–3.6.3.2) have three common characteristics that facilitate implementation and success and contribute to climate-resilient development pathways (Chapter 18). First, availability of multiple types of information (e.g., monitoring, models, climate services, Section 3.6.3.3) exposes the magnitude and nature of the adaptation challenge. Well-developed observation and modelling capabilities (Reusch et al., 2018) offer insights on climate-associated risks at different timescales (Cvitanovic et al., 2018; Hobday et al., 2018), and this facilitates adaptation within multiple areas (e.g., industries over shorter timescales, societies over longer scales) (Hobday et al., 2018). Environmental data has supported building societal and political (socio-institutional) will to adopt national and subnational adaptive management principles (Hobday et al., 2016b; Champion et al., 2018; McDonald et al., 2019). However, incorporating IK and LK at the same time provides more diverse social-environmental insight (Section 3.6.3.4.1, Goeldner-Gianella et al., 2019; Petzold and Magnan, 2019; Wilson et al., 2020b). This can help align adaptation solutions with cultural values and increase their legitimacy with Indigenous and local communities (Chapter 1.3.2.3), achieving climate resilient development pathways (Chapter 18, Adger et al., 2017; Nalau et al., 2018; Peñaherrera-Palma et al., 2018; Raymond-Yakoubian and Daniel, 2018; Wamsler and Brink, 2018). Second, implementation of multiple low-risk options (Hoegh-Guldberg et al., 2019a; Gattuso et al., 2021) such as economic diversification (Section 3.6.2.1) can provide culturally acceptable livelihood alternatives and food supplies (e.g., fishing to ecotourism and mariculture, (Froehlich et al., 2019) while also providing environmental benefits (e.g., seaweed mariculture's potential carbon storage co-benefits (WGIII AR6 Chapter 7, Hoegh-Guldberg et al., 2019a; Gattuso et al., 2021). Third, inclusive governance that is well-aligned to the systems at risk from climate change is fundamental for effective adaptation (Barange et al., 2018). Solutions implemented within polycentric governance systems (Section 3.6.3, Bellanger et al., 2020) benefit from synergies between knowledge, action and socio-ecological contexts and stimulate governance responses at appropriate spatial and temporal scales (Cvitanovic and Hobday, 2018). Governance aligned with Indigenous structures and local structures supports successful outcomes that prioritise the concerns and rights of involved communities (Section 3.6.3, Mawyer and Jacka, 2018) and better leverages existing social organisation (i.e., network structures), learning processes and power dynamics (Barnes et al., 2020).

There is an opportunity to improve current practices when developing new ocean and coastal adaptation efforts so that they routinely contain these successful characteristics and resolve technical, economic, institutional, geophysical, ecological and social constraints (Figure 3.25, Section 3.6.3.3, IPCC, 2018; Singh et al., 2020). Enhancements are needed in human, technical and financial resources; regulatory frameworks (Ojwang et al., 2017); political support (Rosendo et al., 2018); institutional conditions and resources for fair governance (Gupta et al., 2016; Scobie, 2018); political leadership; stakeholder engagement; multidisciplinary data availability (Gopalakrishnan et al., 2018); funding and public support for adaptation (Cross-Chapter Box FINANCE in Chapter 17, Ford and King, 2015); and incorporating IK and LK in decision making (Nalau et al., 2018; Jabali et al., 2020; Petzold et al., 2020). As climate change continues to challenge ocean and coastal regions, there is *high confidence* associated with the benefits of developing robust, equitable adaptation strategies that incorporate scientific projections, employ portfolios of low-risk options, internalise IK and LK, and address social aspects of governance from international to local scales (Finkbeiner et al., 2018; Gattuso et al., 2018; Miller et al., 2018; Raymond-Yakoubian and Daniel, 2018; Cheung et al., 2019; Gattuso et al., 2021).

[START FAQ3.2 HERE]

FAQ3.2: Are we approaching so-called tipping points in the ocean and what can we do about it?

A tipping point is a threshold beyond which an abrupt or rapid change in a system occurs. Tipping points that have already been reached in ocean systems include the melting of sea ice in the Arctic, thermal bleaching of tropical coral reefs and the loss of kelp forests. Human-induced climate change will continue to force ecosystems into abrupt and often irreversible change, absent strong mitigation and adaptation action.

A gradual change in water temperature or oxygen concentration can lead to a fundamental shift in the structure and/or composition of an ecosystem when a tipping point is exceeded. For example, all species have upper temperature limits below which they can thrive. In the tropics, prolonged warm temperatures can cause fatal 'bleaching' of tropical corals, leading reef ecosystems to degrade and become dominated by algae. In temperate regions, marine heatwaves can kill or reduce the growth of kelp, threatening the other species that depend on the tall canopy-forming marine plants for habitat. In the Arctic, rising temperatures are melting sea ice, and reducing the available habitat for communities of ice-dependent species.

Once a tipping point is passed, the effects can be long-lasting and/or irreversible over timescales of decades or longer. An ecosystem or a population can remain in the new state, even if the driver of the change returns to previous levels. For example, once a coral reef has been affected by bleaching, it can take decades for corals to grow back, even if temperatures remain below the bleaching threshold. Crossing a tipping point can cause entire populations to collapse, causing local extinctions.

Tipping points are widespread across oceanic provinces and their ecosystems for climate variables like water temperature, oxygen concentration and acidification. Evidence suggests that ocean tipping points are being surpassed more frequently as the climate changes; scientists have estimated that abrupt shifts in communities of marine species occurred over 14% of the ocean in 2015, up from 0.25% of the ocean in the 1980s. Other human stresses to the ocean, including habitat destruction, overfishing, pollution and the spread of diseases, combine with climate change to push marine systems beyond tipping points. As an example, nutrient pollution from land together with climate change can lead to low-oxygen coastal areas referred to as "dead zones".

Human communities can also experience tipping points that alter people's relationships with marine ecosystem services. Indigenous Peoples and local communities may be forced to move from a particular location due to sea-level rise, erosion, or loss of marine resources. Current activities that help sustain Indigenous Peoples and their cultures may no longer be possible in the coming decades, and traditional diets or territories may have to be abandoned. These tipping points have implications for physical and mental health of marine-dependent human communities.

Adaptation solutions to the effects of ecological tipping points are rarely able to reverse their environmental impacts, and instead often require human communities to transform their livelihoods in different ways. Examples include diversifying income by shifting from fishing to tourism and relocating communities threatened by flooding to other areas to continue their livelihoods. Tipping points are being passed already in coral reefs and polar systems, and more will probably be reached in the near future, given climate-change projections. Nevertheless, the chances of moving beyond additional tipping points in the future will be minimised if we reduce greenhouse gas emissions, and we also act to limit other human impacts on the ocean, such as overfishing and nutrient pollution.

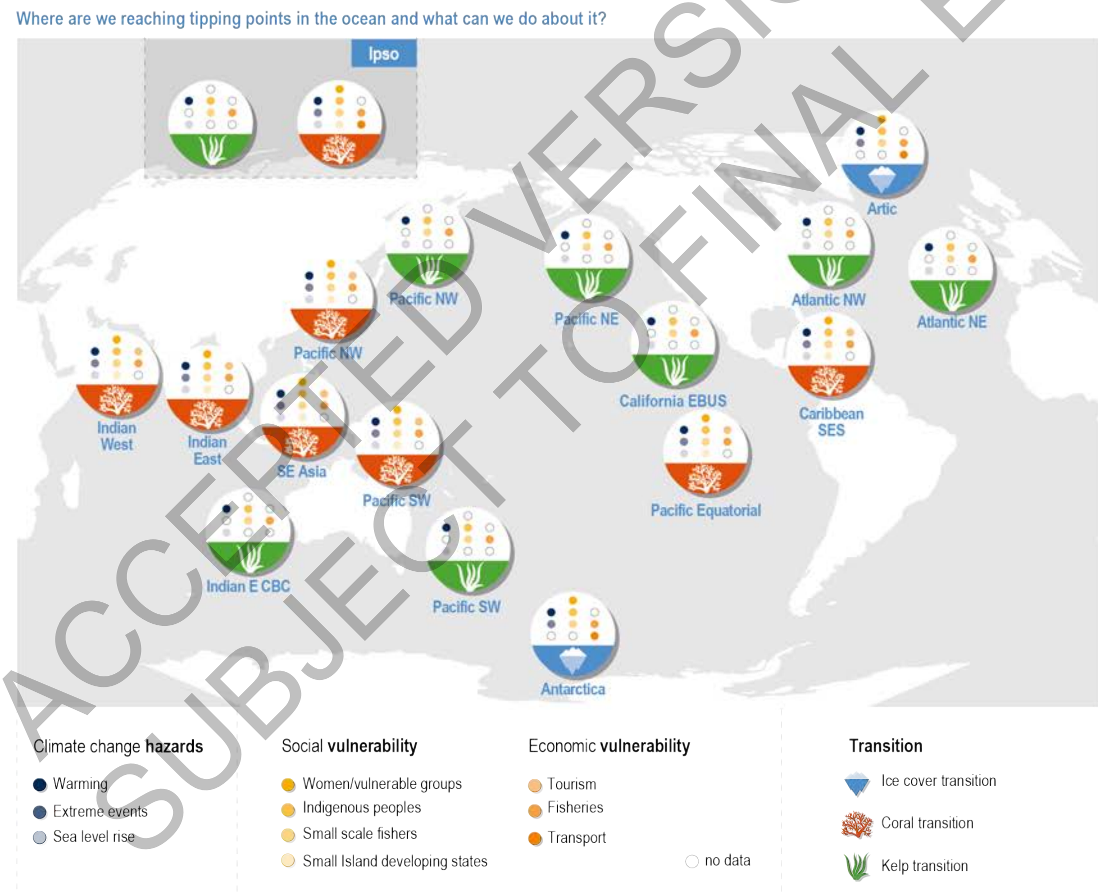

Figure FAQ3.2: Global map with examples of tipping points that have been passed in ocean systems around the world. Tipping points in ecological systems are linked to increasing impacts and vulnerability of dependent human communities. SES: semi-enclosed sea, EBUS: eastern boundary upwelling system, CBC; coastal boundary current.

[START FAQ3.3 HERE]

FAQ3.3: How are marine heatwaves affecting marine life and human communities?

Heatwaves happen in the ocean as well as in the atmosphere. Marine heatwaves (MHWs) are extended periods of unusually warm ocean temperatures, relative to the typical temperatures for that location and time of year. Due to climate change, the number of days with MHWs have increased by 54% over the past century. MHWs cause mortalities in a wide variety of marine species, from corals to kelp to seagrasses to fish to seabirds, and have consequent effects on ecosystems and industries like aquaculture and fisheries.

Extreme events in the ocean can have damaging effects on marine ecosystems and the human communities that depend on them. The most common form of ocean extremes are marine heatwaves (MHWs), extended periods of unusually warm ocean temperatures, which are becoming more frequent and intense due to global warming. Because seawater absorbs and releases heat more slowly than air, temperature extremes in the ocean are not as pronounced as over land, but they can persist for much longer, often for weeks to months over areas covering hundreds of thousands of square kilometres. These MHWs can be more detrimental for marine species, in comparison to land species, because marine species are usually adapted to relatively stable temperatures.

A commonly used definition of MHWs is a period of at least five days whose temperatures are warmer than 90% of the historical records for that location and time of year. MHWs are described by their abruptness, magnitude, duration, intensity, and other metrics. In addition, targeted methods are used to characterize MHWs that threaten particular ecosystems; for example, the accumulated heat stress above typical summer temperatures, described by “degree heating weeks”, is used to estimate the likelihood of coral bleaching.

Over the past century, MHWs have doubled in frequency, become more intense, lasted for longer and extended over larger areas. MHWs have occurred in every ocean region over the past few decades, most markedly in association with regional climate phenomena such as the El Niño/Southern Oscillation. During the 2015–2016 El Niño event, 70% of the world’s ocean surface encountered MHWs.

MHWs cause mortality of a wide variety of marine species, from corals to kelp to seagrasses to fish to seabirds, and they have consequent effects on ecosystems and industries such as mariculture and fisheries. Warm-water coral reefs, estuarine seagrass meadows and cold-temperate kelp forests are among the ecosystems most threatened by MHWs since they are attached to the seafloor (FAQ 3.2). Unusually warm temperatures cause bleaching and associated death of warm-water corals, which can lead to shifts to low-diversity or algae-dominated reefs, changes in fish communities, and deterioration of the physical reef structure, which causes habitat loss and increases the vulnerability of nearby shorelines to large-wave events and sea-level rise. Since the early 1980s, the frequency and severity of mass coral bleaching events have increased sharply worldwide. For example, from 2016 through 2020, the Great Barrier Reef experienced mass coral bleaching three times in five years.

Mass loss of kelp from MHWs effects on the canopy-forming species has occurred across ocean basins, including the coasts of Japan, Canada, Mexico, Australia and New Zealand. In southern Norway and the northeast U.S., mortality from MHWs contributed to the decline of sugar kelp over the last two decades, and to the spread of turf algal ecosystems that prevent recolonisation by the original canopy-forming species.

One of the largest and longest-duration MHWs, nicknamed the 'Blob,' occurred in the Northeast Pacific Ocean, extending from California north towards the Bering Sea, from 2013 through 2015. Warming from the MHW persisted into 2016 off the U.S. West Coast and into 2018 in the deeper waters of a Canadian fjord. The consequent effects of this expansive MHW included widespread shifts in abundance, distribution and nutritional value of invertebrates and fish, a bloom of toxic algae off the US west coast that impacted fisheries, the decline of California kelp forests that contributed to the collapse of the abalone fishery, and mass mortality of seabirds.

The projected increase in the frequency, severity, duration, and areal extent of MHWs threaten many marine species and ecosystems. MHWs may exceed the thermal limits of species, and they may occur too frequently for the species to acclimate or for populations to recover. The majority of the world’s coral reefs are projected to decline and begin eroding due to more frequent bleaching-level MHWs if the world warms by more than 1.5°C. Recent research suggests possible shifts to more heat-tolerant coral communities, but at the expense of species and habitat diversity. Other systems, including kelp forests, are most threatened near the edges of their ranges, although more research is needed into the effect of re-occurring MHWs on kelp forests and other vulnerable systems.

The projected ecological impacts of MHWs threaten local communities' and Indigenous Peoples' cultures, incomes, fisheries, tourism, and, in the case of coral reefs, shoreline protection from waves. High-resolution forecasts and early-warning systems, currently most advanced for coral reefs, can help people and industries prepare for MHWs and also collect data on their effects. Identifying and protecting locations and habitats with reduced exposure to MHWs is a key scientific endeavour. For example, corals may be protected from MHWs in tidally-stirred waters or in reefs where cooler water upwells from subsurface. Marine protected areas and no-take zones, in addition to terrestrial protection surrounding vulnerable coastal ecosystems, cannot prevent MHWs from occurring. But, depending on the location and adherence by people to restrictions on certain activities, the cumulative effect of other stressors on vulnerable ecosystems can be reduced, potentially helping to enhance the rate of recovery of marine life.

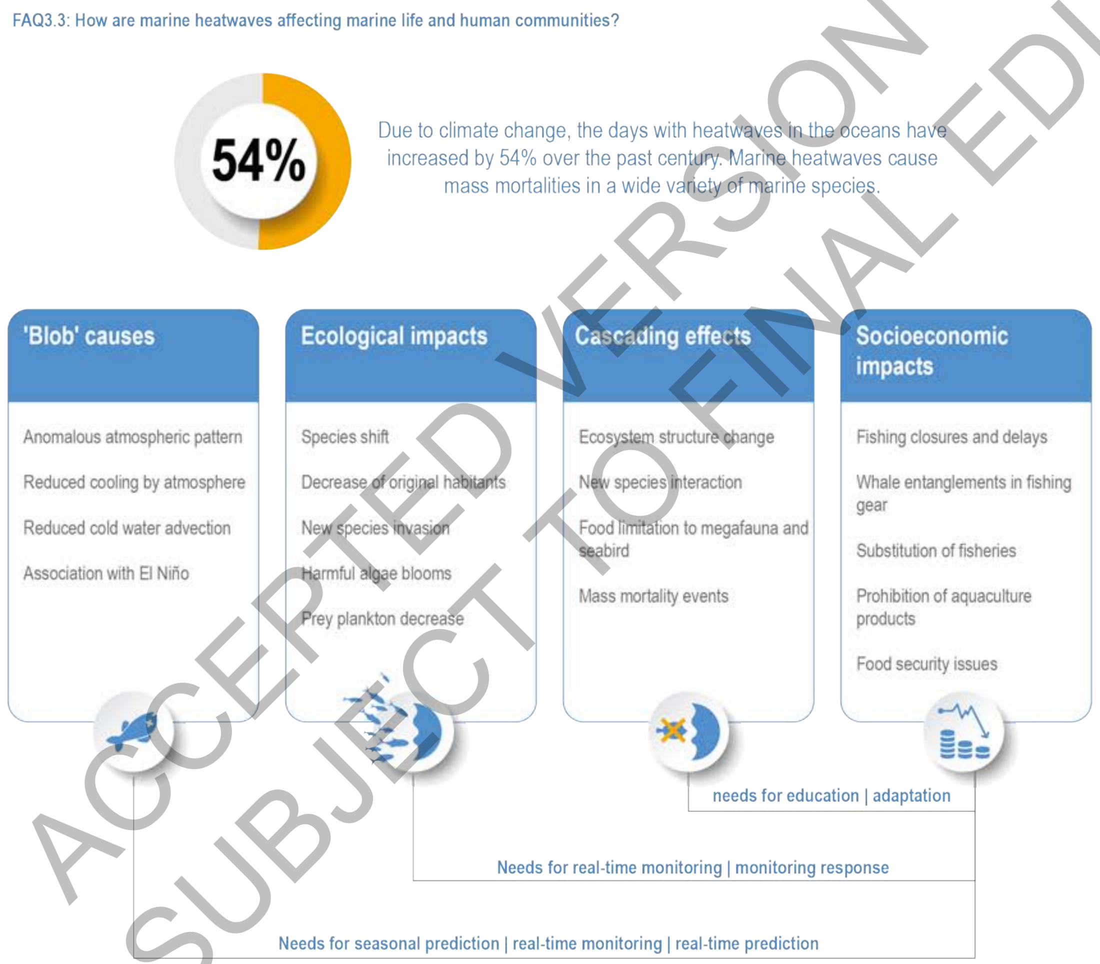

Figure FAQ 3.3: Impact pathway of a massive extreme marine heatwave, the NW Pacific "Blob," from causal mechanisms, to initial effects, resulting non-linear effects, and the consequent impacts for humans. Lessons learnt from the "Blob" include the need to advance seasonal forecasts, real-time predictions, monitoring responses, education, possible fisheries impacts and adaptation.

[START FAQ3.4 HERE]

FAQ3.4: Which industries and jobs are most vulnerable to the impacts of climate change in the oceans?

The global ocean underpins human well-being through the provision of resources that directly and indirectly feed and employ many millions of people. In many regions, climate change is degrading ocean health and altering stocks of marine resources. Together with over-harvesting, climate change is threatening the future of the sustenance provided to Indigenous Peoples, the livelihoods of artisanal fisheries, and marine-based industries including tourism, shipping and transportation.

The ocean is the lifeblood of the planet. In addition to regulating planetary cycles of carbon, water and heat, the ocean and its vast resources support human livelihoods, cultural practices, jobs and industries. The impacts of climate change on the ocean can influence human activities and employment by altering resource availability, spreading pathogens, flooding shorelines and degrading ocean ecosystems. Fishing and mariculture are highly exposed to change. The global ocean and inland waters together provide more than 3.3 billion people at least 20% of the protein they eat and provide livelihoods for 60 million people. Changes in the nutritional quality or abundance of food from the oceans could influence billions of people.

Substantial economic losses for fisheries resulting from recent climate-driven harmful algal blooms and marine pathogen outbreaks have been recorded in Asia, North America and South America. A 2016 event in Chile caused an estimated loss of 800 million USD in the farmed salmon industry and led to regional government protests. The recent closure of the U.S. Dungeness crab and razor clam fishery due to a climate-driven algal bloom harmed 84% of surveyed residents from 16 California coastal communities. Fishers and service industries that support commercial and recreational fishing experienced the most substantial economic losses, and fishers were the least able to recover their losses. This same event also disrupted subsistence and recreational fishing for razor clams, important activities for Indigenous Peoples and local communities in the Pacific Northwest of the U.S.A.

Other goods from the ocean, including non-food products like dietary supplements, food preservatives, pharmaceuticals, biofuels, sponges and cosmetic products, as well as luxury products like jewellery coral, cultured pearls, and aquarium species, will change in abundance or quality due to climate change. For instance, ocean warming is endangering the "candlefish" ooligan (*Thaleichthys pacificus*), whose oil is a traditional food source and medicine of Indigenous Peoples of the Pacific Northwest of North America. Declines in tourism and real estate values have also been recorded in the United States, France, and England associated with climate-driven harmful algal blooms.

Small-scale fisheries livelihoods and jobs are the most vulnerable to climate-driven changes in marine resources and ecosystem services. The abundance and composition of their harvest depend on suitable environmental conditions and on Indigenous knowledge and local knowledge developed over generations. Large-scale fisheries, though still vulnerable, are more able to adapt to climate change due to greater mobility and greater resources for changing technologies. These fisheries are already adapting by broadening catch diversity, increasing their mobility to follow shifting species, and changing gear, technology and strategies. Adaptation in large-scale fisheries, however, is at times constrained by regulations and governance challenges.

Jobs, industries and livelihoods which depend on particular species or are tied to the coast can also be at risk to climate change. Species-dependent livelihoods (e.g., a lobster fishery or oyster farm) are vulnerable due to a lack of substitutes if the fished species are declining, biodiversity is reduced, or mariculture is threatened by climate change or ocean acidification. Coastal activities and industries ranging from fishing (e.g., gleaning on a tidal flat) to tourism to shipping and transportation are also vulnerable to sea-level rise and other climate-change impacts on the coastal environment. The ability of coastal systems to protect the shoreline will decline due to sea-level rise and simultaneous degradation of nearshore systems including coral reefs, kelp forests and coastal wetlands.

The vulnerability of communities to losses in marine ecosystem services varies within and among communities. Tourists seeking to replace lost cultural services can adapt by engaging in the activity elsewhere. But communities who depend on tourism for income or who have strong cultural identity linked to the ocean have a more difficult time. Furthermore, climate-change impacts exacerbate existing inequalities already experienced by some communities, including Indigenous Peoples, Pacific Island countries and territories, and marginalized peoples, like migrants and women in fisheries and mariculture. These inequities increase the risk to their fundamental human rights by disrupting livelihoods and food security, while leading to loss of social, economic, and cultural rights. These maladaptive outcomes can be avoided by securing tenure and access rights to resources and territories for all people depending on the ocean, and by supporting decision-making processes that are just, participatory and equitable.

A key adaptation solution is improving access to credit and insurance in order to buffer against variability in resource access and abundance. Further actions that decrease social and institutional vulnerability are also important, such as inclusive decision-making processes, access to resources and land to Indigenous Peoples, and participatory approaches in management. For the fishing industry, international fisheries agreements and investing in sustainable mariculture and fisheries reforms is often recommended. Immediate adaptations to other challenges, such as harmful algal blooms, frequently include fishing-area closures. These can be informed by early-warning forecasts, public communications, and education. These types of adaptations are more effective when built on trusted relationships and effective coordination among involved parties, and are inclusive of the diversity of actors in a coastal community.

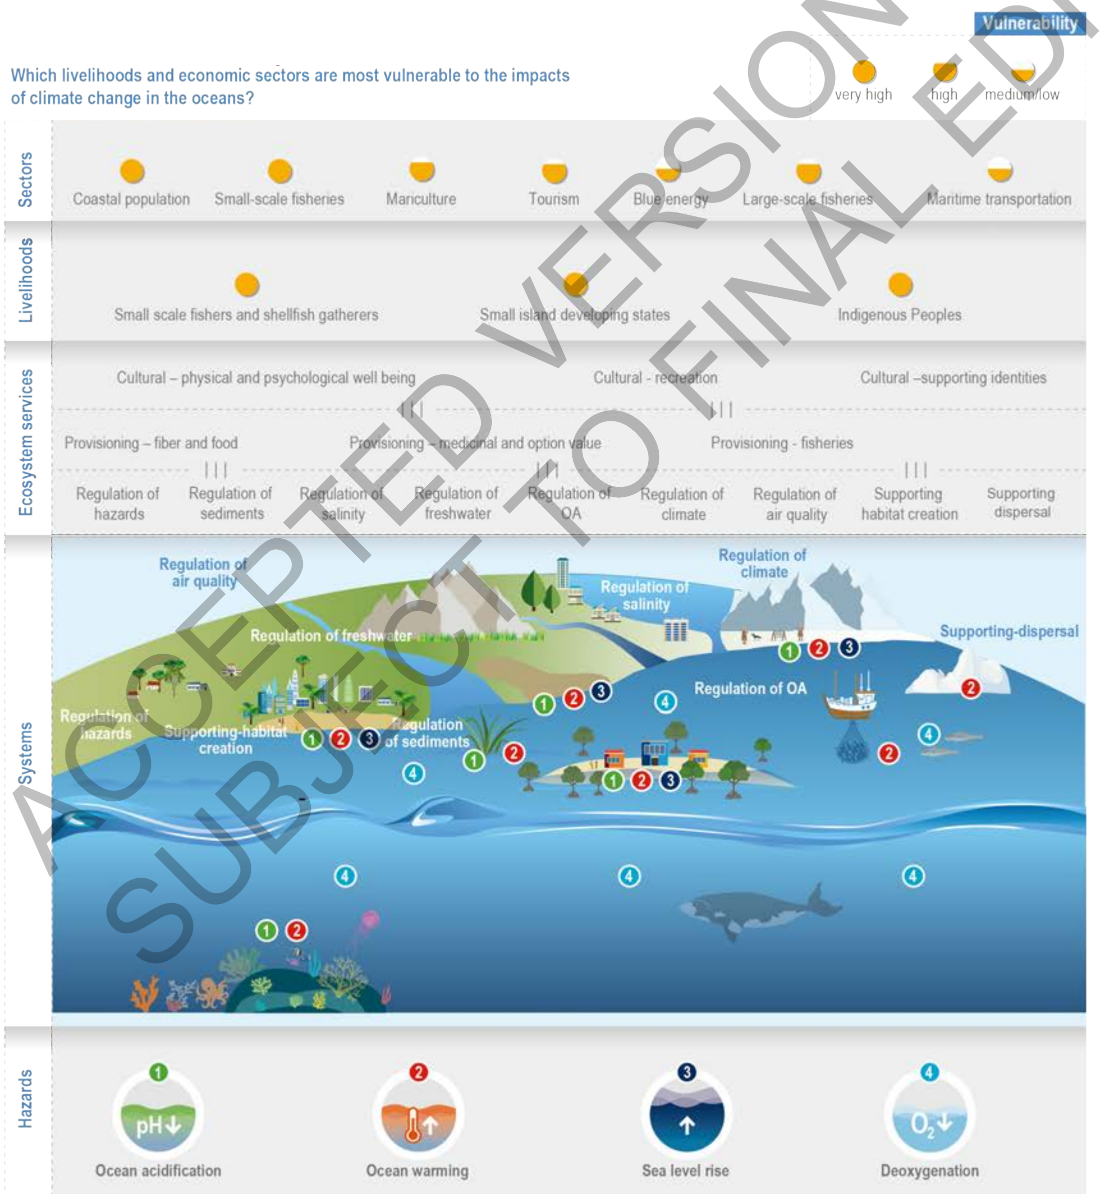

Figure FAQ3.4: Illustration that identifies vulnerable groups and stresses the hazards or impacts over coastal and ocean systems.

[END FAQ3.4 HERE]

[START FAQ3.5 HERE]

FAQ3.5: How can nature-based solutions, including marine protected areas, help us to adapt to climate driven changes in the oceans?

Coastal habitats like mangroves or vegetated dunes protect coastal communities from sea-level rise and storm surges, while supporting fisheries, sequestering carbon and providing other ecosystem services as well. Efforts to restore, conserve and/or recover these natural habitats help people confront the impacts of climate change. These marine nature-based solutions like marine protected areas, habitat restoration and sustainable fisheries are cost-effective and provide myriad benefits to society.

In the oceans, nature-based solutions comprise attempts to recover, restore or conserve coastal and marine habitats to reduce the impacts of climate change on nature and society. Marine habitats such as seagrasses and coral reefs provide services like food and flood regulation, in the same way as forests do so on land. Coastal habitats like mangroves or vegetated dunes protect coastal communities from sea-level rise and storm surges, while supporting fisheries, recreational and aesthetic services as well. Seagrasses, coral reefs and kelp forests also provide important benefits that help humans adapt to climate change, including sustainable fishing, recreation and shoreline protection services. By recognizing these services and benefits of the ocean, nature-based solutions can improve the quality and integrity of the marine ecosystems.

Nature-based solutions offer a wide range of potential benefits, including protecting ecosystem services, supporting biodiversity and mitigating climate change. Coastal and marine examples include marine protected areas, habitat restoration, habitat development and maintaining sustainable fisheries. While local communities with limited resources might find nature-based solutions challenging to implement, they are generally “no-regret” options, which bring societal and ecological benefits regardless of the level of climate change.

Carefully designed and placed marine protected areas, especially when they exclude fishing, can increase resilience to climate change by removing additional stressors on ecosystems. While marine protected areas do not prevent extreme events like marine heatwaves (FAQ3.3), they can provide marine plants and animals with a better chance to adapt to a changing climate. Current marine protected areas, however, are often too small, too poorly connected and too static to account for climate-induced shifts in the range of marine species. Marine protected area networks that are large, are connected, have adaptable boundaries, and are designed following systematic analysis of future climate projections can better support climate resilience.

Habitat restoration and development in coastal systems can support biodiversity, protect communities from flooding and erosion, support the local economy, and enhance the livelihoods and wellbeing of coastal peoples. Restoration of mangroves, saltmarshes and seagrass meadows provide effective ways to remove carbon dioxide from the atmosphere and at the same time to protect coasts from the impacts of storms and sea-level rise. Active restoration techniques that target heat-resistant individuals or species are increasingly recommended for coral reefs and kelp forests, which are highly vulnerable to marine heatwaves and climate change.

Sustainable fishing is also seen as a nature-based solution because managing marine commercial species within sustainable limits maximizes the catch and food production, thus contributing to the UN’s Sustainable Development Goal 2 – Zero Hunger. Currently, the oceans provide 17% of the animal protein eaten by the global population, but the contribution could be larger if fisheries were managed sustainably. Aquaculture, such as oyster farming, can be efficient and sustainable means of food production and also provide additional benefits like shoreline protection. Through nature-based solutions that conserve and restore marine habitats and species, we can sustain marine biodiversity, respond to climate change, and provide benefits to society.

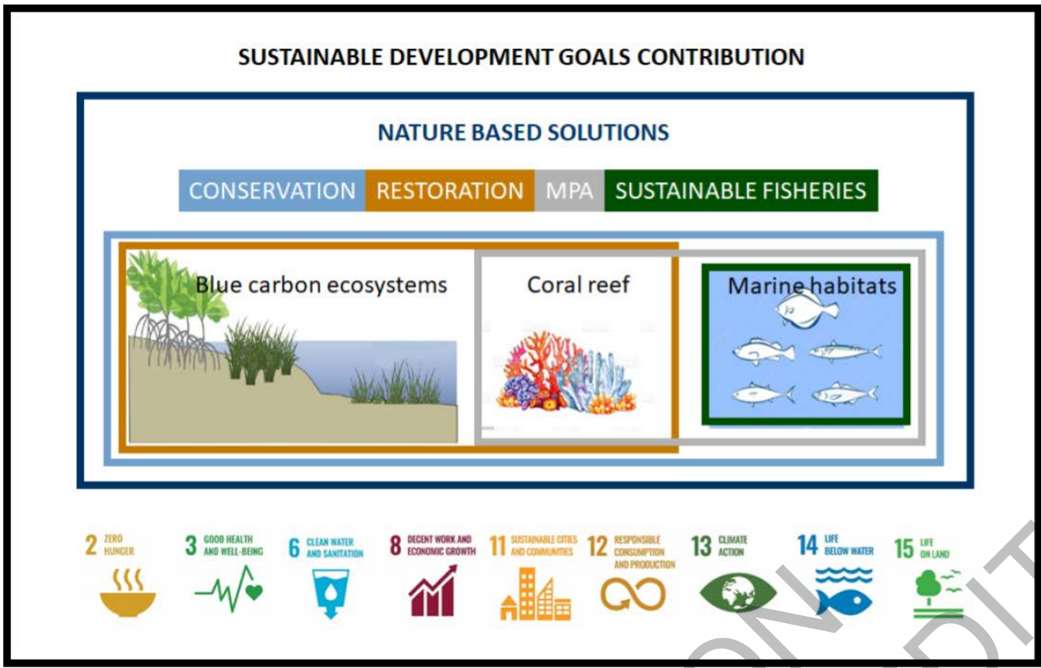

Figure FAQ3.5: Contributions of nature-based solutions in the oceans to the Sustainable Development Goals. The icons in the bottom show the Sustainable Development Goals to which nature-based solutions in the ocean possibly contribute. [Placeholder figure -- authoritative version on FMS]

Executive Summary

This chapter assesses observed and projected climate-induced changes in the water cycle, their current impacts and future risks on human and natural systems and the benefits and effectiveness of water-related adaptation efforts now and in the future.

Currently, ~4 billion out of 7.8 billion people are estimated to experience severe water scarcity for at least one month per year due to climatic and non-climatic factors *(medium confidence*[1]*)*. Since the 1970s, 44% of all disaster events have been flood-related. Not surprisingly, a large share of adaptation interventions (~60%) is forged in response to water-related hazards *(high confidence).* {4.1, Box 4.1, 4.2.1.1, 4.2.1.2, 4.2.2, 4.2.4, 4.2.5, 4.2.6, 4.3.8, 4.6, 4.7}

Intensification of the hydrological cycle due to human-induced climate change is affecting physical aspects of water security *(high confidence),* thereby exacerbating existing water-related vulnerabilities caused by other socioeconomic factors. {4.2, 4.2.1.1, 4.2.1.2, 4.2.1.3, 4.2.2, 4.2.4, 4.2.5, 4.2.6, 4.3}

Nearly half a billion people live in unfamiliarly wet areas, where the long-term average precipitation is as high as previously seen in only about one in six years *(medium confidence)*. Approximately 163 million people live in unfamiliarly dry areas now *(medium confidence).* {4.2.1.1}

The intensity of heavy precipitation has increased in many regions since the 1950s *(high confidence).* Substantially more people (~709 million) live in regions where annual maximum one-day precipitation has increased than regions where it has decreased (~86 million) *(medium confidence)*. At the same time, more people (~700 million) are also experiencing longer dry spells than shorter dry spells since the 1950s *(medium confidence).* {4.2.1.1}

During the last two decades, the global glacier mass loss rate exceeded 0.5 meters water equivalent year^{-1} (*high confidence*), impacting humans and ecosystems, including cultural uses of water among vulnerable high mountain and polar communities *(high confidence).* {4.2.2, 4.3.8}

There is a clear trend of increases in streamflow in the northern higher latitudes *(high confidence),* with climatic factors being more important than direct human influence in a larger share of major global basins *(medium confidence)*. At the same time, groundwater in aquifers across the tropics has experienced enhanced episodic recharge from intense precipitation and flooding events *(medium confidence)*, with implications for sectoral water use. {4.2.3, 4.2.6, 4.3.1, 4.3.4}

Extreme weather events causing highly impactful floods and droughts have become more likely and (or) more severe due to anthropogenic climate change *(high confidence).* {4.2.4, 4.2.5, Cross-Chapter Box DISASTER in Chapter 4}

Anthropogenic climate change has contributed to the increased likelihood and severity of the impact of droughts (especially agricultural and hydrological droughts) in many regions *(high confidence).* Between 1970 to 2019, 7% of all disaster events worldwide were drought-related. Yet, they contributed to 34% of disaster-related deaths, mostly in Africa. {4.2.5, 4.3.1, 4.3.2, Cross-Chapter Box DISASTER in Chapter 4}

Several recent heavy rainfall events, such as in western Europe, China, Japan, the United States, Peru, Brazil and Australia that led to substantial flooding, were made more likely by anthropogenic climate change *(high confidence)*. There is *high confidence* that the warming in the last 40-60 years has led to ~10 days earlier spring floods per decade. Between 1970 to 2019, 31% of all economic losses were flood-related. {4.2.4, Cross-Chapter Box DISASTER in Chapter 4}

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

There is increasing evidence of observed changes in hydrological cycle on people and ecosystems. A significant share of those impacts is negative and felt disproportionately by already vulnerable communities *(high confidence).* {4.3.1, 4.3.2, 4.3.3, 4.3.4, 4.3.5,4.3.6, 4.3.8}

Agriculture and energy production have been impacted by changes in the hydrological cycle *(high confidence)*. Between 1983 and 2009, approximately three-quarters of the global harvested areas (~454 million hectares) experienced yield losses induced by meteorological drought, with the cumulative production losses corresponding to the US $166 billion. There is *medium confidence* that current global thermoelectric and hydropower production has been negatively affected due to droughts with ~4 to 5% reduction in plant utilization rates during drought years compared to long-term average values since the 1980s. {4.3.1, 4.3.2}

Climate change and changes in land use and water pollution are key drivers of loss and degradation of freshwater ecosystems *(high confidence),* with impacts observed on culturally significant terrestrial and freshwater species and ecosystems in the Arctic, high mountain areas *(high confidence)*. In addition, precipitation and extreme weather events are linked to increased incidence and outbreaks of water-related diseases *(high confidence).* {4.3.3, 4.3.4, 4.3.5, 4.3.8}

Changes in water-related hazards disproportionately impact vulnerable populations such as the poor, women, children, Indigenous Peoples, and the elderly in all locations, especially in the Global South, due to systemic inequities stemming from historical, socioeconomic and political marginalization *(medium confidence).* {4.3.1, 4.3.3, 4.3.4, 4.3.8}

Water-related risks are projected to increase with every degree of global warming *(high confidence)*, and more vulnerable and exposed regions and peoples are projected to face greater risks *(medium confidence).* {Box 4.1, 4.4.1, 4.4.1.1, 4.4.4, 4.5.4, 4.5.5, 4.5.6, Box 4.2}

Climate change impacts via water availability changes are projected to increase with every degree of global warming *(high confidence)*, but there are high regional uncertainties. Between 3 to 4 billion people are projected to be exposed to physical water scarcity at 2°C and 4°C global warming levels (GWL), respectively *(medium confidence).* {Box.4.1; 4.4.1, 4.4.3, 4.4.5, 4.6.1}

By 2100, 1/3rd of the 56 large-scale glacierized catchments are projected to experience a mean annual run-off decline by over 10%, with the most significant reductions in Central Asia and Andes (*medium confidence)*. Expected impacts may be felt by roughly 1.5 billion people who are projected to critically depend on run-off from the mountains by the mid-21st century (RCP6.0 scenario). {4.4.2, 4.4.3, 4.5.8}

By 2050, environmentally critical streamflow is projected to be affected in 42% to 79% of the world's watersheds, causing negative impacts on freshwater ecosystems *(medium confidence)*. Modified streamflow is also projected to affect inflows to urban storage reservoirs and increase the vulnerability of urban water services to hydro-meteorological extremes, particularly in less developed countries *(high confidence)*. {4.4.6, 4.5.4, 4.4.5}

Future water-related impacts of climate change on various sectors of the economy are projected to lower global Gross Domestic Product (GDP) (ranging from 0.49% of GDP by mid-century (SSP3) to less than 0.1% (RCP8.5, SSP5), with higher projected losses expected in low-and middle-income countries *(medium confidence).* {4.7.5}

Drought and flood risks and societal damages are projected to increase with every degree of global warming *(medium confidence).* {4.4.4, 4.4.5, 4.4.7, 4.5.1, 4.5.2}

Drought risks are projected to increase over the 21st century in many regions *(very high confidence)*, increasing economy-wide risks *(high confidence)*. With RCP6.0 and SSP2, the global population exposed to extreme-to-exceptional total water storage drought is projected to increase from 3% to 8% over the 21st century *(medium confidence).* {4.4.5}

The projected increase in precipitation intensity *(high confidence)* will increase rain-generated local flooding *(medium confidence)*. Direct flood damages are projected to increase by 4 to 5 times at 4°C compared to 1.5°C *(medium confidence).* {Box 4.1, 4.4.1, 4.4.1.1, 4.4.4, 4.5.4, 4.5.5}

At 4°C global warming by the end of the century, approximately 10 % of the global land area is projected to face simultaneously increasing high extreme streamflow and decreasing low extreme streamflow, affecting roughly over 2.1 billion people *(medium confidence). {4.4.3}.* The increase in extreme events is projected to compromise the efficacy of WaSH services and slow progress towards reductions in WaSH-related disease burdens *(medium confidence).* {4.5.3}

Limiting global warming to 1.5°C would reduce water-related risks across regions and sectors *(high confidence). {*4.4.2, 4.4.5, 4.5.2, 4.5.3, 4.5.4, 4.5.6, 4.5.7, 4.6.1, 4.7.2}

Projected increases in hydrological extremes pose increasing risks, with a potential doubling of flood risk between 1.5°C and 3°C of warming and an estimated 120% to 400% increase in population at risk of river flooding at 2°C and 4°C, respectively. Projected losses include a 1.2 to 1.8-fold increase in GDP loss due to flooding between 1.5°C and 2°C warming *(medium confidence).* {4.4.3, 4.4.4, 4.4.5, 4.5.6, 4.6.1, 4.7.2}

Over large areas of northern South America, the Mediterranean, western China and high latitudes in North America and Eurasia, extreme agricultural drought are projected to be at least twice as likely at 1.5°C global warming, 150 to 200% more likely at 2°C warming, and over 200% at 4°C *(medium confidence)*. Due to the combined effects of water and temperature changes, risks to agricultural yields could be three times higher at 3°C compared to 2°C *(medium confidence).* {4.5.1, 4.6.1}

In Mediterranean parts of Europe, hydropower potential reductions of up to 40% are projected under 3°C warming, while declines below 10% and 5% are projected under 2°C and 1.5°C warming levels, respectively.

Climate-induced hydrological changes are projected to increase migration in the last half of the century, with an almost 7-fold increase in asylum seekers to the EU for RP4.5 compared to RCP2.6. The number of internally displaced people in Sub-Saharan Africa, South Asia and Latin America increased almost 5 times for RCP 8.5 compared to RCP2.6 (*low confidence).* {4.5.7}

Observed water adaptation responses have multiple benefits *(high confidence)*, yet evidence of effectiveness of adaptation in reducing climate risks is not clear due to methodological challenges *(medium confidence)*. {4.6, 4.7.1, 4.7.3}

A large share of adaptation interventions (~60%) are shaped in response to water-related hazards *(high confidence)* and involve water interventions (irrigation, rainwater harvesting, soil moisture conservation). Adaptation responses in developing countries tend to be autonomous, incremental and focused on managing water-related risks in agriculture. In contrast, responses are more policy-oriented and urban-focused in developed countries *(high confidence).* {4.6.2, box 4.3, 4.6.5, 4.7.1, 4.7.2}

Irrigation helps stabilise and increase crop yields and is often a preferred strategy for farmers and policymakers for risk reduction, but irrigation is also associated with a range of adverse outcomes, including groundwater over-extraction (*medium confidence*). In addition, large-scale irrigation also affects local to regional climates, both in terms of temperature and precipitation change (*high confidence*) {4.2.6, 4.6.2, Box. 4.2}.

Water adaptation measures tend to have positive economic and environmental outcomes in developing and developed countries, respectively *(high confidence).* Roughly 1/3rd and 1/4th of case studies on water adaptation also documents maladaptation and co-benefits, respectively *(high confidence).* A significant knowledge gap remains in knowing if observed adaptation benefits also translate to climate risk reduction, if so, by how much and under what conditions *(medium confidence).* {4.7.1, 4.7.2, 4.7.4}

Future projected adaptations are effective in reducing risks to a varying extent *(medium confidence)*, but effectiveness falls sharply beyond 2°C, underscoring the need for limiting warming to 1.5°C *(high confidence).* {4.6, 4.7.2, 4.7.3}

Adaptations that are beneficial now (e.g., crop and water-related ones) are also projected to effectively reduce specific future risks to a moderate to a large extent *(medium confidence)*. However, residual impacts remain for some options and regions at all levels of warming, and the overall effectiveness decreases at higher warming levels *(high confidence)*, further underscoring the need for limiting warming to 1.5°C. {Box 4.2, 4.7.1, 4.7.2, 4.7.3, 4.7.4}

At warming levels beyond 1.5°C, the potential to reach biophysical limits to adaptation due to limited water resources are reported for Small Islands (*medium confidence*) and regions dependent on glaciers and snowmelt (*medium confidence*). {4.7.4}

Water security is critical for meeting Sustainable Development Goals (SDGs) and systems transitions needed for climate-resilient development, yet many mitigation measures have high water footprint which can compromise SDGs and adaptation outcomes *(high confidence)*. {4.1, Box 4.4, 4.6, 4.6.2, 4.6.3, 4.7, 4.7.1, 4.7.4, 4.7.5.7}

Water features prominently in Nationally Determined Contributions (NDCs) and National Adaptation Plans of most countries. SDGs cannot be met without adequate and safe water *(high confidence),* and water is fundamental to all systems transition *(high confidence)*. {4.1, 4.7, 4.7.1, 4.8, 4.8.7}

Water garners a significant share of public and private adaptation funds *(high confidence)*. However, barriers remain for low-income countries to access funds *(medium confidence)*, and there is insufficient evidence on benefits for marginalized groups *(medium confidence). {4.8.2}*

Many mitigation measures, such as carbon capture and storage, bio-energy, and afforestation and reforestation, can have a high-water footprint (*high confidence*). The water intensity of mitigation must be managed in socially and politically acceptable ways to increase synergies with SDGs, improve water security, and reduce trade-offs with adaptation *(medium confidence)*. {4.7.6}

A common set of enabling principles underpinned by strong political support can help meet the triple goals of water security, sustainable and climate-resilient development *(high confidence*) *{4.8, 4.8.3, 4.8.4. 4.8.5, 4.8.6, 4.8.7*

Many countries and social groups most threatened by climate change have contributed the least to the problem and do not have the adequate resources to adapt *(high confidence)*. Water adaptation policies enabled through ethical co-production between holders of Indigenous Knowledge, local knowledge and technical knowledge *(medium confidence)*; through cooperation and coordinated actions among multiple actors, including women and all marginalized groups, at various levels of governance *(medium confidence)* is needed for effective transitions towards Climate Resilient Development. {4.8, 4.8.3,4.8.4, 4.8.5, 4.8.6}

4.1 Centrality of Water Security in Climate Change and Climate Resilient Development

Water security is defined as "*the capacity of a population to safeguard sustainable access to adequate quantities of acceptable quality water for sustaining livelihoods, human well-being, and socio-economic development, for ensuring protection against water-borne pollution and water-related disasters, and for preserving ecosystems in a climate of peace and political stability*" (Grey and Sadoff (2007)). Risks emanating from various aspects of water insecurity have emerged as a significant global challenge. The Global Risks Report by the World Economic Forum lists water crisis as one of the top five risks in all its reports since 2015 (WEF, 2015; WEF, 2016; WEF, 2017; WEF, 2018; WEF, 2019; WEF, 2020). Water also features prominently in the Sustainable Development Goals (SDGs) (4.8) and plays a central role in various systems transitions needed for climate-resilient development. Most SDGs cannot be met without access to adequate and safe water (Ait-Kadi, 2016; Mugagga, 2016}. In addition, without adequate adaptation, future water-related impacts of climate change on various sectors of the economy are projected to lower global gross domestic product (GDP) by mid-century, with higher projected losses expected in low-and middle-income countries (World Bank, 2017; GCA, 2019).

There are at least four reasons for the centrality of water security in adapting to, and mitigating climate change.

First, approximately half the world's population (~4 billion out of 7.8 billion people) are assessed as being currently subject to severe water scarcity for at least one month per year (*medium confidence*) due to climatic and non-climate factors (Box 4.1). Water insecurity arises from many factors, both environmental and societal. Environmental factors include too little freshwater due to drought or pollution, and too much water, due to extreme precipitation and flooding, and are being affected by climate change. Societal factors include economic and governance-related barriers to water access or protection from water-related damages. Currently, many people are experiencing climate change on a day to day basis through water-related impacts such as the increased frequency and intensity of heavy precipitation (*high confidence*) (4.2.1.1, WGI 11.4.2); accelerated melting of glaciers (*high confidence*) (4.2.2, WGI 8.3.1); changes in frequency, magnitude and timing of floods (*high confidence*) (4.2.4, WGI 11.5.2); more frequent and severe droughts in some places (*high confidence*) (4.2.5, WGI 11.6.2); decline in groundwater storage and reduction in recharge (*medium confidence*) (4.2.6, WGI 8.3.1) and water quality deterioration due to extreme events (*medium confidence*) (4.2.7). For example, since the 1970s, 44% of all disaster events have been flood-related (WMO, 2020). With the added stressor of climate change, globally, a larger fraction of land and population are projected to face increased water scarcity due to climate change. For example, at approximately 2°C global warming level (GWL), between 0.9 and 3.9 billion people are projected to be at increased exposure to water stress, depending on regional patterns of climate change and the socio-economic scenarios considered (Koutroulis et al., 2019).

Second, while climate change directly affects freshwater availability across space and time, it also affects water requirements for different uses, such as irrigation, potentially adding to existing societal challenges (Bijl et al., 2018). Vulnerability to water-related impacts of climate change and extreme weather are already felt in all major sectors and are projected to intensify in the future, e.g., in agriculture (*high confidence*) (4.3.1, 4.5.1); energy and industry (*high confidence* for observed drought impacts and projected impacts) (4.3.2, 4.5.2); water for health and sanitation (*high confidence* about links to precipitation extremes and disease outbreaks) (4.3.3, 4.5.3); water for urban, peri-urban and municipal sectors (*medium confidence*) (4.3.4, 4.5.4) and freshwater ecosystems (*high confidence* in climate change as a driver in degradation of freshwater ecosystems) (4.3.5, 4.5.5). Agriculture and irrigation account for the most significant proportion of consumptive water use and accounts for 60-70% of total water withdrawals (Hanasaki et al., 2018; Burke et al., 2020; Müller Schmied et al., 2021). Globally, 10% of the most water-stressed basins account for 35% of global irrigated calorie production (Qin et al., 2019), and food production is at risk in those basins, and worldwide due to changes in hydrological components of climate change. Lack of access to clean water and sanitation has been one of the leading causes of water-borne diseases. In 2017, approximately 2.2 billion people lacked access to safe drinking water, and roughly 4.2 billion people could not access safe sanitation (WHO and UNICEF, 2019). Inequities in access to safe water are being amplified during the current COVID-19 pandemic (Box 4. 5 and Cross-Chapter Box COVID in Chapter 7). The same 10% of most water-stressed basins also account for 19% of global thermal electricity generation (Qin et al., 2019), and globally, both production of hydropower and thermal power has been negatively affected by droughts and other extreme events. Globally, between 16% and 39% of cities experienced surface-water deficits between 1971-2000. If environmental flow requirements (EFRs) are accounted for, these numbers increase to 36% and 63%, respectively. Even under a scenario where urban water gets the highest priority, more than 440.5 million people in cities globally are projected to face a water deficit by 2050 (Flörke et al., 2018). The situation is particularly precarious in the Global South, where most of the population lacks access to piped water (WRI, 2019).

Third, a large majority (~60%) of all adaptation responses documented since 2014 are about adapting to water-related hazards like droughts, floods and rainfall variability (Berrang-Ford et al., 2021b) (*high confidence*). Water-related adaptation action features prominently in nationally determined contributions (NDC) pledges by a large majority of countries in both Global North and Global South (GWP, 2018). These adaptation responses and their current benefits and effectiveness in reducing water-related risks in the future are systematically assessed in this chapter (4.6, 4.7.1, 4.7.2 and 4.7.3). These adaptation measures aim to reduce impacts of water-related hazards through responses such as irrigation, water and soil moisture conservation, rainwater harvesting, changes in crops and cultivars, improved agronomic practices, among others (4.6.2; 4.7.1). Only ~20% of all documented case studies on observed water-related adaptations measure outcomes (positive or negative), but the link between positive outcomes and climate risk reduction is unclear and remains challenging to assess (4.7.1) (*medium confidence*). On the other hand, most of the future projected water-related adaptations are effective at lower global warming levels (GWLs) (1.5°C) than at higher GWLs showing the importance of mitigation for future adaptations to remain effective (*high confidence*).

Finally, while limiting global warming to 1.5°C would minimize the increase in risks in the various water use sectors and keep adaptation effective, many mitigation measures can potentially impact future water security. For example, bioenergy with carbon capture and storage (BECCS) and afforestation and reforestation can have a considerable water footprint if done at inappropriate locations (4.7.6, see also Canadell et al. (2021)). Therefore, minimizing the risks to water security from climate change will require a full-systems view that considers the direct impacts of mitigation measures on water resources and their indirect effect via limiting climate change (*high confidence*).

This chapter draws on previous IPCC reports and new methodologies (4.1.1 and SM4.1, SM4.2) and assesses the impacts of climate change on natural and human dimensions of the water cycle with a particular focus on water-related vulnerabilities and adaptation responses (Figure 4.1). Section 4.2 assesses observed changes in the hydrological cycle, and Section 4.3 focuses on their societal impacts and detects which parts of these changes are directly attributable to climate change. Section 4.4 assesses projected risks of changes in the hydrological cycle on various components of the hydrological cycle, and Section 4.5 assesses the same for sectoral risks. Projections and risks assessments for future impacts are framed in terms of GWLs and time horizons, as these are useful for informing mitigation policy under the Paris Agreement and informing adaptation planning. Sections 4.6 and 4.7 assesses current and future water-related adaptation responses in reducing climate and associated impacts and risks and looks at limits to adaptations, especially in a future warmer world. Finally, Section 4.8 outlines the enabling principles for meeting water security, sustainable development goals and climate-resilient development.

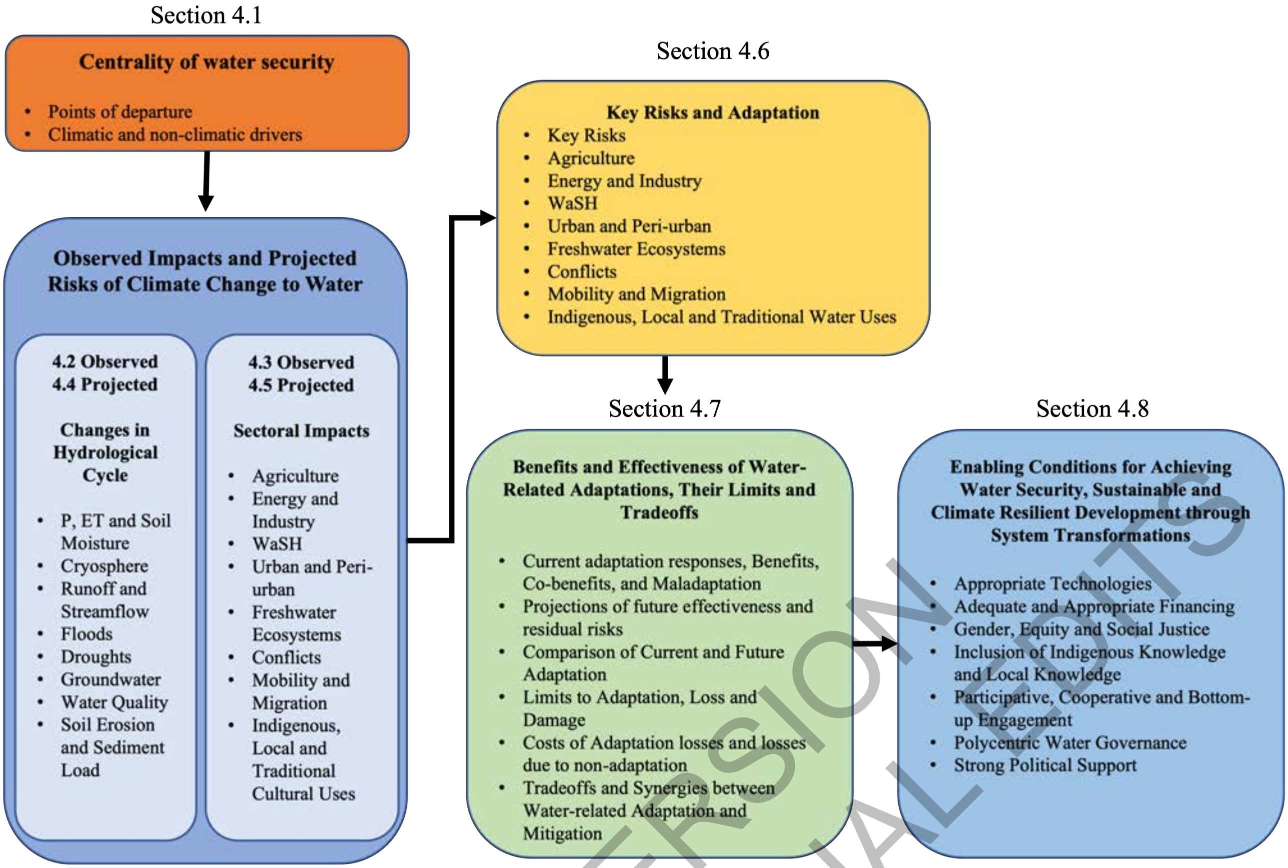

Figure 4.1: Chapter structure.

[START BOX 4.1 HERE]

Box 4.1: Implications of Climate Change for Water Scarcity and Water Insecurity

Water scarcity and water insecurity are related concepts but not identical, and each has a range of interpretations leading to some overlap. Water scarcity can be broadly described as a mismatch between the demand for fresh water and its availability, quantified in physical terms. Water security/insecurity is a broader concept with definitions beyond physical water scarcity, encompassing access to water services, safety from poor water quality and flooding, and appropriate water governance that ensures access to safe water (Sadoff et al., 2020). Metrics of water security include both physical and socio-economic components and are a tool for comparison between different locations and countries regarding relative levels of water security in the context of water-related risks. Some definitions of water scarcity also incorporate these broader issues. For example, 'economic water scarcity' has been defined as a situation where "human, institutional, and financial capital limit access to water, even though water in nature is available locally to meet human demands" (Comprehensive Assessment of Water Management in Agriculture, 2007). Economic water scarcity can also occur where infrastructure exists, but water distribution is inequitable (Jaeger et al., 2017). Much of the literature exploring the impacts of climate change on water security, however, focuses on quantifying physical water scarcity. Discussions in this box consider physical water scarcity as a quantifiable measure of water availability compared to its demand and consider the societal elements of economic water scarcity to be part of the more comprehensive concept of water insecurity.

Physical water scarcity

Definitions of water scarcity have evolved to take account of a broader set of factors. For example, physical water scarcity indicates that an insufficient quantity of water is available to meet requirements. A commonly-used measure of physical water scarcity is the Falkenmark index which measures the amount of renewable freshwater available per capita (Falkenmark et al., 1989; White et al., 2014). However, the Falkenmark index is now regarded as an incomplete measure, as it does not account for water needed for non-human needs (as quantified with Environmental Flow Requirements, EFRs). Therefore, EFRs have begun to be incorporated in recent water scarcity assessments (Liu et al., 2016; Liu et al., 2017b). Quality-induced water scarcity is an additional factor beginning to be considered (Liu J. and D., 2020).

Using a Water Scarcity Index (WSI) defined as the ratio of demand and availability, accounting for EFRs, it is estimated that 4 billion people live under conditions of severe water scarcity for at least one month per year (Figure Box 4.1.1(a): (Mekonnen and Hoekstra, 2016)). Nearly half of these people live in India and China. Although regions with high water scarcity are already naturally dry (*virtually certain*[2]), human influence on climate is leading to reduced water availability in many regions. It is *very likely* that global patterns of soil moisture change are being driven by human influence on climate, and an overall global decline in soil moisture is attributable to greenhouse forcing [4.2.1.3]. Climate-change patterns of streamflow change include declines in western North America, north-east South America, the Mediterranean and South Asia (*medium confidence*) [4.2.3]. However, quantification of the contribution of anthropogenic climate change to current levels of water scarcity is not yet available.

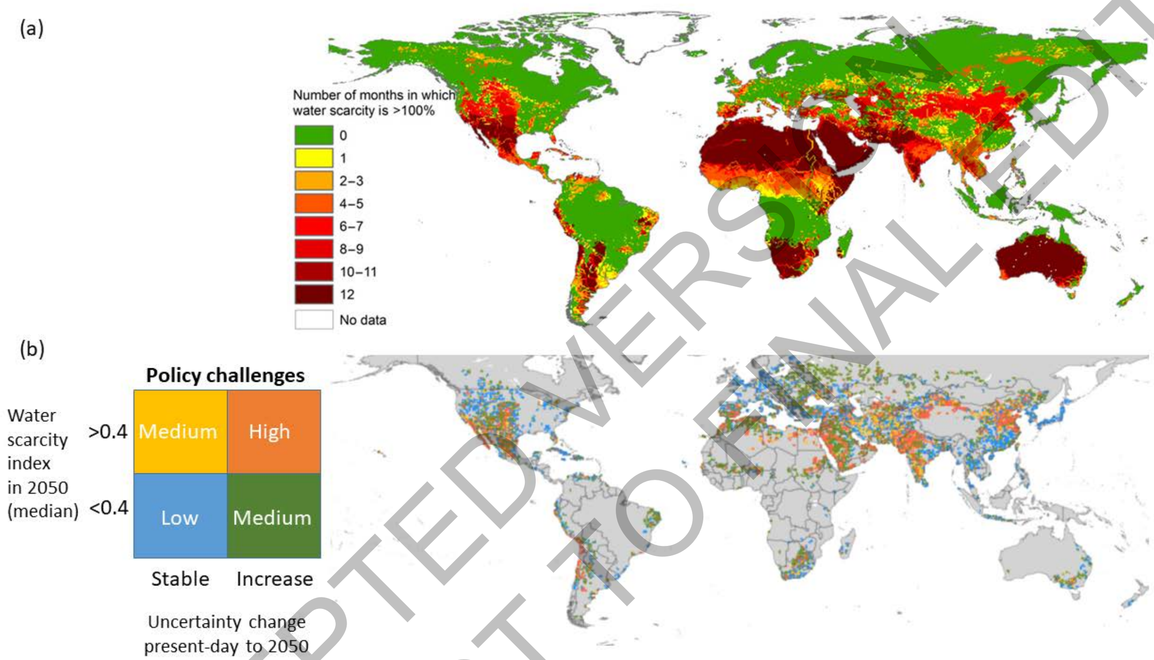

Figure Box 4.1.1: Geographical distributions of current water scarcity and levels of challenge for policies addressing future change. (a) The number of months per year with severe water scarcity (ratio of water demand to availability > 1.0). Reproduced from (Mekonnen and Hoekstra, 2016). (b) Local levels of policy challenges for addressing water scarcity by 2050, considering both the central estimate (median) and the change uncertainty in projections of a Water Scarcity Index (WSI) from the present day to 2050 (Greve et al., 2018). Projections used five CMIP5 climate models, three global hydrological models from ISIMIP, and three Shared Socioeconomic Pathways (SSPs). Levels of policy challenges refer to the scale and nature of policies to address water scarcity and range from monitoring and reviewing risks ('low') through transitional changes in water systems ('medium') to transformational changes ('high'). Low policy challenges arise when the projected water scarcity in 2050 is lower (< 0.4), and the level of uncertainty remains relatively stable in future projections. Medium policy challenge arises when either the central estimate of water scarcity remains low, but uncertainty increases or the uncertainty is stable, but the central estimate of water scarcity for 2050 is higher (>0.4). High policy challenges arise when the central estimate of water scarcity is higher and the uncertainty increases. Grey areas show gridpoints defined as non-water scarce (75th quantile of the WSI < 0.1 at all times) or very low average water demand. Hatched areas show countries with no data for at least one component. Reproduced from (Greve et al., 2018).

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

Water demand is projected to change as a direct result of socio-economic changes. For example, the global water demand for domestic, industrial and agricultural uses, presently about 4,600 km³ per year, is projected to increase by 20% to 30% by 2050 (Greve et al., 2018), depending on the socio-economic scenario. Changes in water availability and demand have been projected in several studies using climate models and socio-economic scenarios (e.g., (Arnell and Lloyd-Hughes, 2014; Gosling and Arnell, 2016; Greve et al., 2018; Koutroulis et al., 2019)). In such studies, the projected changes in water availability arise from differences in precipitation (P) and evapotranspiration (ET). However, both P and ET are also subject to very high uncertainty in key processes such as regional climate change patterns (Uhe et al., 2021) and the influence of vegetation responses to elevated CO_2 on transpiration (Betts et al., 2015).

Human factors are projected to be the dominant driver of future water scarcity on a global scale (Graham et al., 2020a). However, at regional scales, high uncertainty in climate changes means that reduced water availability is *more likely than not* in many major river basins and remains a risk in most basins even where the central estimate is for increased water availability due to climate change (Figure 4.12). Such substantial uncertainties in projected water scarcity are crucial factors causing water management policies and planning challenges in the future. Therefore, locations projected to see significant increases in water scarcity with large uncertainty can be considered to be subject to the highest challenges for water management policy (Figure Box 4.1.1(b): (Greve et al., 2018)).

Water security and insecurity

Unlike physical water scarcity, water security or insecurity cannot be quantified in absolute terms. However, relative levels of water security in different places can be compared using metrics representing critical aspects of security (Gain et al., 2016; Young et al., 2019), ideally with thresholds for secure/insecure compared with local experience to assess validity (Young et al., 2019).

(Gain et al., 2016) define a Global Water Security Index (GWSI) metric on a scale of 0 to 1 combining indicators of relative levels of availability of freshwater, accessibility to water services, water management, and water quality and safety (including flood risk, which can affect water quality as well as being a direct physical hazard). Global application of this index indicates large worldwide differences in water security arising from different combinations of reasons (Figure Box 4.1.2(a)). In North Africa, the Middle East, large parts of the Indian Subcontinent and north China, low water security arises predominantly from low water availability. However, many areas with relatively high-water availability have relatively low levels of water security due to other factors. In 2015, 29% of the world's population did not have access to safe drinking water (Ritchie and Roser, 2019). In large parts of South and South-East Asia, significant contributions to water insecurity came from increased flood risk and deteriorated water quality (Burgess et al., 2010; Ward et al., 2017; Farinosi et al., 2018). Water availability is relatively high across most of Africa, but water security is relatively low due to low accessibility, management, and safety/quality standards. Most people in Africa do not have access to safe drinking water and improved sanitation (Marson and Savin, 2015; Naik, 2017; Armah et al., 2018).

In contrast, some high physical water scarcity areas, such as some parts of the USA, Australia, and Southern Europe, show relatively high-water security levels due to good governance, safety and quality, and accessibility. Nevertheless, marginalized groups such as Indigenous Peoples experience reduced access to water even within regions in the Global North. For example, in both Canada and the US, many Indigenous Peoples living on reserves lack access to piped water (Collins et al., 2017; Hanrahan, 2017; Marshall et al., 2018) and (or) are on boil water advisories (Patrick et al., 2019). In Australia, 25-40% of Aboriginal people live in remote rural areas with poor access to clean water (Bowles, 2015; NCCARF, 2018).

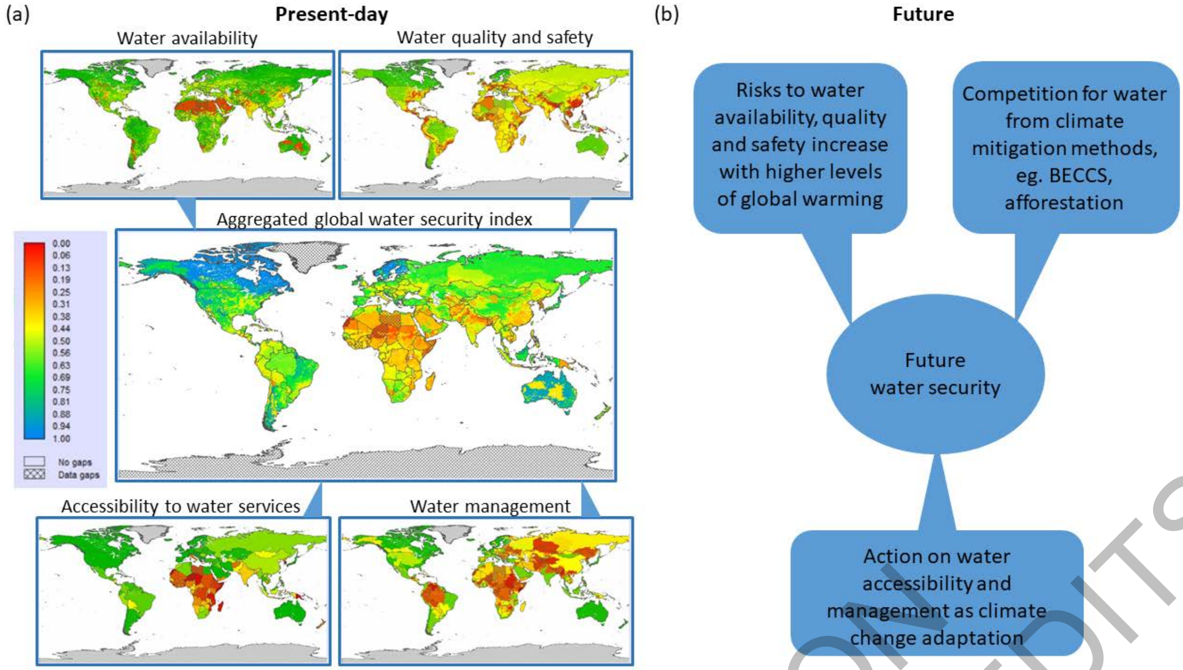

Figure Box 4.1.2: Global Water Security Index (GWSI) and its components for the present day, and factors affecting future change in water security. Low values (red) indicate the lowest levels of water security (a) Centre: a global map of local values of GWSI, constructed from the following components with their subjectively-weighted contribution to the combined metric indicated in brackets. Top left: relative availability of fresh water (45%), comprising a Water Scarcity Index, Drought Index and the groundwater depletion rate. Top right: relative accessibility to water services (20%), including drinking water and sanitation. Bottom left: relative water quality and safety (20%), including a water quality index and flood frequency index. Bottom right: relative effectiveness of water management (15%), comprising a World Governance index at country scale (itself representing six components: Voice and Accountability, Political Stability and Absence of Violence/Terrorism, Government Effectiveness, Regulatory Quality, Rule of Law, and Control of Corruption) and indicators of transboundary legal frameworks and political tensions at a river basin scale. Data for the components do not apply to the same set of dates but are generally applicable to recent decades up to 2010. For further details, see (Gain et al., 2016). (b) Factors through which climate change or action on mitigation or adaptation could influence water security.

The discrepancy between physical water scarcity and overall water insecurity is a function of socio-economic vulnerabilities and governance gaps. Therefore, improving societal aspects of water management will be key in adapting to climate change-driven increases in water scarcity in the future (*high confidence*).

Future water security will depend on the magnitude, rate and regional details of future climate change and non-climatic factors, including agricultural practices, water demand, governance. In many cases, climate change may not be the dominant factor affecting water security. Nevertheless, climate change poses clear risks to water security in many regions through potential impacts on water availability, quality, and flooding. The range of possible outcomes is extremely large, and assessing the likelihood of particular outcomes depends on consideration of uncertain regional climate changes and uncertain socio-economic futures. Uncertainty in future water scarcity projections makes climate change risks to water security and planning for adaptation challenging. Limiting climate change to lower levels of global warming would reduce the risks to water security arising from climate change, partly because uncertainties in regional climate change is smaller at lower levels of warming.

In summary, approximately 4 billion people are assessed as currently subject to severe water scarcity for at least one month per year due to climatic and non-climatic factors, and this is projected to exacerbate at higher levels of warming (*medium confidence*). General water insecurity issues are seen worldwide, particularly in South Asia, North China, Africa and the Middle East, due to high population densities often coupled with low water availability, accessibility, quality, and governance (*high confidence*). Areas with high water availability can also be water-insecure due to increased flood risk, deteriorated water quality, and poor governance (*high confidence*). Future water security will depend on the evolution of all these socio-economic and governance factors and future regional climate change (*high confidence*). The main climate change contribution to water insecurity is the potential for reduced water availability, with a secondary contribution from increased flooding risk (*medium confidence*). Future socio-economic conditions are a crucial driver of water insecurity, implying the need for further adaptation to some level of future climate change (*medium confidence*). However, policy challenges are high in many regions, with uncertainty in the regional climate outcomes being a key factor (*high confidence*).

[END BOX 4.1 HERE]

4.1.1 Points of Departure and Advancements since AR5

The Fifth Assessment Report (AR5) concluded that for each degree of global warming, approximately 7% of the global population, under a scenario of moderate population growth, was projected to be exposed to a decrease of renewable water resources of at least 20%. In addition, AR5 reported negative impacts on streamflow volumes, its seasonality (specifically in cryospheric zones), a decline in raw water quality *(medium evidence, high agreement)*, and projected reduction in renewable surface water and groundwater in most dry tropical regions. AR5 projected an increase in meteorological, agricultural and hydrological droughts in dry regions *(medium confidence)* (Jiménez Cisneros et al., 2014).

The Special Report on Global Warming of 1.5°C (SR1.5) assessed that limiting global warming to 1.5°C is expected to substantially reduce the probability of extreme droughts, precipitation deficits and risks associated with water availability in some regions *(medium confidence)*. On the other hand, higher risks to natural and human systems in a 2.0°C world would mean increased vulnerability for the poor, showing that socio-economic drivers are expected to have a more significant influence on water-related risks and vulnerabilities than changes in climate alone *(medium confidence)* (Hoegh-Guldberg et al., 2018).

The Special Report on Oceans and Cryosphere in a Changing Climate (SROCC) confirmed findings from AR5, with *robust evidence* of declines in snow cover and negative mass balance in most glaciers globally. Glacier melting seriously threatens water supply to mountain communities and millions living downstream through water shortages, jeopardizing hydropower generation, irrigation, and urban water uses (Hock et al., 2019b). Additionally, Arctic hydrology and vegetation will be affected by permafrost changes, negatively impacting Arctic communities' health and cultural identity (Meredith et al., 2019).

The Special Report on Climate Change and Land (SRCCL) stated that groundwater over-extraction for irrigation is causing depletion of groundwater storage (*high confidence*). The report also noted that precipitation changes, coupled with human drivers, will have a role in causing desertification, and water-driven soil erosion is projected to increase due to climate change (*medium confidence*). The population vulnerable to impacts related to water is projected to increase progressively at 1.5°C, 2°C and 3°C of global warming, with half of those impacted residing in South Asia, followed by Central Asia, West Africa and East Asia. SRCCL stated that improved irrigation techniques (e.g., drip irrigation) and moisture conservation (e.g., rainwater harvesting using Indigenous and local practices) could increase farmers' adaptive capacity *(high confidence)* (Mirzabaev et al., 2019).

The Sixth Assessment Report (AR6) Working Group I (WGI) (Douville et al., 2021) concluded that anthropogenic climate change has increased atmospheric moisture and precipitation intensity (*very likely* by 2-3% per 1°C) (*high confidence*), increased terrestrial ET (*medium confidence*) and contributed to drying in dry summer climates including in the Mediterranean, southwestern Australia, southwestern South America, South Africa and western North America (*medium to high confidence*), and has caused earlier onset of snowmelt and increased melting of glaciers (*high confidence*) since the mid-20th century. The report also stated with *high confidence* that the water cycle variability and extremes are projected to intensify, regardless of the mitigation policy. The share of the global population affected by water-related hazards and water availability issues is projected to increase with the intensification of water cycle variability and extremes. They concluded with *high confidence* that strong and rapid mitigation initiatives are needed to avert the manifestation of climate change in all components of the global water cycle.

Building on these previous reports, this chapter advances understanding climate change-induced hydrological changes and their societal impacts and risk in several key ways.

First, since AR5, the methodology of climate change impact studies has advanced and these methodological advances are described in SM4.1. AR6 uses new projections (CMIP6) based on the SSPs and other scenarios and we assess those results in this chapter alongside those using other projections and scenarios.

Second, this chapter follows the developments set in motion by SR 1.5, SRCCL and SROCC to incorporate Indigenous Knowledge (IK), traditional knowledge (TK) and local knowledge (LK). SR 1.5 stated that disadvantaged and vulnerable populations, including Indigenous Peoples and certain local communities, are at disproportionately higher risk of suffering adverse consequences due to global warming of 1.5°C or more (Roy et al., 2018). SRCCL highlighted the enhanced efficacy of decision-making and governance with the involvement of local stakeholders, particularly those most vulnerable to climate change, such as Indigenous Peoples (Arneth et al., 2019). SROCC found adaptation efforts have benefited from the inclusion of IK and LK (Abram et al., 2019). In this chapter, we engage directly with Indigenous contributing authors and use multiple evidence-based approaches, as undertaken by the IPBES (Tengö et al., 2014; Tengö et al., 2017). This approach is guided by the understanding that the co-production of knowledge (between scholars and local communities) about water and climate change vulnerability, impacts and adaptation has the potential to lead to new water knowledge and context-specific governance strategies (Arsenault et al., 2019; Chakraborty and Sherpa, 2021). Additionally, shifting beyond the exclusive use of technical knowledge and Western viewpoints redresses the shortcomings of resource- and security-oriented understandings to water and acknowledges the more holistic and relational approaches common to IK and LK (4.8.4) (Stefanelli et al., 2017; Wilson, 2019; Chakraborty and Sherpa, 2021).

Finally, grounded in the AR6 goal to expand the solution space, this chapter advances the understanding of adaptation in the water sector since AR5 by deploying a meta-analysis of adaptation measures. The meta-analysis focuses on both current adaptation responses (4.7.1) and future projected adaptation responses, which have been modelled (4.7.2). The meta-review assesses the outcomes of current adaptation responses and effectiveness of future projected adaptations in reducing climate and associated risks. Studies derived from Global Adaptation Mapping Initiative (GAMI) database (Berrang-Ford et al., 2021a) (see Chapter 16), were coded systematically following a meta-review protocol developed specifically for this assessment ((Mukherji et al., 2021), SM4.2). A similar meta-review protocol was also developed to assess effectiveness of adaptations to reduce projected climate risks (4.7.2; SM4.2).

4.1.2 Climatic and Non-Climatic Drivers of Changes in the Water Cycle

The water cycle is affected by both climatic and non-climatic factors (Douville et al., 2021). Radiative forcing by changes in greenhouse gas (GHG) concentrations, aerosols, and surface albedo drives global and regional changes in evaporation and precipitation (Douville et al., 2021). A warmer atmosphere holds more moisture, increasing global and regional mean precipitation; and more extreme precipitation (Allan et al., 2014; Giorgi et al., 2019; Allan et al., 2020). Regional precipitation responses vary according to changes in atmospheric circulation. Geographical variation in aerosols drives changes in atmospheric circulation, affecting precipitation patterns such as the Asian monsoon (Ganguly et al., 2012; Singh et al., 2019). (Section 4.2.1)

Warming increases glacier melt and is expected to decrease snowfall globally and lead to shorter snow seasons with earlier but less rapid snowmelt. It can also lead to local increases in snowfall intensity (Allan et al., 2020). These changes affect the seasonality of river flows in glacier-fed or snow-dominated basins. (4.2.2)

Rising atmospheric CO_2 generally decreases plant transpiration, affecting soil moisture, runoff, stream flows, the return of moisture to the atmosphere and surface temperature (Skinner et al., 2017). However, in some regions, these can be offset by increased leaf area ("global greening") driven by elevated CO_2, land-use change, nitrogen deposition and effects of climate change itself (Zhu Z et al., 2016; Zeng Z et al., 2018). Increased ozone can impact plant functioning, reducing transpiration (Arnold et al., 2018). (4.2.1)

Direct human interventions include abstraction of surface water and groundwater for drinking, irrigation, and other freshwater uses, as well as streamflow impoundment behind dams and large-scale inter-basin transfers (Zhao et al., 2015; Donchyts et al., 2016; McMillan et al., 2016; Shumilova et al., 2018). The consequences of these interventions are substantial and are discussed below briefly. In addition, these direct human interventions can change due to various societal and economic factors, including changes in land use and urbanization (4.3 and 4.5).

Irrigation can reduce river flows and groundwater levels via abstraction and increase local precipitation (Alter et al., 2015; Cook et al., 2015), alter precipitation remotely through moisture advection (de Vrese et al., 2016), and change the timing of monsoons through land-sea temperature contrasts (Guimberteau et al., 2012). The land cover change affects ET and precipitation (Li et al., 2015; Douville et al., 2021), interception of precipitation by vegetation canopies (de Jong and Jetten, 2007), infiltration (Sun et al., 2018a), and runoff (Bosmans et al., 2017) (4.5.1, 4.6.2, Box 4.3). Land cover impacts on the hydrological cycle are of similar magnitude as human water use (Bosmans et al., 2017).

Urbanization decreases land surface permeability (Choi et al., 2016), which can increase fast runoff and flooding risks and reduce local rainfall by decreasing moisture return to the atmosphere (Wang et al., 2018). But urbanization can also increase the sensible heat flux driving greater or more extreme precipitation (Kusaka et al., 2014; Niyogi et al., 2017). (4.3.4, 4.5.4)

In summary, radiative forcing by GHG and aerosols drives changes in evapotranspiration and precipitation at global and regional scales, and the associated warming shifts the balance between frozen and liquid water (*high confidence*). Rising CO_2 concentrations also affect the water cycle via plant physiological responses affecting transpiration, including via reduced stomatal opening and increased leaf area (*high confidence* regarding the individual processes; *medium confidence* regarding their net impact). Land cover changes and urbanization affect both the climate and land hydrology by altering the exchanges of energy and moisture between the atmosphere and surface (*high confidence*) and changing the permeability of the land surface. Direct human interventions in river systems and groundwater systems are non-climatic drivers with substantial impacts on the water cycle (*high confidence*) and have the potential to change as part of societal responses to climate change (Figure 4.2).

Figure 4.2: The water cycle, including direct human interventions. Water fluxes on land precipitation, land evaporation, river discharge, groundwater recharge, and groundwater discharge to the ocean from (Douville et al., 2021). Human water withdrawals for various sectors are shown from (Hanasaki et al., 2018; Sutanudjaja et al., 2018; Burek et al., 2020; Droppers et al., 2020; Müller Schmied et al., 2021). Green water use (Abbott et al., 2019) refers to the use of soil moisture for agriculture and forestry. Irrigation water use (called blue water) is not included in green water use).

4.2 Observed Changes in Hydrological Cycle due to Climate Change

All components of the global water cycle have been modified due to climate change in recent decades (*high confidence*) (Douville et al., 2021), with hundreds of millions of people now regularly experiencing hydrological conditions that were previously unfamiliar (4.2.1.1, 4.2.4, 4.2.5). Extensive records from weather stations, satellites and radar clearly show that precipitation patterns have shifted worldwide. Three major shifts documented are (a) some regions receiving more annual or seasonal precipitation and others less, (b) many regions have seen increased heavy precipitation, and many have seen either increases or decreases in dry spells, (c) some regions have seen shifts towards heavier precipitation events separated by more prolonged dry spells (4.2.1.1). Observationally-based calculations suggest that evapotranspiration (ET) has changed in response to changes in precipitation and increasing temperatures, resulting in changing patterns of soil moisture worldwide which are now detectable by satellite remote sensing (4.2.1.2, 4.2.1.3). Rising temperatures have caused profound and extensive changes in the global cryosphere, with mountain glaciers, land ice and snow cover shrinking, causing substantial, permanent impacts on the ways of life of people in these regions, particularly Indigenous Peoples with strong cultural links to long-term or seasonally-frozen environments (4.2.2, 4.3.8). Groundwater recharge in spring may have been reduced due to shorter snowmelt seasons, although the dominant impact on groundwater has been non-climatic and through intensification of irrigation (4.2.6). The global-scale pattern of streamflow changes is now attributable to observed historical climate change, with human land and water use insufficient by themselves to explain the observed streamflow changes at global scales (4.2.3). Numerous examples of extreme hydrometeorological events, including heavy precipitation, flooding, drought and wildfire events causing deaths, high levels of economic damage and extensive ecological impacts, have been shown to have been made more *likely* by human influence on climate through increased GHG concentrations in the atmosphere (4.2.1.1, 4.2.4, 4.2.5). Overall, there is a clear picture of human alteration of the global water cycle, which is now affecting societies and ecosystems across the world. This section describes changes in the hydrological cycle through a lens of societal impacts.

4.2.1 Observed Changes in Precipitation, Evapotranspiration and Soil Moisture

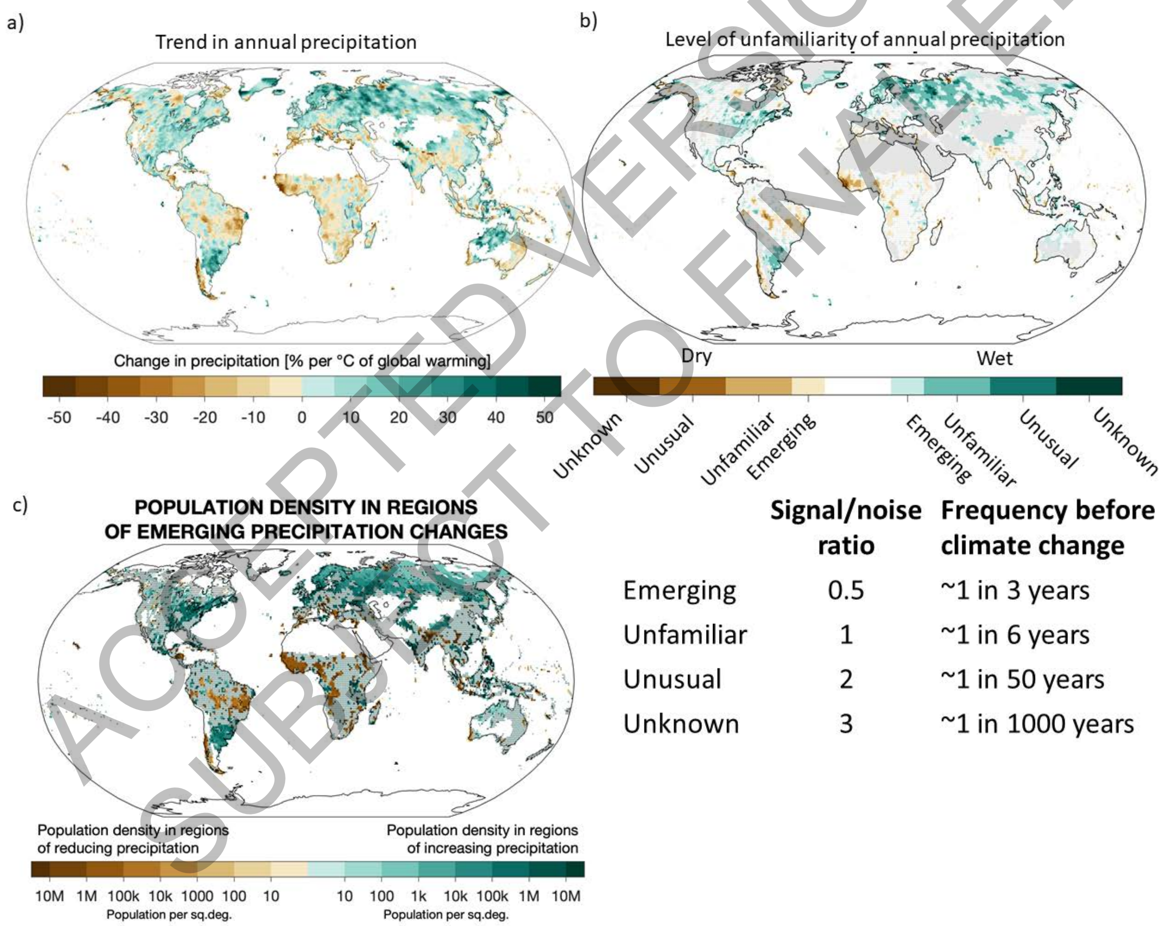
4.2.1.1 Observed Changes in Precipitation and Heavy Precipitation

AR6 WG1 (Douville et al., 2021) concluded that GHG forcing has driven increased contrasts in precipitation amounts between wet and dry seasons and weather regimes over tropical land areas (*medium confidence*), with a detectable precipitation increase in the northern high latitudes (*high confidence*). GHG forcing has also contributed to drying in dry summer climates, including the Mediterranean, south-western Australia, south-western South America, South Africa, and western North America (*medium to high confidence*) (Figure 4.3). AR6 WG1 (Seneviratne et al., 2021) also concluded that the frequency and intensity of heavy precipitation events have *likely* increased at the global scale over most land regions with good observational coverage. Heavy precipitation has *likely* increased on the continental scale over North America, Europe, and Asia. Regional increases in heavy precipitation frequency and (or) intensity have been observed with at least *medium confidence* for nearly half of the AR6 WG1 climatic regions (Figure 4.3). Human influence, in particular GHG emissions, is *likely* the main driver of the observed global-scale intensification of heavy precipitation in land regions

Large numbers of people live in regions where the annual mean precipitation is now “unfamiliar” compared to the mean and variability between 1891 and 2016 (Figure 4.3, g). “Unfamiliar” is defined as the long-term change being greater than one standard deviation in the annual data (Figure 4.3 (b)). In 2020, approximately 498 million people lived in unfamiliarly wet areas, where the long-term average precipitation is as high as previously seen in only about one in six years (*medium confidence*) (Figure 4.3, c). These areas are primarily in mid and high latitudes (Hawkins et al., 2020). On the other hand, approximately 163 million people lived in unfamiliarly dry areas, mostly in low latitudes (*medium confidence*). Due to high variability over time, the signal of long-term change in annual mean precipitation is not distinguishable from the noise of variability in many areas (Hawkins et al., 2020), implying that the local annual precipitation cannot yet be defined “unfamiliar” by the above definition.

Notably, many regions have seen increased precipitation for part of the year and decreased precipitation at other times (*high confidence*) (Figure 4.3, d, e), leading to small changes in the annual mean precipitation. Therefore, the numbers of people seeing unfamiliar seasonal precipitation levels are expected to be higher than those quoted above for unfamiliar annual precipitation changes (*medium confidence*). Still, quantified analysis of this is not yet available.

The intensity of heavy precipitation has increased in many regions (*high confidence*), including much of North America, most of Europe, most of the Indian sub-continent, parts of northern and south-eastern Asia, much of southern South America, parts of southern Africa and parts of central, northern and western Australia (Figure 4.3, f) (Dunn et al., 2020; Sun et al., 2020). Conversely, heavy precipitation has decreased in some regions, including eastern Australia, north-eastern South America and western Africa. The length of dry spells has also changed, with increases in annual mean consecutive dry days (CDD) in large areas of western, eastern and southern Africa, eastern and south-western South America, and South-East Asia and decreases across much of North America. Precipitation extremes have changed in some places where annual precipitation shows no trend. Some regions such as southern Africa and parts of southern South America are seeing increased heavy precipitation and longer dry spells. Many regions with changing extremes are highly populated, such as the Indian sub-continent, South-East Asia, Europe, and parts of North America, South America and Southern Africa (Figure 4.3, h). Substantially more people (~709 million) live in regions where annual maximum one-day precipitation has increased than regions where it has decreased (~86 million) (*medium confidence*). However, more people are experiencing longer dry spells than shorter dry spells: approximately 701 million people live in places where annual mean CDD is longer than in the 1950s, and ~404 million in places with shorter CDD (*medium confidence*) (Figure 4.3)).



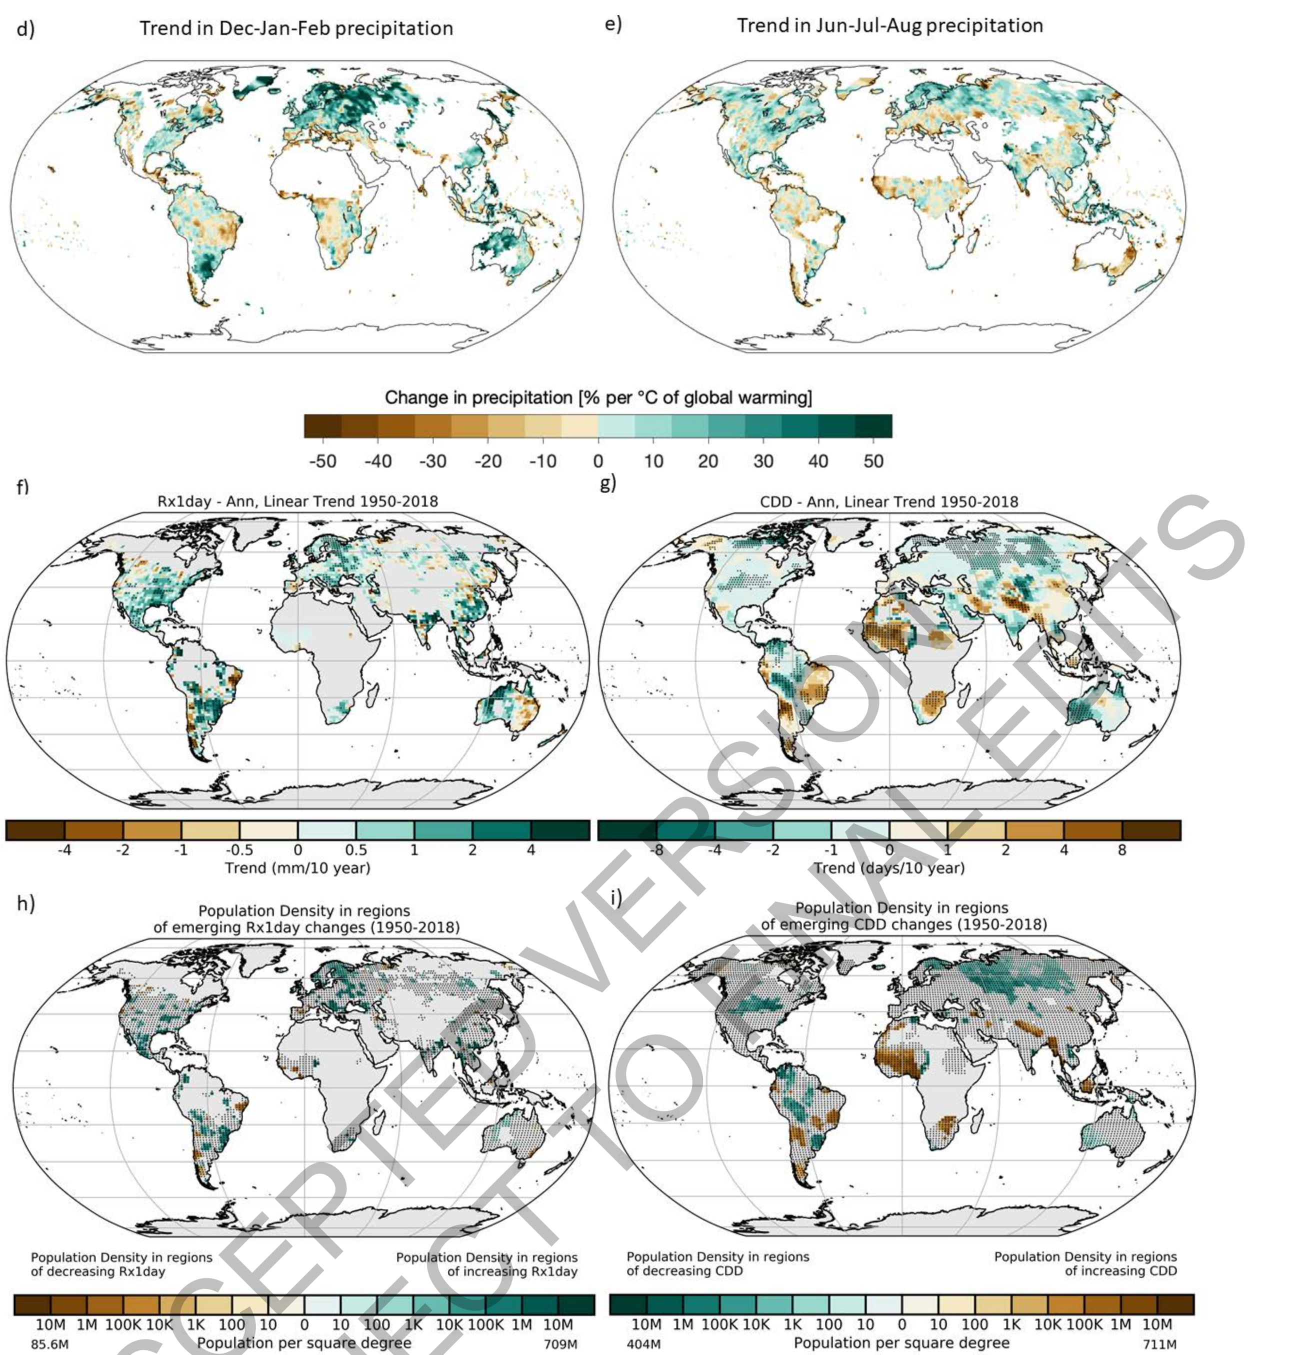


Figure 4.3: Observed mean and extreme precipitation changes, and people experiencing the emergence of historically unfamiliar precipitation and changes in extreme precipitation. (a) Changes in annual mean precipitation over land (1891–2019) in the Global Precipitation Climatology (GPCC) v2020 dataset (Schneider et al., 2017; Schneider et al., 2020). Green shows increasing precipitation, orange/red show decreases. (b) Emergence of wetter and drier climates, defined as the ratio of the signal S of change to the noise N of variability, where the latter is defined as one standard deviation in annual data with the trend removed, i.e., occurs approximately one in six years: "unfamiliar": S/N>1.0; "unusual": S/N>2.0; "unknown": S/N>3.0. Grey regions are either unobserved (oceans) or deserts (<250 mm/year). Stippling indicates where the signal of change is not significant. See (Hawkins et al., 2020) for further details. (c) Precipitation trends from the CRU dataset in December, January, and February (mm day^{-1} decade^{-1}). [to be replaced with GPCC for consistency with panel; (b) (d) As (c) for June-July-August. (e) Changes in annual mean maximum 1-day precipitation (Rx1day) in the HadEX3 dataset (Dunn et al., 2020). (f) Trend in annual mean consecutive dry days (CDD), 1950 – 2018, in HadEX3. (g) Population densities in grid boxes with emerging precipitation changes, at 1° resolutions. (h) Population densities per grid box where the trend in Rx1day is significantly different from zero. (i) Population densities per grid box where the trend in CDD is significantly different from zero. Stipples in (h) and (i) show where HadEX3 data is available. Population data in (g), (h) and (i) are for 2020 from (CIESIN, 2018a; CIESIN, 2018b).

In summary, annual mean precipitation is increasing in many regions worldwide and decreasing over a smaller area, particularly in the tropics. Nearly half a billion people live in areas with historically unfamiliar wet conditions, and over 160 million in areas with historically unfamiliar dry conditions (*medium confidence*). Over 600 million people experience heavy precipitation significantly more intense than in the 1950s, but less than 80 million experience decreased heavy precipitation. Compared to the 1950s, 601 million people now experience longer dry spells and 364 million experience shorter dry spells.

4.2.1.2 Observed and Reconstructed Changes in Evapotranspiration

WG1 (Douville et al., 2021) conclude with *high confidence* that global terrestrial annual ET has increased since the early 1980s, driven by both increasing atmospheric water demand and vegetation greening (*medium confidence*), and can be partly attributed to anthropogenic forcing (*high confidence)*.

Regional changes in ET depend on changes in both the climate and the properties of the land surface and ecosystems. The latter also responds to changes in climate and atmospheric composition. For example, a warming climate increases evaporative demand (Huang M et al., 2015; Berg et al., 2016), although seasonal rainfall totals (Hovenden et al., 2014) affect the amount of soil moisture available for evaporation. Since transpiration accounts for much of the land-atmosphere water flux (Good et al., 2015), vegetation changes also play a significant role in overall changes in ET.

With higher CO_2, the increase in evaporative demand can, to some extent, be counteracted by reduced stomatal conductance ('physiological effect'), which reduces transpiration and increases leaf-level water use efficiency (WUE), but is highly species-specific. There is evidence for recent increases in leaf-scale WUE from tree rings (14 ±10 %, broadleaf to 22 ±6 %, evergreen over the 20th century: (Frank et al., 2015)), carbon isotopes (30 to 35 % increase in 150 years: (van der Sleen et al., 2014)), and satellite-based measurements (1982–2008) combined with data-driven models (Huang M et al., 2015). WUE is also affected by aerodynamic conductance (Knauer et al., 2017), nutrient limitation (Medlyn et al., 2015; Donohue et al., 2017), soil moisture availability (Bernacchi and VanLoocke, 2015; Medlyn et al., 2015), and ozone pollution (King et al., 2013; Frank et al., 2015).

Higher CO_2 also increases photosynthesis rates, though this may not be maintained in the longer term (Warren et al., 2015; Adams et al., 2020), particularly where temperatures exceed the thermal maxima for photosynthesis (Duffy Katharyn et al., 2021). Higher photosynthesis increases leaf area index (LAI) ('structural effect') and therefore transpiration; 55±25% of observed increases in ET (1980–2011) have been attributed to LAI change (Zeng Z et al., 2018). Increases in ET driven by increased LAI (from satellite observations 1982–2012) are estimated at 0.32 ± 0.07 mm month^{-1} per decade, generating a climate forcing of -0.31 Wm^{-2} per decade (Zeng et al., 2017).

Overall regional transpiration change depends on the balance between the physiological and structural effects (e.g. (Tor-ngern et al., 2015; Ukkola et al., 2015)). In dry regions, ET may increase due to increasing LAI (Huang M et al., 2015), but in some densely vegetated regions, the stomatal effect dominates (Mao et al., 2015). Reductions in transpiration due to rising CO_2 concentrations may also be offset by a longer growing season (Frank et al., 2015; Mankin et al., 2019). Other factors modulate the transpiration effect both temporally and spatially, for example, additional vegetation structural changes (Kim et al., 2015; Domec et al., 2017), vegetation disturbance and age (Donohue et al., 2017) and species (Bernacchi and VanLoocke, 2015).

Recent studies report global ET increases from the early 1980s to 2009 and 2013 (Table 4.1). Calculations informed by observations suggest that ET has increased in most regions, with statistically significant ($p<0.05$) trends of up to 10mm yr^{-2} observed in large parts of North America and northern Eurasia. Larger increases in ET are also observed in several regions, including northeast Brazil, western central Africa, southern Africa, southern India, southern China, and northern Australia. Decreases of around 10mm yr^{-2} are reported for western Amazonia and central Africa (Miralles et al., 2014), although not across all datasets (Zeng et al., 2018). In estimates of past changes in long-term drying or wetting of the land surface driven by climate, uncertainties in ET observations or reconstructions make a more substantial contribution to the overall uncertainty than observed changes in precipitation (Greve et al., 2014). Other changes in ET are also driven strongly by land cover changes and irrigation (Bosmans et al., 2017).

Table 4.1: Trends in global evapotranspiration for different periods between 1981-1982 and 2009-2013.

Trend (mm yr^{-2})	Period	Data source	Author(s)
+0.54	1981 to 2012	Observations	(Zhang Y et al., 2016)
+1.18	1982 to 2010	Observations	(Mao et al., 2015)
+0.93±0.31	1982 to 2010	LSMs	(Mao et al., 2015)
+0.88	1982 to 2013	Remote-sensing data	(Zhang K et al., 2015)
+1.5	1982 to 2009	Remote-sensing and surface observations	(Zeng et al., 2014)

The contribution of changes in WUE to observed changes in ET is a key knowledge gap. WG1 assigned *low confidence* to this contribution. Estimating large-scale transpiration response to increased CO_2 based on leaf-level responses of WUE is not straightforward (Bernacchi and VanLoocke, 2015; Medlyn et al., 2015; Tor-ngern et al., 2015; Walker et al., 2015; Kala et al., 2016) and new methodological approaches are needed.

In summary, there is *high confidence* that ET increased by between approximately 0.5 and 1.5mm yr^{-2} between the 1980s and early 2010s due to warming-induced increased atmospheric demand worldwide and greening of vegetation in many regions. Increases in many areas are 10mm yr^{-2} or more, but in some tropical land areas, ET has decreased by 10mm yr^{-2}. Plant stomatal responses to rising CO_2 concentrations may play a role, but there is *low confidence* in quantifying this. Changes in land cover and irrigation have also changed regional ET (*medium confidence*).

4.2.1.3 Observed and Estimated Past Changes in Soil Moisture and Aridity

AR6 WG1 (Douville et al., 2021) find that a global trend in soil moisture is detectable in a reanalysis and is attributable to GHG forcing, and conclude that it is *very likely* that anthropogenic climate change affected global patterns of soil moisture over the 20th century.

Changes in soil moisture and land surface aridity are due to changes in the relative balance of precipitation and ET. Regional trends derived from satellite remote sensing products show increases and decreases in annual surface soil moisture of up to 20% or more between the late 1970s and mid-2010s (Figure 4.4). For example, using the ESA CCI SM v03.2 COMBINED products (van der Schalie et al., 2021), approximately 0.9 billion people live in regions with decreasing surface soil moisture, and 2.1 billion people live in regions with increasing surface soil moisture (Figure 4.4, b). However, there are disagreements between datasets on the direction of change in some regions (Seneviratne et al., 2010; Feng and Zhang, 2015; Feng, 2016), so quantification is subject to *low confidence*.

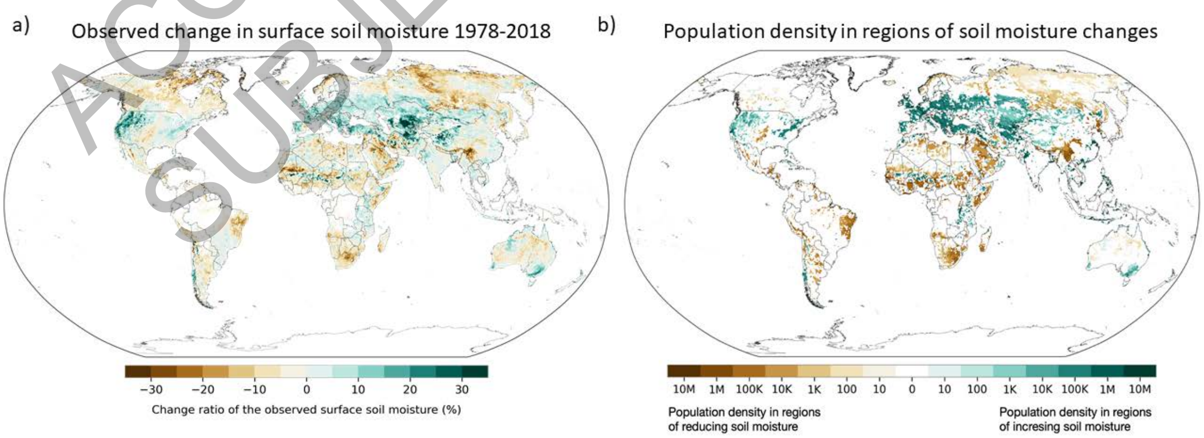

Figure 4.4: Global patterns of changes in soil moisture and people in regions with significant changes. (a) Percentage changes in surface soil moisture (0–5cm) for 1978–2015 from satellite remote sensing: the "COMBINED" product of European Space Agency Climate Change Initiative Soil Moisture (ESA CCI SM v03.2), which blends data products from two microwave instruments, a scatterometer measuring radar backscattering and a radiometer measuring

brightness temperature (van der Schalie et al., 2021). (b) The population density in 0.25°grid boxes with trends of significantly increasing and decreasing soil moisture from (a).

Analysis of changes in precipitation-evapotranspiration estimates for 1948-2005 (Greve et al., 2014) suggests that geographical variations in soil moisture trends are more complex than the "wet get wetter, dry get drier" (WGWDGD) paradigm. This is also supported by remote sensing data, with ESA CCI data for 1979-2013 showing only 15% of land following the WGWDGD paradigm for soil moisture (Feng and Zhang, 2015). Defining arid, humid and transitional areas according to precipitation and temperature regimes, all three classes of regions see more widespread trends of declining soil moisture than increasing soil moisture (Feng and Zhang, 2015). In the ESA CCI product, increasing soil moisture trends are mainly seen in humid or transitional areas and are rare in arid regions (Table 4.2)

Table 4.2: Proportions of arid, transitional and humid areas with drying and wetting trends in surface soil moisture from remote sensing, 1979-2013 (Feng and Zhang, 2015).

Areas	% of the area with a drying trend	% of the area with a wetting trend
Arid	38.4	2.9
Transitional	13.0	10.5
Humid	16.3	8.1

Reconstructions of historical soil moisture trends with data-driven models and process-based land surface models indicate drier dry seasons predominantly in extratropical latitudes, including Europe, western North America, northern Asia, southern South America, Australia and eastern Africa, consistent with climate model simulations of changes due to human-induced climate change (Padrón et al., 2020). Furthermore, reduced water availability in the dry season is generally a consequence of increasing ET rather than decreasing precipitation (Padrón et al., 2020).

While observationally-based data for soil moisture are now more widely available, regional trends remain uncertain due to disagreements between datasets, so confident assessments of soil moisture changes remain a knowledge gap.

In summary, global mean soil moisture has slightly decreased, but regional changes vary, with both increases and decreases of 20% or more in some regions (*medium confidence*). Drying soil moisture trends are more widespread than wetting trends, not only in arid areas but also in humid and transitional areas (*medium confidence*). Reduced dry-season water availability is driven mainly by increasing transpiration (*medium confidence*)

4.2.2 Observed Changes in Cryosphere (Snow, Glaciers, and Permafrost)

AR5 reported a decrease in snow cover over most of the Northern Hemisphere, decreases in the extent of permafrost and increases in its average temperature, and glacier mass loss in most parts of the world (Jiménez Cisneros et al., 2014). SROCC (IPCC, 2019c) stated with *very high* or *high confidence* (a) reduction in seasonal snow cover (snow cover extent decreased by 13.4% per decade for 1967-2018); (b) glacier mass budget of all mountain regions (excluding the Canadian and Russian Arctic, Svalbard, Antarctica, Greenland) was 490±100 kg m^{-2} yr^{-1} in 2006-2015; (c) warming of permafrost (e.g. permafrost temperatures increased by 0.39°C in the Arctic for 2007-2017). Tourism and recreation activities have been negatively impacted by declining snow cover, glaciers and permafrost in high mountains (*medium confidence*).

Recent studies confirmed with *high confidence* that snow cover extent continues to decrease across the northern hemisphere in all months of the year (see (Douville et al., 2021; Eyring et al., 2021; Fox-Kemper et al., 2021) for more details). From 1922 to 2018, snow cover extent in the northern hemisphere peaked in the 1950s-1970s (Mudryk et al., 2020) and consistently reduced since the end of the 20th century (Hernández-Henríquez et al., 2015; Thackeray et al., 2016; Mudryk et al., 2017; Beniston et al., 2018; Hammond et al., 2018; Thackeray et al., 2019; Mudryk et al., 2020). The consistently negative snow-mass trend of approximately 5 Gt yr^{-1} in 1981-2018 for all winter-spring months (Mudryk et al., 2020), including 4.6 Gt yr^{-1} decrease of snow mass across North America and a negligible trend across Eurasia, has been observed (Pulliainen et al., 2020). Negative trends in snow-dominated period duration of 2.0 to 6.5 weeks decade-1 was detected from surface and satellite observations during 1971–2014 (Allchin and Déry, 2017), mainly owing to earlier seasonal snowmelt (Fox-Kemper et al., 2021). The observed decrease of snow cover metrics (extent, mass, duration) led to changes in runoff seasonality and has impacted water supply infrastructure (Blöschl et al., 2017; Huss et al., 2017), particularly in south-western Russia, western US and Central Asia. In these regions, snowmelt runoff accounts for more than 30% of irrigated water supplies (Qin et al., 2020). Negative impacts on hydropower production due to changes in the seasonality of snowmelt have also been documented (Kopytkovskiy et al., 2015).

During the last two decades, the global glacier mass loss rate exceeded 0.5-meter water equivalent (m w.e.) year^{-1} compared to an average of 0.33 m w.e. y^{-1} in 1950–2000. This volume of mass loss is the highest since the start of the entire observation period (*very high confidence*) (Zemp et al., 2015; Zemp et al., 2019; Hugonnet et al., 2021) (also see (Douville et al., 2021; Fox-Kemper et al., 2021; Gulev et al., 2021) for more details). Regional estimates of glacier mass balance are also mostly negative (Dussaillant et al., 2019; Menounos et al., 2019; Zemp et al., 2019; Douville et al., 2021; Fox-Kemper et al., 2021; Hugonnet et al., 2021), except for West Kunlun, Eastern Pamir and the northern Karakoram (Brun et al., 2017; Lin et al., 2017; Berthier and Brun, 2019). Changes in glacier metrics estimated in post-SROCC publications are summarized in Figure 4.5.

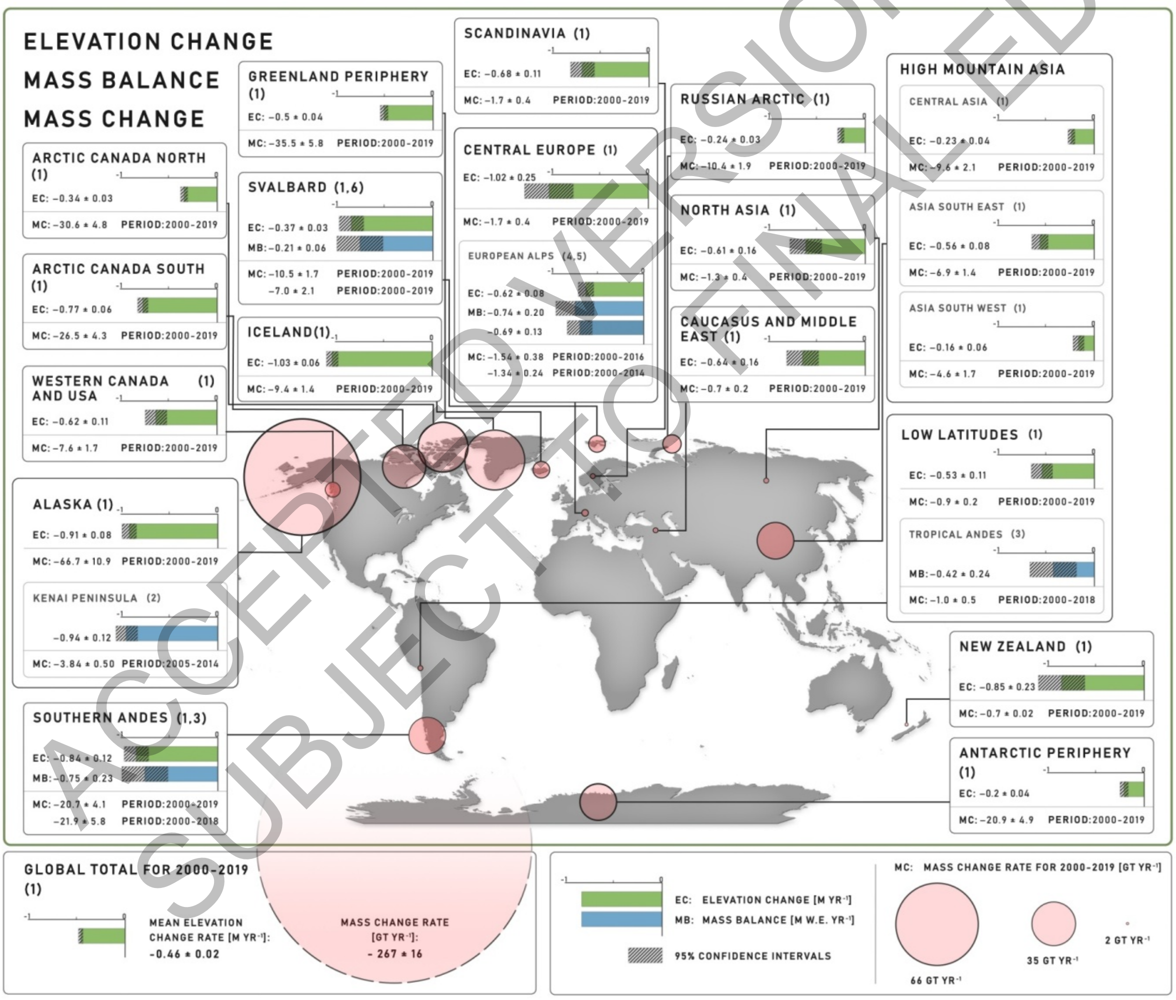

Figure 4.5: Global and regional estimates of changes in glacier characteristics (elevation, m yr^{-1}; mass Gt yr^{-1}, mass balance, m.w.e. yr^{-1}) and 95% confidence intervals of the estimates. Results are taken from the post-SROCC publications, which are labelled in the chart titles as 1 - (Hugonnet et al., 2021); 2 - (Yang et al., 2020); 3 - (Dussaillant et al., 2019); 4 - (Davaze et al., 2020); 5 - (Sommer et al., 2020); 6 - (Schuler et al., 2020).

Regional and global decreasing trends in glacier mass loss are about linear until 1990, after which they accelerated, especially in Western Canada, the USA, and Southern Andes (WGMS, 2017). There is a worldwide growth in the number, total area and total volume of glacial lakes by around 50% between 1990 to 2018 due to the global increase in glacier melt rate (Shugar et al., 2020). An increase in area, number and volume of glacial lakes can potentially increase risks of GLOFs with significant negative societal impacts (Ikeda et al., 2016). A drop in glacier runoff has happened in the regions where the glaciers have already passed their peak water stage, example, as in Canadian Rocky Mountains, European Alps, tropical Andes, North Caucasus (Bard et al., 2015; Hock et al., 2019b; Rets et al., 2020). There is *medium confidence* that the accelerated melting of glaciers has negatively impacted glacier-supported irrigation systems worldwide (Buytaert et al., 2017; Nüsser and Schmidt, 2017; Xenarios et al., 2019). Varying impacts on hydropower production (Schaefli et al., 2019) and tourism industry in some places due to cryosphere changes have also been documented (Hoy et al., 2016; Steiger et al., 2019).

Permafrost changes mainly refer to changes in temperature and active layer thickness (ALT) (Hock et al., 2019b; Fox-Kemper et al., 2021; Gulev et al., 2021). Permafrost temperature near the depth of zero annual temperature amplitude increased globally by 0.29 ± 0.12 °C during 2007–2016: by 0.39 ± 0.15 °C in the continuous permafrost and by 0.20 ± 0.10° in the discontinuous permafrost (Biskaborn et al., 2019). Thus, permafrost is warming during the last 3-4 decades (Romanovsky et al., 2017) with a rate of 0.4−1.4 °C decade^{-1} throughout the Russian Arctic, 0.1−0.8 °C decade^{-1} in Alaska and Arctic Canada during 2007−2016 (Biskaborn et al., 2019) and 0.1-0.24 °C decade^{-1} in Tibetan plateau (Wu et al., 2015). The ALT is also increasing in the European and Russian Arctic and high mountain areas of Eurasia since the mid-1990s (Hock et al., 2019b; Fox-Kemper et al., 2021; Gulev et al., 2021). Unfortunately, unlike glaciers and snow, the lack of in-situ observations on permafrost still cannot be compensated by remote sensing. Still, some methodological progress on this front has been happening recently (Nitze et al., 2018).

There is *high confidence* that degradation of the cryosphere components is negatively affecting terrestrial ecosystems, infrastructure and settlements in the high-latitude and high-altitude areas (Fritz et al., 2017; Oliva and Fritz, 2018; Streletskiy et al., 2019). Similarly, communities in the North polar regions and the ecosystems on which they depend for their livelihoods are at risk (Mustonen, 2015; Pecl et al., 2017; Mustonen and Lehtinen, 2020) (Figure 4.6).

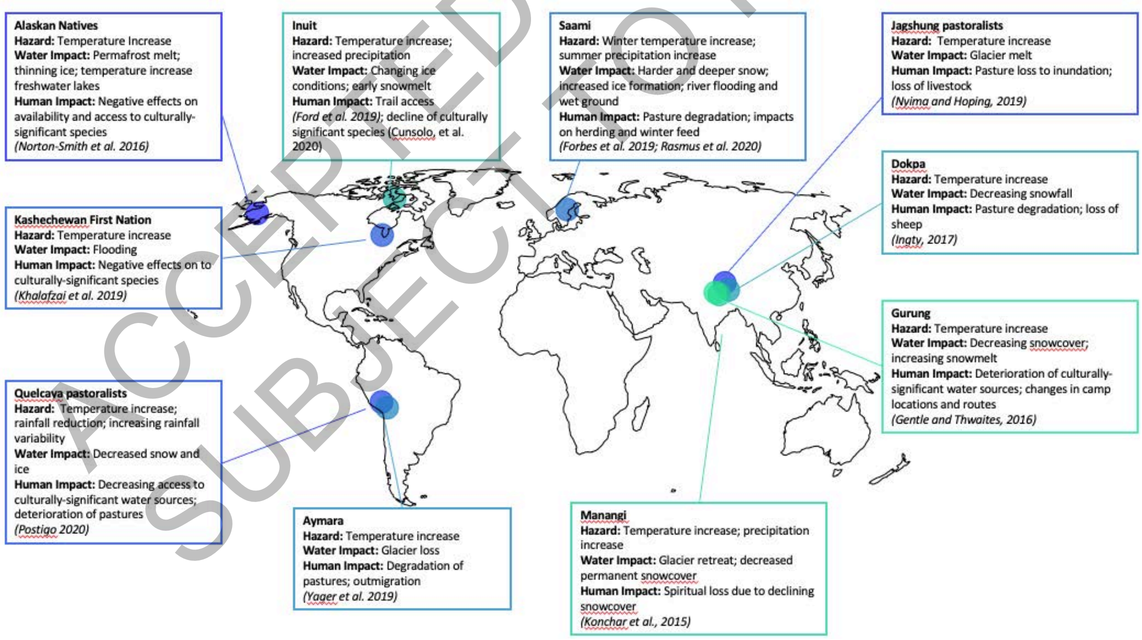

Figure 4.6: Map of selected observed impacts on cultural water uses of Indigenous Peoples of the cryosphere. Map location is approximate; text boxes provide names of the Indigenous Peoples whose cultural water uses have been impacted by climate change; changed climate variable; impact on water; and specific climate impact on cultural water use (4.3.7).

In summary, the cryosphere is one of the most sensitive indicators of climate change. There is *high confidence* that cryosphere components (glaciers, snow, permafrost) are melting or thawing since the end of the 20th and beginning of the 21st century. Widespread cryosphere changes are affecting humans and ecosystems in mid-to-high latitudes and the high mountains regions (*high confidence*). These changes are already impacting irrigation, hydropower, water supply, cultural and other services provided by the cryosphere, and populations depending on ice, snow and permafrost.

4.2.3 Observed Changes in Streamflow

AR5 (Jiménez Cisneros et al., 2014) concluded with *medium evidence* and *high agreement* that trends in annual streamflow have generally followed observed changes in regional precipitation and temperature since the 1950s. AR6 WGI (Eyring et al., 2021; Gulev et al., 2021) (12.4.5) conclude with *medium confidence* that anthropogenic climate change has altered local and regional streamflow in various parts of the world, but with no clear signal in the global mean.

Between the 1950s and 2010s, stream flows showed decreasing trends in parts of western and central Africa, eastern Asia, southern Europe, western North America and eastern Australia, and increasing trends in northern Asia, northern Europe, and northern and eastern North America (Dai, 2016; Gudmundsson et al., 2017; Gudmundsson et al., 2019; Li et al., 2020b; Masseroni et al., 2020). Significant spatial heterogeneity is also found in streamflow changes at the regional scale. For instance, in Canada, annual streamflow trends were mixed. Significant declines occurred at 11% of stations and significant increases at 4% of stations, with most decreases occurring in southern Canada (Bonsal et al., 2019). An increasing trend (1950-2010) is found in the northern region, mainly due to climate warming. Mixed trends are found in other regions.

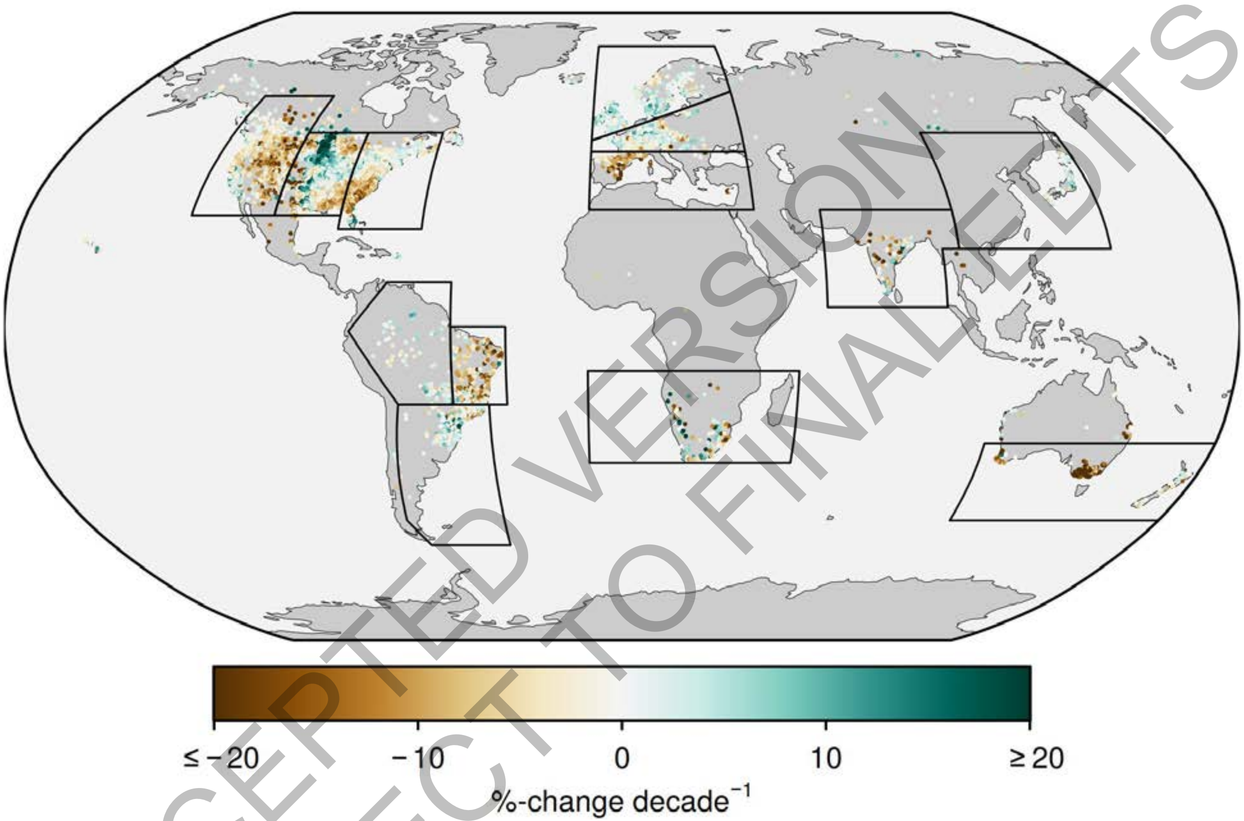
The spatial differences in annual mean streamflow trends around the world are influenced by climatic factors, particularly changes in precipitation and evaporation (Zang and Liu, 2013; Greve et al., 2014; Hannaford, 2015; Ficklin et al., 2018), as well as by anthropogenic forcing (Gudmundsson et al., 2016; Gudmundsson et al., 2017; Gudmundsson et al., 2021). Other factors (e.g. land-use change and CO_2 effects on vegetation) dominate in some areas, especially dryland regions (Berghuijs et al., 2017b). Human activities can reduce run-off through water withdrawal and land-use changes (Zaherpour et al., 2018; Sun et al., 2019a; Vicente-Serrano et al., 2019), and human regulation of streamflows via impounding reservoirs can also play a major role (Hodgkins et al., 2019).

Streamflow trends are attributed to varying combinations of climate change and direct human influence through water and land use in different basins worldwide, with conclusions on the relative contribution of climatic and anthropogenic factors sometimes depending on the methodology (Dey and Mishra, 2017). Precipitation explains over 80% of the changes in discharge of large rivers from 1950 to 2010 in northern Asia and northern Europe, where the impact of human activities is relatively limited (Li et al., 2020b). In northwest Europe, precipitation and evaporation changes explain many observed trends in streamflow (Vicente-Serrano et al., 2019). In several polar areas in Northern Europe (e.g. Finland), North America (e.g. British Columbia in Canada), and Siberia, many studies reported increased wintertime streamflow primarily due to climate warming, for instance, more rainfall instead of snowfall and more glacier run-off in the winter period (e.g. (Bonsal et al., 2020)) (4.2.2). A similar phenomenon of the earlier snowmelt run-off is also found in North America during 1960-2014 (Dudley et al., 2017). Thus, climate drivers largely explain changes in the average and maximum run-off of predominantly snow-fed rivers (Yang et al., 2015a; Bring et al., 2016; Tananaev et al., 2016; Frolova et al., 2017b; Ficklin et al., 2018; Magritsky et al., 2018; Rets et al., 2018).

In contrast, in southwestern Europe, land cover changes and increased water demands by irrigation are the main drivers of streamflow reduction (Vicente-Serrano et al., 2019) (4.3.1). In addition, the human intervention also contributed to the increase of the wintertime streamflow due to the release of water in the winter season for hydropower generation in large rivers in the northern regions (Rawlins et al., 2021). In some regions, the impact of human activities on run-off and streamflow outplays the climate factors, e.g. in typical basins in China after 2000 (Zhai and Tao, 2017).

(Shi et al., 2019) find that in 40 major basins worldwide, both climatic and direct human impact contribute to observed flow changes to varying degrees. Climate change or variability is the main contributor to changes in basin-scale trends for 75% of rivers, while direct human effects on streamflow dominate for 25%. However, this does not consider attribution of the climate drivers to anthropogenic forcing. Using time series of low, mean, and high river flows from 7250 observatories around the world (1971 to 2010) and global hydrological models (GHMs) driven by Earth System Model simulations with and without anthropogenic forcing of climate change, (Gudmundsson et al., 2021) also found direct human influence to have a relatively small impact on global patterns of streamflow trends. (Gudmundsson et al., 2021) further identified anthropogenic climate change as a causal driver of the global pattern of recent trends in mean and extreme river flow (Figure 4.7). Overall, the sign of observed trends and simulations accounting for human influence on the climate system was found to be consistent for decreased mean flows in western and eastern North America, southern Europe, north-east South America and the Indian subcontinent, and increased flows in northern Europe. Similar conclusions were drawn for low and high flows, except for the Indian subcontinent. However, in some regions, the observed trend was opposite to that simulated with anthropogenic climate forcing. Thus, human water and land use alone did not explain the observed pattern of trends.

a)



b)

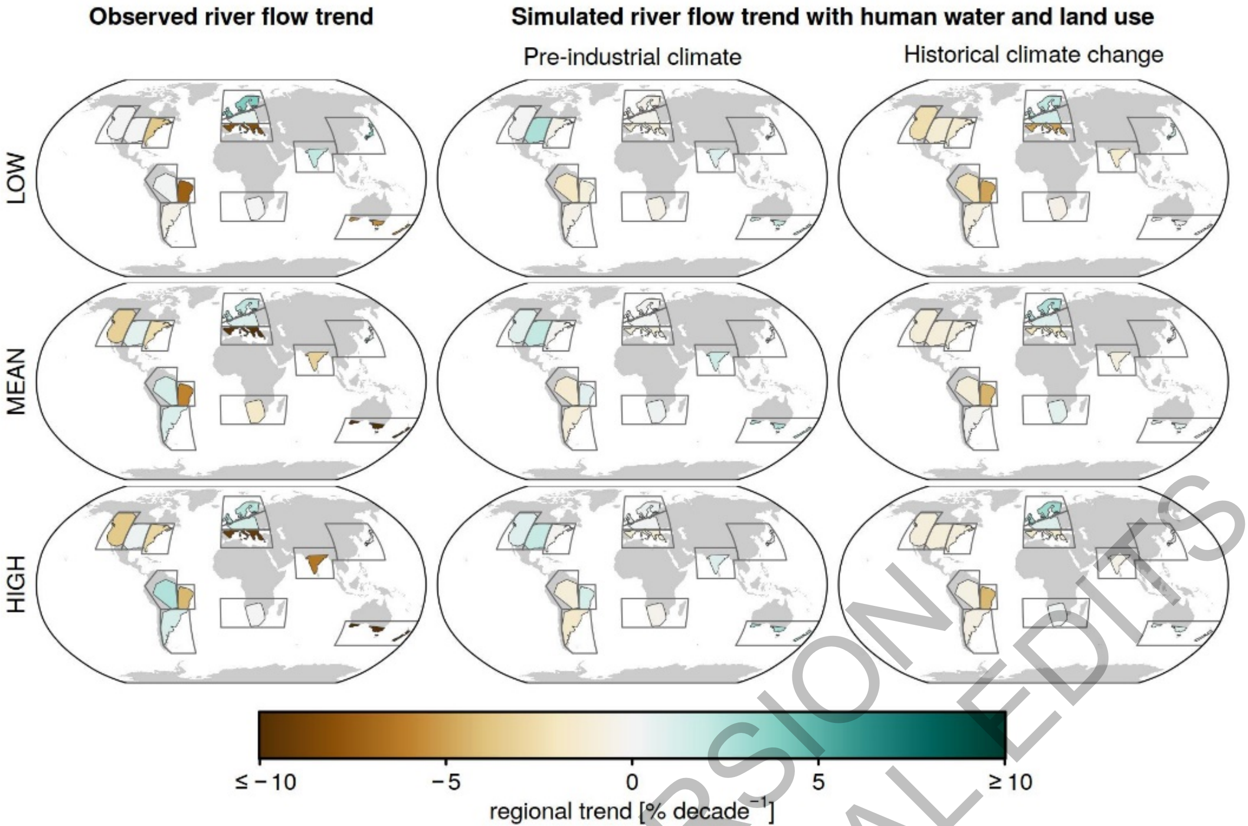


Figure 4.7: Observed changes in river flows and attribution to externally forced climate change. (a) Percentage changes in flow in individual rivers 1971 to 2010. Black box outlines show climatic regions with at least 80 gauging stations with almost complete daily observations over 1971-2010, using the SREX (Seneviratne et al., 2012) regions. (b) Left column: observed regional median trends from 1971 to 2010 in SREX regions with at least 80 gauging stations with almost complete daily observations over that period. Middle column: trends simulated by eight Global Hydrological Models driven by four CMIP5 Earth System Models, with human water and land use from 1971 to 2020 and the pre-industrial control climate state. Right column: same as the middle column but with ESM-simulated climates from 1971 to 2010 with both anthropogenic forcings (greenhouse gases, aerosols and land use) and natural external forcings (solar variability and volcanic eruptions). Top row: low flows (annual 10th percentile); Middle row: mean flows; Bottom row: high flows (annual 90th percentile). Reproduced from (Gudmundsson et al., 2021).

Although there are different observational and simulated run-off and streamflow datasets (e.g., Global Runoff Data Center, GRDC), it is still challenging to obtain and update long-term river discharge records in several regions, particularly Africa, South and East Asia (Dai, 2016). When observed data are scarce, hydrological models are used to detect trends in run-off and streamflow. However, simulations of streamflow can differ between models depending on their structures and parameterizations, contributing to uncertainties for trend detection, especially when considering human intervention (e.g. (Caillouet et al., 2017; Hattermann et al., 2017; Smith et al., 2019b; Telteu et al., 2021)).

In summary, both climate change and human activities influence the magnitude and direction of change in run-off and streamflow. There are no clear trends of changing streamflow on the global level. However, trends emerge on a regional level (a general increasing trend in the northern higher latitude region and mixed trend in the rest of the word) (*high confidence*). Climatic factors contribute to these trends in most basins (*high confidence*). They are more important than direct human influence in a larger share of major global basins (*medium confidence*), although direct human influence dominates in some (*medium confidence*). Overall anthropogenic climate change is attributed as a driver to the global pattern of change in streamflow (*medium confidence*).

4.2.4 Observed Changes in Floods

AR6 WGI Chapter 11 (Seneviratne et al., 2021) assessed with *high confidence* the increase in the extreme precipitation and associated increase in the frequency and magnitude of river floods. However, there is *low* *confidence* in changes in the river flooding regionally, which is strongly dependent upon complex catchment characteristics and land use patterns. SROCC (Hock et al., 2019b) summarized with *high confidence* that changes in the cryosphere have led to changes in frequency, magnitude and location of rain-on-snow floods, snowmelt floods and glacier-related floods.

There is *high confidence* that the frequency and magnitude of river floods have changed in the past several decades in some regions mentioned below (and in WGI 11.5.2; SM4.1) with impacts across human and natural systems (4.3). A global flood database based on *in situ* measurement and satellite remote-sensing during 1985–2015 show that floods have increased 4-fold and 2.5–fold in the tropics and northern mid-latitudes, respectively (Najibi and Devineni, 2018). Estimates of flood exposure using satellite-derived inundation area and high-resolution population data showed a 20-24% increase during 2000–2018 (Tellman et al., 2021). Analyses of in situ streamflow measurement showed both increases and decreases in the frequency of river floods for 1960–2010 in Europe (Berghuijs et al., 2017a; Blöschl et al., 2019a) and the United States (Berghuijs et al., 2017a), an overall increase in China, Brazil and Australia (Berghuijs et al., 2017a) but decrease in some areas in the Mediterranean (Tramblay et al., 2019) and southern Australia (Ishak et al., 2013; Do et al., 2017). Warming in the last 40-60 years has led to 1 to10 day earlier per decade spring flood occurrence depending on the location (the most frequent being 2 to 4 days/decade) (*high confidence*) (Yang L. et al., 2015; Blöschl et al., 2017; Dudley et al., 2017; Solander et al., 2017; Rokaya et al., 2018; Kireeva et al., 2020).

Between 1970 to 2019, 44% of all disasters, and 31% of all economic losses were flood related (WMO, 2021). Observed flood risks changes in recent decades are often caused by human factors such as increased urbanization and population growth rather than climate change alone (Tramblay et al., 2019). There is *medium confidence* that flood vulnerability varies among various regions and countries (Jongman et al., 2012; Scussolini et al., 2016; Tanoue et al., 2016) (Figure 4.8), reflecting differences in GDP, severity and characteristics of hazard and political and social conditions (Rufat et al., 2015). Flood vulnerability has decreased with economic development in many regions, while increased exposure has elevated risk in some places (Mechler, 2016; Tanoue et al., 2016). Global annual mean exposed population considering the current flood protection standard is estimated to be US$ 54 million under the climate of 1976-2005 and unevenly distributed (Alfieri et al., 2017). Similar estimation using different models shows an increase of flood exposure in the past (US$31 million for 1971-1990 and US$ 45 million for 1991-2010 without population change as fixed in 2010) (Tanoue et al., 2016) (4.7.5).

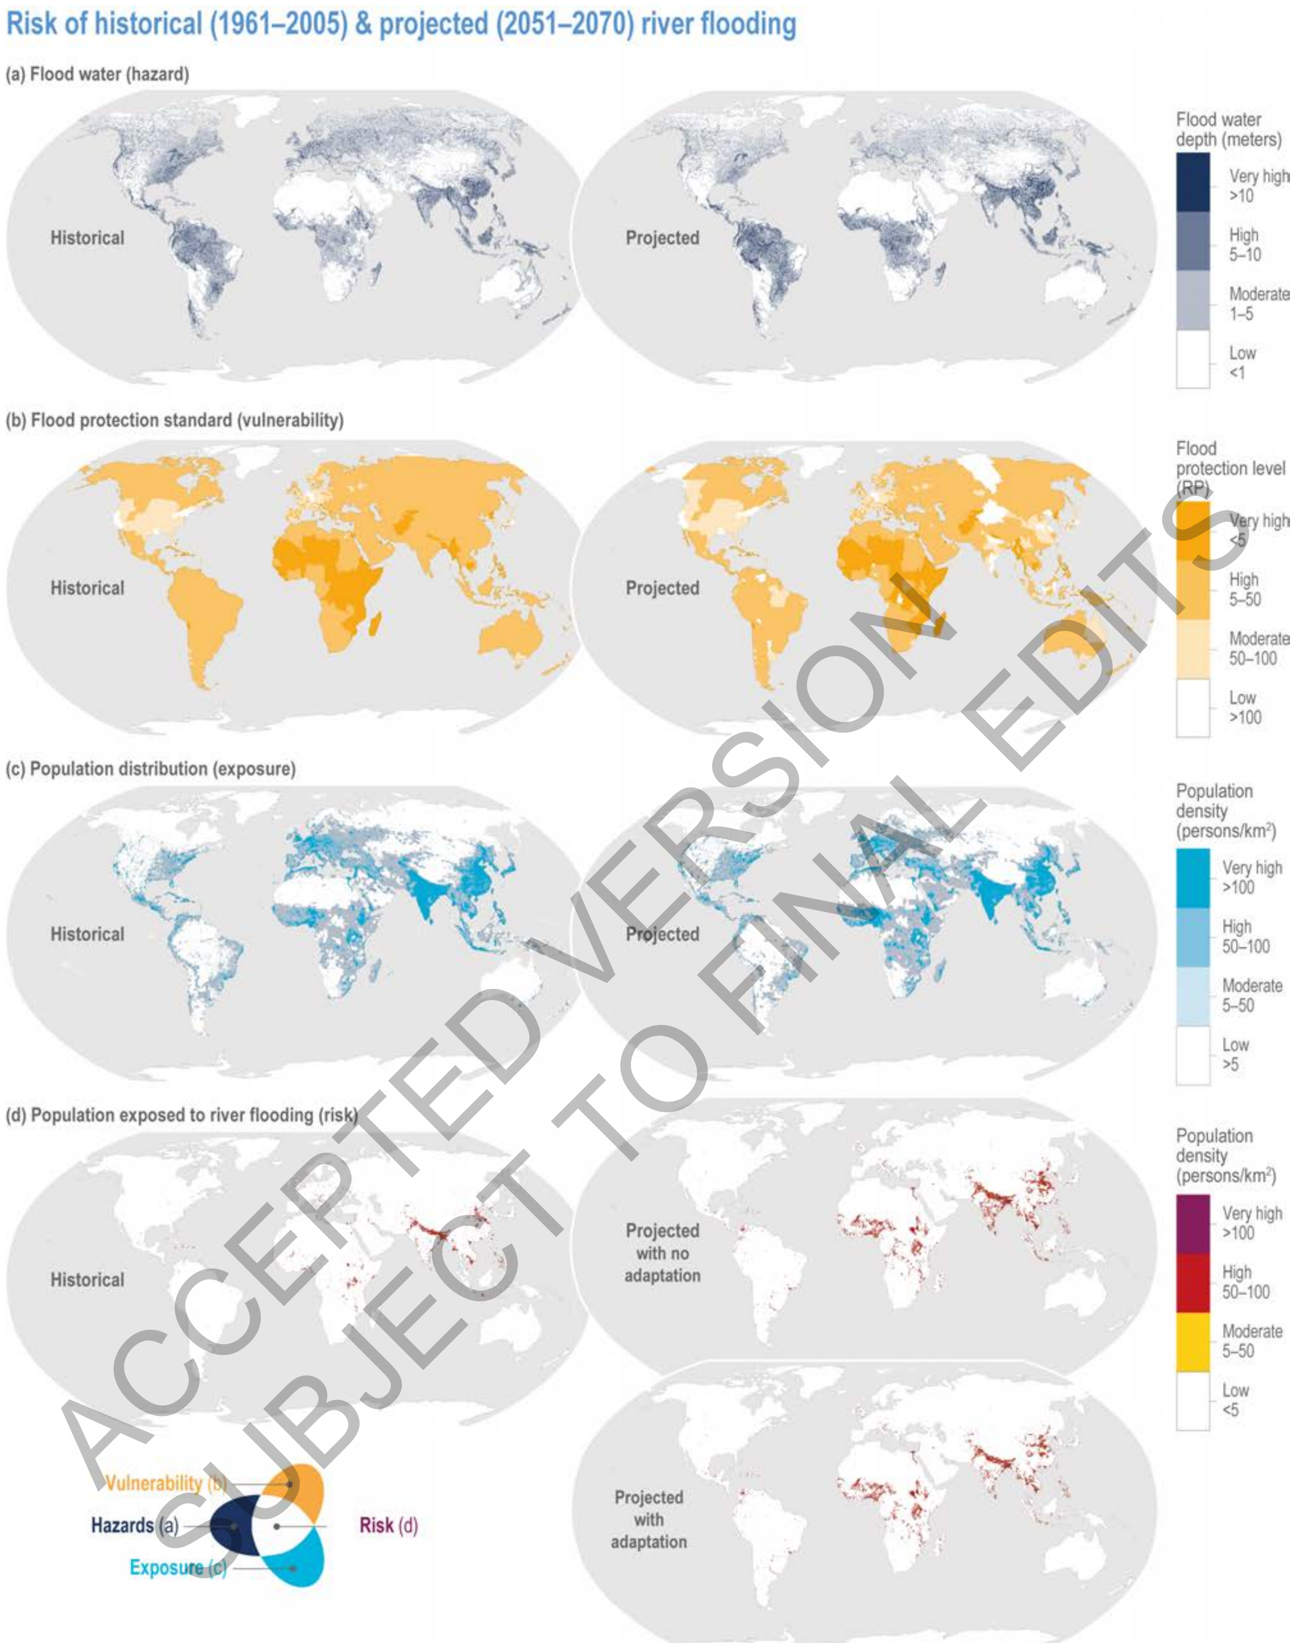

Figure 4.8: (a) Local flood protection standard (return period) at sub-country scale (Scussolini et al., 2016) based on published reports and documents, websites and personal communications with experts. Note that the vulnerability of this map reflects local flood protection such as complex infrastructure and does not fully reflect the other source of vulnerabilities, including exposure. (b) Modelled mean global fluvial flood water depth (Tanoue et al., 2016; Tanoue et al., 2021) based on a land surface model and a river and inundation model driven by reanalysis climate forcing of 5 CMIP5 GCMs (metres). The annual maximum daily river water was allocated along elevations, and inundation depth was calculated for each year and averaged for the target period. (c) Population distribution per 30 arc second grid cell (Klein Goldewijk et al., 2010; Klein Goldewijk et al., 2011). (d) Population exposed to flood (number of people where inundation occurs) per 30 arc-second grid cell. Population under inundation depth > 0 m (a) was counted when the

return period of annual maximum daily river water exceeds the flood protection standard (c) calculated by the authors. All values are averages for the period 1958-2010 for the past and 2050-2070 for the future.

The link between rainfall and flooding is complex. While observed increases in extreme precipitation have increased the frequency and magnitude of pluvial floods and river floods in some regions, floods could decrease in some regions due to other factors. These factors could include soil wetness condition, cryosphere change, land cover change and river system management, adaptation measures or water usage within the river basin (WGI FAQ8.2). For example, in the USA and Europe, a study indicated that major (e.g., 25–100-year return period) floods did not show significant long-term trends (Hodgkins et al., 2019). Nevertheless, anthropogenic climate change increased the likelihood of a number of major heavy precipitation events and floods that resulted in disastrous impacts in southern and eastern Asia, Europe, North America and South America (Table 4.3) (*high confidence*). (Davenport et al., 2021) demonstrated that anthropogenic changes in precipitation extremes had contributed one-third of the cost of flood damages (from1988 to 2017) in the USA. Anthropogenic climate change has altered 64% (8 out of 22 events increased, 8 decreased) of floods events with significant loss and damage during 2010-2013 (Hirabayashi et al., 2021a). (Gudmundsson et al., 2021) attributed observed change in extreme river flow trends to anthropogenic climate change (4.2.3). Although there is growing evidence on the effects of anthropogenic climate change on each event, given the relatively poor regional coverage and high model uncertainty, there is *low confidence* in the attribution of human-induced climate change to flood change on the global scale.

Table 4.3: Selected major heavy precipitation events from 2014-2021 that led to flooding and their impacts. Studies were selected for presentation based on the availability of impacts information. This is not a systematic assessment of event attributions studies and their physical science conclusions. "Sign of influence" indicates whether anthropogenic climate change was found to have made the event *more or less likely*, and "mechanism/magnitude of influence" quantifies the change in likelihood and the processes or quantities involved.

Year	Country / Region	Impact	Anthropogenic climate change influence the likelihood of an event		Reference
			Sign of influence	Mechanism / magnitude of influence	
2021	Germany, Belgium, Luxembourg and neighbouring countries	At least 222 fatalities, substantial damage to infrastructure, economic costs of €4.5 to €5.5 billion in Germany and over €0.35 billion in Belgium.	Increase	1-day rainfall intensity increased by 3 - 19%, the likelihood of event increased by a factor between 1.2 and 9	(Kreienkamp et al., 2021)
2019	Canada (Ottawa)	Thousands of people evacuated, extended states of emergency, and about $200 million in insured losses	Increase	Spring maximum 30-day rainfall accumulation in 2019 was 3 times as likely with anthropogenic forcing	(Kirchmeier-Young et al., 2021)
	Southern China	Over 6 million people across several southern China provinces were affected by heavy rains, floods, and landslides. These extremes caused at least 91 deaths, collapsed over 19,000 houses, damaged around 83,000 houses, and affected 419,400 ha of crops (China Ministry of Emergency Management 2020). The direct economic loss was estimated to be more than 20 billion	Decrease	Anthropogenic forcings have reduced the likelihood of heavy precipitation in southern China like the 2019 March–July event by about 60%	(Li et al., 2021b)

		RMB (equivalent to 3 billion USD)			
2018	USA (Mid-Atlantic)	1 fatality, $12 million damages	Increase	1.1 to 2.3 times more likely	(Winter et al., 2020)
	Central Western China	Persistent heavy rain led to floods, landslides and house collapse affecting 2.9 million people. The direct economic loss of over US$ 1.3 billion	Decrease	~47% reduction in the probability	(Zhang et al., 2020b)
	North-western China	Extreme flooding in the Upper Yellow River basin affected about 1.4 million people and led to 30 deaths and disappearances.	Decrease	34% reduction in the probability	(Ji et al., 2020)
	Japan	237 fatalities, more than 6,000 buildings destroyed by floods and landslides	Increase	7% increase in total precipitation	(Kawase et al., 2020)
	Australia (Tasmania)	$100 million in insurance claims	Unknown	Unknown	(Tozer et al., 2020)
2017	Peru	Widespread flooding and landslides affected 1.7 million people, 177 fatalities, estimated total damage of $3.1 billion	Increase	At least 1.5 times more likely	(Christidis et al., 2019)
	Uruguay and Brazil	Direct economic loss in Brazil of US$102 million, displacement of more than 3,500 people in Uruguay	Increase	At least double, with a most likely increase of about fivefold	(de Abreu et al., 2019)
	North-East Bangladesh	Flash flood-affected ~850,000 households, ~220,000 ha of nearly harvestable Boro rice damaged. Crop failure contributed to a record 30% rice price hike compared to the previous year	Increase	Doubled the likelihood of the 2017 pre-monsoon extreme 6-day rainfall event	(Rimi et al., 2019)
	China	7.8 million people affected 34 fatalities, about 0.8 million people displaced, 605,000 hectares of crops affected, 116,000 hectares without harvest. 32,000 houses collapsed, 41,000 were severely damaged. Direct economic loss 24.12 billion Chinese Yuan (~ US$3.6 billion)	Increase	Doubled the probability from 0.6% to 1.2%	(Sun et al., 2019b)
2016	South China	Widespread severe flooding, waterlogging, and landslides in the Yangtze–Huai region.	Increase	1.5-fold (0.6 to 4.7) increase in the probability	(Sun and Miao, 2018)
	China (Wuhan)	237 fatalities, 93 people missing, at least US$22 billion in damage	Increase	Approximately 60% of the risk	(Zhou et al., 2018a)

	China (Yangtze River)	The direct economic loss of about US$10 billion	Increase	Increased probability by 38% (± 21%)	(Yuan et al., 2018)
	Australia	Flooding and wild weather impacted some agriculture and power generation.	None	Minimal	(Hope et al., 2018)
2015	India (Chennai)	City declared a disaster area. Damages estimated as $3 billion	None	None	(van Oldenborgh et al., 2017a)
2014	Indonesia (Jakarta)	26 reported deaths Thousands of buildings flooded, much infrastructure damaged. Losses up to US $384 million	Unclear	2-day rain event approximately 2.4 times more likely compared to 1900, but cause not established	(Siswanto et al., 2015)

In snow-dominated regions, 1~10 days earlier spring floods per decades due to warmer temperature are reported for the last decades (*high confidence*), such as in Europe (Morán-Tejeda et al., 2014; Kormann et al., 2015; Matti et al., 2016; Vormoor et al., 2016; Blöschl et al., 2017), the European part of Russia (Frolova et al., 2017a; Frolova et al., 2017b; Kireeva et al., 2020), Canada (Yang L. et al., 2015; Burn et al., 2016; Rokaya et al., 2018), and the United States (Mallakpour and Villarini, 2015; Solander et al., 2017).

There is a knowledge gap in how ice-related floods, including glacier-related and ice-jam floods, respond to ongoing climate change. Despite the increase in the number of glacial lake studies (Wang and Zhou, 2017; Harrison et al., 2018; Begam and Sen, 2019; Bolch et al., 2019), changes in the frequency of occurrence of glacier-related floods associated with climate change remain unclear (*medium confidence*). Studies show that the compound occurrence of high surges and high river discharge has increased in some regions (WGI Chapter 11), but few studies quantify changes and impacts. Increases in precipitation from tropical cyclones (WGI Chapter 11) and associated high tide are expected to exacerbate coastal flooding. However, more studies are required to quantify their impacts. In addition, limitations in the duration of data hinder the assessment of trends in low-likelihood high-impact flooding (WGI BOX 11.2).

In summary, the frequency and magnitude of river floods have changed in the past several decades with high regional variations (*high confidence*). Anthropogenic climate change has increased the likelihood of extreme precipitation events and the associated increase in the frequency and magnitude of river floods (*high confidence*). There is *high confidence* that the warming in the last 40-60 years has led to ~10 days earlier spring floods per decade, shifts in timing and magnitude of ice-jam floods and changes in frequency and magnitude of snowmelt floods.

4.2.5 Observed Changes in Droughts

There are different types of droughts, and they are interconnected in terms of processes (Douville et al., 2021). *Meteorological droughts* (periods of persistent low precipitation) propagate over time into deficits in soil moisture, streamflow, and water storage, leading to a reduction in water supply (*hydrological drought*). Increased atmospheric evaporative demand increases plant water stress, leading to *agricultural and ecological drought*.

Hydrological drought can result in shortages of drinking water and cause substantial economic damages. Agricultural drought threatens food production through crop damage and yield decreases (e.g. (Tigkas et al., 2019), 4.3.1) (*high confidence*) and consequent economic impacts (Table 4.4). For example, drought in India in 2014 was reported to have led to an estimated US $30 billion in losses (Ward and Makhija, 2018). Ecological drought increases the risks of wildfire (Table 4.4). Cascading effects of droughts can include health issues triggered by a lack of sanitation (4.3.3); can cause human displacements, loss of social ties, sense of place and cultural identity; and migration to unsafe settlements (*medium confidence*) (Serdeczny et al., 2017) (4.3.7). Between 1970 and 2019, only 7% of all disaster events were drought-related, yet they contributed disproportionately to 34% of disaster-related death, mostly in Africa (WMO, 2021). Nevertheless, Indigenous knowledge, traditional knowledge and local knowledge have increased drought resilience among crop and livestock farmers, for example, in South Africa (Muyambo et al., 2017), Uganda (Barasa et al., 2020) and India (Patel et al., 2020) (4.8.4).

When hazard, vulnerability, and exposure are considered together, drought risk is lower for sparsely populated regions, such as tundra and tropical forests, and higher for populated areas and intensive crop and livestock farming regions, such as South and Central Asia, the Southeast of South America, Central Europe, and the Southeast of the USA (Figure 4.9). Dynamics in exposure and vulnerability are rarely addressed (Jurgilevich et al., 2017; Hagenlocher et al., 2019). Quantifying economic vulnerability to drought in terms of damages as a percentage of exposed Gross Domestic Product, (Formetta and Feyen, 2019) show a disproportionate burden of drought impact on low-income countries, but with a clear decrease in global economic drought vulnerability between 1980–1989 and 2007–2016 including a convergence between lower-income and higher-income countries due to stronger vulnerability reduction in less-developed countries. Nevertheless, in 2007-2016 economic vulnerability to drought was twice as high in lower income countries compared to higher-income countries (Formetta and Feyen, 2019).

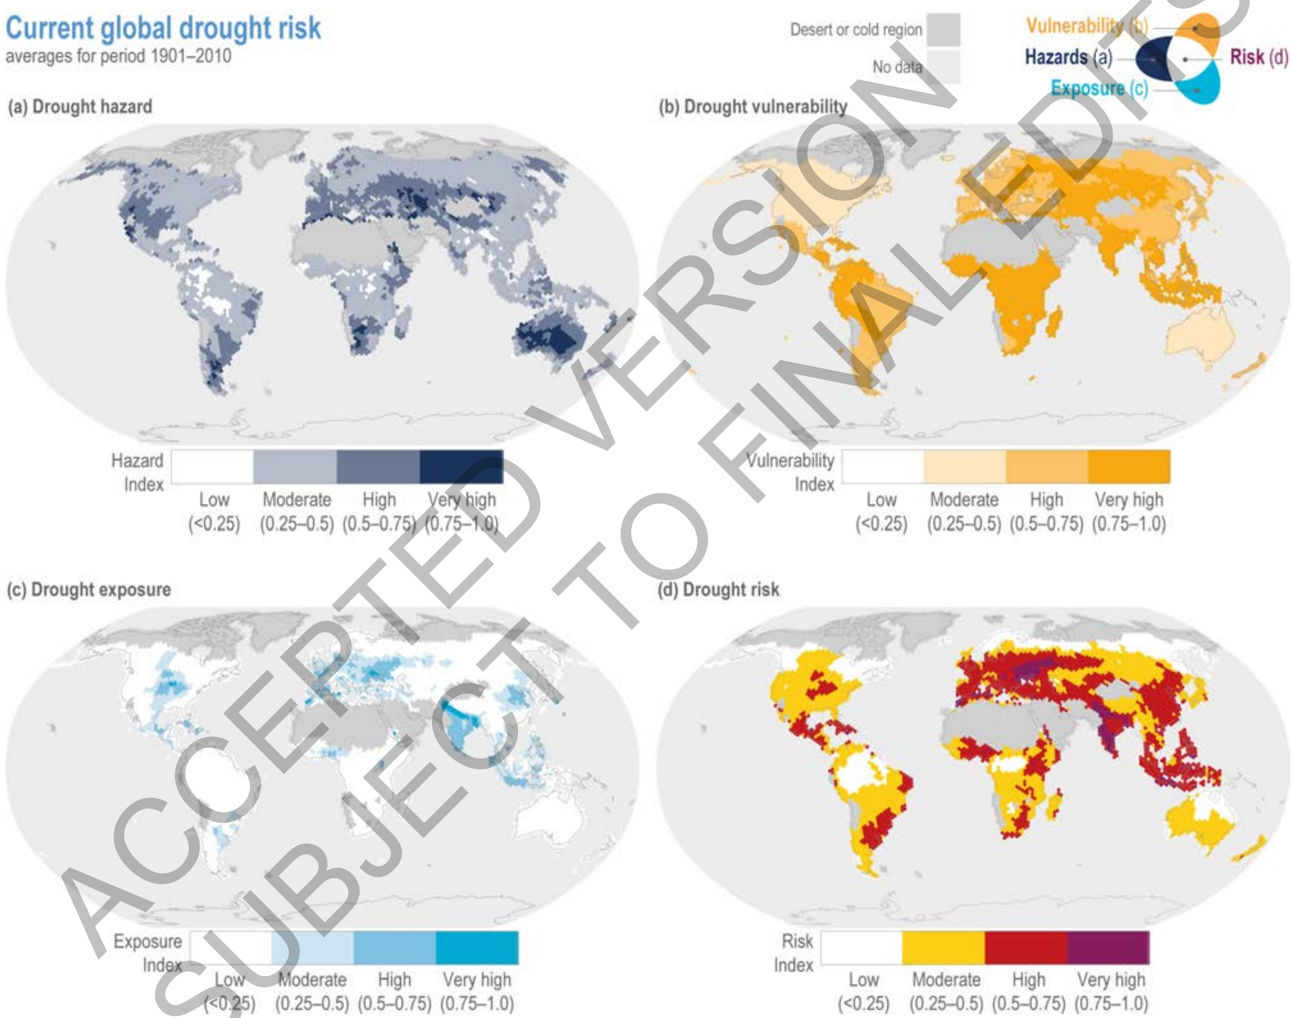

Figure 4.9: Current global drought risk and its components. (a) Drought hazard computed for the events between 1901–2010 by the probability of exceedance the median of global severe precipitation deficits, using precipitation data from the Global Precipitation Climatology Center (GPCC) for 1901–2010. (b) Drought vulnerability is derived from an arithmetic composite model combining social, economic, and infrastructural factors proposed by (UNISDR, 2004). (c) Drought exposure computed at the sub-national level with the non-compensatory DEA (Data Envelopment Analysis) model (Cook et al., 2014). (d) Drought risk based on the above components of hazard, vulnerability and exposure, scored on a scale of 0 (lowest risk) to 1(highest risk) with the lowest and highest hazard, exposure, and vulnerability (Carrão et al., 2016).

AR6 WG1 (Douville et al., 2021; Seneviratne et al., 2021) found that increasing agricultural and ecological droughts trends are more evident than increasing trends in meteorological drought in several regions due to increased evaporative demand. Therefore, WG1 concluded with *high confidence* that the increased frequency and the severity of agricultural/ecological droughts over the last decades in the Mediterranean and western North America can be attributed to anthropogenic warming.

In addition, there is *high confidence* in anthropogenic influence on increased meteorological drought in south-western Australia and *medium confidence* that recent drying and severe droughts in southern Africa and south-western South America can be attributed to human influence. Increased agricultural/ecological and (or) meteorological and (or) hydrological drought is also seen with either *medium confidence* or *high confidence* in the trend but with *low confidence* on attribution to anthropogenic climate change in western, north-eastern and central Africa; central, eastern and southern Asia; eastern Australia; southern and north-eastern South America and the South American monsoon region; and western and central Europe. Finally, decreased drought in one or more categories is seen with *medium confidence* in western and eastern Siberia; northern and central Australia; south-eastern South America; central North America and northern Europe, but with *low confidence* in attribution to anthropogenic influence except in northern Europe where anthropogenic influence on decreased meteorological drought is assessed with *medium confidence*.

Major drought events worldwide have had substantial societal and ecological impacts, including reduced crop yields, shortages of drinking water, wildfires causing deaths of people, very large numbers of animals and impacting the habitats of threatened species, and widespread economic losses (Table 4.4, Cross-Chapter Box DISASTER in Chapter 4). In addition, anthropogenic climate change was found to have increased the likelihood or severity of most such events examined in event attribution studies.

Table 4.4: Selected major drought events from 2013-2020 and their societal impact. Studies were selected for presentation based on the availability of impacts information, including an example of events which was not found to have a component attributable to climate change. This is not a systematic assessment of event attributions studies and their physical science conclusions. "Sign of influence" indicates whether anthropogenic climate change was found to have made the event more or less likely, and "mechanism/magnitude of influence" quantifies the change in likelihood and the processes or quantities involved.

Year	Country / region	Impact	Influence of anthropogenic climate on the likelihood of an event		Reference
			Sign of influence	*Mechanism/magnitude of influence*	
2019 / 2020	Australia	Wildfires burning ~97,000 km^2 across southern and eastern Australia. 34 human fatalities; 5900 buildings destroyed; millions of people affected by hazardous air quality; between 0.5 and 1.5 billion wild animals and tens of thousands of livestock killed; at least 30% of habitat affected for seventy taxa, including 21 already listed as threatened with extinction, over US$110 billion financial loss.	Increase	Extreme high temperatures causing drying of fuel. The likelihood of extreme heat at least doubled due to the long-term warming trend, and the likelihood of Fire Weather Index as severe or worse as observed in 2019/20 by at least 30 %, despite no attributable increase in meteorological (precipitation) drought.	(van Oldenborgh et al., 2020; Ward et al., 2020; Haque et al., 2021)
2019	Western Cape, South Africa	Water supply was reduced to 20% of capacity in January 2018. Agricultural yields in 2019 declined by 25%	Increase	Anthropogenic greenhouse forcing at least doubled the likelihood of drought levels seen in 2015-2019, offsetting anthropogenic aerosol forcing.	(Kam et al., 2021)
	Yunnan, south-western China	Water scarcity affected nearly 7 million residents and resulted in crop failure over at least 1.35 × 104 km2 cropland (Fig. 1).	Increase	Anthropogenic influence increased the risk of 2019 March–June hot and dry extremes over Yunnan province in south-western	(Wang et al., 2021b)

		More than 94% of the total area in the province was drought-stricken, and around 2 million people faced drinking water shortages, with a direct economic loss of about 6.56 billion RMB		China by 123%–157% and 13%–23%, respectively.	
	Southwestern China	Over 640,100 hectares of crops with rice, corn, and potatoes were extensively damaged. Over 100 rivers and 180 reservoirs dried out. Over 824,000 people and 566,000 head of livestock having a severe lack of drinking water, with a direct economic loss of 2.81 billion Chinese Yuan ($400 million)	Increase	Anthropogenic forcing has likely increased the like-lihood of the May–June 2019 severe low precipita-tion event in south-western China by approximately 1.4 to 6 times.	(Lu et al., 2021)
	South China	A lightning-caused forest fire in Muli County killed 31 firefighters and burned about 30 ha of forest	Increase	Anthropogenic global warming increased the weather-related risk of extreme wildfire by 7.2 times. In addition, the El Niño event increased risk by 3.6 times.	Du et al. (2021)
	Middle and lower reaches of the Yangtze River, China	Reduced agriculture productivity and increased load on power system supplies and transportations, and on human health.	Decrease	Anthropogenic forcing reduced the probability of rainfall amount in the extended rainy winter of 2018/19 by ~19% but exerted no influence on the excessive rainy days	Hu et al. (2021)
2018	South China	Shrinking reservoirs, water shortages. Area and yield for early rice reduced by 350 thousand hectares and 1.28 million tons relative to 2017	Increase	Likelihood increased by 17 times in the HadGEM3-A model. However, the event did not occur without human influence in the CAM5 model.	Zhang et al. (2020)
	China (Beijing)	A record 145 Consecutive Dry Days (|CDD), severe drought, increased risk of wildfires.	Increase	The likelihood of the record 145 CDD was increased by between 1.29 and 2.09 times by anthropogenic climate change and between 1.43 and 4.59 times by combining the La Niña event and weak Arctic polar vortex.	(Du et al., 2021)
2017	USA (Northern Great Plains)	"billion-dollar disaster"; widespread wildfires (one of Montana's worst wildfire seasons on record) compromised water resources, destruction of property, livestock sell-offs, reduced agricultural production, agricultural losses of $2.5 billion	Increase	1.5 times more likely due to increased evapotranspiration (minimal anthropogenic impact on precipitation)	(Hoell et al., 2019)
	East Africa	Extensive drought across Tanzania, Ethiopia, Kenya, and Somalia contributed to extreme food insecurity	Increase	Likelihood doubled	(Funk et al., 2019)

		approaching near-famine conditions			
2016	Southern Africa	Millions of people were affected by famine, disease, and water shortages. In addition, a 9-million ton cereal deficit resulted in 26 million people in need of humanitarian assistance.	Increase	Anthropogenic climate change *likely* increased the intensity of the 2015/16 El Niño, and a drought of this severity would have been very unlikely (probability ~9%) in the pre-industrial climate.	(Funk et al., 2018)
2016	Brazil	Três Marias, Sobradinho, and Itaparica reservoirs reached 5% of volume capacity. (Ceará), registered 39 (of 153) reservoirs empty in Ceará. Another 42 reached inactive volume. 96 (of 184) Ceará municipalities experienced water supply interruption.	Not found	Not found	(Martins et al., 2018)
2016	Thailand	Severe drought affected 41 Thai provinces, had devastating effects on major crops, such as rice and sugar cane, and incurred a total loss in the agricultural production of about half a billion US dollars	Increase	The record temperature of April 2016 in Thailand would not have occurred without the influence of both anthropogenic forcings and El Niño. Anthropogenic forcing has contributed to drier Aprils, but El Niño was the dominant cause of low rainfall.	(Christidis et al., 2018)
2015	Washington state, USA	The US $335 million loss for the agricultural industry	Increase	Snowpack drought resulted from exceedingly high temperatures despite normal precipitation	(Fosu et al., 2016)
2014	São Paulo, Brazil	In January 2015, the largest water supply system used for Sao Paulo, Cantareira, sank to a water volume of just 5% of capacity, and the number of people supplied fell from 8.8 million people to 5.3 million people, with other systems taking over supplies for the remainder.	No impact	Anthropogenic climate change is not found to be a major influence on the hazard, whereas increasing population and water consumption increased vulnerability.	(Otto et al., 2015)
2014	Southern Levant, Syria	While the extent to which the 2007/08 drought in the Levant region destabilized the Syrian government was not clear, "there is no questioning the enormous toll this extreme event took on the region's population. The movement of refugees from both the drought and war-affected regions into Jordan and Lebanon ensured that the anomalously low precipitation in the winter of 2013/14 amplified	Increase	The persistent drought in the 2014 rainy season was unprecedented for the critical January–February period in the observational record, and was made ~45% more likely by anthropogenic climate change.	(Bergaoui et al., 2015)

		impacts on already complex water and food provisions."			
2013-2014	Mediterranean coastal Middle East, northward through Turkey and eastward through Kazakhstan, Uzbekistan and Kyrgyzstan	The Eastern (main) basin of the Aral Sea dried up for the first time in modern history	Unclear	High western Pacific sea surface temperatures (SSTs) linked to drought in the Middle East and central-southwest Asia, and the SSTs in that region showed a strong warming trend.	(Barlow and Hoell, 2015)
2014	East Africa	Some isolated food security crises	Increase	Anthropogenic warming contributed to the 2014 East African drought by increasing East African and west Pacific temperatures, and increasing the gradient between standardized western and central Pacific SST causing reduced rainfall, evapotranspiration, and soil moisture.	(Funk et al., 2018)

Although long-term drought trends are clearer for agricultural or ecological drought compared to meteorological droughts (Douville et al., 2021; Seneviratne et al., 2021), most attribution studies for individual extreme events focus on meteorological (precipitation) drought and sometimes also considers temperature anomalies. A complete examination of drought relevant to societal impacts often requires consideration of hydrological and agricultural drought, so extreme event attribution conclusions relating to precipitation alone may not fully capture the processes leading to societal effects. There is, therefore, a critical knowledge gap in the attribution of changes in drought indicators more closely related to societal impacts such as soil moisture and the availability of fresh water supplies.

In summary, droughts can have substantial societal impacts (*virtually certain*), and agricultural and ecological drought conditions in particular have become more frequent and severe in many parts of the world but less frequent and severe in some others (*high confidence*). Drought-induced economic losses relative to GDP are approximately twice as high in lower-income countries compared to higher-income countries, although the gap has narrowed since the 1980s and at the global scale there is a decreasing trend of economic vulnerability to drought (*medium confidence*). Nevertheless, anthropogenic climate change has contributed to the increased likelihood or severity of drought events in many parts of the world, causing reduced agricultural yields, drinking water shortages for millions of people, increased wildfire risk, loss of lives of humans and other species and loss of billions of dollars of economic damages (*medium confidence*).

4.2.6 Observed Changes in Groundwater

AR5 concluded that the extent to which groundwater abstractions are affected by climate change is not well known due to the lack of long-term observational data (Jiménez Cisneros et al., 2014). AR 6 (Douville et al., 2021) confirmed that, despite considerable progress since AR5, limitations in the spatio-temporal coverage of groundwater monitoring networks, abstraction data, and numerical representations of groundwater recharge processes continue to constrain understanding of climate change impacts on groundwater.

Globally groundwater use has societal and economic benefits providing a critical buffer against precipitation variability. Groundwater irrigation has ensured food security, livelihood support, and poverty alleviation, for example, in India (Sekhri, 2014), Bangladesh (Salem et al., 2018), and sub-Saharan Africa (Taylor et al., 2013a; Cuthbert et al., 2019b). Groundwater is a safe drinking water source during natural hazard-induced disasters (Richts and Vrba, 2016). However, groundwater over-exploitation leads to the attenuation of societal benefits, including reduced agricultural production (Asoka and Mishra, 2020; Jain et al., 2021), decrease in adaptive capacity of communities (Blakeslee et al., 2020), and water quality deterioration (Mas-Pla and Menció, 2019). Loss of traditional water systems based on groundwater, such as *foggara* in Tunisia (Mokadem et al., 2018), *qanat* in Pakistan (Mustafa and Usman Qazi, 2008), *aflaj* in Oman (Remmington, 2018), and spring boxes in the Himalayas (Kumar and Sen, 2018) also leads to loss of cultural values for local communities.

Even though global groundwater abstraction (789 ± 30 km3 yr−1) is just about 6 percent of the annual recharge (~13,466 km^3) (Hanasaki et al., 2018), few hotspots of groundwater depletion have emerged at local to regional scales since the end of 20th century to beginning of 21st century due to intensive groundwater use for irrigation. The variability in groundwater storage is a function of human abstraction and natural recharge, which is in turn controlled by local geology (Green, 2016). In humid regions, precipitation influences recharge, and linear associations between precipitation and recharge are often observed (Kotchoni et al., 2019); for example, over humid locations in sub-Saharan Africa (Cuthbert et al., 2019b).

A global review (Bierkens and Wada, 2019) of groundwater storage changes highlight that estimates of depletion rates at the global scale are variable. These estimates range from approximately 113 to 510 km^3 $year^{-1}$ and variation in estimates is due to methods and spatio-temporal scales considered (*high confidence*). Global hydrological models (Herbert and Döll, 2019) show that human-induced groundwater depletion at rates exceeding 20 mm $year^{-1}$ (2001–2010) is occurring in the major aquifers systems such as the High Plains and California Central Valley aquifers (USA), Arabian aquifer (Middle East), North-Western Sahara aquifer (North Africa), Indo-Gangetic Basin (India) and North China Plain (China) (*high confidence*). Groundwater depletion at lower rates (<10 mm $year^{-1}$) is taking place in the Amazon Basin (Brazil) and Mekong River Basin (South East Asia), primarily due to climate variability and change (*high confidence*). A global-scale analysis (Shamsudduha and Taylor, 2020) of GRACE satellite measurements (2002–2016) for the 37 world's large aquifer systems reveals that trends in groundwater storage are mostly nonlinear and declines are not secular (*high confidence*). There are strong statistical associations between changes in groundwater storage and extreme annual precipitation from 1901 to 2016 in the Great Artesian Basin (Australia) and the California Central Valley aquifer (USA). Groundwater recharge of high magnitudes can be generated from intensive precipitation events. On the other hand, recharge can become more episodic, mostly in arid to semi-arid locations (*robust evidence, medium agreement*). For example, in central Tanzania, seven rainfall events between 1955 and 2010 generated 60% of total recharge (Taylor et al., 2013b). Similarly, in southern India (Asoka et al., 2018) and southwestern USA (Thomas et al., 2016), focused recharge via losses from ephemeral river channels, overland flows, and floodwaters is documented (Cuthbert et al., 2019b).

In cold regions, where snowmelt dominates the local hydrological processes (Irannezhad et al., 2016) and (Vincent et al., 2019) show high recharge to aquifers from glacial meltwater; while (Nygren et al., 2020) report a decrease in groundwater recharge due to a shift in main recharge period from spring (snowmelt) to winter (rainfall). In Finland, a sustained reduction (almost 100 mm in 100 years) of long-term snow accumulation combined with early snowmelt has reduced spring-time recharge (Irannezhad et al., 2016) (*medium confidence*).

Data from ground-based long-term records in the Indo-Gangetic Basin reveals that sustainable groundwater supplies are constrained more by extensive contamination (e.g., arsenic, salinity) than depletion (MacDonald et al., 2016). Many low-lying coastal aquifers are contaminated with increased salinity due to land-use change, rising sea levels, reduced stream flows, and increased storm surge inundation (Lall et al., 2020). Nearly 26 million people are currently exposed to very high (>1500 $\mu S\ cm^{-1}$) salinity in shallow groundwater in coastal Bangladesh (Shamsudduha and Taylor, 2020).

Groundwater Dependent Ecosystems (GDEs), such as terrestrial wetlands, stream ecosystems, estuarine and marine ecosystems (Kløve et al., 2014), support wetlands, biodiversity, provide water supply, baseflows to rivers, offers recreational services, and help control floods (Rohde et al., 2017). Globally, 10% to 23% of the watersheds have reached the environmental flow limits due to groundwater pumping (de Graaf et al., 2019). A recent study of 4.2 million wells across the USA shows that induced groundwater recharge in nearly two-thirds of these wells could reduce stream discharges, thereby threatening GDEs (Jasechko et al., 2021). (Work, 2020) found reduced spring flow due to increased groundwater abstraction in 26 out of 56 springs studied in Florida (USA). GDEs in semi-arid and arid regions tend to have much longer groundwater response times and may be more resilient to climate change than those in humid areas where groundwater occurrence is mostly at shallow levels (Cuthbert et al., 2019a; Opie et al., 2020). However, groundwater depletion impacts on the full range of ecosystem services remain understudied (Bierkens and Wada, 2019).

A better understanding of and incorporating subsurface storage dynamics into earth system models will improve climate-groundwater interactions under global warming (Condon et al., 2020). Long-term groundwater-level monitoring data are of critical importance (Famiglietti, 2014) for understanding the sensitivity of recharge processes to climate variability and, more critically, calibration and validation of hydrological models (Goderniaux et al., 2015). GRACE satellite-derived groundwater storage estimates provide important insights at a regional scale (Rodell et al., 2018) but overlook more localized depletion or short-term storage gains. Low and middle-income countries, e.g., in Central Asia and Sub-Saharan Africa, lack such monitoring networks, which is a significant knowledge gap.

In summary, groundwater storage has declined in many parts of the world, most notably since the beginning of the 21st century, due to the intensification of groundwater-fed irrigation (*high confidence*). Groundwater in aquifers across the tropics appears to be more resilient to climate change as enhanced recharge is observed to occur mostly episodically from intense precipitation and flooding events (*robust evidence, medium agreement*). In higher altitudes, warmer climates have altered groundwater regimes and may have led to reduced spring-time recharge due to reduced duration and snowmelt discharges (*medium confidence*).

4.2.7 Observed Changes in Water Quality

AR5 (Jiménez Cisneros et al., 2014) concluded with *medium evidence* and *high agreement* that climate change affected water quality, posing additional risks to drinking water quality and human health (Field et al., 2014b), particularly due to increased eutrophication at higher temperatures or release of contaminants due to extreme floods (Jiménez Cisneros et al., 2014). In addition, SROCC (Hock et al., 2019b; Meredith et al., 2019) assessed that glacier decline and permafrost degradation impacts water quality through increases in legacy contaminants *(medium evidence, high agreement)*.

Warming temperatures and extreme weather events are can potentially impact water quality (Khan et al., 2015). Water quality can be compromised through algal blooms that affect the taste and odour of recreational and drinking water and can harbour toxins and pathogens (Khan et al., 2015). Warming directly affects thermal water regimes, promoting harmful algal blooms (Li et al., 2018; Noori et al., 2018) (4.3.5). Additionally, permafrost degradation leads to an increased flux of contaminants (MacMillan et al., 2015; Roberts et al., 2017; Mu et al., 2019). The increased meltwater from glaciers (Zhang et al., 2019) releases deposited contaminants and reduces water quality downstream (Zhang et al., 2017; Hock et al., 2019b).

Floods intensify the mixing of floodwater with wastewater and the redistribution of pollutants (Andrade et al., 2018). In addition, contaminated floodwaters pose an immediate health risk through waterborne diseases (Huang et al., 2016b; Paterson et al., 2018; Setty et al., 2018). Wildfires, along with heavy rainfalls and floods, can also affect turbidity, which increases drinking water treatment challenges and has been linked to increases in gastrointestinal illness (de Roos et al., 2017. Droughts reduce river dilution capacities and groundwater levels {Wen, 2017 #2093), increasing the risk of groundwater contamination (Kløve et al., 2014). More generally, contaminated water diminishes its aesthetic value, compromising recreational activities, reducing tourism and property values, and creating challenges for management and drinking water treatment (Eves and Wilkinson, 2014; Khan et al., 2015; Walters et al., 2015).

Between 2000−2010, ~10% of the global population faced adverse water quality issues (van Vliet et al., 2021). Adverse drinking water quality has been associated with extreme weather events in countries located in Asia, Africa, and South and North America (Jagai et al., 2015; Levy et al., 2016; Huynh and Stringer, 2018; Leal Filho et al., 2018; Abedin et al., 2019) (*medium evidence, high agreement*). Dilution factors in 635 of 1049 US streams fell extremely low during drought conditions. Additionally, the safety threshold for endocrine-disrupting compound concentration exceeded in roughly a third of streams studied (Rice and Westerhoff, 2017). Natural acid rock drainage, which can potentially release toxic substances, has experienced an intensification in an alpine catchment of Central Pyrenees due to climate change and severe droughts in the last decade. River length affected by natural acid drainage increased from 5 km in 1945 to 35 km in 2018 (Zarroca et al., 2021). Three-fold increases in contaminants and five-fold increases in nutrients have been observed in water sources after wildfires (Khan et al., 2015). Due to permafrost thawing, the concentration of major ions, especially SO_4^{2-} in two high Arctic lakes, has rapidly increased up to 500% and 340% during 2006–2016 and 2008–2016, respectively (Roberts et al., 2017). The exports of Dissolved Organic Carbon, Particulate Organic Carbon and Mercury in six Arctic rivers were reported to increase with significant deepening active layers caused by climate warming during 1999−2015 (Mu et al., 2019). Sustained warming in Lake Tanganyika in Zambia during the last ∼150 years reduced lake mixing, which has depressed algal production, shrunk the oxygenated benthic habitat by 38%, and further reduced fish yield and mollusc (Cohen et al., 2016). From 1994 to 2010, coastal benthos at King George Island in Antarctica has observed a remarkable shift primarily linked to ongoing climate warming and the increased sediment runoff triggered by glacier retreats (Sahade et al., 2015). The recovery time of macroinvertebrates from floods was found longer in cases of pre-existing pollution problems (Smith et al., 2019a).

In summary, although climate-induced water quality degradation due to increases in water and surface temperatures or melting of the cryosphere has been observed (*medium confidence*), evidence of global-scale changes in water quality is *limited* because many studies are isolated and have limited regional coverage.

4.2.8 Observed Changes in Soil Erosion and Sediment Load

AR5 established potential impacts of climate change on soil erosion and sediment loads in mountain regions with glacier melt (*low to medium evidence*) (Jiménez Cisneros et al., 2014). SRCCL (Olsson et al., 2020) reported with *high confidence* that rainfall changes attributed to human-induced climate change have already intensified drivers of land degradation. Nonetheless, attributing land degradation to climate change alone is challenging because of the role of land management practices (*medium evidence, high agreement*).

Climate change impacts soil erosion and sedimentation rates both directly from increasing rainfall or snowmelt intensity (Vanmaercke et al., 2014; Polyakov et al., 2017; Diodato et al., 2018; Golosov et al., 2018; Li et al., 2020a; Li et al., 2020b) and indirectly from increasing wildfires (Gould et al., 2016; Langhans et al., 2016; DeLong et al., 2018), permafrost thawing (Schiefer et al., 2018; Lafrenière and Lamoureux, 2019; Ward Jones et al., 2019), vegetation cover changes (Micheletti et al., 2015; Potemkina and Potemkin, 2015; Carrivick and Heckmann, 2017; Beel et al., 2018). In addition, accelerated soil erosion and sedimentation have severe societal impacts through land degradation, reduced soil productivity and water quality (4.2.7), increased eutrophication and disturbance to aquatic ecosystems (4.3.5), sedimentation of waterways and damage to infrastructure (Graves et al., 2015; Issaka and Ashraf, 2017; Schellenberg et al., 2017; Hewett et al., 2018; Panagos et al., 2018; Sartori et al., 2019) (*medium confidence*).

In the largest river basin of the Colombian Andes, regional climate change and land use activities (ploughing, grazing, deforestation) caused a 34% erosion rate increase over 10 years, with the anthropogenic soil erosion rate exceeding the climate-driven erosion rate (Restrepo and Escobar, 2018). Sedimentation increases due to soil erosion in mountainous regions burned by wildfires, as a result of warming and altered precipitation, is documented with *high confidence* in the USA (Gould et al., 2016; DeLong et al., 2018), Australia (Nyman et al., 2015; Langhans et al., 2016), China (Cui et al., 2014), Greece (Karamesouti et al., 2016), and can potentially damage downstream aquatic ecosystems (4.3.5) and water quality (4.2.7) (Cui et al., 2014; Murphy et al., 2015; Langhans et al., 2016) (*medium confidence*). In Australia, for instance, sediment yields from post-fire debris flows (113–294 t ha^{-1}) are 2–3 orders of magnitude higher than annual background erosion rates from undisturbed forests (Nyman et al., 2015). The positive trend in sediment yield in small ponds in the semi-arid southwestern USA over the last 90 years was not entirely related to the rainfall or runoff trends, but was a result of complex interaction between long-term changes in vegetation, soil, and channel networks (Polyakov et al., 2017).

Regional climate changes (precipitation decrease) and human activities (landscape engineering, terracing, large-scale vegetation restoration, soil conservation) over the Loess Plateau (China) caused a distinct stepwise reduction in sediment loads from the upper-middle reach of the Yellow River, with 30% of the change related to climate change (Tian et al., 2019). Substantial increases in sediment flux were identified on the Tibetan Plateau (Li et al., 2020a; Li et al., 2021a), e.g. the sediment load from the Tuotuohe headwater increased by 135% from 1985-1997 to 1998-2016, mainly due to climate change (Li et al., 2020a). In 1986-2015, the sedimentation rate in dry valley bottoms of the Southern Russian Plain was 2 to 5 times lower than in 1963–1986 due to the warming-induced surface runoff reduction during spring snowmelt (Golosov et al., 2018). Declining erosion trends are primarily associated with soil conservation management in northern Germany (Steinhoff-Knopp and Burkhard, 2018) and reforestation in southwestern China (Zhou et al., 2020).

The climate change impact on erosion and sediment load varies significantly over the world (Li et al., 2020b) (*high confidence*). There was a statistically significant correlation between sediment yield and air temperature for the non-Mediterranean region of Western and Central Europe (Vanmaercke et al., 2014) and Northern Africa (Achite and Ouillon, 2016). Still, such correlation is yet to be found for the other European rivers (Vanmaercke et al., 2015). Increased sediment and particulate organic carbon fluxes in the Arctic regions are caused by permafrost warming (Schiefer et al., 2018; Lafrenière and Lamoureux, 2019; Ward Jones et al., 2019). (Potemkina and Potemkin, 2015) demonstrate that regional warming and permafrost degradation have contributed to an increased forested area over the last 40–70 years, reducing soil erosion in Eastern Siberia. The sediment dynamics of small rivers in the eastern Italian Alps, depending on extreme floods, is sensitive to climate change (Rainato et al., 2017). In the north-eastern Italian Alps, precipitation change in 1986-2010 affected soil wetness conditions, influencing sediment load (Diodato et al., 2018). Regional warming in northern Africa (Algeria) dramatically changed river streamflow and increased sediment load over 4 decades (84% more every decade compared to the previous) (Achite and Ouillon, 2016).

A long-term global soil erosion monitoring network based on the unified methodological approach is needed to correctly evaluate erosion rate, detect its changes and attribute them to climate or other drivers.

In summary, in the areas with high human activity, the latter impact soil erosion and sediment flux more significantly than the climatic factors (*high confidence*). On the other hand, in natural conditions, e.g. in high latitudes and high mountains, the influence of climate change on the acceleration of the erosion rate is observed (*limited evidence, medium agreement*).

4.3 Observed Sectoral Impacts of Current Hydrological Changes

The intensification of the hydrological cycle due to anthropogenic climate change has multifaceted and severe impacts for cultural, economic, social and political pathways. In this section, we assess burgeoning evidence since AR5 which shows that environmental quality, economic development, and social well-being have been affected by climate induced hydrological changes since many aspects of the economy, environment, and society are dependent upon water resources. We advance previous IPCC reports by assessing evidence on the impacts of climate change-induced water insecurity for energy production (4.3.2), urbanization (4.3.4), conflicts (4.3.6), human mobility (4.3.7) and cultural usage of water (4.3.8).

Integrating qualitative and quantitative data, we show that it is evident that societies heightened exposure to water-induced disasters – as floods and droughts – and other hydrological changes have increased vulnerability across most sectors and regions, with few exceptions. Through the assessment of literature relying on Indigenous knowledge, we are also able to present evidence on how observed changes impact particularly Indigenous Peoples, local communities, and marginalized groups, as women, people without social protections and minorities.

Importantly, we note, that climate change induced hydrological changes are, for most sectors, one of the several factors, often coupled with urbanization, population growth and heightened economic disparities, that have increased societal vulnerability and required communities across the globe to alter their productive and cultural practices.

4.3.1 Observed Impacts on Agriculture

AR5 concluded with *high confidence* that agricultural production was negatively affected by climate change, with droughts singled out as a major driver of food insecurity. In contrast, evidence of floods on food production was *limited* (Porter et al., 2014).

Globally 23% of croplands are irrigated, providing 34% of global calories production. Of these lands, 68% experience blue water scarcity at the least one month-yr and 37% up to 5 months-yr. Such agricultural water scarcity is experienced in mostly drought-prone areas in low-income countries (Rosa et al., 2020a). Approximately three-quarters of the global harvested areas (~454 million hectares) experienced drought-induced yield losses between 1983 and 2009, and the cumulative production losses corresponded to US$166 billion (Kim et al., 2019). Globally, droughts affected both harvested areas and yields, with a reported cereal production loss of 9-10% due to weather extremes between 1964 and 2007. Yield losses were greater by about 7% during recent droughts (1985-2007) due to greater damage – reducing harvested area - compared to losses from earlier droughts (1964-1984), with 8-11% greater losses in high-income countries than in low-income ones (Lesk et al., 2016). Globally, between 1961 and 2006, it has been estimated that 25% yield loss occurred, with yield loss probability increasing by 22% for maize, 9% for rice, and 22% for soybean under drought conditions (Leng and Hall, 2019). Mean climate, and climate extremes are responsible for 20-49% of yield anomalies variance, with 18-45% of this variance attributable to droughts and heatwaves (Vogel et al., 2019). Drought has been singled out as a major driver of yield reductions globally (*high confidence*) (Lesk et al., 2016; Meng et al., 2016; Zipper et al., 2016; Anderson et al., 2019; Leng and Hall, 2019).

Yields of major crops in semi-arid regions, including the Mediterranean, sub-Saharan Africa, South Asia and Australia, are negatively affected by precipitation declines in the absence of irrigation (Iizumi et al., 2018; Ray et al., 2019), but this trend is less evident in wetter regions (Iizumi et al., 2018). Precipitation and temperature changes reduced global mean yields of maize, wheat and soybeans by 4.1%, 1.8% and 4.5%, respectively (Iizumi et al., 2018). Of the global rice yield variability of ~32%, precipitation variability accounted for a larger share in drier South Asia than in wetter East and Southeast Asia (Ray et al., 2015). Between 1910-2014 agro-climatic conditions became more conducive to maize and soybean yield growth in the American Midwest due to increases in summer precipitation and cooling due to irrigation (Iizumi and Ramankutty, 2016; Mueller et al., 2016) (Box 4.3). In Australia, between 1990 and 2015, the negative effects of reduced precipitation and rising temperature led to yield losses, but yield losses were partly avoided because of elevated CO_2 atmospheric concentration and technological advancements (Hochman et al., 2017a). Overall, temperature-only effects are stronger in wetter regions like Europe and East and Southeast Asia, and precipitation-only effects are stronger in drier regions (Iizumi et al., 2018; Ray et al., 2019) *(medium evidence, high agreement)*. In Asia, the gap between rainfed and irrigated maize yield widened from 5% in the 1980s to 10% in the 2000s (Meng et al., 2016). In North America, yields of maize and soybeans have increased (1958-2007), yet meteorological drought has been associated with 13% of overall yield variability. However, yield variability was not a concern where irrigation is prevalent (Zipper et al., 2016). However, when water scarcity has reduced irrigation, yields have been negatively impacted (Elias et al., 2016). In Europe, yields have been affected negatively by droughts (Beillouin et al., 2020), with losses tripling between 1964 and 2015 (Brás et al., 2021). In West Africa between 2000 and 2009, drought, among other altered climate conditions, led to millet and sorghum yield reductions between 10-20% and 5-15%, respectively (Sultan et al., 2019). Between 2006 to 2016, droughts contributed to food insecurity and malnutrition in northern, eastern, and southern Africa, Asia and the Pacific. In 36% of these nations – mainly in Africa – where severe droughts occurred, undernourishment rose (Phalkey et al., 2015; Cooper et al., 2019). An attribution study showed that anthropogenic emissions increased the chances of October-December droughts over the region by 1.4 to 4.3 times and resulted in below-average harvests in Zambia and South Africa (Nangombe et al., 2020). Root crops, a staple in many tropics and sub-tropical countries, and vegetables are particularly prone to drought, leading to smaller fruits or crop failure (Daryanto et al., 2017; Bisbis et al., 2018). Livestock production has also been affected by changing seasonality, increasing frequency of drought, rising temperatures and vector-borne diseases and parasites through changes in the overall availability, as well as reduced nutritional value, of forage and feed crops (Varadan and Kumar, 2014; Naqvi et al., 2015; Zougmoré et al., 2016; Henry et al., 2018; Godde et al., 2019) *(medium confidence)*.

Floods have led to harvest failure, crop and fungal contamination (Liu et al., 2013; Uyttendaele et al., 2015). Globally, between 1980 and 2018, excess soil moisture has reduced rice, maize, soybean and wheat yields between 7 and 12% (Borgomeo et al., 2020). Changes in groundwater storage and availability, which are affected by the intensity of irrigated agriculture, also negatively impacted crop yields and cropping patterns (4.2.6, Box 4.3, 4.7.2). Moreover, extreme precipitation can lead to increased surface flooding, waterlogging, soil erosion and susceptibility to salinization (*high confidence*). For example, in Bangladesh, in March and April 2017, floods affected 220,000 ha of nearly ready to be harvested summer paddy crop and resulted in almost a 30% year on year increase in paddy prices. An attribution study of those pre-monsoon extreme rainfall events in Bangladesh concluded that anthropogenic climate change doubled the likelihood of the extreme rainfall event (Rimi et al., 2019). Moreover, floods, extreme weather events and cyclones have led to animal escapes and infrastructure damage in aquaculture (Beveridge et al., 2018; Islam and Hoq, 2018; Naskar et al., 2018; Lebel et al., 2020) (see 5.9.1).

Worldwide, the magnitudes of climate-induced water-related hazards and their impact on agriculture are differentiated across populations and genders (4.3.6; 4.8.3). Evidence shows that hydroclimatic factors pose high food insecurity risks to subsistence farmers, whose first and only source of livelihood is agriculture, and who are situated at low latitudes where the climate is hotter and drier (Shrestha and Nepal, 2016; Sujakhu et al., 2016). Historically, they have been the most vulnerable to observed climate-induced hydrological changes (Savo et al., 2016). Indigenous and local communities, often heavily reliant on agriculture, have a wealth of knowledge about observed changes. These are important because they shape farmers' perceptions, which in turn shape the adaptation measures farmers will undertake (Caretta and Börjeson, 2015; Savo et al., 2016; Sujakhu et al., 2016; Su et al., 2017) (4.8.4) (*high confidence)*.

In summary, ongoing climate change in temperate climates has some positive impacts on agricultural production. In subtropical/tropical climates, climate-induced hazards such as floods and droughts negatively impact agricultural production (*high confidence*). People living in deprivation and Indigenous people have been disproportionally affected. They often rely on rain-fed agriculture in marginal areas with high exposure and high vulnerability to water-related stress and low adaptive capacity (*high confidence)*.

4.3.2 Observed Impacts on Energy and Industrial Water Use

AR5 (Jiménez Cisneros et al., 2014) concluded with *medium evidence* and *high agreement* that hydropower negatively impacts freshwater ecosystems. SROCC (IPCC, 2019a) concluded with *medium confidence* that climate change has led to both increases and decreases in annual/seasonal water inputs to hydropower plants.

Water is a crucial input for hydroelectric and thermoelectric energy production, which together account for 94.7% of the world's current electricity generation (Petroleum, 2020). Climate change impacts hydropower production through changes in precipitation, evaporation, volume, and timing of run-off; and impacts cooling of thermoelectric power plants through reduced streamflow and increased water temperatures (Yalew et al., 2020). In addition, extreme weather events, like tropical cyclones, landslides, and floods, damage energy infrastructure (MCTI, 2020; Yalew et al., 2020), while high temperature and humidity increase the energy requirement for cooling (Maia-Silva et al., 2020).

With 1,308 GW installed capacity in 2019, hydropower became the world's largest single source of renewable energy (IHA, 2020) (also see Figure 6.12, WGIII). While hydropower reduces emissions relative to fossil fuel-based energy production, hydropower reservoirs are being increasingly associated with GHG emissions caused by submergence and later re-emergence of vegetation under reservoirs due to water level fluctuations (Räsänen et al., 2018; Song et al., 2018; Maavara et al., 2020). A recent global study concluded that reservoirs might emit more carbon than they bury, especially in the tropics (Keller et al., 2021) (*medium confidence*).

In Ghana, between 1970 and 1990, rainfall variability accounted for 21% of inter-annual variations in hydropower generation (Boadi and Owusu, 2019). In Brazil's São Francisco River, following drought events in 2016 and 2017, hydropower plants operated with an average capacity factor of only 23% and 17%, respectively (de Jong et al., 2018). In Switzerland, increased glacier melt contributed to 3% to 4% of hydropower production since 1980 (Schaefli et al., 2019) (4.2.2). In the USA, hydropower generation dropped by nearly 27% for every standard deviation increase in water scarcity. Equivalent social costs of loss in hydropower generation between 2001-2012 were approximately US$330,000 (at 2015 value) per month for every power plant that experienced water scarcity (Eyer and Wichman, 2018). Globally, for the period 1981-2010, the utilization rate of hydropower was reduced by 5.2% during drought years compared to long-term average values (van Vliet et al., 2016a). Thus, there is a growing body of evidence of negative impacts of extreme events on hydropower production (*high confidence*).

Impacts of water scarcity on thermoelectric plants are more unequivocal than hydropower plants. For example, a simulation study showed that 32% of the world's coal-fired power plants are currently experiencing water scarcity for at least five months or more in a year. The majority of these plants are in China (52%), followed by India (15%) and the USA (11%) (Rosa et al., 2020c). In the United Kingdom, almost 50% of freshwater thermal capacity is lost on extreme high-temperature days, causing losses in the range of average GBP 29-66 million/year. In the case of ~20% of particularly vulnerable power plants, these losses could increase to GBP 66-95 million/year annualized over 30 years (Byers et al., 2020). Globally, for the period 1981-2010, the utilization rate of thermoelectric power was reduced by 3.8% during drought years compared to long-term average values (van Vliet et al., 2016a); and none of the studies reported increases in thermoelectric power production as a consequence of climate change (*high confidence*).

In energy sector, a large number of studies document the impact of extreme climate events (e.g., droughts, or extreme temperature days) on production of hydropower and thermo-electric power, yet, there are limited studies that measure trends in energy production due to long term climate change. This remains a knowledge gap.

Mining in regions already vulnerable to climate change-induced water scarcity is under threat, leading some countries like El Salvador to ban metal mining completely (Odell et al., 2018). Likewise, food and agro-processing companies are aware of water-related threats to their operations, with 77% of 35 publicly traded companies evaluated in 2019 explicitly citing water as a risk factor in their annual reports, up from 59% in 2017 (CDP, 2018; CERES, 2019). Changes in water availability affect the mining, electrical, metal, and agro-processing sector (UNIDO, 2017; Odell et al., 2018; Frost and Hua, 2019), but these impacts are less understood due to the lack of studies.

In summary, there is *high confidence* that climate change has had negative impacts on hydro and thermal power production globally due to droughts, changes in the seasonality of river flows, and increasing ambient water temperatures.

4.3.3 Observed Impacts on Water, Sanitation and Hygiene (WaSH)

AR5 showed that local changes in temperature and rainfall had altered the distribution of some water-related diseases (*medium confidence*), and extreme weather events disrupt water supplies, impacting morbidity, mortality, and mental health (*very high confidence*) (Field et al., 2014b). In addition, melting and thawing of snow, ice, and permafrost (4.2.2) have also adversely impacted water quality, security, and health (*high confidence*) (IPCC, 2019a) (4.2.7).

Literature since AR5 confirms that temperature, precipitation, and extreme weather events are linked to increased incidence and outbreaks of water-related and neglected tropical diseases (Colón-González et al., 2016; Levy et al., 2016; Azage et al., 2017; Harp et al., 2021) (*high confidence*). For example, the rainy season in Senegal has been associated with an 84% increase in relative risk of childhood diarrhoea, and an additional wet day per week was associated with up to 2% increases in diarrheal disease in Mozambique (Thiam et al., 2017; Horn et al., 2018). In Ecuador, increases of 1.5 cases of diarrhoea per 1000 were associated with heavy rainfall after dry periods, while a decrease of 1 case per 1000 was associated with heavy rain after wet periods (Carlton et al., 2014). Floods have been associated with 22% increases in relative risk of diarrhoea in China (Liu et al., 2018c). In addition, higher levels of faecal contamination of drinking water and hands (i.e., lack of WaSH) has been statistically significantly associated with increased child diarrhoea (Goddard et al., 2020).

In 2020, 2 billion people lacked access to uncontaminated water, while 771 million lacked basic sanitation services, primarily in sub-Saharan Africa and rural areas (WHO and UNICEF, 2021). Even in high-income countries, poor quality drinking water can be a health issue (Murphy et al., 2014). For example, in a sampled population in Canada, reported exposure to exposure routes for waterborne illness included 7% from private wells and 71.8% from municipal water (David et al., 2014). Drinking water treatment can be compromised by degraded source water quality and extreme weather events, including droughts, storms, ice storms and wildfires that overwhelm or cause infrastructure damage (Sherpa et al., 2014; Khan et al., 2015; Howard et al., 2016; White et al., 2017) (*high confidence*). Adverse health effects are exacerbated due to the absence of adequate WaSH, particularly in poorer households (Khan et al., 2015; Kostyla et al., 2015; Cissé et al., 2016), WaSH infrastructure failure (Khan et al., 2015; Wanda et al., 2017), or inadequate WaSH facilities in emergency shelters (Alam and Rahman, 2014). For example, WaSH coverage decreased from 65% to 51% due to damage from floods and earthquakes in Malawi (Wanda et al., 2017). Loss of electricity also impacts WaSH service delivery (Cashman, 2014), and infrastructure damage caused by climate hazards may reverse progress on universal access to WaSH (Kohlitz et al., 2017) (*limited evidence, high agreement*). In addition, wastewater outflows have been associated with a 13% increased relative risk of gastrointestinal illness through contaminated drinking water sources (Jagai et al., 2015) (*limited evidence, high agreement*). Harmful algal blooms represent an emerging health risk, but lack of monitoring and reporting prevent risk exposure assessments (Carmichael and Boyer, 2016; Nichols et al., 2018) (*limited evidence, high agreement*). Chemical contaminants (e.g., nitrates, arsenic) have been linked to non-communicable diseases, including neurological disorders, liver and kidney damage, and cancers (Jones Rena et al., 2016), and to some water-related diseases (e.g., schistosomiasis) (*low evidence, medium agreement*).

Water insecurity and inadequate WaSH have been associated with increased disease risk (*high confidence*), stress and adverse mental health (*limited evidence, medium agreement*), food insecurity and adverse nutritional outcomes, and poor cognitive and birth outcomes (*limited evidence, medium agreement*) (Workman and Ureksoy, 2017; Sclar et al., 2018; Boateng et al., 2020; Rosinger and Young, 2020; Wutich et al., 2020). Climate-induced water scarcity and supply disruptions disproportionately impact women and girls. The necessity of water collection takes away time from income-generating activities, child care, and education (Yadav and Lal, 2018; Schuster et al., 2020) (*medium evidence, medium agreement*). Consumption of larger volumes of water is essential for healthy women during pregnancy, lactation, and caregiving, which increases the amount of water that has to be fetched. Fetching of water is associated with increased risk of sexual abuse, demand for sexual favours at controlled water collection points, physical injuries (e.g., musculoskeletal or from animal attacks), domestic violence for not completing daily water-related domestic tasks (*limited evidence, high agreement*), and poorer maternal and child health (Mercer and Hanrahan, 2017; Pommells et al., 2018; Anwar et al., 2019; Collins et al., 2019a; Geere and Hunter, 2020; Venkataramanan et al., 2020) (*medium evidence, high agreement*). Menstrual hygiene management is a public health issue but poorly linked to climate change, despite relationships between lack of adequate WaSH, poor menstrual hygiene, and urinary tract infections (Ellis et al., 2016; Pouramin et al., 2020). Water insecurity also affects emotional, spiritual, and cultural relationships that are often critical to Indigenous health (Wilson et al., 2019) (*limited evidence, high agreement*).

There are gaps in data on climate-driven water-related disease burden for both infectious and non-communicable diseases. Increased demands for water and WaSH services for infectious diseases, such as HIV/AIDs and COVID-19 (Box4.4) exacerbate existing vulnerabilities and inequities (Stanley et al., 2017; Armitage and Nellums, 2020a; Rodriguez-Lonebear et al., 2020). Additionally, limited research has been undertaken to quantify the effects of climate-compromised WaSH on health and wellbeing.

In summary, WaSH-related household water insecurity and disease incidence are products of geography, politics, social and environmental determinants, vulnerability, and climate change (Bardosh et al., 2017; Stoler et al., 2021).

4.3.4 Observed Impacts on Urban and Peri-Urban Sectors

All previous IPCC reports have focused on future water-related risks to urban areas due to climate change rather than documented observed impacts.

Climate extremes have profound implications for urban and peri-urban water management, particularly in an increasingly urbanized world (*high confidence*). Over half (54%) of the global population currently lives in cities (WWAP, 2019), and global urbanization rates continue to increase across all SSPs (Jiang and O'Neill, 2017). Using observed station data for 217 urban areas worldwide, (Mishra et al., 2015) noted that 17% of cities experienced statistically significant increases (p-value <0.05) in the frequency of daily precipitation extremes from 1973 to 2012. (Mishra et al., 2015) hypothesized that such observed climate changes in urban areas were largely due to large scale changes rather than local land cover changes.

Since AR5, factors such as rapid population growth, urbanization, ageing infrastructure, and changes in water use have also magnified climate risks, such as drought and flooding, and contributed to urban and peri-urban water insecurity (*medium agreement, medium evidence*) (4.1.2). For example, despite an increase in flooding events from 1.1 flood events per year (1986-2005) to 5 flood events per year (2006-2016) in Ouagadougou (Burkina Faso), analyses of rainfall indices showed few have significant trends at 5% level over the period 1961-2015 and that the generalized extreme value distribution fit the time-series of annual maximum daily rainfall (Tazen et al., 2019). On the other hand, long-term annual variations of maximum hourly precipitation in Shanghai (China) increased significantly during 1916-2014, especially from 1981.

Advances in the attribution of extreme weather events have made it possible to determine the causal relationship between droughts, floods, and climate change for some cities, particularly those with long hydro-meteorological records (Bader et al., 2018; Otto et al., 2020). Attribution analysis shows that urbanization contributed to the increase in both frequencies of local and abrupt heavy rainfall events in the city, at a rate of 1.5 and 1.8 (10yr)-1, respectively (Liang and Ding, 2017). A multi-method attribution showed that the likelihood of prolonged rainfall deficit in Cape Town (South Africa) during 2015-17 was made more likely by a factor of 3.3 (1.4-6.4) due to anthropogenic climate change (Otto et al., 2018). These results show that climate change has impacted the return time of extreme droughts in the Western Cape, exceeding the capacity of the existing water supply system to cope (Otto et al., 2018) (Box 9.4; 9.8.2). In Baton Rouge (USA), a rapid attribution study showed that the probability of an event such as the intense precipitation and flash flooding of August 2016 has increased by at least a factor of 1.4 due to radiative forcing (USA) (van der Wiel et al., 2017). In Houston (USA), a study found that the combination of urbanization and climate change nearly doubled peak discharge (84%) during Hurricane Harvey (August 2017), suggesting that land-use change magnified the effects of climate change on catchment response to extreme precipitation events (Sebastian et al., 2019) (14.4.3.1; Box 14.5 The Economic Consequences of Climate Change in North America, Cross-Chapter Box DISASTER in Chapter 4). According to a multi-method approach, the 2014/15 drought event in Sao Paulo (Brazil) was more likely to have been driven by water use changes and population growth than climate change (Otto et al., 2015) (Cross-Chapter Box DISASTER in Chapter 4).

The science of weather event attribution requires high-quality observational data and climate models that are currently available only in highly developed countries (Otto et al., 2020). In addition, further research is necessary to determine the impacts of climate change on water-related extremes in the urban areas of developing countries (Bai et al., 2018). For example, a combination of observational analysis and global coupled climate models showed that the 2015 flooding event in Chennai (India) could not be attributed to anthropogenic climate change, with the effects of that being relatively small in the region due to the impact of greenhouse gas increases being largely counteracted by those of aerosols (van Oldenborgh et al., 2017a) (4.2.5). Further research is also required to determine the impacts of climate change on water-related extremes in informal settlements where vulnerability to water insecurity is high due to poverty, overcrowding, poor-quality housing, and lack of basic infrastructure (Scovronick et al., 2015; Grasham et al., 2019; Williams et al., 2019; Satterthwaite et al., 2020).

In summary, water-related hazards such as drought and flooding have been exacerbated by climate change in some cities (*high confidence*). Further research is necessary to determine the extent and nature of water-related climate change impacts in the urban areas of developing countries (*high confidence*).

[START CROSS-CHAPTER BOX DISASTER HERE]

Cross-Chapter Box DISASTER: Disasters as the Public Face of Climate Change

Authors: Aditi Mukherji (India, Chapter 4), Guéladio Cissé (Mauritania/Switzerland/France, Chapter 7), Caroline Zickgraf (Contributing Author), Paulina Aldunce (Chile, Chapter 7), Liliana Raquel Miranda Sara (Peru, Chapter 12), William Solecki, (USA, Chapter 17), Friederike Otto (United Kingdom, WGI), François Gemenne (France, WGI), Martina Angela Caretta (Sweden, Chapter 4);, Richard Jones (United Kingdom, WGI); Richard Betts (United Kingdom, Chapter 4), Maarten van Aalst (Netherlands, Chapter 16), Jakob Zscheischler (Switzerland), Kris Murray (UK), Mauro E. González (Chile).

Introduction

Some extreme weather events are increasing in frequency and (or) severity as a result of climate change (Seneviratne et al., 2021) (*high confidence*). These include extreme rainfall events (Roxy et al., 2017; Myhre et al., 2019; Tabari, 2020); extreme and prolonged heat leading to catastrophic fires (Bowman et al., 2017; Krikken et al., 2019; van Oldenborgh et al., 2020); and more frequent and stronger cyclones/hurricanes and resulting extreme rainfall (Griego et al., 2020). These extreme events, coupled with high vulnerability and exposure in many parts of the world, turn into disasters and affect millions of people every year. New advances enable the detection and attribution of these extreme events to climate change (Otto et al., 2016; Seneviratne et al., 2021), with the most recent study saying that heavy rains leading to devasting floods in the Western Europe that captured the world's attention in July 2021 was made more likely due to climate change (Kreienkamp et al., 2021). Most WGII chapters (this volume) report various extreme event-induced disasters and their societal impacts. This cross-chapter box brings together authors from WGI and WGII to underscore that disasters following extreme events have become the most visible and public face of climate change (Solecki and Rosenzweig, 2014). These disasters reflect immediate societal and political implications of rising risks (*high confidence*) but also provide windows of opportunity to raise awareness about climate change and to implement disaster reduction policies and strategies (*high confidence*) (Albright, 2020; Boudet et al., 2020).

Here, we document eight catastrophic climate-related disasters that took place between 2017-2021. These disasters resulted in the loss of lives, livelihoods, had adverse impacts on biodiversity, health, infrastructure, and the economy. It provided important rallying points for discussions around climate change, equity, and vulnerability in some cases. These disasters also offer valuable lessons about the role of effective climate change adaptation in managing disaster risks and the importance of loss and damage mechanisms in global negotiation processes (Jongman et al., 2014; Mechler et al., 2014; Cutter and Gall, 2015).

Case 1. Compounded Events and Impacts on Human Systems: Cyclones Idai and Kenneth in Mozambique in 2019

While individual events alone can lead to major disasters, when several events occur in close spatial and temporal proximity, impacts get compounded with catastrophic results (Zscheischler et al., 2018; Zscheischler et al., 2020). In March 2019, Cyclone Idai (Category 2) was the deadliest storm on record to strike the African continent, with the coastal city of Beira in Mozambique being particularly hard hit with at least 602 deaths (CRED, 2019; Zehra et al., 2019; Phiri et al., 2020). Nationally, Idai caused massive housing, water supply, drainage and sanitation destruction, but its impact extended to South Africa through disruption of the regional electricity grid (Yalew et al., 2020). In April 2019, amidst heightened vulnerabilities in the aftermath of cyclone Idai, cyclone Kenneth (Category 4) hit the country, affecting 254,750 people and destroying more than 45,000 homes (Kahn et al., 2019). These circumstances caused the rapid spread of cholera, which triggered a massive vaccination program to control the epidemic (Kahn et al., 2019; Lequechane et al., 2020). While there were no specific detection and attribution studies for Idai and Kenneth, overall, there is *high confidence* that the rainfall associated with tropical cyclones is more intense because of global warming. However, there remain significant uncertainties about the impact of climate change on the numbers and strength of tropical cyclones *per se* (Walsh et al., 2019; Zhang G. et al., 2020).

Case 2. COVID-19 as the compounding risk factor: Cyclone Amphan in India and Bangladesh, 2020

Cyclone Amphan hit coastal West Bengal and Bangladesh on 20th May 2020. It was the first super cyclone to form in the Bay of Bengal since 1999 and one of the fiercest to hit West Bengal, India, in the last 100 years. The cyclone intensified from a cyclonic storm (Category 1) to a super cyclone (Category 5) in less than 36 hours (Balasubramanian and Chalamalla, 2020). Several hours before and on 20th May, extreme rain events resulted in heavy cumulative rainfall, flash flooding, and landslides in several adjoining districts (Mishra and Vanganuru, 2020). As per the initial estimates, about 1,600 km^2 area in the mangrove forests of *Sundarbans* were damaged, and over 100 lives were lost. Earlier cyclones in the region have shown that impacts of these events are gendered (Roy, 2019). The cyclone damage was somewhat lessened due to the delta's mangroves (Sen, 2020). The estimated damage was US$13.5 billion. Cyclone Amphan was the largest source of displacement in 2020, with 2.4 million displacements in India alone, of which 800,000 were pre-emptive evacuations by authorities (IDMC., 2020). Because it happened amidst the COVID19 crisis, evacuation plans were constrained due to social distancing norms (Baidya et al., 2020). Social media played an important role in disseminating pre-cyclone warnings, and information on post-cyclone relief work (Crayton et al., 2020; Poddar et al., 2020).

Case 3. Further exacerbating inequities in Human Systems: Hurricane Harvey, US, 2017

Hurricane Harvey, a Category 4 hurricane, made landfall on Texas and Louisiana in August 2017, causing catastrophic flooding and 80 deaths and inflicting $125 billion (2017 USD) in damage, of which $67 billion (2017 USD) was attributable to climate change (Frame et al., 2020). Several studies estimated the return period of the rainfall associated with this event and assessed that human-induced climate change increased the likelihood by a factor of approximately 3 using a combination of observations and climate models (Risser and Wehner, 2017; van Oldenborgh et al., 2017b). The impacts of Hurricane Harvey were exacerbated by extensive residential development in flood-prone locations. A study showed that urbanization increased the probability of such extreme flood events several folds (Zhang W. et al., 2018) through the alteration of ground cover and disruption and redirection of water flow. Water quality in cities also deteriorated (Horney et al., 2018; Landsman et al., 2019) and 85% of flooded land subsided at a rate of 5mm/yr following the event (Miller and Shirzaei, 2019). Notably, the impacts of Harvey were unequally distributed along racial and social categories in the greater Houston area. Neighbourhoods with larger Black, Hispanic and disabled populations were the worst affected by the flooding following the storm and rainfall (Chakraborty et al., 2018; Chakraborty et al., 2019; Collins et al., 2019b). In addition, racial and ethnic disparities were shown to impact post-disaster needs, ranging from household damage to mental health and recovery (Collins et al., 2019b; Flores et al., 2020; Griego et al., 2020).

Case 4. Impacts worsened due to socio-cultural and political conditions: The "Coastal Niño" in Peru, 2017

The Coastal Niño event of 2017 led to extreme rainfall in Peru, which was made more likely by at least 1.5 times as compared to pre-industrial times due to anthropogenic climate change and Coastal Niño (Christidis et al., 2019) and comparable to the El Niño events of 1982–83 and 1997–98 (Poveda et al., 2020). This event showed evidence of larger anomalies in flood exposure (Muis et al., 2018; Christidis et al., 2019; Rodríguez-Morata et al., 2019) and sediment transport (Morera et al., 2017). In Peru, this Niño event led to 6 to 9 billion US dollars of monetary losses, more than a million inhabitants were affected, 6,614 km of roads were damaged, 326 bridges were destroyed, 41,632 homes were damaged or became uninhabitable, and 2,150 schools and 726 health posts were damaged (French and Mechler, 2017; French et al., 2020), leaving half of the country in a state of emergency (Christidis et al., 2019). Furthermore, institutional and systemic socio-cultural and political conditions at multiple levels significantly worsened disaster risk management which hampered response and recovery (French et al., 2020). Citizens and zero-orders responders proved to be more effective and quicker than national disaster risk management response (Briones et al., 2019).

Case 5. Triggering institutional response for future preparedness: Mega Fires of Chile, 2017

The megafire that occurred in Chile in January 2017 had the highest severity recorded on the planet (CONAF, 2017), burning in three weeks an area close to 350,000 hectares in south-central Chile. These events have been associated with the prolonged ongoing drought that has persisted for more than one decade and with the increase in heat waves (González et al., 2018; Miranda et al., 2020). This extreme drought and the total burned area of the last decades have been attributed to anthropogenic climate change in at least 25% and 20% of their severity, respectively (Boisier et al., 2016). The megafire of summer 2017 resulted in 11 deaths, more than 1,500 houses burned and the destruction of the small town of Santa Olga. The smoke from these fires exposed 9.5 million people to air pollution, causing an estimated 76 premature deaths (Bowman et al., 2017; González et al., 2020). The direct costs incurred by the State exceeded USD 360 million (González et al., 2020). The 2017 megafires led to a series of institutional responses such as management plans that include preventive forestry techniques, regulatory plans containing rural-urban interface areas, an emergency forest fire plan, and promotion of native species (González et al., 2020).

Case 6. Loss of human lives and biodiversity: Bushfires in Australia, 2019/20

In the summer of 2019/20, bushfires in Australia killed 417 people due to smoke, between 0.5 and 1.5 billion wild animals and tens of thousands of livestock (van Oldenborgh et al., 2020). These fires also destroyed approximately 5,900 buildings and burnt 97,000 km^2 of vegetation, which provided habitat for 832 species of native vertebrate fauna. Seventy taxa had more than 30% of their habitat impacted, including 21 already identified as threatened with extinction (Ward et al., 2020). In addition, millions of people experienced levels of smoke 20 times higher than the government-identified safe level. The year 2019 had been Australia's warmest and driest year on record. In 2019/20 summer, the seasonal mean and mean maximum temperatures were the hottest by almost 1°C above the previous record. Eight of the ten hottest days on record for national mean temperatures occurred in December 2019. While the prevailing weather conditions were strongly influenced by the Indian Ocean Dipole pressure pattern, with a contribution from weakly positive ENSO conditions in the Pacific, the fact that Australia is approximately 1°C warmer than the early 20th century demonstrates links to anthropogenic climate change. Eight climate models using event attribution methodologies (comparison of simulations with present-day and pre-industrial forcings) indicates that anthropogenic climate change made the heat conditions of December 2019 more than twice as likely (van Oldenborgh et al., 2020).

Case 7. Improved preparedness reduced mortality: Heatwave in Europe, 2019

In 2019, Europe experienced several record-breaking heatwaves. In June, the first one featured record heat for that time in early summer, with temperatures of 6-10°C above normal over most of France and Germany, northern Spain, northern Italy, Switzerland, Austria, and the Czech Republic (Climate., 2019). The second heatwave also resulted in all-time records for Belgium, Germany, Luxembourg, the Netherlands, and the United Kingdom in July. Attribution studies (Vautard et al., 2020) demonstrated that these would have had extremely small odds in the absence of human-induced climate change or would have been 1.5-3°C colder without human-induced climate change. This study concluded that state-of-the-art climate models underestimate the trends in local heat extremes compared to the observed trend. Since the 2003 heatwave, which resulted in tens of thousands of deaths across Europe, many European countries have adopted heatwave plans, including early warning systems. Therefore, mortality in 2019 was substantially lower than it might have been. Unfortunately, mortality is not registered systematically across Europe, and therefore comprehensive analyses are missing. But even based on the countries that provide the numbers, more specifically France, Belgium and the Netherlands, the European heatwave of 2019 resulted in over 2500 deaths (CRED, 2019). Despite their deadliness and the fact that climate change increases the frequency, intensity and duration of heatwaves globally (Perkins-Kirkpatrick and Lewis, 2020) , heatwaves are not consistently reported in many countries (Harrington and Otto, 2020), rendering it currently impossible to estimate climate change impacts on lives and livelihoods comprehensively.

Case 8. Loss of human lives and property: Floods in Europe in 2021

From 12th to 15th July 2021, extreme rainfall in Germany, Belgium, Luxembourg and neighbouring countries led to severe flooding. The severe flooding was caused by very heavy rainfall over a period of 1-2 days, wet conditions prior to the event and local hydrological factors. The observed rainfall amounts in the Ahr/Erft region and the Belgian part of the Meuse catchment substantially exceeded previous records for observed rainfall. An attribution study (Kreienkamp et al., 2021) focused on the heavy rainfall rather than river discharge and water levels, because sufficient hydrological data was not available, partly because hydrological monitoring systems were destroyed by the event. Considering a larger region of Western Europe between the northern side of the Alps and the Netherlands, in any given location one such event can be expected every 400 years on average in the current climate. The floods resulted in least 222 fatalities and substantial damage to houses, roads, communication infrastructure, motorways, railway lines and bridges.

Table Cross-Chapter Box DISASTER.1: Summarizing impacts, loss and damage, displacement, and climate change detection and attribution of these seven disasters case studies

Name of the disaster event	Impacts, loss and damage; and displacement	Climate change detection and attribution

Cyclones Idai and Kenneth, March and April 2019, Mozambique, Africa	254,750 affected people, and more than 45,000 houses were destroyed. Sparked cholera outbreaks that resulted in 6,600 cases and over 200 deaths. More than 500,000 people were displaced in 2019. As of 31st December 2019, more than 132,000 people were internally displaced in Mozambique (IDMC., 2020).	There are no D&A studies on Idai and Kenneth, but it is known that rainfall associated with tropical cyclones are now more intense because of global warming, but there remain significant uncertainties concerning changes in the number and strength of the cyclones themselves (Walsh et al., 2019; Zhang G. et al., 2020).
Cyclone Amphan, May 2020, West Bengal, India and Bangladesh	About 1,600 km^2 area in the mangrove forests of Sundarbans was damaged. The city of Kolkata lost a substantial portion of its green cover due to Amphan. The estimated damage was US$13.5 billion. Cyclone Amphan was the largest source of displacement in 2020, with 2.4 million displacements in India and a similar number in Bangladesh. Out of these 2.4 million, roughly 800,000 were pre-emptive evacuations or organized by the authorities (IDMC., 2020).	The combined decline of both aerosols (due to COVID-19 related lockdowns) and clouds may have contributed to the increased sea surface temperature, further compounding the climate change-related warming of the oceans (Vinoj and Swain, 2020). However, there are no attribution studies on tropical cyclones in the Indian Ocean.
Hurricane Harvey, 2017, USA	Catastrophic flooding and many deaths inflicted $125 billion (2017 USD). In addition, economic costs due to the rainfall are estimated at $90 billion, of which $67bn are attributed to climate change (Frame et al., 2020).	Several attribution studies found that the rainfall associated with Harvey has increased by a factor of 3, while intensity in rainfall and wind speed also increased due to human-induced climate change (Emanuel, 2017; Risser and Wehner, 2017; Patricola and Wehner, 2018; van Oldenborgh et al., 2020)
Coastal Niño 2017, Peru	US$ 6 to 9 billion monetary losses with 114 deaths, 414 injuries and 1.08 million inhabitants affected. In addition, 6,614 km of improved roads were damaged, 326 bridges destroyed, 41,632 homes destroyed or uninhabitable, and 242,433 homes, 2,150 schools and 726 health centres damaged.	Clear anthropogenic climate change fingerprint detected. For example, while the anomalously warm ocean favoured extreme rainfall of March 2017 in Peru, the human influence was estimated to make such events at least 1.5 times more likely (Christidis et al., 2019).
Mega fires in Chile, January 2017	The megafire that occurred in Chile in January 2017 burned in three weeks an area close to 3500 km^2 in south-central Chile. As a result, thousands of people were displaced.	There is no attribution study on the fires in Chile (yet). Still, there is an increasing number of attribution studies on wildfires worldwide, finding that because climate change has increased the likelihood of extreme heat, which is part of the fire weather, the likelihood of wildfire weather conditions has increased too (Krikken et al., 2019; van Oldenborgh et al., 2020).
Australian bushfires of 2019/2020	Killed 417 people due to smoke, between 0.5 and 1.5 billion wild animals and tens of thousands of livestock. Destroyed ~ 5,900 buildings and burnt 97,000 km^2 of vegetation that provided habitat for 832 species of native vertebrate fauna.	Anthropogenic climate change made the extreme heat condition of December 2019 more than twice as likely (van Oldenborgh et al., 2020).
Heatwaves of Europe, 2019	Record heat in several European countries, and deadliest global disaster of 2019, with over 2500 deaths (CRED, 2019).	There have been many attribution studies on heatwaves in Europe, finding that human-induced climate change is increasing the frequency and intensity of

		heatwaves. In the case of 2019, the observed heat would have been extremely unlikely without climate change. The studies also find that climate models underestimate the increase in heat waves in Europe compared to observed trends (Vautard et al., 2020).
Floods in Western Europe (Germany, Belgium), July 2021	Severe flooding resulting in at least 222 fatalities and substantial damage to houses, roads, communication infrastructure, motorways, railway lines and bridges. Some communities were cut off for days due to road closures, inhibiting emergency responses including evacuation. The cost of the event was estimated at €4.5 to €5.5 billion in Germany and over €0.35 billion in Belgium.	Climate change was found to have increased the intensity of the maximum 1-day rainfall event in the summer season in this large region by about 3 - 19% compared to a global climate 1.2 °C cooler than at the present day. The increase was similar for the 2-day event. The likelihood of such an event today was found to have increased by a factor between 1.2 and 9 for both the 1-day and 2-day events in the large region (Kreienkamp et al., 2021).

Disaster risk reduction needs to be a central component of adaptation and mitigation for meeting SDGs and for climate-resilient future

Disasters resulting from extreme events are increasingly experienced by a large section of human population (Hoegh-Guldberg et al., 2018). Disasters expose inequalities in natural and managed systems and human systems as they disproportionately affect poor and marginalized communities like ethnic minorities, people of colour, Indigenous Peoples, women and children. Therefore, disaster risk reduction is fundamental for climate justice and climate-resilient development (UNISDR., 2015). Far from being disconnected policy objectives, disaster risk reduction and climate change mitigation/adaptation are two sides of the same coin as recognized explicitly by the Paris Agreement and Sendai Framework of 2015. There can be no sustainable development without disaster risk reduction, as explicitly recognized by the Sustainable Development Goals of 2015. Furthermore, disaster events can increase awareness among citizens and provide a platform for all important stakeholders, including climate activists, to come together, and give a clarion call for the urgency of climate action.

In summary, disasters are a stark illustration of the potential for extreme weather events to impact people and other species. With the frequency, severity and (or) likelihood of several types of extreme weather increasing, disasters can increasingly be regarded as “the public face of climate change” (*high confidence*). Detection and attribution studies make the climate change fingerprint of several types of disasters increasingly clear (*high confidence*). Moreover, existing vulnerabilities and exposures play an important role in turning extreme events into disasters, further exacerbating existing racial, gender and social inequalities (*high confidence*). Therefore, disaster risk reduction needs to be central to adaptation and mitigation efforts to meet the Sustainable Development Goals (SDGs) and the Paris Agreement for a climate-resilient future.

[END CROSS-CHAPTER BOX DISASTER HERE]

4.3.5 Observed Impacts on Freshwater Ecosystems

The loss and degradation of freshwater ecosystems have been widely documented, and SRCCL assessed with *medium confidence* the loss of wetlands since the 1970s (Olsson et al., 2020).

The links between air and water temperatures and ecological processes in freshwater ecosystems are well recognized. Increasing temperatures affect wetlands by influencing biophysical processes, affecting feeding and breeding habits and species' distribution ranges, including their ability to compete with others. Increased temperatures can also cause deoxygenation in the lower depths of the water columns and throughout the entire water column if heating destabilizes the water column. Under extreme heat, often associated with minimal rainfall or water flows, the drying of shallower areas and the migration or death of individual organisms can occur (Dell et al., 2014; Miller et al., 2014; Scheffers et al., 2016; Szekeres et al., 2016; Myers et al., 2017; FAO, 2018a) (*high confidence*). A global systematic review of studies since 2005 shows that climate change is a critical direct driver of freshwater ecosystems impacts through increasing temperatures or declining rainfall, for example, by causing physiological stress or death (thermal stress, dehydration or desiccation), limiting food supplies, or resulting in migration of animals to other feeding or breeding areas, and possibly increased competition with animals already present in those migrating locations (Bustamante et al., 2018; Diaz et al., 2019). Other drivers include land-use changes, water pollution, extraction of water, drainage and conversion, and invasive species, which to varying extents interact synergistically with climate change or are exacerbated due to climate change (Finlayson et al., 2017; Ramsar Convention, 2018).

The Global Wetland Outlook (Ramsar Convention, 2018) reported that between 1970 and 2015, the area of freshwater wetlands declined by approximately 35% (Davidson and Finlayson, 2018), with high levels of the overall percentage of threatened species recorded in Madagascar and Indian Ocean Islands (43%); in Europe (36%); in the tropical Andes (35%); and New Zealand (41%) (Ramsar Convention, 2018). Where long term data are available, only 13% of the wetlands recorded in and around the year 1700 remained by 2000. However, these data may overestimate the rate of loss (Davidson, 2014) (*limited evidence, medium agreement*). Many wetland-dependent species have seen a long-term decline, with the Living Planet Index showing that 81% of populations of freshwater species are in decline and others being threatened by extinction (Davidson and Finlayson, 2018; Darrah et al., 2019; Diaz et al., 2019) (*high confidence*).

Temperature changes lead to changes in the distribution patterns of freshwater species. Poleward and up-elevation range shifts due to warming temperatures tend to ultimately lead to reduced range sizes. Freshwater species in the tropics are particularly vulnerable (Jezkova and Wiens, 2016; Sheldon, 2019). Systematic shifts towards higher elevation and upstream were found for 32 stream fish species in France (Comte and Grenouillet, 2013). In North America, for the bull trout (*Salvelinus confluentus*) a reduction in the number of occupied sites was documented in a watershed in Montana (Eby et al., 2014). Other impacts include disruption of seasonal movements of migratory waterbirds that regularly visit freshwater ecosystems, with adverse impacts on their feeding and breeding (Finlayson et al., 2006; Bussière et al., 2015). Keystone species, such as the beaver (*Caster Canadensis*) in North America, have been moving into new areas as the vegetation structure has changed in response to higher temperatures enabling shrubs to establish in the Arctic and alpine tundra ecosystems (Jung et al., 2016). Increased occurrence and intensity of algal blooms have occurred due to the interactive effects of thermal extremes and low dissolved oxygen concentrations in water (Griffith and Gobler, 2020) (4.2.7). A global review found that almost 90% of all studies reviewed documented a decline in salmonid populations in North Amercia and Europe, and identified knowledge gaps elsewhere (Myers et al., 2017). Another review (Pecl et al., 2017) found declines in Atlantic salmon in Finland, and poleward shift in coastal fish species, while another review (Scheffers et al., 2016) noted hybridization between freshwater species like invasive rainbow trout (*Oncorhynchus mykiss*) and native cutthroat trout (*O. clarkia*).

Lakes have been warming, as shown by an increasing trend of summer surface water temperatures between 1985 and 2009 of 0.34°C per decade (O'Reilly et al., 2015). However, responses of individual lakes to warming were very dependent on local characteristics (O'Reilly et al., 2015), with warming enhancing the impacts of eutrophication in some instances (Sepulveda-Jauregui et al., 2018). For example, temperature increases led to lower oxygen concentrations in eutrophied coastal wetlands due to phytoplankton and microbial respiration (Jenny et al., 2016) and stimulated algal blooms (Michalak, 2016) and affected the community structure of fish and other biotas (Mantyka-Pringle et al., 2014; Poesch et al., 2016).

Rising temperatures have a strong impact in the arctic zone, where the southern limit of permafrost is moving north and leading to changes in the landscape (Arp et al., 2016; Minayeva et al., 2018). Thawing of the permafrost leads to increased erosion and runoff and changes in the geomorphology and vegetation of arctic peatlands (Nilsson et al., 2015; Sun et al., 2018b). Permafrost thawing has led to the expansion of lakes in the Tibetan Plateau (Li et al., 2014). As northern high latitude peatlands store a large amount of carbon, permafrost thawing can increase methane and carbon dioxide emissions (Schuur et al., 2015;

Moomaw et al., 2018). This represents a major gap in our understanding of the rates of change and their consequences for freshwater ecosystems.

The extent of past degradation due to multiple drivers is important as climate change is expected to interact synergistically and cumulatively with these (Finlayson et al., 2006), exacerbate existing problems for wetland managers, and potentially increase emissions from carbon-rich wetland soils (Finlayson et al., 2017; Moomaw et al., 2018). Freshwater ecosystems are also under extreme pressure from changes in land use and water pollution, with climate change exacerbating these, such as the further decline of snow cover (DeBeer et al., 2016) and increased consumptive use of fresh water, and leading to the decline, and possibly extinction, of many freshwater-dependent populations (*high confidence*). Thus, differentiating between the impacts of multiple drivers is needed, especially given the synergistic and cumulative nature of such impacts, which remains a knowledge gap.

In summary, climate change is one of the key drivers of the loss and degradation of freshwater ecosystems and the unprecedented decline and extinction of many freshwater dependent populations. The predominant key drivers are changes in land use and water pollution (*high confidence*).

4.3.6 Observed Impacts on Water-related Conflicts

According to AR5, violent conflict increases vulnerability to climate change (Field et al., 2014a) (*medium evidence, high agreement*). Furthermore, the IPCC SRCCL (Hurlbert et al., 2019) concluded with *medium confidence* that climatic stressors can exacerbate the negative impacts of conflict.

Since AR5, only a few studies focused specifically on the association between observed changes in the hydrological cycle linked to climate change and conflicts (Zografos et al., 2014; Dinar et al., 2015). Some studies associate conflicts with local abundance of water (Salehyan and Hendrix, 2014; Selby and Hoffmann, 2014; de Juan, 2015), mainly because of political mobilization around abundant waters and the need for developing new rules of allocation among competing users. Others provide evidence that the increase in water availability in some areas versus a decrease in other surrounding areas can affect the risk of a conflict in a region (de Juan, 2015) *(low to medium confidence).* However, the large majority acknowledges reduction of water availability due to climate change as having the potential to exacerbate tensions (de Stefano et al., 2017; Waha et al., 2017), especially in regions and within groups dependent on agriculture for food production (von Uexkull et al., 2016; Koubi, 2019) (*high confidence*). Particularly representative is the case of Syria, where drought aggravated existing water and agricultural insecurity (Kelley et al., 2015). However, whether drought caused civil unrest in Syria remains highly debated (Gleick, 2014; Kelley et al., 2017; Selby et al., 2017; Ash and Obradovich, 2019). Additionally, there is no consensus on the causal association between observed climate changes and conflict (Hsiang Solomon et al., 2013; Burke et al., 2015; Selby, 2019). However, evidence suggests that changes in rainfall patterns amplify existing tensions (Abel et al., 2019); examples include Syria, Iraq (Abbas et al., 2016; von Lossow, 2016) and Yemen (Mohamed et al., 2017) (*medium confidence*). There is also *medium evidence* that in some regions of Africa (e.g., Kenya, Democratic Republic of Congo), there are links between observed water stress and individual attitude for participating in violence, particularly for the least resilient individuals (von Uexkull et al., 2020) (*medium confidence*). A reverse association from conflict to climate impacts has also been observed (Buhaug, 2016). For example, conflict-affected societies cannot address climate-change impacts due to other associated vulnerabilities such as poverty, food insecurity, and political instability.

For transboundary waters, the probability of inter-state conflict can both increase and decrease (Dinar et al., 2019) depending on climatic variables (e.g. less precipitation) and other socio-economic and political factors, such as low levels of economic development and political marginalization (Koubi, 2019). Climate change concerns also play a role in stimulating cooperative efforts, as in the case of the Ganges-Brahmaputra-Meghna River Basin (Mirumachi, 2015; Link et al., 2016) (*medium confidence*). More generally, there is some evidence that when hydrological conditions change in transboundary river basins, formal agreements (e.g., water treaties or river basin organizations) can enhance cooperation (de Stefano et al., 2017; Dinar et al., 2019) (*medium evidence, high agreement*). Still, more cooperation does not necessarily reduce the risk of conflict, especially when water variability increases beyond a certain threshold (*low evidence, medium agreement*) (Dinar et al., 2015; Dinar et al., 2019).

In summary, there is no consensus on the causal association between observed climate change and conflicts. Still, evidence exists that those tensions can be amplified depending on climatic variables and other concomitant socio-economic and political factors.

4.3.7 Observed Impacts on Human Mobility and Migration

AR5 (Adger and Pulhin, 2014), found links between climate change and migration in general (*medium evidence, high agreement*), but provided no assessment of climate-induced hydrological changes and migration specifically. Likewise, SRCCL (Mirzabaev et al., 2019; Olsson et al., 2020) and SROCC (Hock et al., 2019b) noted that migration is complex and that migration decisions and outcomes are influenced by a combination of social, demographic, economic, environmental and political factors and contexts (see Cross-Chapter Box MIGRATE in Chapter 7). This chapter confirms this evidence, focusing on climate-induced hydrological changes.

Climate-induced hydrological changes can, through slow-onset (e.g. drought) or rapid onset (e.g., flood) events, influence human mobility and migration through effects on the economy and livelihoods (Adger et al., 2018). There is *medium confidence* that climate-induced hydrological changes have affected bilateral migration (Backhaus et al., 2015; Cattaneo and Peri, 2016; Falco et al., 2019). However, there is *medium evidence* and *low agreement* on the effects on the movements of refugees globally (Missirian and Schlenker, 2017; Owain and Maslin, 2018; Abel et al., 2019; Schutte et al., 2021).

There is *robust evidence* that floods and droughts have, mainly through adverse impacts on agriculture (Mastrorillo et al., 2016; Nawrotzki and Bakhtsiyarava, 2017; Bergmann et al., 2021; Zouabi, 2021) (4.6.2), both increased and decreased the risk of temporary or permanent migration (Obokata et al., 2014; Afifi et al., 2016; Thiede et al., 2016; Murray-Tortarolo and Salgado, 2021; Wesselbaum, 2021). However, migration effects depend on the nature of the hydrological change, for example, whether it is a slow-onset or rapid onset event (Kaczan and Orgill-Meyer, 2020), the perception of change (Koubi et al., 2016; de Longueville et al., 2020), as well as the socio-economic situation of the affected communities (Ocello et al., 2015; Afifi et al., 2016; Thiede et al., 2016) *(robust evidence; medium agreement)*.

The Internal Displacement Monitoring Centre (IDMC) estimates that an average of 12 million new displacements happen each year due to droughts and floods alone. By the end of 2020, there were 7 million people displaced due to natural disasters, including drought and floods (IDMC., 2020). Furthermore, household water insecurity has also been singled out as a driver of migration, given its physical and mental health and socio-economic effects (Stoler et al., 2021) *(medium confidence)*.

More research is needed to understand better the contexts in which climate-induced hydrological changes affect the likelihood of migration or alters existing patterns (Obokata et al., 2014; Gray and Wise, 2016; Cattaneo et al., 2019).

In summary, climate-induced hydrological changes can increase and decrease the likelihood of migration *(robust evidence, medium agreement).* The outcome is determined mainly by the socio-economic, political, and environmental context *(medium confidence)*.

4.3.8 Observed Impacts on the Cultural Water Uses of Indigenous Peoples, Local Communities and Traditional Peoples

AR5 concluded with *high confidence* that the livelihoods and cultural practices of the diverse Indigenous Peoples of the Arctic have been impacted by climate change (Larsen et al., 2014). SROCC found with *high confidence* that cryospheric and associated hydrological changes have affected culturally significant terrestrial and freshwater species and ecosystems in high mountain and polar regions, thus impacting residents' livelihoods and cultural identity, including Indigenous Peoples (Hock et al., 2019b; IPCC, 2019a; Meredith et al., 2019). SROCC also concluded that Indigenous Knowledge (IK) and Local Knowledge (LK) are vital in determining community responses to environmental risk. The report further noted that IK and LK helps increase adaptive capacity and reduces long-term vulnerability, but did not assess climate-related impacts on cultural water uses on low-lying islands (Oppenheimer et al., 2019).

Freshwater (including ice and snow) has diverse meanings and symbolic representations, as well as associated practices, management and reciprocal responsibilities for many Indigenous Peoples, local communities and traditional peoples (Cave and McKay, 2016; Craft, 2018; Hansen and Antsanen, 2018; Ngata, 2018; Chiblow 2019; Wilson et al., 2019; Moggridge and Thompson, 2021). Climate-driven hydrological changes are affecting culturally significant terrestrial and freshwater species and ecosystems, particularly for Indigenous Peoples, local communities and traditional peoples in the Arctic, high-mountain areas, and small islands (*high confidence*). These climate impacts on cultural water uses are influencing travel, hunting, herding, fishing, and gathering practices, which have negative implications for livelihoods, cultural traditions, economies, and self-determination (Table 4.5).

Some of these losses may be classified as non-economic loss and damage, such as loss of culture and traditions (Thomas and Benjamin, 2018b; McNamara et al., 2021). The vulnerability of these cultural uses to climate change is exacerbated by historical and ongoing processes of colonialism and capitalism, which dispossessed Indigenous Peoples and disrupted culturally significant multi-species relationships (Whyte, 2017; Whyte, 2018; Wilson et al., 2019; Whyte, 2020; Rice et al., 2021) (14.4.7.3; 9.13.2.4). Despite these significant structural barriers, there is *medium confidence* that some Indigenous Peoples, local communities and traditional peoples are adapting to the risks of climate-driven hydrological changes to cultural water uses and practices (4.6.9).

There is *high confidence* that the prospect of loss (anticipatory grief) due to climate-related hydrological change, such as inundation, or relocation, affects Indigenous Peoples, local communities and traditional peoples. These communities are especially susceptible to detrimental mental health impacts because of the implications of climate change for their cultural, land-based practices (du Bray et al., 2017). For example, fears of cultural loss in Tuvalu (Gibson et al., 2019) are resulting in worry, anxiety and sadness among local people, with similar responses reported in Fiji and other Pacific islands (du Bray et al., 2017; Yates et al., 2021) (Box 15.1).

There is *high confidence* that glacier retreat and increasing glacier runoff variability are negatively affecting cultural beliefs and practices in high mountain areas. For example, the loss of glaciers threatens the ethnic identity of the Indigenous Manangi community of the Annapurna Conservation Area of Nepal (Konchar et al., 2015; Mukherji et al., 2019). Likewise, ice loss in the Cordillera Blanca in the Peruvian Andes has challenged traditional approaches of interacting with the glaciers (Motschmann et al., 2020) (4.2.2). There is *high confidence* that cryosphere changes in high mountain areas also impact traditional pastoral practices by altering seasonal conditions, pasture quality, and water availability. For example, pasture quality in India (Ingty, 2017), Tibet Autonomous Region (Nyima and Hopping, 2019), and Bolivia (Yager et al., 2019) has been negatively impacted by climate-related hydrological changes, leading some Indigenous herders to diversify livestock, while herders in Nepal (Popular and Rik, 2016) and Peru (Postigo, 2020) have altered their routes in response to local water scarcity. Local communities in high mountain areas understand these hydrological changes through cultural and spiritual frameworks (*medium evidence, high agreement*). For instance, in the Peruvian Andes and the Hindu Kush Himalaya, changing ice is attributed to a lack of spiritual devotion (Drenkhan et al., 2015; Konchar et al., 2015; Scoville-Simonds, 2018). Communities in the Peruvian Andes also interpret climate impacts in the broader context of socio-economic and political injustice and inequality (Drenkhan et al., 2015; Paerregaard, 2018).

In polar areas, there is *high confidence* that the appearance of land previously covered by ice, changes in snow cover, and thawing permafrost are contributing to changing seasonal activities. These include changes in accessibility, abundance and distribution of culturally important plant and animal species. These changes are harming the livelihoods and cultural identity of Indigenous Peoples, local communities and traditional peoples. In northern Fennoscandia, for example, reindeer herders reported experiences of deteriorated foraging conditions due to changes in the winter climate (Forbes et al., 2019; Rasmus et al., 2020). In addition, Inuit and First Nations communities in Canada (Ford et al., 2019; Khalafzai et al., 2019) and Alaskan Natives and Native American communities in the United States (Norton-Smith et al., 2016) identified disruption to access routes to traditional hunting grounds and climate-related stresses to culturally-important species.

Further research is needed to provide culturally informed integrated assessments of climate change impacts on Indigenous Peoples', local communities' and traditional uses of water in the context of multiple stresses, disparities, and inequities (Yates et al., 2021). In the Arctic, for example, increased rates of development and resource extraction, including hydropower dams, mining, fisheries, and sport hunting, all threaten water quality, habitat condition, and the ecosystem services provided by Arctic freshwaters (Mustonen and Mustonen, 2016; Knopp et al., 2020).

In summary, the cultural water uses of Indigenous Peoples, local communities and traditional peoples are being impacted by climate change (*high confidence*), with implications for cultural practices and food and income security, particularly in the Arctic, high mountain areas, and small low-lying islands.

Table 4.5: Selected Observed Impacts on Cultural Water Uses of Indigenous Peoples (also see Figure 4.6).

Region	Indigenous Peoples	Climate hazard	Water-related impact	Situated knowledge	Reference
Asia	Manangi	Increased temperatures; increased precipitation	Glacier retreat; decreased permanent snow cover	Manangi villagers reported a deep sense of spiritual loss associated with the decline of mountain snows and the receding glacier, which some attributed to a lack of spiritual devotion.	(Konchar et al., 2015);(Mukherji et al., 2019)
Asia	Gurung	Increased temperatures	Decreasing snow; increased snowmelt	Indigenous Gurung herders reported water scarcity in traditional water sources such as streams and wells along traditional livestock migration routes. As a result of these changes, they have altered their routes and camp locations.	(Popular and Rik, 2016)
Asia	Dokpa	Increased temperatures	Decreasing snowfall	Dokpa herders reported that pasture conditions have deteriorated due to shallower snowpack, shorter winters and erratic rainfall, which has impacted sheep populations. As a result of these changes, Dokpa herders are replacing traditionally important sheep with yaks, which are more tolerant to poor-quality pasturage.	(Ingty, 2017)
Asia	Jagshung pastoralists	Increased temperatures	Glacier melt	Due to the expansion of the majority of large lakes on the Tibetan Plateau, herders in Jagshung Village have lost large areas of pastures to inundation. As a result, the quality of nearby feed has also deteriorated, which has led to reduced livestock populations and productivity.	(Nyima and Hopping, 2019)
Central and South America	Aymara	Increased temperatures	Glacier loss	Decreasing rain and snow have led to degraded and dry peatland pastures (*bofedales*). This reduction of pasture contributes to out-migration, over-grazing, and the loss of ancestral practices and community commitment to pasture management (Table 12.5).	(Yager et al., 2019)
Central and South America	Quelcaya pastoralists	Increased temperatures; reduced rainfall; increasing precipitation variability	Decreased snow and ice	Pastoralists reported water scarcity in traditional water sources along migration routes. As a result, women pastoralists had to herd livestock farther to find water. Pastoralists also reported the deterioration of pasture due to decreasing water availability Table 12.5).	Postigo, 2020 #4261}
Europe	Saami	Increased Winter temperature;	Harder and deeper snow	Changes in the quality of winter pastures (especially decreased access to forage and the amount of forage)	(Forbes et al., 2019); (Rasmus et al., 2020)

		Increased Summer precipitation	cover; increased ice formation; flooding rivers and wet ground	have increased the number of working hours and altered reindeer herding practices. Rainy summers increase the difficulty of gathering and moving reindeer to round-up sites and limit hay production for supplementary winter feed (13.8.1.2).	
North America	Kashechewan First Nation	Increased temperatures	Flooding	The timing and extent of spring flooding have changed, which, combined with inadequate infrastructure, have increased the frequency and risk of flooding for the Kashechewan community. Earlier snowmelt has also affected the migration patterns of migratory birds and reduced the duration of traditional hunting and harvesting camps for culturally important species 14.4.6.7, 14.4.7.1.	(Khalafzai et al., 2019)
North America	Inuit	Increased temperatures (an average of 2.18°C from 1985 to 2016)	Changing ice conditions	Trail access models showed that overall land and water trail access in the Inuit Nunangat had been minimally affected by temperature increase between 1985 to 2016. However, these findings illustrate that although Inuit are developing new trails and alternative forms of transport, these changes could negatively impact cultural identity and well-being 14.4.6.7, 14.4.7.1.	(Ford et al., 2019)
North America	Inuit	Increased temperatures; increased precipitation	Early snowmelt	Inuit in Labrador, Canada, are grieving the rapid decline of culturally significant caribou, which is partly due to rising temperatures in the circumpolar north and the associated changes to caribou habitat and migration. In addition, the decline of this species is negatively affecting their sense of cultural identity because of the importance of hunting and cultural continuity 14.4.6.7, 14.4.7.1..	(Cunsolo et al., 2020)
North America	Alaskan Natives	Increasing temperatures	Increasing temperature of freshwater lakes; permafrost melt; thinning ice	In Alaska, permafrost melting and the shorter ice season make it more difficult for hunters to access traditional hunting grounds. Increased temperatures are changing the habitats and migration patterns of culturally important freshwater species. Declining fish health and populations threaten requirements of treaty rights and tribal shares of harvestable fish populations 14.4.6.7, 14.4.7.1.	(Albert et al., 2018); (Norton-Smith et al., 2016)
Small Islands	iTaukei	Sea level rise	Flooding, inundation and salt-water intrusion	The village of Vunidogola was relocated in response to inundation, storm surges and flooding, which villagers found emotionally and spiritually distressing. Although the village was relocated as a single unit and on customary lands, the shift away from the coast has impacted spiritual relationships, as the ocean is an integral part of village culture (15.6.5).	(Charan et al., 2017); (Piggott-McKellar et al., 2019a)

Small Islands	iTaukei	Sea level rise	Coastal erosion; inundation	Villagers of Viti Levu reported their grief at the potential loss of their traditions and livelihoods. In addition, they are concerned as to how climate change is affecting their cosmology and cultural traditions and understand possible relocation as another source of cultural loss (15.6.5).	(du Bray et al., 2017); (McNamara et al., 2021)
Small Islands	Funafuti	Sea level rise	Coastal erosion; inundation	In addition to climate impacts and stresses affecting Tuvalu, the potential for further environmental hardships in the future exacerbated worry and distress for local people, who are anxious about future cultural loss arising from sea level rise (15.6.5)..	(Gibson et al., 2019); (Yates et al., 2021); (McNamara et al., 2021)

4.4 Projected Changes in Hydrological Cycle due to Climate Change

The terrestrial hydrological cycle is projected to intensify through a higher exchange of water between the land surface and the atmosphere. A rise of near-surface atmospheric water capacity is projected because of greater warming leading to changes in the atmospheric circulation patterns, the intensification of the convection processes, and the increased temperature of the underlying surface. Continuation of projected warming and other physical mechanisms will further accelerate the melting of the snow cover, glaciers and permafrost *(high confidence).*

Methodologically, the projected changes in the hydrological cycle due to climate change are assessed directly from climate models or hydrological system models driven by the climate models' projections (SM4.1). The latter is simulated by the CMIP-based multi-model experiments carried out under the scenarios of future climate forcing and socio-economic changes (e.g., RCPs, SSPs scenarios) or the pre-assigned global warming levels over the 21st century. Since AR5, there has been an improvement of the physical basis of the climate change impact projections owing to the advances in modelling clouds, precipitation, surface fluxes, vegetation, snow, floodplains, groundwater and other processes relevant to the water cycle (Douville et al., 2021), SM4.1).

The sub-sections highlight the projected responses of these hydrological systems/processes to multiple drivers, high variability and the uncertainty of the projections, depending on regions, seasons, temporal and spatial scales, the influence of the non-climatic factors.

4.4.1 Projected Changes in Precipitation, Evapotranspiration, and Soil Moisture

4.4.1.1 Projected Changes in Precipitation and Heavy Precipitation

WG1 (Douville et al., 2021) conclude with *high confidence* that without large-scale reduction in GHG emissions, global warming is projected to cause substantial changes in the water cycle at both global and regional scales. However, WG1 also note large uncertainties in many aspects of regional water cycle projections by climate models. Water cycle variability and extremes are projected to increase faster than average changes in most regions of the world and under all emission scenarios (*high confidence*). The concept of "wetter-regions-get-wetter, drier-regions-get-drier" from AR5 (Collins et al., 2013) is assessed by AR6 WG1 (Douville et al., 2021) as too simplistic. WG1 (Seneviratne et al., 2021) further conclude that heavy precipitation will generally become more frequent and more intense with additional global warming.

In the CMIP6 multi-model ensemble, as in previous generations of ensembles, the projected changes in annual mean precipitation vary substantially across the world. Importantly, in most land regions the future changes are subject to high uncertainty even in the sign of the projected change (*high confidence*). Figure 4.10 illustrates this using the 5th, 50th and 95th percentile changes across the ensemble at individual grid points. For any given location, the range of projected changes generally increases with global warming (*high confidence*).

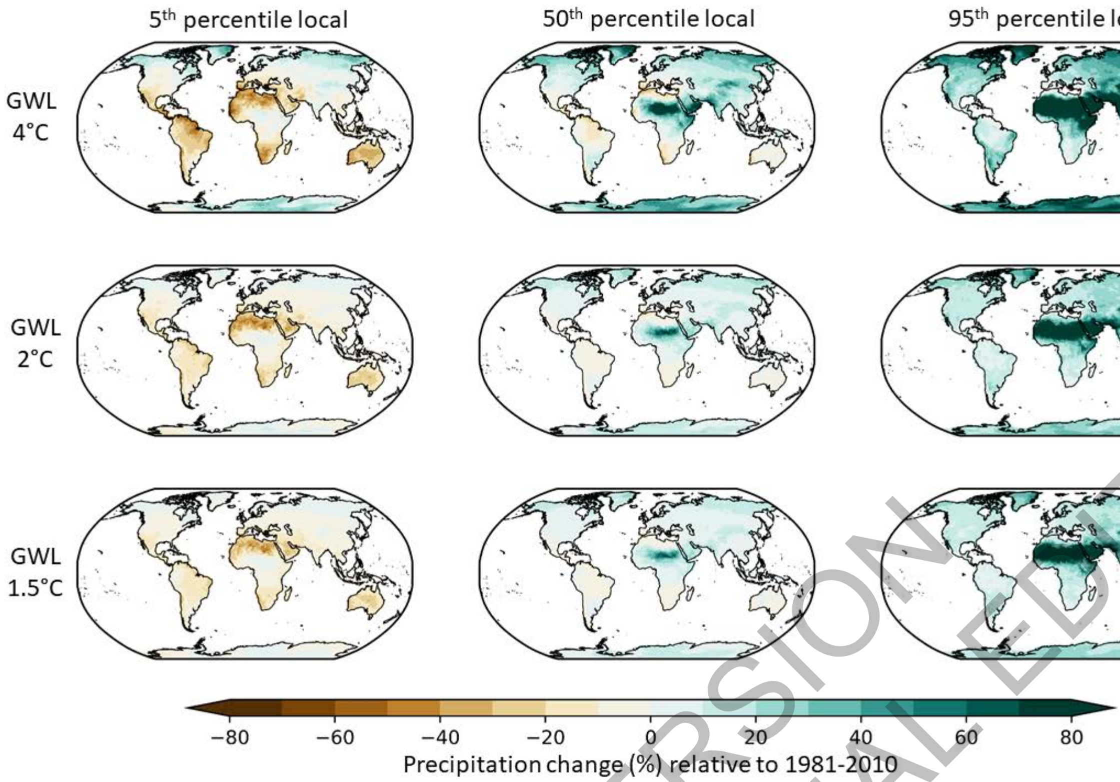

Figure 4.10: Projected percentage changes in annual mean precipitation at global warming levels (GWLs) of 4°C (top), 2°C (middle) and 1.5°C (bottom) for the CMIP6 multi-model ensemble of GCMs driven by the SSP5-85 scenario. For any given GWL, similar ranges of changes are seen with other scenarios that reach that GWL, and the difference between scenarios is smaller than the ensemble uncertainty (Seneviratne et al., 2021). The distribution of outcomes is shown at local scales with the 5th, 50th and 95th percentile precipitation changes in individual grid boxes. Note that these are uncertainties at the individual point and are not spatially coherent, i.e., they do not represent plausible global patterns of change. Results for 1.5°C, 2°C and 4°C global warming are defined as 20-year means relative to 1850-1900 and use 40, 40 and 31 ensemble members respectively, due to some members not reaching 4°C global warming.

For example, in parts of the Indian subcontinent, the projected changes in mean precipitation at 1.5°C global warming range from a 10-20% decrease to a 40-50% increase. The multi-model median change is close to zero. Most other regions show a smaller range of changes (except for very dry regions where a small absolute change in precipitation appears as a larger percentage change). Nevertheless, across most global land regions, both increases and decreases in precipitation are projected across the ensemble. At 1.5°C global warming, a complete consensus on increased precipitation is seen only in the central and eastern Sahel, south-central Asia, parts of Greenland and Antarctica, and the far northern regions of North America and Asia, with projected increases in the latter ranging up to 20-30%. No land regions see a complete consensus on decreased precipitation, but South America, southern Africa and the Mediterranean region show a stronger consensus towards reduced precipitation.

The geographical patterns of local agreement/disagreement in projected precipitation change remain broadly similar with increased global warming, but the range of uncertainty generally increases (*high confidence*). For example, in the north-eastern Amazonia, the driest projections increase from a 10% decrease at 1.5°C global warming to a 40% decrease at 4°C global warming. In comparison, the wettest projections remain at up to a 10% increase. In the far north of North America and Asia, the higher end of projected increases in precipitation extends to approximately 40-60%. A few regions are projected to see a shift in the consensus on the sign of the change. These include parts of the Indian subcontinent where at 4°C global warming, the projected changes shift to a consensus on increased precipitation ranging between a few per cent to over 70%.

Notably, the multi-model median change in precipitation is relatively small in many regions – less than 10% over most of the global land surface at 1.5°C global warming. In contrast, in many locations, the 5^{th} to 95^{th} percentile range can include changes that are much larger changes than the median and also changes that are relatively large but opposite in sign. At 4°C global warming, the median projected changes are larger, ranging from a 20% decrease to a 40% increase (excluding very dry areas, where percentage changes can be much larger due to very small baseline values), but nevertheless often remain a poor indicator of the range of changes across the ensemble. Therefore, use of the median or mean projected changes for future adaptation decisions could substantially underestimate the risk of large changes in precipitation. It could mean that the risk of the opposite sign of changes are not accounted for. Indeed, for mean precipitation, different multi-model ensembles can show different levels of significance of the central estimate of change ((Uhe et al., 2021): Figure 4.11.a). Consequently, information on the range of possible outcomes can be valued by users for effectively informing risk assessments (Lowe et al., 2018).

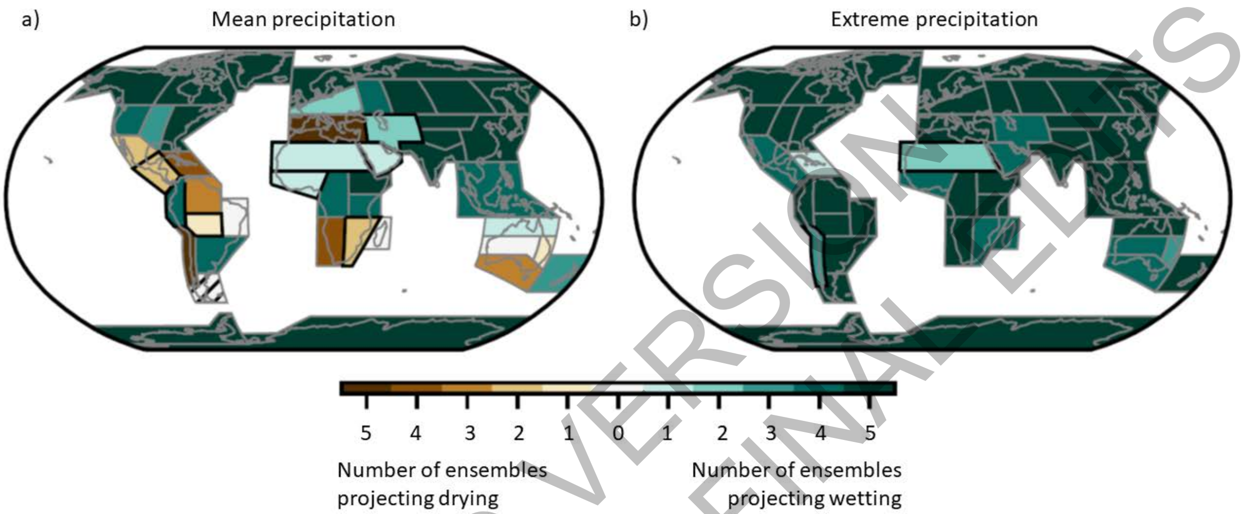

Figure 4.11: Agreement between different multi-model ensembles on significant changes in (a) annual mean precipitation and (b) annual maximum 1-day precipitation (Rx1day), at 2°C global warming (Uhe et al., 2021). Using central estimates from 5 ensembles of climate models (CMIP5, CMIP6, HAPPI, HELIX and UKCP18) using different models and different experimental designs for the ensembles, the maps show the number of ensembles for which the central estimate shows a significant drying or wetting change at 2°C global warming relative to pre-industrial. The different ensembles reach 2°C global warming at different times. The projected changes are aggregated over the new climatic regions defined for IPCC AR6 (Iturbide et al., 2020). Hatched regions show where different ensembles project significant changes in opposite directions, i.e., there is no agreement on either drying or wetting. Regions with thick outlines are where CMIP6 disagrees with 3 of the other 4 ensembles on the significance of the change, highlighting where over-relying on CMIP6 alone may not fully represent the level of confidence in the projections.

There is a stronger consensus on changes in heavy precipitation than mean precipitation within individual ensembles such as CMIP6 (Figure 4.12, a,b,c) and especially between the means of the different ensembles (Figure 4.11, b). At 4°C global warming, the 50^{th} percentile projection is for increased annual maximum 1-day precipitation over virtually all global land, with the median increase being over 20% for a majority of the land. The 95^{th} percentile increase is 20-40% over most mid-latitude areas and at least 40-70% over the tropics and sub-tropics, exceeding 80% over western Amazonia, central Africa, and most Indian subcontinent. The 5^{th} percentile also shows an increase over most global land, i. e: decreased heavy precipitation has less than a 5% probability in these regions (Figure 4.12, a), although decreases remain possible but of low probability in some regions particularly northern South America and northern and western Africa. At the 50^{th} and 95th percentiles, similar global patterns of change are projected at 2°C and 1.5°C global warming, with smaller local magnitudes (Figure 4.12, e,f,h,i). At the 5^{th} percentile, decreased Rx1day is seen over much larger land areas Figure 4.12, d,g), which may be a result of internal climate variability being relatively larger than the long-term trend at lower GWLs In CMIP5, precipitation extremes are projected to be *more likely* to increase than to decrease on average over both the humid and arid regions of the world, but with larger uncertainty in arid areas (Donat et al., 2019).

Annual maximum daily precipitation (Rx1day)

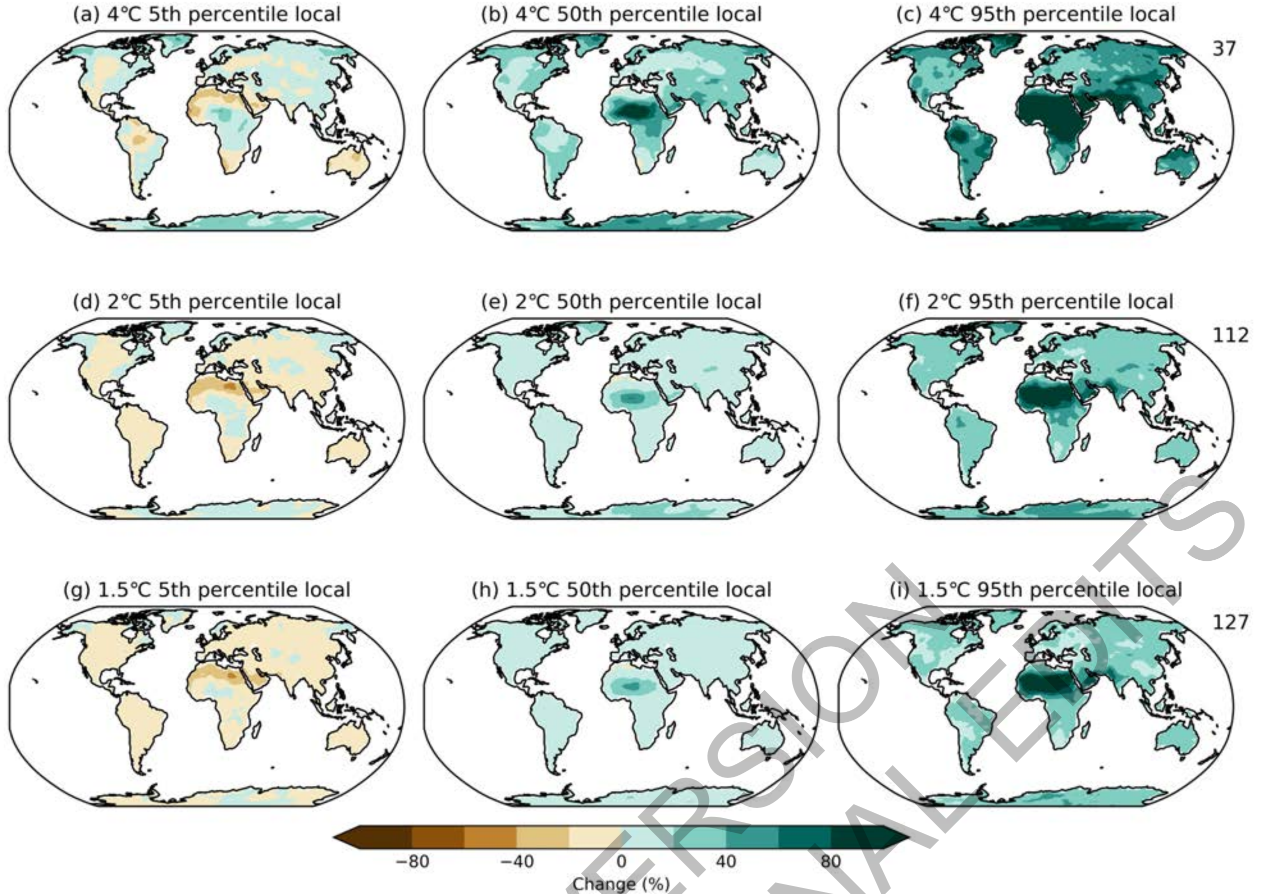

Figure 4.12: Projected percentage changes in annual maximum daily precipitation (RX1day) averaged over 20-years centred at the time of first passing (a-c) 4°C, (d-f) 2°C and (g-i) 1.5°C global warming levels (GWLs) relative to 1851-1900. Results are based on simulations from the CMIP6 multi-model ensemble under the SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5 scenarios. Uncertainties in the projections are quantified with the (a,d,g) 5th, (b,e,h) 50th and (c,f,i) 95th percentile local values from the ensemble at each GWL. Note that these are uncertainties at the individual point and are not spatially coherent, i.e., they do not represent plausible global patterns of change. The 50th percentile maps (b, e h,) present the same data over land as Figure 11.16 of (Seneviratne et al., 2021). The numbers on the right indicate the number of simulations included at each warming level, including multiple realisations from some models with varying initial conditions, depending on data availability. Results for the 1.5°C GWL include 37 unique models. Fewer models and realisations are available for the 2°C and 4°C GWLs as fewer scenarios and/or models reach those warming levels. For individual models, the global patterns of changes are very similar across scenarios and any differences between scenarios are smaller than the ensemble uncertainty for an individual scenario. The CMIP6 projections of changes in mean and extreme precipitation are discussed in more detail by WG1 (Doblas-Reyes et al., 2021; Seneviratne et al., 2021).

In the 50th percentile projections at 4°C global warming, dry spells are projected to become up to 40 days longer in South America and southern Africa and up to 20 days shorter in large parts of Asia (Figure 4.13, a,b,c). In most regions, the projected changes in dry spell lengths are highly uncertain. In southern Africa, the increase in dry spell length ranges from 10 days to over 40 days. In northeast Asia, dry spells are projected to become shorter by up to 20-30 days. In much of South America, dry spells could increase by over 40 days or decrease by over 10 days. Similar global patterns with smaller magnitudes of change are projected for 2°C and 1.5°C global warming in all three percentiles (Figure 4.13, d,e,f,g,h,i).

Consecutive dry days

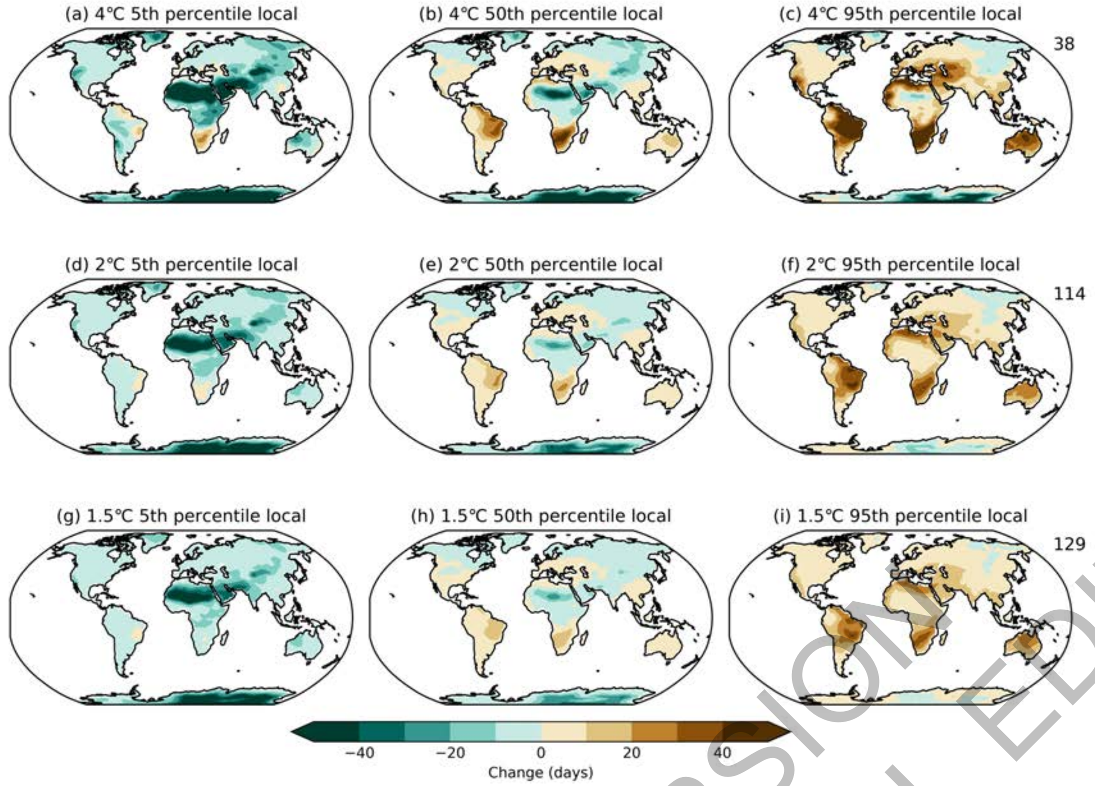

Figure 4.13: As Figure 4.12 for projected changes in annual consecutive dry days (CDD), the highest number of days per year with precipitation < 1mm. The 50th percentile maps (b, e h,) present the same data as Figure 11.19 (a,b,c) of (Seneviratne et al., 2021).

Taken together, these projections of more intense precipitation and changes in the length of dry spells give a clear picture of increasingly volatile precipitation regimes, with many regions seeing both longer dry spells and heavier events when precipitation does occur (*high confidence*).

The critical knowledge gap for precipitation projections is the ability to make precise projections. With such large uncertainties in many regions, climate model projections can inform risk assessments but cannot provide confident predictions of specific outcomes.

In summary, the annual mean precipitation range is projected to increase or decrease by up to 40% or more at 4°C global over many land areas. The ranges of projected precipitation changes are smaller at lower levels of global warming (*high confidence*). Either an increase or decrease is possible in most regions, but there is an agreement among models on the increase in the far north (*high confidence*). There is a stronger model consensus on heavy precipitation increasing with global warming over most land areas (*high confidence*). There are widely varying projections of change in dry spell length (*high confidence*), but in regions with increasing projected dry spells, the potential increase is larger at higher levels of global warming (*high confidence*).

4.4.1.2 Projected Changes in Evapotranspiration

AR5 (Collins et al., 2013) found that the CMIP5 model projections of ET increases or decreases followed the same pattern over land as precipitation projections, with additional impacts of reduced transpiration due to plant stomatal closure in response to rising CO_2 concentrations. AR6 WG1 (Douville et al., 2021) assessed that it is *very likely* that evapotranspiration will increase over land, with regional exceptions in drying areas.

In most CMIP5 and CMIP6 models, projected ET changes are driven not just by meteorological conditions and soil moisture but also by plant physiological responses to elevated CO_2, which themselves influence meteorology and soil moisture through surface fluxes (Halladay and Good, 2017; Lemordant and Gentine, 2019). Elevated CO_2 causes stomatal closure which decreases ET, but also increases leaf area index (LAI) which in turn increases ET, but these do not necessarily compensate (Skinner et al., 2017). Higher LAI increases transpiration, depleting soil moisture but increasing shading, thus reducing soil evaporation (Skinner et al., 2017), but LAI may not increase in areas where it is already high (Lemordant et al., 2018). Projected ET decreases from physiological effects alone are widespread but greatest in tropical forests (Swann et al., 2016; Kooperman et al., 2018).

Future changes in regional evapotranspiration (ET) are therefore highly uncertain. The CMIP6 multi-model ensemble projects changes in ET varying both in magnitude and sign across the ensemble members (Figure 4.14). At 4°C global warming, the ensemble median projection shows increased ET of approximately 25% in mid/high latitudes but decreases of up to 10% across most of tropical South America, southern Africa, and Australia. These CMIP6 ensemble projections resemble ET changes projected by the CMIP5 ensemble, except over central Africa and Southeast Asia (Berg and Sheffield, 2019). However, the ensemble ranges are wide and include both increases and decreases in projected ET in many locations, with mid-latitude ET increases being up to approximately 50% and ET decreases in southern Africa being up to approximately 30%. Projected changes are proportionally smaller at lower levels of global warming, while patterns of change remain similar.

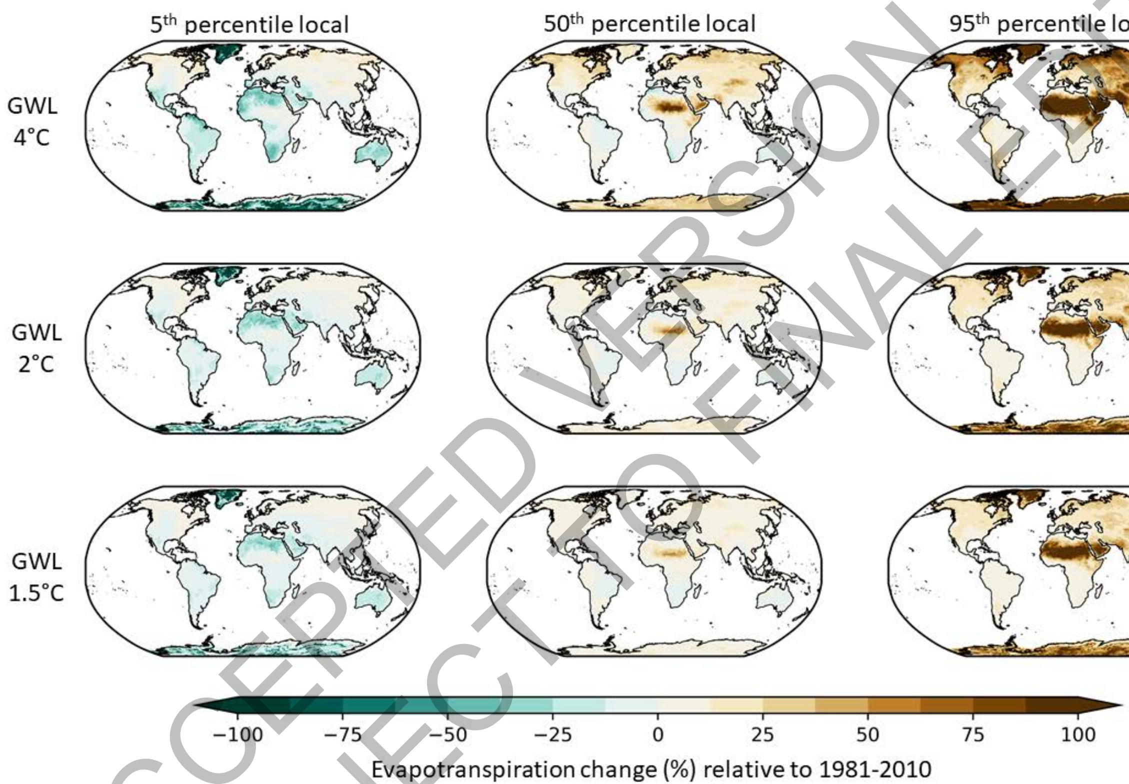

Figure 4.14: Projected percentage changes in annual mean ET at global warming levels (GWLs) of 4°C (top), 2°C (middle) and 1.5°C (bottom) for the CMIP6 multi-model ensemble of GCMs driven by SSP5-85 concentrations. The distribution of outcomes is shown at local scales with the 5th, 50th and 95th percentile ET changes in individual grid boxes. Note that these are uncertainties at the individual point and are not spatially coherent, i.e., they do not represent plausible global patterns of change. Results for 1.5°C, 2°C and 4°C global warming are defined as 20-year means relative to 1850-1900 and use 40, 40 and 31 ensemble members respectively, due to some members not reaching 4°C global warming.

The relative importance of the physiological and radiative effects of CO_2 on future ET is a crucial knowledge gap, partly because many Earth System Model land surface schemes still use representations of this process based on older experimental studies. Furthermore, large-scale experimental studies using Free-Air CO_2 Enrichment (FACE) techniques to constrain the models have not yet been performed in certain critical ecosystems, such as tropical forests. Finally, uncertainties in Equilibrium Climate Sensitivity (ECS) imply uncertainties in the CO_2 concentration accompanying any given level of warming (Betts et al., 2018).

In summary, the sign of projected ET change depends on region, but there is *medium confidence* that ET will increase in the global mean and mid/high latitudes and decrease in northern South America and southern

Africa. In addition, the impacts of rising CO_2 concentrations on plant stomata and leaf area play a role in model projections of evapotranspiration change (*high confidence*), but there is *low confidence* in their overall contribution to global ET change.

4.4.1.3 Projected Changes in Soil Moisture

AR5 (Collins et al., 2013) mainly focused on surface (upper 10cm) soil moisture, summarizing multi-model projections of 21st-century annual mean soil moisture changes as broadly decreasing in the subtropics and Mediterranean region and increasing in east Africa and central Asia across the RCPs, with the changes tending to become stronger as global warming increases. AR6 WG1 (Douville et al., 2021) draw broadly similar conclusions based on new Earth System Models, noting that compared to CMIP5, the CMIP6 models project more consistent drying in the Amazon basin, Siberia, westernmost North Africa and southwestern Australia. WG1 (Douville et al., 2021) also note that soil moisture in the upper 10cm shows more widespread drying than in the total soil column.

The CMIP6 multi-model ensemble of Earth System Models (ESMs) shows varying levels of consensus on projected changes in surface soil moisture with global warming (Figure 4.15). As in CMIP5 (Cheng et al., 2017), uncertainties are substantial, often associated with uncertainties in projected regional precipitation changes (4.4.1.1), and in most regions, both increases and decreases are projected across the ensemble. In the far north of North America and Asia, projected changes in soil moisture at 4°C global warming range from a 20–30% decrease to an increase of 30-40%. In northern mid-latitudes, projection range from a 10-20% decrease to an increase of 20-30%, except for eastern North America where the projected changes (both increases and decreases) are less than 10%, and western Europe and the Mediterranean where there is a stronger consensus towards decreased soil moisture of up to 25%. South America and southern Africa, and Asia also show a stronger consensus towards decreased soil moisture of up to 40% or more in some regions.

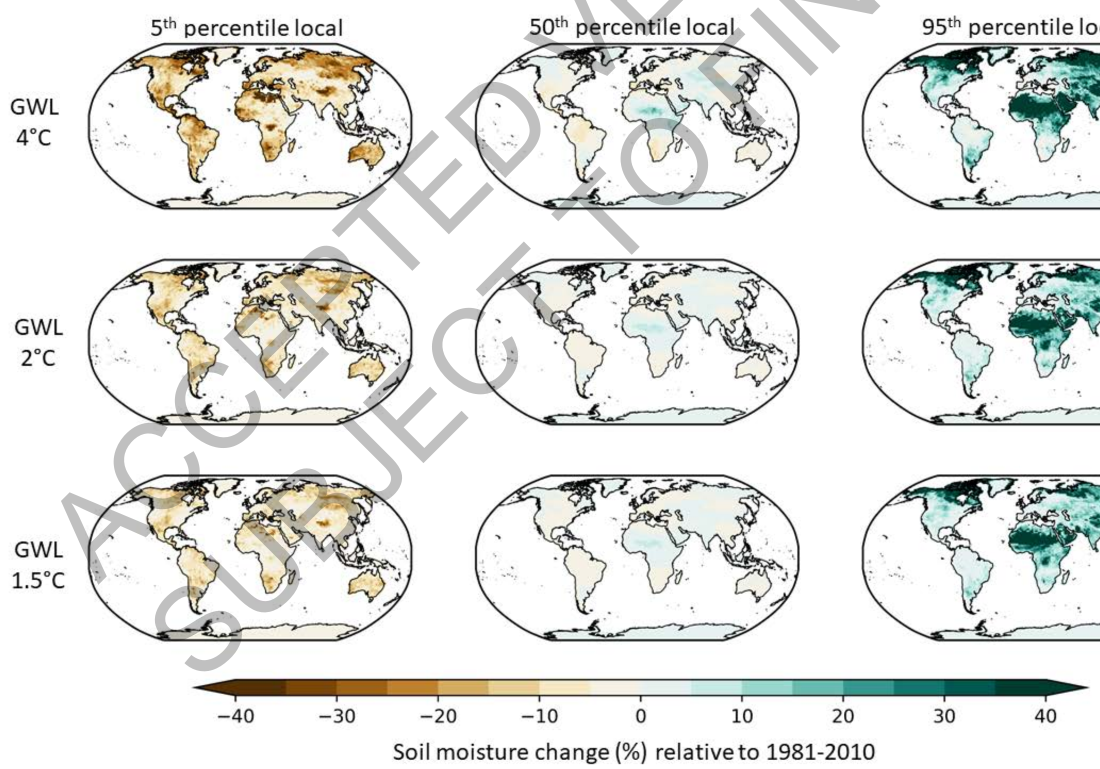

Figure 4.15: Projected percentage changes in annual mean total column soil moisture relative to 1981-2010 at global warming levels (GWLs) of 4°C (top), 2°C (middle) and 1.5°C (bottom) for the CMIP6 multi-model ensemble of GCMs driven by SSP5-85 concentrations. The distribution of outcomes is shown at local scales with the 5th, 50th and 95th percentile soil moisture changes in individual grid boxes. Note that these are uncertainties at individual points and are not spatially coherent, i.e., they do not represent plausible global patterns of change. Results for 1.5°C, 2°C and 4°C global warming are defined as 20-year means relative to 1850-1900 and use 34, 34 and 26 ensemble members respectively, due to some members not reaching 4°C global warming. Fewer models are shown here than in Figure 4.10 on precipitation and Figure 4.14 on ET because some do not provide soil moisture output.

Most CMIP6 models simulate direct CO_2 effects on plant transpiration, which has been shown to be a strong influence on projected future changes in soil moisture (Milly and Dunne, 2016). Approaches that neglect this process project greater decreases in soil moisture availability than the climate models (Roderick et al., 2015; Swann et al., 2016). Therefore, although several studies project increased global aridity and dryland expansion (Feng and Fu, 2013; Sherwood and Fu, 2014; Huang et al., 2016a), these may overestimate future drying (Berg et al, 2017). Nevertheless, land surface models, including vegetation responses to $CO_{2,}$ still project reduced soil moisture in many regions (Grillakis, 2019).

A critical knowledge gap concerns the relative importance of climate and CO_2 physiological effects on soil moisture, in relation to uncertainties in climate sensitivity. For a given level of global warming, the relative importance of climate effects and the direct effects of CO_2 on transpiration depend on the CO_2 concentration accompanying that level of warming (Betts et al., 2018). Some CMIP6 models have very high climate sensitivities (Meehl et al., 2020), which are assessed as being of low probability on the basis of other lines of evidence (Sherwood et al., 2020). This means that the CO_2 concentration accompanying specific global warming levels may be too low and lead to overly-large projections of soil moisture decrease in those models.

In summary, projected soil moisture changes increase with levels of global warming (*high confidence*), although there remains substantial disagreement on specific regional changes. In the CMIP6 multi-model ensemble at 4°C global warming, decreased soil moisture of up to 40% is projected in Amazonia, southern Africa and western Europe in all models (*high confidence*). In all other regions, there is no consensus on the sign of projected soil moisture changes, and projected changes at 4°C global warming include decreases of up to 30% and increases of up to 40%. Projected changes are smaller at lower levels of global warming, with similar geographical patterns of change.

4.4.2 Projected Changes in Cryosphere (Snow, Glaciers, and Permafrost)

The AR5 noted that global glacier mass loss is *very likely* to increase further during the 21^{st} century (Jiménez Cisneros et al., 2014). According to the SROCC (Hock et al., 2019b), it is *very likely* that glaciers will continue to lose mass throughout the 21st century: from 18% (by 2100, relative to 2015) for RCP2.6 to 36% for RCP8.5. The AR5 (Collins et al., 2013) and the SROCC (Meredith et al., 2019) reported with *high confidence* that permafrost would continue to thaw in the 21st century, but the projections are uncertain. Constraining warming to 1.5°C would prevent the thawing of a permafrost area of 1.5 to 2.5 million km^2 compared to thawing under 2°C (*medium confidence*) (IPCC, 2018b). The AR5 (Collins et al., 2013) and the SROCC (Meredith et al., 2019) concluded that Northern hemisphere snow extent and mass would likely reduce by the end of the 21^{st} century, both in plain and mountain regions. AR6 assessed with *medium confidence* that under RCP 2.6 and RCP 8.5 from 2015 to 2100, glaciers are expected to lose 18% and 36% of their early 21st-century mass, respectively (AR6 WGI, (Fox-Kemper et al., 2021)).

Global glacier mass loss between 2015 and 2100 was estimated at the level 18 ± 13% under the RCP2.6 scenario and 36 ± 20% under the RCP8.5 scenario (Marzeion et al., 2020), which corresponds with previous findings (Radić et al., 2014; Hock et al., 2019a; Shannon et al., 2019). The regional glacier loss rates projections are unevenly distributed worldwide and considerably vary between scenarios (Huss and Hock, 2018; Hock et al., 2019a). In most regions 'peak water' has already been reached, or is expected to be reached, before mid-century (with an earlier 'peak water' for RCP2.6 scenario compared with RCP8.5) (Huss and Hock, 2018; Pritchard, 2019; Marzeion et al., 2020; Rounce et al., 2020). The influence of the expected subsequent decrease in glacier run-off by the end of the 21^{st} century will be more pronounced during droughts and dry seasons (Farinotti et al., 2016; Huss and Fischer, 2016; Hanzer et al., 2018; Brunner et al., 2019).

Such changes in run-off could potentially lead to water shortages for over 200 million people in the High Mountains of Asia (Pritchard, 2019; Shahgedanova et al., 2020). There is *medium confidence* that under a 4ºC warming scenario, 40% of current irrigated demand in sub-basins relying primarily on snow-melt run-off would need to be supplemented from other water sources (Qin et al., 2020). Basins, where such alternate sources are not available, will face agricultural water scarcity (4.5.1). Globally, 1.5 billion people are projected to critically depend on run-off from the mountains by the mid-21st century under a 'middle of the road' (RCP6.0) scenario (Viviroli et al., 2020). Furthermore, there is *medium confidence* that projected changes in snow and glacier melt run-off will affect water inputs to hydropower, leading to a decline in hydroelectricity production in mountain basins, e.g., in India (Ali et al., 2018), Switzerland (Schaefli et al., 2019), USA (Lee et al., 2016) (4.5.2), IPCC AR6 WGI, 2021 (Sections 9.5.1.3 and 8.4.1.7.1).

Projections of snow cover metrics (IPCC AR6 WGI, 2021 (Section 9.5.3.3)) suggest a further decrease in snow water equivalent (SWE) and snow cover extent (SCE), though the inter-model spread is considerable (Lute et al., 2015; Thackeray et al., 2016; Kong and Wang, 2017; Henderson et al., 2018) (*high confidence*). The projected CMIP6 SCE and SWE changes share the broad features of the CMIP5 projections: SCE is expected to decrease in the northern hemisphere by approximately 20%, relative to the 1995–2014 mean value, around 2060 and stabilize afterwards under the RCP2.6 scenario, while RCP8.5 scenario leads to snow cover losses up to 60% by 2100 (Mudryk et al., 2020). Regionally, the SWE loss will probably lead to more frequent snow droughts, e.g., the frequency of consecutive snow droughts is projected to increase to 80-100% of years at 4˚C warming in western Canada (Shrestha et al., 2021) and 42% of years under the RCP8.5 scenario in the western US (Marshall et al., 2019) by 2100. Thus, by the mid-to-late-21st century, for more than 2/3 of snow-dominated areas in the western US, the ability to predict seasonal droughts and prepare robust water management plans will decline (Livneh and Badger, 2020)(4.4.5).

There is a *high agreement* between the CMIP6 projections and the previous findings that permafrost will undergo increasing thaw and degradation during the 21st century worldwide (IPCC AR6 WG1, 2021 (Sections 9.5.2.3)). The CMIP6 models project that the annual mean frozen volume in the top 2 m of the soil could decrease by 10 %–40 % for every degree increase of global temperature (Burke et al., 2020; Yokohata et al., 2020b). The CMIP5-based equilibrium sensitivity of permafrost extent to stabilized global mean warming is established to be about 4.0×10^6 km^2 $°C^{-1}$ (Chadburn et al., 2017). The southern boundary of the permafrost is projected the move to the North: 1–3.5° northward (relative to 1986–2005), at the level of 1.5 °C temperature rise (Kong and Wang, 2017).

The observational knowledge gaps (4.2.2) impede efforts to calibrate and evaluate models that simulate the past and future evolution of the cryosphere and its social impacts.

In summary, in most basins fed by glaciers, runoff is projected to increase initially in the 21st century and then decline (*medium confidence*). Projections suggest a further decrease in seasonal snow cover extent and mass in mid-to-high latitudes and high mountains (*high confidence*) though the projection spread is considerable. Permafrost will continue to thaw throughout the 21st century (*high confidence*). There is *medium confidence* that future changes in cryospheric components will negatively affect irrigated agriculture and hydropower production in regions dependent on snow-melt run-off.

4.4.3 Projected Changes in Streamflow

AR5 (Jiménez Cisneros et al., 2014) concluded that increases in the mean annual run-off are projected in high latitudes and the wet tropics and decreases in dry tropical regions, but with very considerable uncertainty. Both the patterns of change and uncertainties were found to be primarily driven by projected changes in precipitation. SR1.5 (Hoegh-Guldberg et al., 2018) concluded with *medium confidence* that areas with either positive or negative changes in mean annual run-off/streamflow are projected to be smaller for 1.5°C than for 2°C of global warming. AR6 WG1 (Douville et al., 2021) conclude with *medium confidence* that global run-off will increase with global warming but with significant regional and seasonal variations. WG1 further concluded with *high confidence* that run-off will increase in the high northern latitudes and decrease in the Mediterranean and southern Africa. However, there was *medium confidence* that run-off will increase in central and eastern African regions and decrease in Central America and parts of southern South America. The magnitude of the change is projected to increase with emissions. There is *medium confidence* that the seasonality of run-off and streamflow will increase with global warming in the subtropics. In snow-dominated regions, there is *high confidence* that peak flows associated with spring snowmelt will occur earlier in the year and *medium confidence* that snowmelt-induced run-off will decrease with reduced snow, except in glacier-fed basins where run-off may increase in the near term.

Changes in run-off and streamflow are projected over most of the ice-free land surface with all recent climate and hydrological model ensembles (Figure 4.16). Changes in streamflow could increase the number of people facing water scarcity or insecurity (*high confidence*) (Schewe et al., 2014; Gosling and Arnell, 2016; McMillan et al., 2016). Projections of future run-off at basin scales show considerable uncertainty in many regions, including differences in signs in many regions (Figure 4.16). This uncertainty is driven by uncertainties in regional precipitation patterns and hydrological models (Koirala et al., 2014; Asadieh et al., 2016), including vegetation responses to CO_2 and its effects on ET (Betts et al., 2015). This uncertainty in future water availability contributes to the policy challenges for adaptation, for example, for managing risks of water scarcity ((Greve et al., 2018); Box 4.1). In many regions, some models project large changes in run-off/streamflow but with low consistency between models on the sign of the change (Figure 4.16). In streamflow projections driven by 11 CMIP5 models with the RCP8.5 scenario, strong model consistency (agreement by at least ten models) is only seen over 21% of global land (Koirala et al., 2014). Consensus on the sign of projected change is smaller with the RCP4.5 scenario.

Considering a wider set of projections, the consensus on increased flows becomes stronger at higher GWLs in (for example) the Yukon, Mackenzie, Kemijoki, Amur, Hwang Ho, Yangtze, Mekong, Ganges-Brahmaputra, Nile, Zaire and Parana basins (Figure 4.16). The consensus on decreased flows becomes stronger for higher GWLs in (for example) the Colorado, Tagus, Helmand, Tigris-Euphrates and Amazon. However, in both cases, some models have projected changes of the opposite sign to the consensus. Moreover, the distribution of projected outcomes becomes notably broader at higher GWLs in (for example) the Mississippi, Yangtze and Amazon. Therefore, even with a strong global climate change signal, uncertainties in changes in mean run-off/streamflow can remain large or even increase. Nevertheless, since projected changes typically increase with global warming, limiting warming to 1.5°C or 2°C substantially reduces the potential for either large increases or decreases in mean streamflow compared to 3°C or 4°C ((Warszawski et al., 2014; Falkner, 2016; Gosling et al., 2017); Figure 4.16) (*high confidence*).

In CMIP5, strong model consistency on changes in high and low streamflows is seen with similar global patterns to the mean flows, but over smaller areas (Koirala et al., 2014) (Koirala et al., 2014). By the end of the 21st century with RCP8.5, increases in mean, high and low flows are projected for the Lena; mean and low flows for the MacKenzie (Gelfan et al., 2017; Pechlivanidis et al., 2017; Döll et al., 2018). Increased mean and high flows are projected in the Ganges, high flow in the Rhine and Mississippi while decreasing mean and low flows in the Rhine (Krysanova et al., 2017; Pechlivanidis et al., 2017; Vetter et al., 2017). Decreases in mean, high and low flows are projected for the Tagus Krysanova, 2017 #1394; Vetter, 2017 #697}. Low flows are projected to decrease in the Mediterranean region and increase in the Alps and Northern Europe (Marx et al., 2018). A general shift in the run-off distribution towards more extreme low run-off in Mexico, western United States, Western Europe, southeastern China, West Siberian Plain and more extreme high run-off in Alaska, northern Canada, and large parts of Asia are projected (Zhai et al., 2020).

While projected changes in high and low flows are similar to those in mean flows in many regions, this is not the case everywhere. When a single hydrological model and a sample of climate models are selected to explore uncertainties systematically, approximately 56% of the global population is projected to be affected by increased extreme high flows at 1.5°C warming, rising to 61% at 2°C warming (Zhai et al., 2020). Those affected by extreme low flows decrease is projected to remain close to 45% at both 1.5°C and 2°C warming. However, these results are based on the median of the ensemble projections, so they are subject to high uncertainty. At 1.5°C global warming, 15% of the population is projected to be affected concurrently by decreased extreme low flows and increased extreme high flows, increasing to 20% at 2°C warming. In 25 combinations of five CMIP5 climate models and five global hydrological models under the RCP8.5 scenario reaching approximately 4°C GWL at the end of the century, 10 % of the global land area is projected to face simultaneously increasing high extreme streamflow and decreasing low extreme streamflow. These regions include the British Isles and the shores of the North Sea, large parts of the Tibetan Plateau, South Asia, and western Oceania, and smaller regions of Africa and North and South America, affecting over 2.1 billion people with 2015 population distributions (Asadieh and Krakauer, 2017). With 11 CMIP5 models driving a single hydrological model, simultaneous increases in high flows and decreases in low flows are projected over 7% of global land (Koirala et al., 2014).

By the end of the 21st century, global changes in streamflow extremes are projected to be approximately twice as large with RCP8.5 (over 4°C GWL) than with RCP2.6 (approximately 2°C GWL) (Asadieh and Krakauer, 2017).

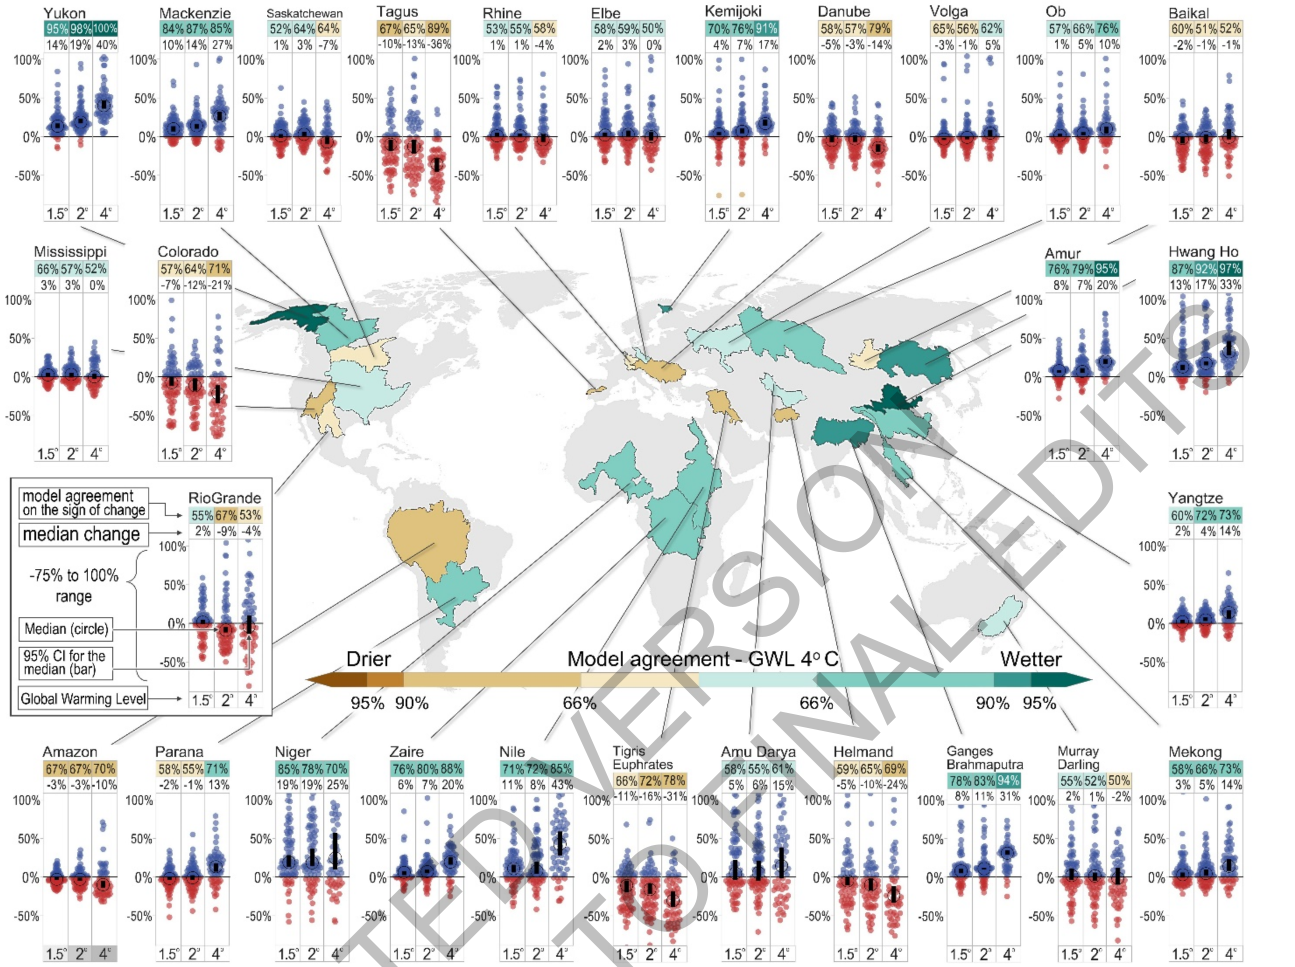

Figure 4.16: Projected changes in the annual mean run-off in selected river basins at Global Warming Levels (GWLs) of 1.5°C, 2°C and 4°C in a combined ensemble. For each named basin, the sinaplot dots show individual model outcomes for percentage increased flows (blue) and decreased flows (red) at each GWL. Black circles show the ensemble median, and black bars show the 95% confidence range in the median. See inset with the Rio Grande sinaplot for additional guidance on interpretation. In the map, the colours in the basins show the percentage model agreement on the sign of the projected change in streamflow at the 4°C GWL. The combined ensemble is comprised of 4 multi-model ensembles: the CMIP5 multi-model ensemble of GCMs driven with RCP8.5; the CMIP6 multi-model ensemble of GCMs driven with SSP5-85; varying combinations of hydrological models with 5 GCMs in the Inter-Sectoral Impacts Model Intercomparison Project (ISIMIP), and; the JULES land ecosystems and hydrology model driven by GCMs from the HELIX study (Betts et al., 2018; Koutroulis et al., 2019). In CMIP5 and CMIP6, the projected run-off changes are directly from the GCM land surface schemes without bias correction. In ISIMIP and HELIX, bias-corrected climate model outputs were used to drive the hydrology models. A comparison of the projected changes at the 4°C GWL for the four individual ensembles is shown in Figure Cross-Chapter Box CLIMATE.1 in Chapter 1.

Glacier retreat and associated run-off changes represent a major global sustainability concern (4.4.2). By 2100, using an ensemble of 14 CMIP5 climate models driven by the RCP4.5 scenario, 1/3rd of the 56 large-scale glacierized catchments are projected to experience a mean annual run-off decline by over 10%, with the most significant reductions in central Asia and the Andes (Huss and Hock, 2018). Thus, communities dependent on glacier run-off are particularly vulnerable (Jiménez Cisneros et al., 2014).

Societal impacts of change in run-off spread throughout several socio-economic sectors, such as agriculture, health, energy production, affecting overall water security (Wang et al., 2021a). Decreases in run-off may lead to water scarcity and result in increased multisectoral effects in Sub-Saharan Africa (Serdeczny et al., 2017), Western Africa, Middle East, Mexico, North Eastern Brazil, Central Argentina, Mediterranean Africa and Europe (Gosling and Arnell, 2016; Greve et al., 2018), and South-Eastern Australia (Barnett et al., 2015).

In summary, mean and extreme streamflow changes are projected over most of the ice-free land surface (*high confidence*). The magnitude of streamflow change is projected to increase with global warming in most regions (*high confidence*), but there is often high uncertainty on the sign of change. There is *high confidence* that mean streamflows will increase in the northern high latitudes and decrease in the Mediterranean and southern Africa. Annual mean run-off in one-third of glacierized catchments is projected to decline by at least 10% by 2100, with the most significant reductions in central Asia and the Andes (*medium confidence*). Elsewhere, projections include both increased and decreased flows. Substantial fractions of ensemble projections disagree with the multi-model mean (*high confidence*), with implications for long-term planning for water management. With 1.5°C and 2°C global warming, approximately 15% and 20% of the current global population would experience both an increase in high streamflows and a decrease in low streamflows (*medium confidence*). At 4°C global at the end of the century, 10 % of the global land area is projected to simultaneously experience an increase in high extreme streamflow and decrease in low extreme streamflow.

4.4.4 Projected Changes in Floods

SR1.5 (Hoegh-Guldberg et al., 2018) concluded with *medium confidence* that global warming of 2°C would lead to an expansion of the area affected by flood hazards, compared to conditions at 1.5°C global warming. Both AR5 (Jiménez Cisneros et al., 2014) and SROCC (Hock et al., 2019b) concluded that spring snowmelt floods would be earlier (*high confidence*), and hazards from floods involving meltwater will gradually diminish, particularly at low elevation (*medium confidence*). SROCC (Hock et al., 2019b) and AR6 WGI Chapter 9 stated that given *limited evidence* and the complexity of the process, the changes of glacier-related floods under climate change are not clear. AR6 WGI Chapters 8 and 11 summarized that there is *medium confidence* for a general increase in flooding due to warming, but there are significant regional and seasonal variations.

There is *high confidence* that the frequency and magnitude of river floods are projected to change at a global scale. For example, the frequency of river floods is projected to increase in many regions, including Asia, central Africa, western Europe, Central and South America and eastern North America, and decrease in northern North America, southern South America, Mediterranean, eastern Europe in 2050 and beyond (Koirala et al., 2014; Arnell et al., 2016) (Figure 4.17). There is *low agreement* in projections in changes to snowmelt flood magnitude. A negative trend in snowmelt flood magnitude, together with an increase in rain-fed winter floods, is projected with *medium confidence*, for example, in mid-latitudes and low-altitude basins of Scandinavia (Arheimer and Lindström, 2015; Vormoor et al., 2016) and throughout Europe as a whole (Kundzewicz et al., 2017), and northeastern North America (Arnell and Lloyd-Hughes, 2014). With *medium confidence*, a positive trend is projected in high-latitude basins, e.g., for large Arctic Rivers, such as Lena and Mackenzie (Eisner et al., 2017; Gelfan et al., 2017; Pechlivanidis et al., 2017) and high-altitude upstreams, such as Ganges, Brahmaputra, Salween, Mekong and the upper Indus Basin (Lutz et al., 2014) and Alpine catchments (Hall et al., 2014). Moderate decreasing trends or insignificant changes are projected for snowmelt floods in the Fraser River Basin of British Columbia (Shrestha et al., 2017).

There is *high confidence* that climate change and projected socio-economic development would increase exposure in inundation areas (Figure 4.17), resulting in a large increase in direct flood damages as several times more in all warming levels (Table 4.6). (Alfieri et al., 2017) estimated a 120% and 400% increase in population affected by river flooding for 2°C and 4 °C warming, respectively, and a 170% increase in damage for 2°C warming without socio-economic impact development (4.7.5). (Dottori et al., 2018) estimated the same but with a 134% increase in fatalities with population increase under the SSP3 scenario. The highest numbers of people affected by river flooding are projected for countries in southern, eastern and south-eastern Asia, with tens of millions of people per year per country projected to be affected (Figure 4.17; (Alfieri et al., 2017; Hirabayashi et al., 2021b). (Kinoshita et al., 2018) showed that climate change contributes a 2.8 to 28.8% increase in global fatality for the period 2071-2100, compared to 1991-2005, but socio-economic change (~131.3% increase) and associated vulnerability change (~72.1% reduction) have a greater impact of the projected flood-related fatality rate than climate change alone. (Winsemius et al., 2016) discussed that projected flood damage could be reduced to 1/20th in absolute value with adequate adaptation strategies. Direct flood damages are projected to increase by 4-5 times at 4°C compared to 1.5°C, highly depending on scenarios and assumptions (Table 4.6; Box 4.7).

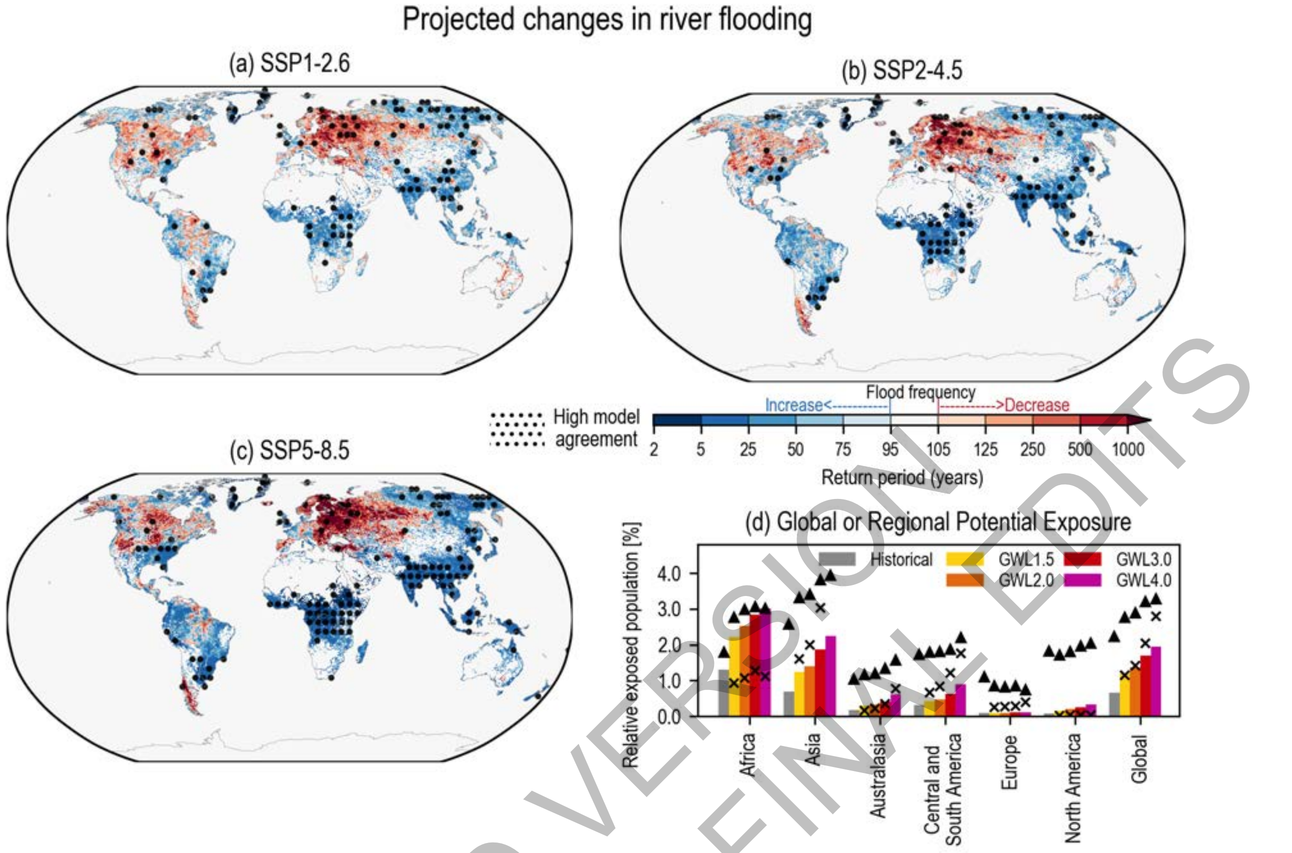

Figure 4.17: Multi-model median return period (years) in the 2080s for the 20th-century 100-year river flood, based on a global river and inundation model, CaMa-Flood, driven by runoff output of 9 CMIP6 Models in the SSP1-2.6 (a), SSP2-4.5 (b) and SSP5-8.5 (c) scenario respectively. All changes are estimated in 2071-2100 relative to 1970-2000. A dot indicates regions with high model consistency (more than 7 models out of 9 show the same direction of change). (d) Global or regional potential exposure (% to the total population affected by flooding) under different warming levels with constant population scenario of CMIP5 (Alfieri et al., 2017) and with population scenario of SSP5 of CMIP6 (bar chart, (Hirabayashi et al., 2021b)). Inundation is calculated when the magnitude of flood exceeds current flood protection (Scussolini et al., 2016). Note that number of GCMs used to calculate Global Warming Level (GWL) 4.0 is less than that for other SWLs, as the global mean temperature of some GCMs did not exceed 4°C.

Table 4.6: Projected economic impact by river flooding in billion US$ in different emission scenarios or for different global warming levels (GWL). The percentage of the total GDP of the region is given in brackets.

Description	The economic impact in billion US$ (% of GDP)	Reference
No adaptation with current flood protection, no economic development (fixed at the level of 2010), US$ at 2010 PPP, mean of 7 GCMs with RCP8.5 scenario	• Current (1976-2005): 75 (0.11 %) • GWL 1.5°C: 145 (0.22 %) (Asia 92, Australasia 8, Europe 29, Africa 7, North America 3, Central and South America 5) • GWL 2°C: 172 (0.26 %) (Asia 114, Australasia 7, Europe 32, Africa 9, North America 4, Central and South America 7) • GWL 3°C: 249 (0.37 %) (Asia 176, Australasia 9, Europe 38, Africa 11, North America 4, Central and South America 11) • GWL 4°C: 343 (0.51 %) (Asia 241, Australasia 19, Europe 55, Africa 9, North America 6, Central and South America 14)	(Alfieri et al., 2017), with regional aggregation and currency conversion
No adaptation with current flood protection, US$ at 2010 PPP,	• Current (1976-2005): 142 (0.21 %) • GWL 1.5°C, SSP3: 370 (0.55 %), SSP5: 485 (0.72%)	(Dottori et al., 2018) with

mean of 5 CMIP5 GCMs and 10 hydrological models	• GWL 2°C, SSP3: 597 (0.89 %), SSP5: 888 (1.32%) • GWL 3°C, SSP3: 1,024 (1.52 %), SSP5: 1,616 (2.40%)	currency conversion
No adaptation and no flood protection, mean value in 2030 (2010-2030) and 2080 (2010-2080), US$ at 2010 PPP, mean of 5 CMIP5 GCMs	• Current (1960-1999): 1,032 (1.6 %) • RCP2.6, SSP1: 2030: 2,366 (1.44%), 2080: 7,429 (1.43%) • RCP6.0, SSP3: 2030: 1,987 (1.44%), 2080: 3,353(1.14%) • RCP8.5, SSP5: 2030: 2,304 (1.37%), 2080: 3,684(1.77%)	(Winsemius et al., 2016)
Partial adaptation (protected against 100-year floods in high-income countries, against 5-year floods for all others), mean value in 2030 (2010-2030) and 2080 (2010-2080), US$ at 2010 PPP, mean of 5 CMIP5 GCMs	• Current (1960-1999): 163 (0.25 %) • RCP2.6, SSP1: 2030: 558 (0.34%), 2080: 851 (0.48%) • RCP6.0, SSP3: 2030: 418 (0.29%), 2080: 413(0.32%) • RCP8.5, SSP5: 2030: 418 (0.33%), 2080: 441 (0.57%)	(Winsemius et al., 2016)
A model calibrated to fit reported damages, future vulnerability scenarios considering autonomous adaptation, US$ at 2005 PPP, mean of 11 CMIP5 GCMs,	• Current (1991-2005): 14 (0.044 %) • RCP2.6, SSP1: 2081-2100, 121 (0.037 %) • RCP6.0, SSP2: 2081-2100, 133 (0.042 %) • RCP8.5, SSP3: 2081-2100, 130 (0.063 %)	(Kinoshita et al., 2018)
No adaptation and current flood protection, US$ at 2005 PPP, mean of 5 CMIP5 GCMs	• Current (1961-2005): 102 (0.39 %) • RCP2.6, SSP1: 2020-2100, 2333 (0.99 %) • RCP4.5, SSP2: 2020-2100, 2221 (0.99 %) • RCP6.0, SSP3: 2020-2100, 1328 (0.80%) • RCP8.5, SSP5: 2020-2100, 4007 (1.21 %)	(Tanoue et al., 2021)
Optimized adaptation, US$ at 2005 PPP, mean of 5 CMIP5 GCMs	• Current (1961-2005): 102 (0.39 %) • RCP2.6, SSP1: 2020-2100, 1621 (0.69 %) • RCP4.5, SSP2: 2020-2100, 1567 (0.70 %) • RCP6.0, SSP3: 2020-2100, 872 (0.52 %) • RCP8.5, SSP5: 2020-2100, 2558 (0.77 %)	(Tanoue et al., 2021)

In all climate scenarios projected, earlier snowmelt leads to earlier spring floods (*high confidence*), for example, in northern and eastern Europe (Gobiet et al., 2014; Hall et al., 2014; Etter et al., 2017; Lobanova et al., 2018), northern North America (Vano et al., 2015; Musselman et al., 2018; Islam et al., 2019b), large Arctic rivers (Gelfan et al., 2017; Pechlivanidis et al., 2017), and high-altitude Asian basins (Lutz et al., 2014; Winsemius et al., 2016). There is *high confidence* that snowmelt floods will occur 25-30 days earlier in the year by the end of the 21st century with RCP8.5, but there is only *low agreement* in the projected magnitude of snowmelt flood (Arheimer and Lindström, 2015; Vormoor et al., 2016; Islam et al., 2019b).

Challenges to projecting flood risk are large because of the complexity of the projecting snowmelt, high-intensity rainfall and soil wetness in large river basins. Even though increases in the number and area of glacier lakes may cause increases in glacier-related floods (4.2.2), knowledge of the frequency or magnitude of glacier-related projected floods is limited. Some local studies indicate that the severity of ice-jam flooding is projected to decrease (Rokaya et al., 2019; Das et al., 2020), but a model study in Canada projected increases in damage of ice-jam floods (Turcotte et al., 2020). While most flood risk projections do not consider the impact of urban expansion, (Güneralp et al., 2015) estimate that urban areas exposed to flooding will increase by a factor of 2.7 due to urban growth by 2030 (4.5.4). Given the significant differences in assumption in flood protection, exposure or vulnerability scenario among studies, uncertainties in the global estimation of flood loss and damages are large (Table 4.6, 4.7.5).

Floods and their societal impacts, especially the enhancement of hazards and increase in vulnerability, depend on complex political, economic, and cultural processes (Carey et al., 2017; Caretta et al., 2021). Thus, assessments that analyze long term flood impacts need to account for the interplay of water and society relations. Unfortunately, such studies remain scarce (Pande and Sivapalan, 2017; Ferdous et al., 2018; Caretta et al., 2021). In particular, projected socio-economic, cultural and political impacts on the vulnerable group are understudied, as is their resourcefulness through local knowledge, adaptive capacity and community-led adaptation (4.6.9; 4.8.4; Cross-Chapter Box INDIG in Chapter 18).

In summary, there is *high confidence* that the magnitude, frequency and seasonality of flood are projected to increase in many regions, including Asia, central Africa, western Europe, Central and South America and eastern North America, and decrease in northern North America, southern South America, Mediterranean and Eastern Europe. Projected increases in flooding pose increasing risks, with a 1.2 to 1.8 and 4 to 5 times increase in global GDP loss at 2°C and 4°C compared to 1.5°C warming, respectively (*medium confidence*). However, regional differences in risks are large because of the strong influence of socio-economic conditions and significant uncertainty in flood hazard projection. In small river basins and urban areas, there is *medium confidence* that projected increases in heavy rainfall would contribute to increases in rain-generated local flooding. However, the snowmelt floods are projected to decrease (*medium confidence*) and occur 25-30 days earlier in the year by the end of the 21st century with RCP8.5 (*high confidence*).

4.4.5 Projected Changes in Droughts

AR6 WG1 (Douville et al., 2021) concluded that the total land area subject to increasing drought frequency and severity would expand (*high confidence*), and in the Mediterranean, south-western South America, and western North America, future aridification will far exceed the magnitude of change seen in the last millennium (*high confidence*). WG1 (Seneviratne et al., 2021) also find many consistencies among projections of climate change effects on different forms of drought (meteorological, agricultural/ecological and hydrological and drought, 4.2.5), but also significant differences in some regions, particularly in the levels of confidence in projected changes.

Many studies focus on precipitation-based drought indices (Carrão et al., 2018), but higher evaporative demands and changes in snow cover are additional drivers of hydrological, agricultural and ecological drought (*medium confidence*) in many regions of the world (Koirala et al., 2014; Prudhomme et al., 2014; Touma et al., 2015; Wanders et al., 2015; Zhao and Dai, 2015; Naumann et al., 2018; Cook et al., 2020a). Furthermore, these droughts (hydrological, agricultural and ecological) are often modulated by prevailing soil and hydro-morphological characteristics. Therefore, the choice of drought definition can affect the magnitude and even the sign of the projected drought change.

In a study with multiple climate models, global water models and scenarios, the choice of drought definition was the dominant source of uncertainty in the sign of projected change in drought frequency in over 17% of global land by 2070-2099, including several major wheat and maize-growing areas where agricultural (soil moisture) drought is of high importance (Satoh et al., 2021). (Cook et al., 2020a) noted that in the CMIP6 projections, soil moisture and runoff drying is more robust, spatially extensive, and severe than precipitation, resulting in the frequency of agricultural drought increasing over wider areas than for meteorological drought. At 1.5°C global warming, the likelihood of extreme agricultural (soil moisture) drought is projected to at least double (100% increase) over large areas of northern South America, the Mediterranean, western China and high latitudes in North America and Eurasia (Figure 4.18, left column). The likelihood is projected to increase by 150% to 200% in these regions at 2°C global warming, with an expansion of the affected areas, and increase by over 200% at 4°C global warming. Agricultural drought likelihood also increases by 100% to 250% at 4°C global warming in south-western North America, south-west Africa, southern Asia and Australia. The likelihood of extreme drought is projected to decrease in central North America, the Sahel, the horn of Africa, the eastern Indian sub-continent, and parts of western and eastern Asia. Using eight global hydrological models driven by a subset of four of the CMIP5 climate models, (Lange et al., 2020) projected a 370% (30–790%) increase of the global population annually exposed to agricultural (soil moisture) droughts in response to 2°C global warming. Therefore, it is essential to consider the drought type when applying drought projections to impact and risk in decision-making, especially for informing adaptation. For example, if responses are explicitly tailored to agricultural (soil moisture) drought changes, projected changes in a meteorological (precipitation) drought metric may not provide accurate information.

Compared to CMIP5, the CMIP6 ensemble projects more consistent drying in the Amazon basin (Parsons, 2020), more extensive declines in total soil moisture in Siberia (Cook et al., 2020a), and stronger declines in westernmost North Africa and south-western Australia. Projected declines in soil moisture in these geographies would cause a significant risk of agricultural drought. Also, importantly, projected changes in drought in many regions depend on the season and may not be evident in annual mean changes. For example, in north-western Asia, hydrological (runoff) drought frequency is projected to decrease by 50-100% in autumn and winter but increase by up to 250% in spring and summer (Cook et al., 2020a). In contrast, meteorological (precipitation) drought frequency is projected to increase by up to 350% throughout the year.

Drought projections are subject to uncertainties due to limits of predictability and understanding of the relevant biophysical processes. Uncertainties in regional climate changes are significant in many regions (see Figure 4.10, Figure 4.13, Figure 4.15), and in climate model ensembles, the range of regional outcomes generally increases with global warming. This widening of the range of outcomes can contribute to the increased likelihood of extreme droughts across the ensemble as a whole (Figure 4.18, right column). The response of transpiration to elevated CO_2 is also a significant uncertainty. The inclusion of CO_2 physiological effects leads to smaller projected increases in agricultural, ecological or hydrological drought (Milly and Dunne, 2016; Yang et al., 2020). However, the level of uncertainties in representing the effects of CO_2 is still very high, precluding conclusive results in a global analysis (de Kauwe et al., 2013; Prudhomme et al., 2014; Yang et al., 2016). Most CMIP6 climate models include CO_2 physiological effects, but many hydrological models used for impacts studies do not.

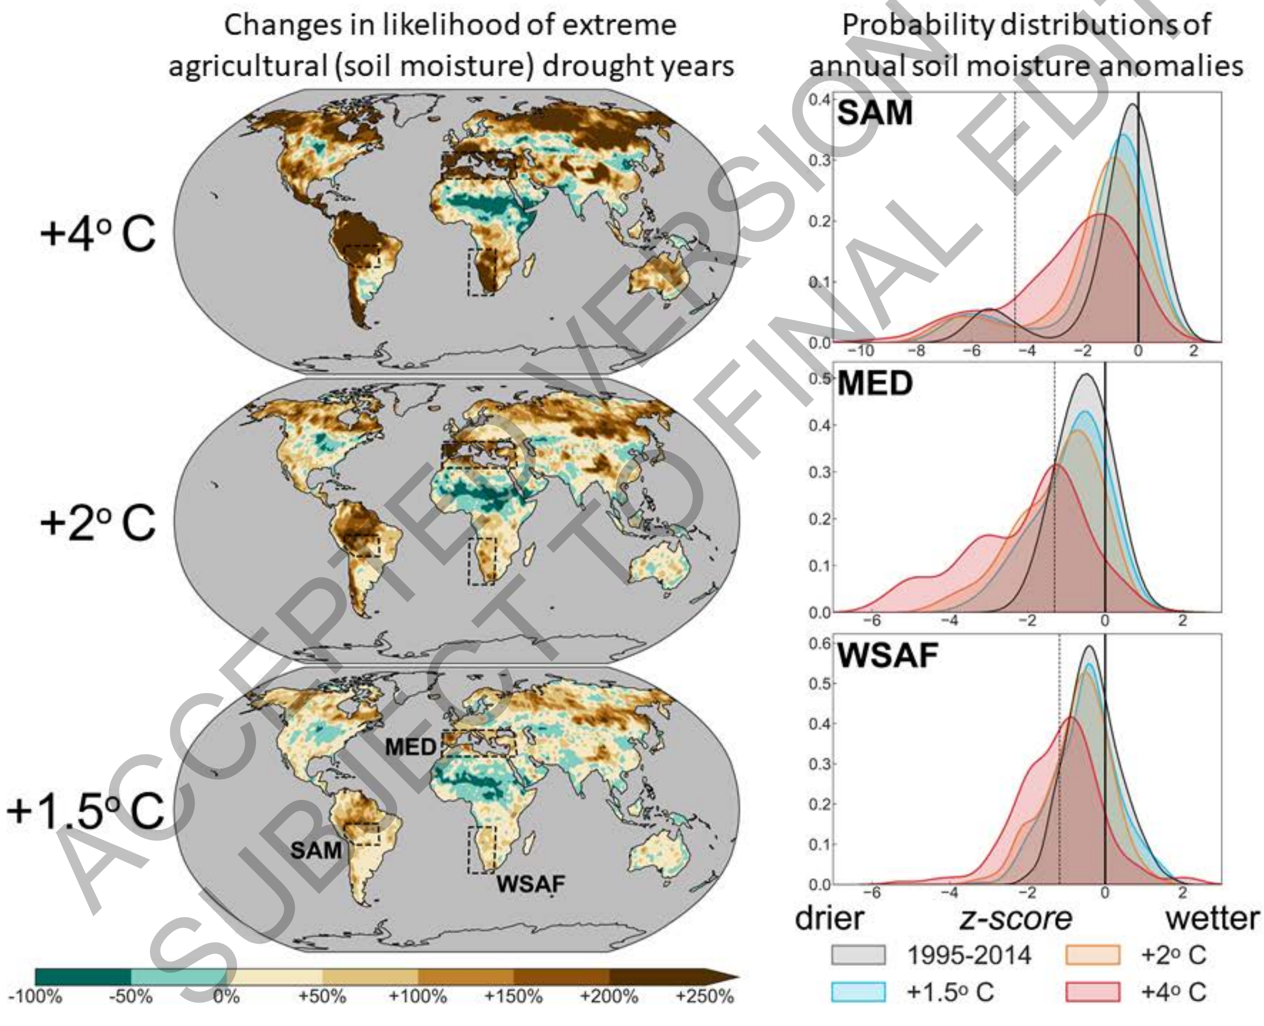

Figure 4.18: Projected changes in the likelihood of an extreme single-year agricultural (soil moisture) drought event, with extreme drought defined as the driest 10% of years from 1995-2014, using total soil moisture projections pooled from the CMIP6 ensemble following (Cook et al., 2020a). All ensemble members are treated as equally likely potential outcomes, and likelihoods are calculated using the whole ensemble, left: Percentage change in the likelihood of extreme drought at GWLs of 4°C (top), 2°C (middle) and 1.5°C (bottom), with "extreme drought" defined locally as the 10th percentile in individual grid boxes. Right: probability distribution functions of regional mean soil moisture anomalies for the climatic regions Mediterranean (MED), South American Monsoon (SAM) and West Southern Africa (WSAF) (Iturbide et al., 2020), at 1.5°C, 2°C and 4°C GWLs. The solid vertical line shows the baseline, i.e., 50th percentile in 1995-2014. The dashed vertical line shows the 10th percentile for 1995-2014, defining "extreme drought" at the regional scale. Projections used the SSP5-8.5 scenario to maximize the number of ensemble members at higher GWLs, but

global patterns of change are very similar for all scenarios (Cook et al., 2020a) and for any given GWL, similar results can be expected with other scenarios (Seneviratne et al., 2021).

Terrestrial water storage (TWS) is the sum of continental water stored in canopies, snow and ice, rivers, lakes and reservoirs, wetlands, soil and groundwater (Pokhrel et al., 2021). TWS drought can therefore be considered to be a combination of agricultural, ecological and hydrological drought. The proportion of the global population exposed to TWS drought is projected to increase with ongoing climate change (Figure 4.19). By the late 21st century, under RCP6.0, the global land area in extreme-to-exceptional TWS drought is projected to increase from 3% to 7% (Pokhrel et al., 2021), with increasing uncertainty over time. Combined with a medium population growth scenario (SSP2), this leads to the global population in this level of drought increasing from 3% to 8%, again with increasing uncertainty over time. Hydrological droughts can also be driven by direct human impact via water abstraction (Javadinejad et al., 2019).

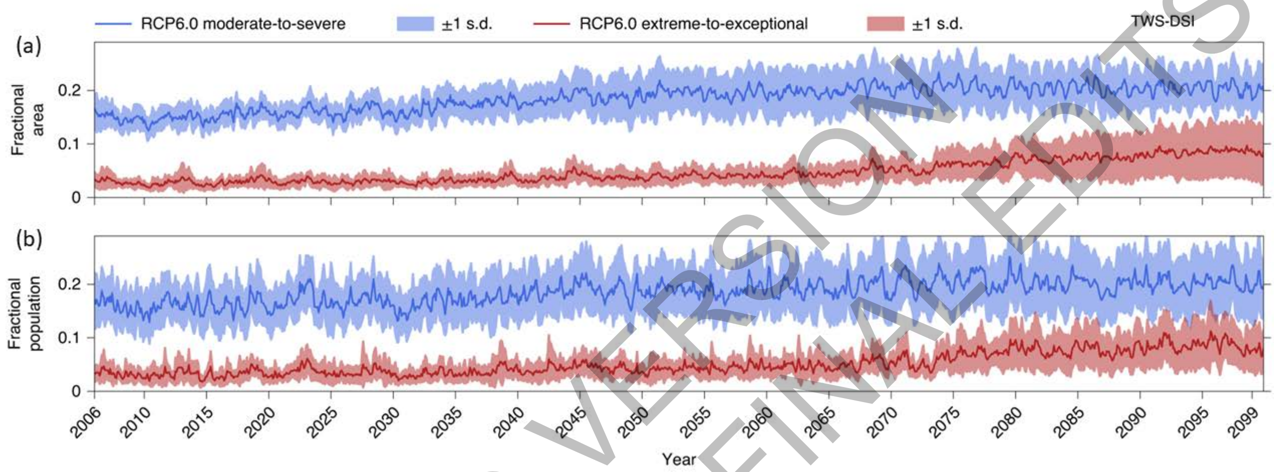

Figure 4.19: Projected changes in the area under drought and population affected, defined with changes in Terrestrial Water Storage – Drought Severity Index (TWS-DSI) projected with 7 terrestrial hydrology models driven by 4 CMIP5 climate models using the RCP6.0 concentration pathway. (a) Fractional global land area under moderate-to-severe drought (blue), defined as −0.8 ≤ TWS-DSI < −1.6, and extreme-to-exceptional drought (red), defined as TWS-DSI < −1.6. (b) Fraction of global population exposed to moderate-to-severe (blue) and extreme-to-exceptional (red) drought, using the SSP2 population projection. Dark lines show the ensemble means; shaded areas indicate uncertainty as ±1 standard deviation. Reproduced from (Pokhrel et al., 2021).

Critical knowledge gaps include uncertainties in regional drought due to regional climate change uncertainties, challenges in constraining plant physiological responses to atmospheric CO_2, and the uncertainties in modelling the role of different population projections in projecting regional drought risk.

In summary, the likelihood of drought is projected to increase in many regions over the 21st century (*high confidence*) even with strong climate change mitigation, more severely in the absence of this. Different forms of drought broadly show similar patterns of projected change in many regions (*high confidence*), but the frequency of agricultural drought is projected to increase over wider areas than for meteorological drought (*medium confidence*). Clarity on the definition of drought is therefore important for informing decision-making. With the RCP6.0 and SSP2 scenarios, the global population exposed to extreme-to-exceptional terrestrial water storage drought is projected to increase from 3% to 8% over the 21st century.

4.4.6 Projected Changes in Groundwater

AR5 concluded that the range of projected future changes in groundwater storage was large, from statistically significant declines to increases due to several uncertainties in existing models (Jiménez Cisneros et al., 2014). AR6 (Douville et al., 2021) concluded with *high confidence* that projected increases in precipitation alone cannot ensure an increase in groundwater storage under a warming climate unless unsustainable trends in groundwater extraction are also reversed.

Projected impacts of climate change on groundwater systems are commonly simulated using models at local to global scales (Bierkens and Wada, 2019). The relations between climate change and groundwater are more complex than those embedded in current numerical models (Cuthbert et al., 2019b). For instance, groundwater systems register effects of drought with several years of lag effect, and aquifer response times to changes in hydraulic forcing also vary across aquifers (Cuthbert et al., 2019a). For instance, long groundwater response times can buffer drought impacts and lengthen recovery times to sustained drought events (Van Lanen et al., 2013; Opie et al., 2020).

Global total and non-renewable groundwater withdrawals are projected to increase from 952 km^3 $year^{-1}$ (2010) to 1,621 km^3 $year^{-1}$ (2099) and from 304 km^3 $year^{-1}$ (2010) to 597 km^3 $year^{-1}$ (2099), respectively (Bierkens and Wada, 2019). At the same time, groundwater depletion is projected to increase from approximately 204 (±30) km^3 $year^{-1}$ in 2000 to 427 (±56) km^3 $year^{-1}$ by 2099 (Wada, 2016). Much of the projected depletion is a function of increased future abstraction of groundwater for irrigation and increased evapotranspiration (Condon et al., 2020) in a warmer climate. For example, the projected doubling of average water use by 2050 in Tunisia is attributed partly (3.8% to 16.4%) to climate change and mainly to socioeconomic policies (Guermazi et al., 2019). Similarly, groundwater depletion in the Bengal Basin and North China Plain is more due to irrigation development than climate change per se (Leng et al., 2015; Kirby et al., 2016).

A recent synthesis of modelling studies conducted in various climates showed that out of 33 studies, 21 reported a decrease in the projected groundwater recharge or storage, eight reported an increase, and the rest showed no substantial change (Amanambu et al., 2020). A global-scale multi-model ensemble study projected decreasing recharge in southern Chile, Brazil, central continental USA, the Mediterranean, and East China, but consistent and increasing recharge for northern Europe and East Africa (Reinecke et al., 2021). In continental Spain, a modelling study (Pulido-Velazquez et al., 2018) projected significant reductions in groundwater recharge in the central and southeast region but a small and localized increase in east and north-eastern areas. In subarctic Alaska, increased contribution of glacier melts to streamflow and aquifer recharge under a warming climate is projected (Liljedahl et al., 2017). In contrast, over the Iranian and Anatolia Plateaus, groundwater recharge is projected to reduce by ~77% in the spring season (March-May) due to a decrease in snowfall (Wu et al., 2020). Overall, several recent studies of climate change impacts on groundwater in different parts of the world have concluded that projected groundwater recharge could either increase or decrease, and results are often uncertain (*high confidence*) (Meixner et al., 2016; Zaveri et al., 2016; Hartmann et al., 2017; Mehran et al., 2017; Tillman et al., 2017; Kahsay et al., 2018; Herbert and Döll, 2019).

(Wu et al., 2020) report a projected increase in future groundwater storage in the semi-arid regions of northwest India, North China Plain, Guarani Aquifer in South America, and Canning Basin in Australia due to significant increases in projected precipitation. However, the projected irrigation expansion could negate this positive gain in groundwater storage (Sishodia et al., 2018; Wu et al., 2020). In drylands (e.g., playas in Southwestern USA), where focused groundwater recharge processes dominate, greater recharge is projected to occur from the increased number of significant runoff-generating extreme precipitation events in the future (McKenna and Sala, 2018). Overall, an emerging body of studies have projected amplification of episodic recharge in the tropics and semi-arid regions due to extreme precipitation under global warming (*medium confidence*).

Climate change is also projected to impact groundwater dependent ecosystems and groundwater quality negatively (*medium confidence*). Projected increase in precipitation intensity and storms can contaminate groundwater by mobilizing contaminants such as chemical fertilizers, pesticides, antibiotics, and leaching of human waste from pit latrines into groundwater (Amanambu et al., 2020; Lall et al., 2020). By 2050, environmentally critical streamflow is projected to be affected in 42% to 79% of the world's watersheds. The majority of these watersheds currently experience intensive groundwater use, and changes in critical streamflow are projected to negatively impact aquatic ecosystems (de Graaf et al., 2019). Using a global synthesis of 9,404 data points from 32 countries across six continents, (McDonough et al., 2020) report increases in dissolved organic carbon (DOC) concentrations in groundwater following projected changes in precipitation and temperature. For example, hotspots of high DOC concentration (increases of up to 45%)

are associated mainly with increased temperatures in the wettest quarter of the year in the south-eastern USA under RCP8.5 scenarios.

The projected rise in sea levels can lead to saline intrusion into aquifers in low-lying areas and small islands and threaten coastal ecosystems and livelihoods resilience, for example, in already vulnerable countries like Bangladesh and vulnerable ecosystems like the Mangrove Forest of *Sundarbans* (Befus et al., 2020; Dasgupta et al., 2020; Shamsudduha et al., 2020). However, hydrogeologic properties, aquifer settings, and impacts of over-abstraction are more important determinants of salinization of coastal aquifers than slowly rising sea levels (Michael et al., 2013; Taylor et al., 2013a). The projected contribution of global groundwater depletion to sea-level rise is expected to increase from 0.57 (±0.09) mm year^{-1} in 2000 to 0.82 (±0.13) mm year^{-1} by 2050, driven by a growing trend in groundwater extraction (Wada, 2016). However, several uncertainties around model parameterization remain (Wada et al., 2017).

There are several knowledge gaps in our understanding of the global-scale sensitivity of groundwater systems to climate change and resulting feedbacks (Maxwell and Condon, 2016; Cuthbert et al., 2019a). There are process uncertainties in groundwater recharge simulation due to the potential impact of atmospheric CO_2 on vegetation and resulting changes in evapotranspiration (Reinecke et al., 2021). There are uncertainties in impact models due to poor representation of recharge pathways (diffuse vs. focused) and inability to adequately capture feedbacks among climate, land use, and groundwater systems (Meixner et al., 2016). Finally, there are gaps in long-term observational data, especially in less-developed countries (Amanambu et al., 2020), making it challenging to evaluate the of performance of impact models (Gleeson et al., 2020).

In summary, groundwater abstraction is projected to deplete the long-term, non-renewable storage as withdrawals are projected to increase significantly in all major aquifers worldwide (*medium evidence, high agreement*). In the tropics and semi-arid regions, growing precipitation intensification under global warming may enhance the resilience of groundwater through increased episodic recharge (*medium confidence*). However, in the semi-arid areas, over-abstraction continues to be a threat to groundwater storage and can nullify the benefits of increased future recharge.

4.4.7 Projected Changes in Water Quality

AR5 concluded that climate change was projected to reduce water quality (Jiménez Cisneros et al., 2014). SR 1.5 assessed with *low confidence* differences in projected impacts under 1.5°C versus 2°C of warming (Hoegh-Guldberg et al., 2018). In addition, SROCC reported the water quality degradation due to the release of legacy contaminants in glaciers and permafrost (*medium confidence*) (Hock et al., 2019b). AR6 WGI Report does not explicitly mention water quality issues.

Water insecurity due to water quality degradation is projected to increase under climate change due to warming, enhanced floods and sea-level rise (Arnell and Lloyd-Hughes, 2014; Dyer et al., 2014; Whitehead et al., 2015) (*medium confidence*). Drought-driven diminishing river and lake levels (Jeppesen et al., 2015) and continued water abstraction for irrigation (Aragüés et al., 2015) may contribute to the salinization of soil and water. In addition, warming is projected to disrupt the historical sequestration of contaminants in permafrost in the Arctic and mountain regions (Bond and Carr, 2018).

Quantitative projections on climate-induced water quality degradation are sparse. Aminomethylphosphonic acid and glyphosate are projected to exceed drinking water quality standards in dry years in a high emissions scenario in the Meuse River in Europe by 2050 (Sjerps et al., 2017). From 2020 to 2050, based on scenarios RCP2.6, RCP4.5, and RCP8.5, the incidences of total nitrogen pollution are projected as 97.3%, 97.1% and 94.6% in drought–flood abrupt alternation months comparing to 69.3%, 69.7% and 67.5% in normal months in the Luanhe river basin in China (Bi et al., 2019). From 2012 to 2050, freshwater river area is expected to decrease from 40.8% to 17.1%-19.7% under different sea-level rise scenarios in the southwest coastal zone of Bangladesh (Dasgupta et al., 2013). Under the warming scenario +4.8°C increase by the end of the century, the average nutrient abundance are projected to triple in a shallow lake in the Northwest of England (Richardson et al., 2019).

While there is some understanding of the potential effect of glacier and permafrost degradation on water quality, projections are lacking. Research is limited mainly in Europe and North America, and quantifying the future water quality changes is still incipient.

In summary, climate change is projected to increase water pollution incidences, salinization, and eutrophication due to increasing drought and flood events, sea level rise, and water temperature rise, respectively in some local rivers and lakes, but there is dearth of exact quantification at a global scale (*medium confidence*).

4.4.8 Projected Changes in Soil Erosion and Sediment Load

AR5 stated that soil erosion and sediment load are projected to change (*low confidence*) due to warming and increased rainfall intensity (Jiménez Cisneros et al., 2014). SRCCL concluded that future climate change will increase, with *medium confidence*, the potential for water-driven soil erosion in many dryland areas, causing soil organic carbon decline (Mirzabaev et al., 2019). SR1.5 (Hoegh-Guldberg et al., 2018) concluded that, because of the complex interactions among climate change, land cover, soil management, etc., the differences between mean annual sediment load under 1.5°C and 2°C of warming are unclear.

Globally, climate change is estimated to be responsible for 30-66% increase of soil erosion by 2070, while socioeconomic developments impacting land use may lead to ±10% change of soil erosion (Borrelli et al., 2020). At a regional scale, different effects of the climate change impact on soil losses are found owing to the ensemble experiments with climate models coupled with regional/local models of soil erosion and sediment yield. In the 21st century, the soil erosion rates are projected to increase for the European countries (Czech Republic (Svoboda et al., 2016), Belgium (Mullan et al., 2019), Spain (Eekhout et al., 2018; Eekhout and de Vente, 2019a; Eekhout and De Vente, 2019b), Germany (Gericke et al., 2019) by 10-80% depending on the emission scenario and time period of the projection, as well as for the USA (Garbrecht and Zhang, 2015) and Australia (Yang et al., 2015b; Zhu et al., 2020). Only a few studies demonstrated decreasing trend in soil erosion, e.g. up to 9% with RCP8.5 scenario in Greece (Vantas et al., 2020). Sediment yield is projected to both increase (5-16% with the SRES A1, B1, B2 scenarios in Vietnam and Laos (Giang et al., 2017), 11% with the RCP8.5 scenario and 8% with the SRES A2 scenario in the U.S. (Yasarer et al., 2017) and (Wagena et al., 2018), respectively), 19-37% with the RCP4.5, RCP8.5 scenarios in Burkina Faso (Op de Hipt et al., 2018)) and decrease (30% with the SRES A1B scenario in the southwest U.S. ((Francipane et al., 2015), 8-11% with the SRES A1B scenario in Spain (Rodríguez-Blanco et al., 2016), 11-52% with the RCP4.5, RCP8.5 scenarios in Ethiopia (Gadissa et al., 2018), 13-62% with the RCP2.6, RCP8.5 scenarios in Canada (Loiselle et al., 2020)) over the different regions of the world in the 21st century.

Post-fire sedimentation is projected to increase for nearly nine tenths of watersheds by >10% and for more than one third of watersheds by >100% by the 2041 to 2050 decade in the western USA with SRES A1B scenario (Sankey et al., 2017).

In summary, soil losses mainly depend on the combined effects of climate and land use changes. Herewith, recent studies demonstrate increasing impact of the projected climate change (increase of precipitation, thawing permafrost) on soil erosion (*medium confidence*).

4.5 Projected Sectoral Water-related Risks

Observed sectoral water-related impacts have been documented across world regions. Climate change is projected to further exacerbate many of these risks, especially at warming levels above 1.5°C (Figure 4.20). For some sectors and regions, climate change may also hold the potential for beneficial outcomes, though feedback and cascading effects as well as risks of climate extremes are not always well understood and often underestimated in impact projections. Risks manifest as a consequence of the interplay of human and natural vulnerability, sector-specific exposure as well as the climate hazard as a driver of climate change. Challenges to water security are driven by factors across these components of risk, where climate change is but one facet of driving water insecurity in the face of global change. While the focus of this chapter is on climate change and its effects on water security, for many sectors and regions the dynamics of socio-economic conditions is a core driver. They play an essential role in understanding and alleviating water security risks. The following sections outline sectoral risks for both, risks driven by water-related impacts, such as drought, flood or changes in water availability, as well as risks with effects on water uses, mainly focusing on changing water demand as a consequence of climate change. It therefore does not cover all climate change driven risks to the respective sectors, but is limited to those that stand in relation to water. The focus within this chapter is on global to regional processes (additional regional to local information in Table SM4.4; Figure 4.20 as well as across regional chapters of this report).

4.5.1 Projected Risks to Agriculture

AR5 concluded that overall irrigation water demand would increase by 2080, while the vulnerability of rainfed agriculture will further increase (Jiménez Cisneros et al., 2014). SR1.5 concluded that both the food and the water sectors would be negatively impacted by global warming with higher risks at 2°C than at 1.5°C, and these risks could coincide spatially and temporally, thus increasing hazards, exposures and vulnerabilities across populations and regions *(medium confidence)*. SR1.5 further reinforced AR5 conclusions in terms of projected crop yield reductions, especially for wheat and rice (*high confidence*), loss of livestock, and increased risks for small-scale fisheries and aquaculture *(medium confidence)* (Hoegh-Guldberg et al., 2018), conclusions which are further corroborated by SRCCL (Mbow et al., 2019).

Climate change impacts agriculture through various pathways (5.4 – crop-based systems), with projected yield losses of up to 32% by 2100 (RCP8.5) due to the combined effects of temperature and precipitation. Limiting warming could significantly reduce potential impacts (up 12% yield reduction by 2100 under RCP4.5) (Ren et al., 2018a). Though overall changes differ across models, regions and seasons, differences in impacts between 1.5°C and 2°C can also be identified (Ren et al., 2018a; Ruane et al., 2018; Schleussner et al., 2018). Globally, 11% (±5%) of croplands are estimated to be vulnerable to projected climate-driven water scarcity by 2050 (Fitton et al., 2019).

Overall drought-driven yield loss is estimated to increase by 9% to 12% (wheat), 5.6% to 6.3% (maize), 18.1% to19.4% (rice) and 15.1% to16.1%(soybean) by 2071-2100, relative to 1961-2016 (RCP8.5) (Leng and Hall, 2019). In addition, temperature-driven increases in water vapour deficit could have additional negative effects, further exacerbating drought-induced plant mortality and thus impacting yields (Grossiord et al., 2020) (see also Cross-Chapter Box 1 in Chapter 5 of WGI report). Currently, global agricultural models do not fully differentiate crop responses to elevated CO_2 under temperature and hydrological extremes (Deryng et al., 2016) and largely underestimate the effects of climate extremes (Schewe et al., 2019).

Flood-related risks to agricultural production are projected to increase over Europe, with a mean increase of expected annual output losses of approximately € 11million (at 1.5°C GWL); €12m (at 2°C GWL) and €15 million (at 3°C GWL) relative to the 2010 baseline (Koks et al., 2019). In parts of Asia, where flooding impacts on agriculture are already significant, projections indicate an increase in damage to area under paddy by up to 50% in Nepal; 16% in the Philippines; 55% in Indonesia; 23% in Cambodia and Vietnam and 13% in Thailand (2075-2099 vs 1979-2003; RCP8.5) (Shrestha et al., 2019a).

Global crop water consumption of green water resources (soil moisture) is projected to increase by about 8.5% by 2099 relative to 1971-2000 as a result of climate drivers (RCP6.0), with additional smaller contributions by land-use change (Huang et al., 2019) (4.4.1.3, 4.4.8). In India, a substantial increase in green and blue water consumption is projected for wheat and maize, with a slight reduction of blue water consumption for paddy (Mali et al., 2021). Temperate drylands, especially higher latitude regions, may become more suitable for rain-fed agriculture (Bradford et al., 2017). Locally and regionally, however, some of those areas with currently larger areas under rain-fed production, for example, in Europe, may become less suitable for rain-fed agriculture (Table 1 to 4.5.1) (Bradford et al., 2017; Shahsavari et al., 2019).

While global crop models and estimates of yield impacts often focus on major staple crops relevant for global food security, crops of high economic value are projected to become increasingly water dependent. For example, climate-driven yield increases for tea are projected for various tea-producing regions if no water limitations and full irrigation is assumed but decreases in yields are projected under continued present-day irrigation assumptions (Beringer et al., 2020). Water-related impacts on global cotton production are highly dependent on the CO_2-fertilisation effect, with increases projected for higher CO_2 concentration if no water limitations are implemented. However, substantial decreases in cotton production are projected if lower or no fertilization effects are accounted for due to increasing water limitations (Jans et al., 2018). Reductions in economically valuable crops will probably increase the vulnerability of population groups, especially small-holder farmers with limited response options (Morel et al., 2019).

To stabilize yields against variations in moisture availability, irrigation is the often the most common adaptation response (4.6.2, Box 4.3). Projections indicate a potentially substantial increase in irrigation water requirements (Boretti and Rosa, 2019). Increasing agricultural water demand is driven by various factors, including population growth, increased irrigated agriculture, cropland expansion and higher demand for bio-energy crops for mitigation ((Chaturvedi et al., 2015; Grafton et al., 2015; Turner et al., 2019), 4.7.6). Depending on underlying assumptions and the constraints on water resources implemented in the global agricultural models, irrigation water requirements are projected to increase two to three-fold by the end of the century (Hejazi et al., 2014; Bonsch et al., 2015; Chaturvedi et al., 2015; Huang et al., 2019). While the combined effects of population and land-use change as well as irrigation expansion account for the significant part of the projected increases in irrigation water demand by the end of the century, around 14% of the increase are directly attributed to climate change (RCP6.0) (Huang et al., 2019).

With various degrees of water stress being experienced under current conditions and further changes in regional water availability projected, as well as continuing groundwater depletion as a consequence of over-abstraction for irrigation purposes (4.2.6 and 4.4.6), limitations to major irrigation expansion will occur in some regions, including South and Central Asia, the Middle East, parts of North and Central America (Grafton et al., 2015; Turner et al., 2019). Constraining projections of available irrigation water through consideration of environmental flow requirements further reduces the potential for irrigation capacity and expansion (Bonsch et al., 2015). Changes in land use and production patterns, e.g. expansion of rain-fed production and increasing inter-regional trade, would be required to meet growing food demand while preserving environmental flow requirements, though this may increase local food security-related vulnerabilities (Cross-Chapter Box INTERREG in Chapter 16) (Pastor et al., 2014). Where climate impacts on yields are not a consequence of water limitations (mainly for C4 crops), irrigation cannot offset negative yield impacts (Levis et al., 2018).

Over 50% of the global lowlands equipped for irrigation will depend heavily on run-off contributions from the mountain cryosphere by 2041–2050 (SSP2–RCP6.0) and are projected to make unsustainable use of blue water resources (Viviroli et al., 2020). Projected changes in snowmelt patterns indicate that for all regions dependent on snowmelt for irrigation during warm seasons, alternative water sources will have to be found for up to 20% (at 2°C GWL) and up to 40% (at 4°C GWL) of seasonal irrigation water use, relative to current water use patterns (1986-2015) (Qin et al., 2020). Regional studies further corroborate these global findings (Biemans et al., 2019; Malek et al., 2020). Basins, where such alternate sources are not available, will face agricultural water scarcity.

Elevated CO_2 concentrations play an important role in determining future yields in general and have the potential to beneficially affect plant water use efficiency (Deryng et al., 2016; Ren et al., 2018a; Nechifor and Winning, 2019). The elevated CO_2 effects are projected to be most prominent for rain-fed C3 crops (Levis et al., 2018). Combined results from field experiments and global crop models show that CO_2 fertilization could reduce consumptive water use by 4-17% (Deryng et al., 2016). To account for uncertainties, global agricultural models provide output with and without account for CO_2 fertilization effects, though recent progress on reducing model uncertainty indicates that non-CO_2 model runs may no longer be needed for adequate projections of yield impacts (Toreti et al., 2019).

Due to the complex interactions among determinants for livestock production, the future signal of water-related risks to this sector is unclear. Globally, 10% (±5%) of pasture areas are projected to be vulnerable to climate-induced water scarcity by 2050 (Fitton et al., 2019). Water use efficiency gains through elevated CO_2 concentrations have the potential to increase forage quantities, though effects of nutritional values are ambiguous (Augustine et al., 2018; Derner et al., 2018; Rolla et al., 2019). In addition, spatial shifts in temperature-humidity regimes may shift suitable regions for livestock production, opening up new suitable areas for some regions or encouraging shifts in specific breeds better adapted to future climatic regimes (Rolla et al., 2019) (5.5 – Livestock Systems and 5.10. Mixed Systems).

Projections of climate impacts on freshwater aquaculture are limited (5.9.3.1 – Projected Impacts; Inland freshwater and brackish aquaculture). In particular, in tropical regions, reductions in water availability, deteriorating water quality, and increasing water temperatures pose risks to terrestrial aquaculture, including temperature-related diseases and endocrine disruption ((Kibria et al., 2017), Section 4.4.7). On the other hand, freshwater aquaculture in temperate and arctic polar regions may benefit from temperature increases with an extension of the fish growing season (Kibria et al., 2017).

Global crop models, which provide the basis for most projections of agricultural risk, continue to have limitations in resolving water availability. As a result, they do not fully resolve the effects of elevated CO_2 for changing water use efficiency, for example (Durand et al., 2018), potentially overestimating drought impacts on maize yield (Fodor et al., 2017) and may underestimate limitations to further expansion of irrigation (Elliott et al., 2014; Frieler et al., 2017b; Winter et al., 2017; Jägermeyr and Frieler, 2018; Kimball et al., 2019; Yokohata et al., 2020a).

In summary, agricultural water use is projected to increase globally due to cropland expansion and intensification and climate change-induced changes in water requirements (*high confidence*). Parts of temperate drylands may experience increases in suitability for rain-fed production based on mean climate conditions; however, risks to rain-fed agriculture increase globally because of increasing variability in precipitation regimes and changes in water availability (*high confidence*). Water-related impacts on economically valuable crops will increase regional economic risks (*medium evidence, high agreement*). Regions reliant on snowmelt for irrigation purposes will be affected by substantial reductions in water availability (*high confidence*).

4.5.2 Projected Risks to Energy and Industrial Water Use

AR5 concluded with *high confidence* that climate induced changes, including changes in water flows, will affect energy production, and the actual impact will depend on the technological processes, and location of energy production facilities (Arent et al., 2014). SR1.5 concluded with *high confidence* that climate change is projected to affect the hydropower production of Northern European countries positively. However, Mediterranean countries like Greece, Spain, and Portugal are projected to experience approximately a 10% reduction in hydropower potential under 2°C warming level, which could be reduced by half if global warming could be limited to 1.5°C (Hoegh-Guldberg et al., 2018). In addition, SROCC concluded with *high confidence* that an altered amount and seasonality of water supply from snow and glacier melt is projected to affect hydropower production negatively (IPCC, 2019a).

Since AR5, a large number of studies have modeled future changes in hydropower production due to climate-induced changes in volume and seasonality of streamflow and changes in sediment load due to accelerated melting of cryosphere at both global (van Vliet et al., 2016b; Turner et al., 2017) and regional scales (Tarroja et al., 2016; Ali et al., 2018; de Jong et al., 2018; Tobin et al., 2018; Arango-Aramburo et al., 2019; Carvajal et al., 2019; Arias et al., 2020; Meng et al., 2021).

For hydropower production at a global scale, (Turner et al., 2017), projected an uncertainty in the direction of change in global hydropower production to the tune of +5% to -5% by 2080s, under a high emissions scenario. On the other hand, (van Vliet et al., 2016b), projected an increase in global hydropower production between +2.4% to +6.3% under RCP 4.5 and RCP 8.5 respectively by 2080s, as compared to a baseline period of 1971-2000, but with significant regional variations (*high confidence*). For example, regions like Central Africa, India, Central Asia, and northern high-latitude areas are projected to see more than 20% increases in gross hydropower potential (*high confidence*). On the other hand, Southern Europe, Northern Africa, southern United States, and parts of South America, southern Africa, and southern Australia are projected to experience more than 20% decreases in gross hydropower potential. The Mediterranean region is projected to see almost a 40% reduction in hydropower production (*high confidence*) (Turner et al., 2017). On the other hand, northern Europe and India are projected to add to their hydropower production capacity due to climate change by mid-century (*high confidence*) (van Vliet et al., 2016b; Turner et al., 2017; Emodi et al., 2019).

In hydropower plants located in the Zambezi basin, electricity output is projected to decline by 10-20% by 2070 compared to baseline (1948-2008) under a drying climate; only marginal increases are projected under a wetting climate (Spalding-Fecher et al., 2017). In the Mekong basin, the total hydropower generation is projected to decline by 3.0% and 29.3% under 1.5°C and 2°C (Meng et al., 2021). In this context, 1.5°C will come up in 2036 under RCP2.6 and in 2033 under RCP6.0; and 2°C will come up in 2056 under RCP6.0 (Frieler et al., 2017a). In India, hydropower production is projected to increase by up to 25% by the end of the 21st century due to increased temperature and precipitation under the RCP8.5 scenario. However, hydropower production is projected to decline in plants located in snow-dominated rivers due to earlier snowmelt (Ali et al., 2018). In Colombia, hydropower production is projected to decrease by ~10% under the RCP4.5 dry scenario by 2050 (Arango-Aramburo et al., 2019). In a sub-basin of the Amazon River (one of the hydropower hotspots in Brazil), dry season hydropower potential is projected to decline by -7.4 to -5.4% from historical baseline conditions under RCP4.5 (Arias et al., 2020). In the São Francisco basin of Brazil, hydropower production is projected to reduce by -15% to -20% by 2100 under the IPCC A1B scenario (de Jong et al., 2018), which will affect the Brazilian energy mix in the future. In Ecuador, under various policy pathways and dry and wet scenarios under RCP4.5, hydropower production is projected to increase by +7% to +21% or decline by -25% to -44% by 2050 (Carvajal et al., 2019). In Europe, different impacts are projected across different sub-regions (WGII, Chapter 13, Table 13.7- Projected climate change risks for energy supply in Europe by 2100). In Northern Europe, up to 20% of hydropower potential increases are projected under 3°C warming; increases of up to 15% and 10% are projected under 2°C and 1.5°C warming levels. In Mediterranean parts of Europe, hydropower potential reductions of up to -40% are projected under 3°C warming; while reductions below -10% and -5% are projected under 2°C and 1.5°C warming levels, respectively (van Vliet et al., 2016b; Tobin et al., 2018). Hydropower plants in Switzerland are projected to lose ~ 1.0 TWh of hydroelectricity production per year by 2070-90 due to net glacier mass loss in the earlier part of the century (Schaefli et al., 2019). In the Italian Alps, under the warmest scenario of RCP8.4, up to 4% decreases in hydropower production are projected (Bombelli et al., 2019). The magnitude of change differs significantly among models. In California, USA, the average annual hydropower generation is expected to decline by 3.1% under RCP4.5 by 2040-2050, compared to the baseline 2000-2010 (Tarroja et al., 2016). In the Skagit river basin in the US, hydropower generation is projected to increase by 19% in the winter/spring, and a decline by 29% in summer by the 2080s (Lee et al., 2016).

Apart from climate impacts on hydropower production, climate-induced flood loads and reservoir water level change may lead to dam failure under RCP2.6 and RCP4.5 scenarios (Fluixá-Sanmartín et al., 2018; Fluixá-Sanmartín et al., 2019) (*medium confidence*). For example, the incidence of 100-year floods in the Skagit river basin in the US and peak winter sediments are projected to increase by 49% and 335%, respectively, by 2080, necessitating fundamental changes in hydropower plant operation. Nevertheless, some risks, such as floods, will remain unmitigated even with changes in hydropower operation rules (Lee et al., 2016). Overall, impacts of future extreme events on energy infrastructure have been less studied than impacts of gradual changes (Cronin et al., 2018). Furthermore, future hydropower development may also impact areas of high freshwater megafauna in South America, South and East Asia, and in the Balkan region, and sub-catchments with a high share of threatened freshwater species are particularly vulnerable (Zarfl et al., 2019). Therefore, future hydropower dams will need to be sited carefully (Dorber et al., 2020).

There is *high confidence* that changes in future cooling water availability are projected to affect thermoelectric production capacity negatively at global (van Vliet et al., 2016b; Zhou et al., 2018b) and regional scales (Bartos and Chester, 2015; Behrens et al., 2017; Ganguli et al., 2017; Zhou et al., 2018b; Emodi et al., 2019). Global mean water temperature is projected to increase by +1°C for RCP2.6 and +2.7°C for RCP8.5 (van Vliet et al., 2016b). Correspondingly, global cooling water sufficiency is projected to decline by -7.9% to -11.4% by 2040-2069 and -11.3% to -18.6% by 2070-90 (Zhou et al., 2018b), thereby impacting thermoelectric power production.

In Asia, under a 2°C global warming scenario, coal power plants annual usable capacity factor in Mongolia, Southeast Asia, and parts of China and India are projected to decrease due to water constraints (Wang et al., 2019b). In the European Union, an assessment of 1326 thermal electric plants in 818 basins projected that the number of basins with water stress would increase from 47 in 2014 to 54 in 2030 (Behrens et al., 2017) with consequent impacts on cooling water supplies. In the Western USA, by 2050, vulnerable power plants are projected to lose 1.1% to 3.0% of average summertime generation capacity, which could rise to 7.2 to 8.8% loss under a ten-year drought condition (Bartos and Chester, 2015). Further, 27% of thermoelectric production in the USA may be at severe risk of low-capacity utilization due to water stress by 2030 (Ganguli et al., 2017). Thermoelectric plant capacity on the hottest summer day in the USA and EU are projected to fall by 2% under a 2°C global warming and by 3.1% under a 4°C global warming requiring overbuilding of electricity infrastructure by 1% to 7% given the current energy mix portfolio (Coffel and Mankin, 2020). A systematic review showed consistent decreases in mid to end of the century in thermal power production capacity due to insufficiency of cooling water in Southern, Western and Eastern Europe (*high confidence*); North America and Oceania (*high confidence*), Central, Southern, and Western Asia (*high confidence*) and Western and Southern Africa (*medium confidence*) (Emodi et al., 2019). Overall, apart from emissions benefits, moving away from thermal power generation to other renewable energy will also lower the chances of climate induced curtailment of energy production (*high confidence*).

Global freshwater demand for the energy sector is projected to increase under all 2°C scenarios due to the rapid increase in electricity demand in developing countries (Fricko et al., 2016). Despite the water shortage and climate change impacts, industry and energy sectors' share in global water demand has been projected to rise to 24% by 2050 (UN Water, 2020), which will increase the competition among various water-use sectors (Boretti and Rosa, 2019). Furthermore, mining activities, which are highly dependent on sufficient water availability, are also at risk due to climate change (Aleke and Nhamo, 2016). Given that some of the intensely mined regions, such as the Atacama Desert in Chile, are already water-scarce, even small changes in rainfall could destabilize water-intensive mining operations and affect the production and processing activities at mines (Odell et al., 2018). Overall, there is a lack of literature on the impact of climate change on future mining activities and other water-intensive industries.

In summary, globally, hydropower and thermoelectric power capacities are projected to increase and decrease, respectively, due to changes in river run-off and increases in ambient water temperatures (*high confidence*). In the future, freshwater demand for energy and industrial sectors is projected to rise significantly at the global level, triggering competition for water across sectors. Although climate change also poses risks to mining and other water-intensive industries, quantifying these risks is difficult due to limited studies.

4.5.3 Projected Risks to Water, Sanitation and Hygiene (WaSH)

Climate-related extreme events impact WaSH services and local water security. While not WaSH-specific, AR5 showed that more people would experience water scarcity and floods (*high confidence*) and identified WaSH failure due to climate change as an emergent risk (*medium confidence*) leading to higher diarrhoea risk (Field et al., 2014b). In addition, both SR 1.5 (IPCC, 2018a) and SRCCL (IPCC, 2019b) projected the risk from droughts, heavy precipitation, water scarcity, wildfire damage, and permafrost degradation to be higher at 2°C warming than 1.5°C (*medium confidence*) and all these could potentially impact water quality and WaSH services.

Waterborne diseases result from complex causal relationships between climate, environmental, and socio-economic factors that are not fully understood or modelled (Boholm and Prutzer, 2017) (*high confidence*). WaSH-related health risks are related to extreme events, harmful algal blooms and WaSH practices (Chapter 7 WGII 7.3.2). In addition, changes in thermotolerance and chlorine resistance of certain viruses have been observed in laboratory experiments simulating different temperatures and sunlight conditions (Carratalà et al., 2020), increasing potential health risks even where traditional water treatment exists (Jiménez Cisneros et al., 2014) (*low confidence*). Studies show that degraded water quality increases the willingness to pay for clean water regardless of national economic status. However, payment for clean, potable water, particularly in low- and middle-income countries, can represent a significant percentage of people's income, limiting economic wellbeing and the possibility for re-investment in other livelihoods or activities (Constantine et al., 2017; van Houtven et al., 2017; Price et al., 2019).

Collectively, drinking water treatment, sanitation, and hygiene interrupt disease transmission pathways, particularly for water-related diseases. However, WaSH systems themselves are vulnerable to extreme events (4.3.3). For example, sewage overflows resulting from heavy rainfall events are expected to increase waterborne disease outbreaks (Khan et al., 2015). High diarrhoeal disease burdens mean that small changes in climate-associated risk are projected to have significant impacts on disease burdens (Levy et al., 2018). For example, up to 2.2 million more cases of *E. coli* by 2100 in Bangladesh under a 2.1°C GWL is projected (Philipsborn et al., 2016), while up to an 11-fold and 25-fold increase by 2050 and 2080, respectively under 2 to 4ºC GWL, in disability-adjusted life years associated with cryptosporidiosis and giardiasis in Canada is projected (Smith et al., 2015). In addition, and an additional 48,000 deaths in children under 15 years of age globally from diarrhoea by 2030 is also projected (WHO, 2014). Notably, high levels of treatment compliance and boiling water before consumption offset the projected impact of climate change on giardiasis in Canada in the 2050 scenario but could not wholly offset the projected impact in 2080 (Smith et al., 2015). Climate change impacts on WaSH-attributable disease burden are also projected to delay China's progress towards disease reduction by almost 9% under RCP 8.5 (Hodges et al., 2014). Disruptions in the drinking water supply can lead to increased household water storage, potentially increasing vector larvae breeding habitats (see Section 3.6.3). In combination with the projected expansion of vector ranges given climate change (Liu-Helmersson et al., 2019), there is the potential for increased risk of vector-borne disease during periods of water shortage or natural disasters (4.3.3). Moreover, energy requirements for water and wastewater treatment are indirectly responsible for greenhouse gas emissions, while the breakdown of excreta contributes directly to emissions (Box 4.5, Section 4.7.6). These contributions need to be better articulated and accounted for as part of the WaSH and climate change dialogue (Dickin et al., 2020).

In summary, climate change is expected to compromise WaSH services, compounding existing vulnerabilities and increasing water-related health risks (*medium evidence, high agreement*). Therefore, additional research is required on disease-, country-, and population-specific risks due to future climate change impacts (Baylis, 2017; Bhandari et al., 2020; Harper et al., 2020).

4.5.4 Projected Risks to Urban and Peri-Urban Sectors

AR5 reported with *medium confidence* that climate change would impact residential water demand, supply and management (Revi et al., 2014). According to AR5, water utilities are also confronted by changes to the availability of supplies; water quality; and saltwater intrusion into aquifers in coastal areas due to higher ambient and water temperatures (*medium evidence, high agreement*), altered streamflow patterns, drier conditions, increased storm runoff, sea-level rise, and more frequent forest wildfires in catchments (Jiménez Cisneros et al., 2014). SR1.5 found with *medium confidence* that constraining warming to 1.5°C instead of 2°C might mitigate risks for water availability, but socioeconomic drivers could affect water availability more than variations in warming levels, while the risks differ across regions (Hoegh-Guldberg et al., 2018).

In nearly a third of the world's largest cities, water demand may exceed surface water availability by 2050, based on RCP6.0 projections and the WaterGAP3 modelling framework (Flörke et al., 2018). Under all SSPs, the global volume of domestic water withdrawal is projected to reach 700-1500 km^3yr^{-1} by 2050, indicating an increase of 50 to 250%, compared to the 2010 water use intensity (400-450 km^3yr^{-1}) (Wada et al., 2016). Increasing water demand by cities is already spurring competition between cities and agricultural users for water, which is expected to continue (Garrick et al., 2019) (4.5.1). By 2030, South and Southeast Asia are expected to have almost three-quarters of the urban land under high-frequency flood risk (10.4.6). South Asia, South America and Mid-Latitudinal Africa are projected have the largest urban extents exposed to floods and droughts (Güneralp et al., 2015). An analysis of 571 European cities from the Urban Audit database (using RCP8.5 projections without assessing urban heat island effects) found drought conditions are expected to intensify (compared to the historical period 1951-2000) in southern European cities, particularly in Portugal and Spain ((Guerreiro et al., 2018); CCP4.3.3). Changes in river flooding are projected to affect cities in north-western European cities and the United Kingdom between 2051-2100 (Guerreiro et al., 2018) (6.2.3.2, CCP2.2.1, CCP2.2.3).

Globally, climate change is projected to exacerbate existing challenges for urban water services. These challenges include population growth, the rapid pace of urbanisation and inadequate investment, particularly in less developed economies with limited governance capacity (*high confidence*) (Ceola et al., 2016; van Leeuwen et al., 2016; Reckien et al., 2017; Tapia et al., 2017; Veldkamp et al., 2017). More specifically, in Arusha (Tanzania), a combination of urban growth modelling, satellite imagery, and groundwater modelling projected that rapid urbanisation would reduce groundwater recharge by 23% to 44% of 2015 levels by 2050 (under business as usual and RCP8.5 scenario), causing groundwater levels to drop up to 75m (Olarinoye et al., 2020). Flood risk modelling showed a median increase in flood risk of 183% in 2030 based on baseline conditions in Jakarta (Indonesia) with flood risks increasing by up to 45% due to land-use changes alone (Budiyono et al., 2016). A probabilistic analysis of surface water flood risk in London (UK) using the UKCP09 Weather Generator (with 10th and 90th percentile uncertainty bounds) found that the annual damage is expected to increase from the baseline by 101% and 128% under 2030 and 2050 high emission scenarios, respectively (Jenkins et al., 2018).

Modified streamflow is projected to affect the amount and variability of inflow to urban storage reservoirs (*high confidence*), which may exacerbate existing challenges to urban reservoir capacity, such as sedimentation and poor water quality (Goharian et al., 2016; Howard et al., 2016; Yasarer and Sturm, 2016). For example, in Melbourne (Australia), a combination of stochastic hydro-climatological modelling, rainfall-runoff modelling and climate model data projects a mean precipitation shift over catchments by -2% at 1.5ºC and -3.3% at 2ºC, relative to 1961-1990. Considering an annual water demand of 0.75 of the mean yearly inflow, the median water supply shortage risk was calculated to be 0.6% and 2.9% at 1.5ºC and 2ºC warming levels, respectively. At the higher demand level of 0.85 of the mean annual inflow, the median water shortage risk is higher, between 9.6% to 20.4% at 1.5ºC, and at 2ºC warming, respectively, without supply augmentation desalination (Henley et al., 2019).

As climate change poses a substantial challenge to urban water management, further refinement of urban climate models, downscaling and correction methods (e.g. (Gooré Bi et al., 2017; Jaramillo and Nazemi, 2018) is needed. Additionally, given that 90% of urban growth will occur in less developed regions, where urbanisation is largely unplanned (UN-Habitat, 2019), further research is needed to quantify the water-related risks of climate change and urbanisation on informal settlements ((Grasham et al., 2019; Satterthwaite et al., 2020), 4.5.3).

In summary, rapid population growth, urbanisation, ageing infrastructure, and changes in water use are responsible for increasing the vulnerability of urban and peri-urban areas to extreme rainfall and drought, particularly in less developed economies with limited governance capacity (*high confidence*). In addition, modified stream flows due to climate change (4.4.3) is projected to affect the amount and variability of inflows to storage reservoirs that serve urban areas and may exacerbate challenges to reservoir capacity, such as sedimentation and poor water quality (*high confidence*).

4.5.5 Projected Risks to Freshwater Ecosystems

AR5 concluded that climate change is projected to be an important stressor on freshwater ecosystems in the second half of the 21st century, especially under high-warming scenarios of RCP6.0 and RCP8.5 (*high confidence*), even though direct human impacts will continue to be the dominant threat (Settele et al., 2014). Rising water temperatures are also projected to cause shifts in freshwater species distribution and worsen water quality problems (*high confidence*), especially in those systems that already experience high anthropogenic loading of nutrients (Settele et al., 2014).

Changes in precipitation and temperatures are projected to affect freshwater ecosystems and their species through, for example, direct physiological responses from higher temperatures or drier conditions or a loss of habitat for feeding or breeding (Settele et al., 2014; Knouft and Ficklin, 2017; Blöschl et al., 2019b). In addition, increased water temperatures could lead to shifts in the structure and composition of species assemblages following changes in metabolic rates, body size, timing of migration, recruitment, range size and destabilization of food webs. A review of the impact of climate change on biodiversity and functioning of freshwater ecosystems found that under all scenarios, except the one with the lowest GHG emission scenario, freshwater biodiversity is expected to decrease proportionally to the degree of warming and precipitation alteration (Settele et al., 2014) **(***medium evidence, high agreement***)**.

These are several examples of such projected changes. Due to higher water temperatures, changes in macroinvertebrates and fish are projected under all future warming scenarios (Mantyka-Pringle et al., 2014). Decreased abundance of many fish species, such as salmonids, under higher temperatures, are also projected, although the effects between species are variable (Myers et al., 2017). Poleward and shifts of freshwater species are projected as they try to stay within preferred cooler environmental conditions (Pecl et al., 2017). Other anticipated changes include physiological adjustments with impacts on morphology with some species shrinking in body size because large surface-to-volume ratios are generally favoured under warmer conditions (Scheffers et al., 2016) and changes in species communities and food webs as a consequence of increases in metabolic rates in response to increased temperatures with the flow-on effects for many ecosystem processes (Woodward et al., 2010). Changes in the seasonality of flow regimes and variability

(Blöschl et al., 2019b) and more intermittent flows (Pyne and Poff, 2017) are also projected and could result in decreased food chain lengths through the loss of large-bodied top predators (Sabo et al., 2010) and changes in nutrient loadings and water quality (Woodward et al., 2010). The impacts on freshwater systems in drylands are projected to be more severe (Jaeger et al., 2014; Gudmundsson et al., 2016). Changes to snow and glacier melting, including the complete melting of some glaciers (Leadley et al., 2014; Kraaijenbrink et al., 2017), are projected to reduce water availability and cause declines in biodiversity in high altitudes through local extirpations and species extinctions in regions of high endemism. Lake nutrient dynamics are expected to change, for example, at 2 °C warming, net increase in CH_4 emissions by 101% to 183% in hypereutrophic lakes and 47 –56% in oligotrophic lakes in Europe are projected (Sepulveda-Jauregui et al., 2018). Similarly, under the high GHG emission scenario, lake stratification is projected to begin 22.0 ± 7.0 days earlier and end 11.3 ± 4.7 days later by the end of this century (Woolway et al., 2021). While overall future trends on climate change on freshwater species and habitats are largely negative, evidence indicates that different species are projected to respond at different rates, with interactions between species expected to be disrupted and which may result in novel biological communities and rapid change in ecological processes and functions (Pecl et al., 2017).

These impacts are expected to be most noticeable where significant air temperature increases are projected, leading to local or regional population extinctions for cold-water species because of range shrinking, especially under the RCP 4.5, 6.0 and 8.5 scenarios (Comte and Olden, 2017). The consequences for freshwater species are projected to be severe with local extinctions as the freshwater ecosystems dry. In the Americas, under all scenarios that have been examined, the risk of extinction of freshwater species is projected to increase above that already occurring levels due to biodiversity loss caused by pollution, habitat modification, over-exploitation, and invasive species (IPBES, 2019). Freshwater ecosystems are also at risk of abrupt and irreversible change, especially those in the higher latitudes and altitudes with significant changes in species distributions, including those induced by melting permafrost systems (Moomaw et al., 2018; IPBES, 2019).

While changes in the species distribution across freshwater ecosystems are projected, the extent of change and the ability of individual species or populations to adapt is not widely known. Species that cannot move to more amenable habitats may become extinct, whereas those who migrate may relocate. An unknown outcome could be establishing novel ecosystems with new assemblages of species, including invasive alien species, in response to changes in the environment with the prospect of irreversible changes in freshwater ecosystems (Moomaw et al., 2018).

In summary, changes in precipitation and temperatures are projected to affect all types of freshwater ecosystems and their species. Under all scenarios, except the one with the lowest GHG emission scenario, freshwater biodiversity is expected to decrease proportionally to the degree of warming and precipitation change (*medium evidence, high agreement*).

4.5.6 Projected Risks to Water-related Conflicts

AR5 concluded with *medium confidence* climate change can indirectly increase the risks of violent conflicts, though the link to hydrological changes were not spelled out (Jiménez Cisneros et al., 2014). Furthermore, according to IPCC SR1.5 (Hoegh-Guldberg et al., 2018), if the world warms by 2ºC- 4ºC by 2050, rates of human conflict could increase, but again, role of hydrological change in this was not explicit (*medium confidence*).

The impact of climate change on shared water resources might increase tensions among states, particularly in the absence of strong institutional capacity (Petersen-Perlman et al., 2017; Dinar et al., 2019). On the other hand, although the mere existence of formal agreements does not necessarily reduce the risks of conflicts, robust treaties and institutions can promote cooperative events, even under hydrological stress (Link et al., 2016). Yet, since both conflictive and cooperative events are possible under conditions of climatic variability, whether conflict arises or increases depends on several contextual socio-economic and political factors, including the adaptive capacity of the riparian states (Koubi, 2019), the existence of power asymmetries (Dinar et al., 2019) and pre-existing social tensions (*medium confidence*).

At the intra-state level, analysis suggests that additional climate change will increase the probability of conflict risks, with 13% increase probability at 2˚C GWL and 26% probability at 4˚C GWL scenario (Mach et al., 2019). However, to date, other factors are considered more influential drivers of conflict, including lack of natural resource use regulations (Linke et al., 2018b), societal exclusion (von Uexkull et al., 2016; van Weezel, 2019), poor infrastructures and a history of violent conflict (Detges, 2016) (*high confidence*). In addition, *medium-high evidence* exists that climate change imposes additional pressures on regions that are already fragile and conflict-prone (Matthew, 2014; Earle et al., 2015) (*medium agreement*).

Recent research indicates that climatic change can multiply tensions in regions dependent on agriculture when coupled with other socio-economic and political factors (Koubi, 2019), including a low level of human development (Ide et al., 2020) and deterioration of individual living conditions (Vestby, 2019). On the other side, intergroup cohesion (De Juan and Hänze, 2020) and policies that improve societal development and good governance reduce the risk of conflict associated with the challenges to adaptation to climate change (Hegre et al., 2016; Witmer et al., 2017) (*medium confidence*) at both the intra-state and inter-state level.

Increased risk of conflict between different sectors (agriculture, industry, domestic) and needs (urban, rural) is projected to arise in several river basins due to climate change and socio-economic developments, including urbanization (Flörke et al., 2018). Future climatic conditions and population growth are expected to exert additional pressures on managing already stressed basins such as the Nile, the Indus, Colorado, the Feni, the Irrawaddy, the Orange and the Okavango (Farinosi et al., 2018). In addition, recent scenario analysis in global transboundary basins supports the finding that there is more potential for conflict in areas already under water stress, such as Central Asia and the northern parts of Africa (Munia et al., 2020) (*medium confidence*).

In summary, the impact of climate change on water resources might increase tensions, particularly in the absence of strong institutional capacity. However, whether conflict arises or increases depends on several contextual socio-economic and political factors. Evidence exists that climate change imposes additional pressures on regions already under water stress or fragile and conflict-prone *(medium confidence).*

4.5.7 Projected Risks to Human Mobility and Migration

SR1.5 found with *medium confidence* that migration is expected to increase with further warming but that there are major knowledge gaps preventing more detailed assessments (Hoegh-Guldberg et al., 2018). However, as in AR5, there was no specific focus on hydrological changes induced migration.

In general, the projected population growth in at-risk areas, especially in low-income countries, is expected to increase future migration and displacement (McLeman et al., 2016; Rigaud et al., 2018). For example, a study looking at potential flood exposure found that low-income countries, particularly in Africa, are at higher risk for flood-induced displacement (Kakinuma et al., 2020). One model, focusing on slow-onset climate impacts as water stress, crop failure, sea-level rise projected between 31 to 72 million people (RCP2.6, SSP4) and 90 to 143 million people (RCP8.5, SSP4) internally displaced by 2050 in Sub-Saharan Africa, South Asia and Latin America (Rigaud et al., 2018). Another estimate, incorporating temperature increase and precipitation, projects that asylum applications to the EU could increase by between 0.098 million (RCP4.5) and 0.66 million (RCP8.5) per year, as a consequence of temperature increases in agricultural areas of low-income countries (Missirian and Schlenker, 2017) (*limited evidence; medium agreement*).

More detailed local and regional models are needed, incorporating migrant destinations (Abel et al., 2019) and immobility (Zickgraf, 2018).

In summary, research that projects future migration changes due to climate-induced hydrological changes is *limited* and shows significant uncertainties about the number of migrants and their destinations *(limited evidence; medium agreement)*.

4.5.8 Projected Risks to the Cultural Water Uses of Indigenous Peoples, Local Communities and Traditional Peoples

AR5 found that climate change will threaten cultural practices and values, although the risks vary across societies and over time (*medium evidence, high agreement*). Furthermore, AR5 concluded that significant changes in the natural resource base on which many cultures depend would directly affect the cultural core, worldviews, cosmologies and symbols of Indigenous cultures (Adger and Pulhin, 2014). SR1.5 concluded with *high confidence* that limiting global warming to 1.5°C, rather than 2°C, will strongly benefit terrestrial and wetland ecosystems and their services, including the cultural services provided by these ecosystems (Hoegh-Guldberg et al., 2018). SROCC found with *high confidence* that cultural assets are projected to be negatively affected by future cryospheric and associated hydrological changes (Hock et al., 2019b).

There is *high confidence* that the cultural water uses of Indigenous Peoples, local communities, and traditional peoples are at risk of climate change-related hydrological change (Table 4.7). Climate-driven variations in streamflow, saltwater intrusion, and projected increases in water temperature will exacerbate declines of culturally important species and lead to variations or depletion of culturally important places and subsistence practices. For example, in New Zealand, the increasing risk of flood events may impact culturally important fish species for Māori (Carter, 2019), while habitat changes may shift the distribution of culturally significant plants (Bond et al., 2019). In Australia, Yuibera and Koinmerburra Traditional Owners fear the saltwater inundation of culturally significant sites and waterholes (Lyons et al., 2019), while the flooding of culturally significant wetlands will negatively affect the Lumbee Tribe (USA) (Emanuel, 2018). Moreover, changes in the carrying capacity of ice, snow quality and formation will probably increase the physical risks to Saami practising reindeer herding (Jaakkola et al., 2018).

Further research is necessary to assess the extent and nature of climate-driven risks to cultural water uses in the context of broader socio-economic, cultural and political challenges facing diverse Indigenous Peoples, local and traditional communities. In addition, given the significance of Indigenous Knowledge and local knowledge to adaptive capacity and community-led adaptation, the potential risks of climate-related hydrological changes to diverse cultural water uses warrant closer study (4.6.9, 4.8.4, Cross-Chapter Box INDIG in Chapter 18).

In sum, there is *high confidence* that climate-driven hydrological changes to cultural water uses and culturally significant ecosystems and species are projected to pose risks to the physical wellbeing of Indigenous Peoples, local communities and traditional peoples.

Table 4.7: Selected Projected Risks to Indigenous Peoples' Uses of Water.

Region	Indigenous People	Climate hazard	Water-related Risk	Situated knowledge	Reference
Asia	Ifugao	Increased temperatures; increasing rainfall (wet season); decreasing rainfall (dry season)	Flooding (Wet season); Water deficit (dry season)	Increases in future wet season rainfall pose increase risks of excess surface water runoff and potential for soil erosion, which may cause the collapse of Ifugao rice terraces. Reductions in future dry season rainfall and warmer temperatures indicate significant water deficits during the growing season of local *tinawon* rice.	(Soriano and Herath, 2020)
Australasia	Yuibera and Koinmerburra Traditional Owner groups	Sea level rise	Flooding	Culturally important coastal waterholes, wetlands and sites are at risk of saltwater inundation due to rising sea levels. If inundated, traditional owners may not be able to maintain cultural connections to these important sites (11.4.1).	Lyons, 2019 #2810}
Australasia	Māori	Increased precipitation	Flooding	Increasing flood events may negatively impact spawning and fishing sites of the culturally important īnaka (whitebait; *Galaxias maculates*) in the Waikōuaiti River (11.4.2).	(Carter, 2019)
Australasia	Māori	Increased temperature;	Ecosystem change	Changes in temperature and precipitation are projected to shift the range of wetland	(Bond et al., 2019)

		precipitation variability		plants (Kūmarahou and Kuta) in New Zealand, which may decrease access to these culturally significant species, which are used for medicinal and weaving purposes. The changing distribution of these plants may lead to a loss of Indigenous Knowledge and affect inter-tribal reciprocity and gifting practices (11.4.2).	
Central and South America	Warao	Sea level rise	Flooding	The partial or total inundation of the Orinoco Delta will result in the loss of freshwater wetlands and species, which will produce rapid shifts in the culturally significant lands and resources of the Warao. Among the affected species is the *Mauritia* palm, on which Warao culture and livelihoods are based.	(Vegas-Vilarrúbia et al., 2015)
Europe	Saami	Increased temperatures; changes in precipitation	Winter thaw	Reindeer herding is culturally important for Saami and provides a means to maintain traditions, language and cultural identity, thus constituting an essential part of Saami physical and mental wellbeing. More frequent ice formation on soil and snow, which will reduce the availability and quality of winter forage for reindeer, will negatively impact reindeer herding and thus Saami identity and wellbeing (13.8.1.2).	(Jaakkola et al., 2018); (Markkula et al., 2019)
North America	Lumbee Tribe	Increased temperatures; increased rainfall variability	Flooding	Climate-related degradation and flooding of wetlands and streams in the Lumbee River watershed will negatively affect cultural practices of fishing and harvesting that rely on access to and resources obtained from the area.	(Emanuel, 2018)

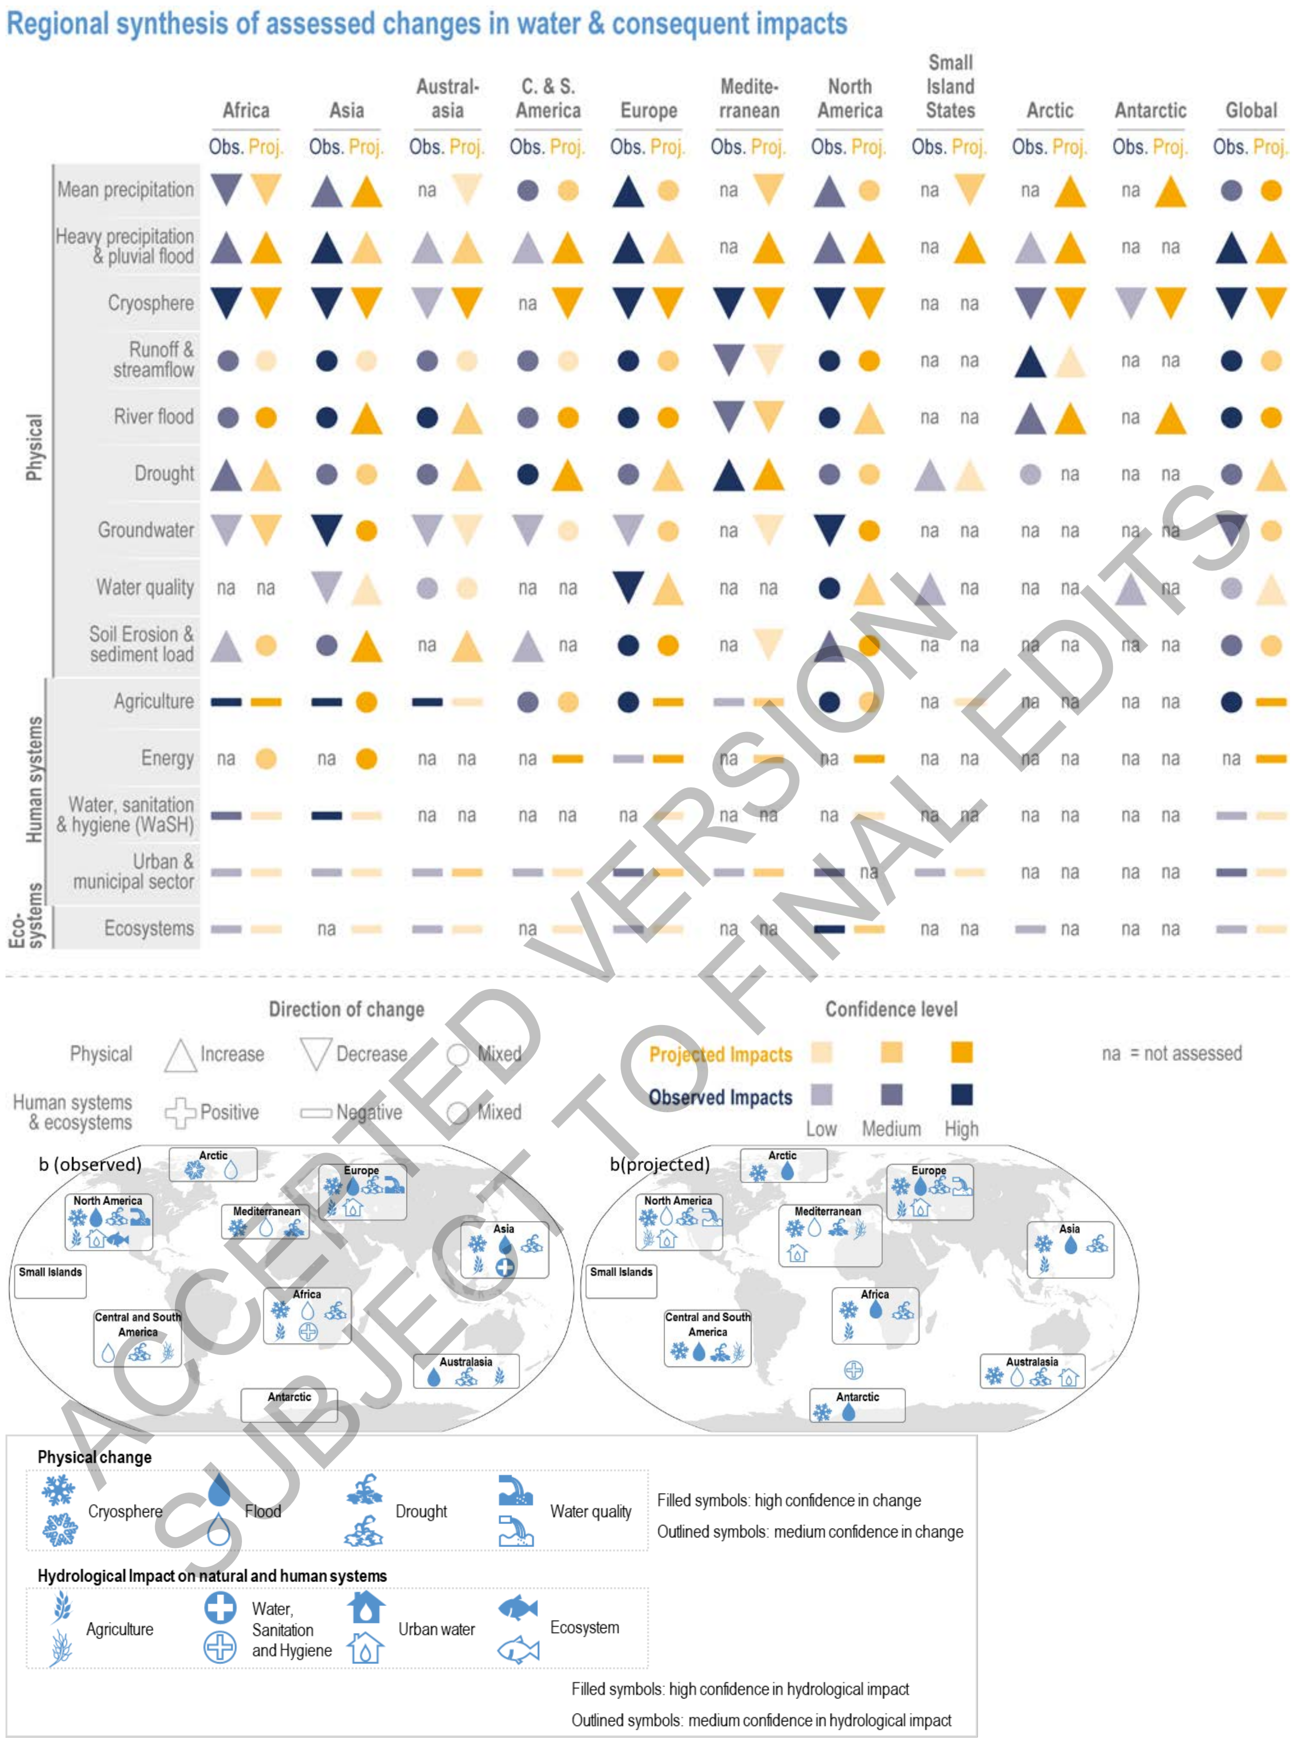

Figure 4.20: Regional synthesis of changes in water and consequent impacts assessed in this chapter. (a) Regional changes and impacts of selected variables. Confidence levels higher than medium are shown. (b) Assessment result of all variables. For each region, physical changes, impacts on ecosystems, and impacts on human systems are shown. For physical changes, upward/downward triangles refer to an increase/decrease, respectively, in the amount or frequency of

the measured variable, and the level of confidence refers to confidence that the change has occurred. For impacts on ecosystems and human systems, plus or minus marks depicts whether an observed impact of hydrological change is positive (beneficial) or negative (adverse), respectively, to the given system, and the level of confidence refers to confidence in attributing an impact on that system to a climate-induced hydrological change. The hydrological impact may be different to the overall change in the system; for example, over much of the world, crop yields have increased overall, largely for non-climatic reasons, but in some areas hydrological impacts of climate change are countering this. Circles indicate that within that region, both increase and decrease of physical changes are found, but are not necessarily equal; the same holds for cells showing 'both' assessed impacts. Cells assigned 'na' indicates variables not assessed due to limited evidences. Decrease (increase) in water quality refers to adverse (positive) change in quality. Agriculture refers to impacts on crop production. Note - Energy refers to impacts on hydro and thermoelectric power generation. Ecosystems refers to impacts on freshwater ecosystem.

4.6 Key Risks and Adaptation Responses in Various Water Use Sectors

Anthropogenic climate change has impacted every aspect of the water cycle (4.2), and risks are projected to intensify with every degree of global warming (4.4), with impacts already visible in all sectors of the economy and ecosystems (4.3) and projected to intensify further (4.5). In response to climate and non-climate induced water insecurity, people and governments worldwide are undertaking various adaptation responses across all sectors. In addition, there are several projected studies for future adaptation responses. We draw upon a list of 359 case studies of observed adaptation and 45 articles on projected future adaptation. Further information on selection and inclusion criteria is available in SM4.2. In this section, we document those adaptation responses (current and future) in different water-use sectors. In the next section (4.7.1, 4.7.2, 4.7.3) benefits of current adaptation, and effectiveness of future adaptation are discussed.

4.6.1 Key Risks Related to Water

The preceding sections have outlined the various pathways along which climate affects water resources and water-using sectors. In synthesis, fundamental changes in observed climate are already visible in water-related outcomes (*high confidence*), including ~500 million people experiencing historically unfamiliar precipitation regimes (4.2.1.1); cryosphere changes impacting various societal and ecosystem components (4.2.2); increasing vulnerability to flood impacts, driven both by climate as well as socio-economic factors (4.2.4); as well as climate change-driven increases in drought impacts (4.2.5).

Further increases in risks are projected to manifest at different levels of warming. Climate change is impacting all components of the hydrological cycle, but the water use sectors are also facing the consequences of climate change, given the central role of water for all aspects of human and environmental systems (4.1, Box 4.1). Therefore, risks to water security are also identified as a Representative Key Risk (RKR) (WGII, Chapter 16, Section 16.5.2.3.7).

Approximately, 4 billion people globally face physical water scarcity for at least one month per year which is driven by climatic as well as non-climatic factors (Mekonnen and Hoekstra, 2016). Increases in physical water scarcity are projected, with estimates between 800 million and 3 billion for 2°C global warming and up to approximately 4 billion for 4°C global warming (Gosling and Arnell, 2016). Projected increases in hydrological extremes pose increasing risks to societal systems globally (*high confidence*), with a potential doubling of flood risk between 1.5°C and 3°C of warming (Dottori et al., 2018) and an estimated 120% to 400% increase in population at risk of river flooding at 2°C and 4°C, respectively (Alfieri et al., 2017). Also projected are increasing risks of fatalities and socio-economic impacts (4.4.4). Similarly, a near-doubling of drought duration (Naumann et al., 2018) and an increasing share of the population affected by various types, durations and severity levels of drought are projected (*high confidence*) (4.4.5). Increasing return periods of high-end hydrological extremes pose significant challenges to adaptation, requiring integrated approaches to risk management, which take into account the various economic and non-economic, as well as direct and indirect losses and damages into account (Jongman, 2018).

Increasing sectoral risks are reported across regions and sectors with rising temperatures and associated hydrometeorological changes (Cross-Chapter Box INTEREG in Chapter 16). Risks to agricultural yields due to combined effects of water and temperature changes, for example, could be three times higher at 3°C compared to 2°C (Ren et al., 2018b), with additional risks as a consequence of increasing climate extremes

(Leng and Hall, 2019). In addition, climate-driven water scarcity and increasing crop water demands, including for irrigation, pose additional challenges for agricultural production in many regions (*high confidence*). Regional water-related risks to agricultural production are diverse and vary strongly across regions and crops (4.5.1). As there are limitations to how well global agricultural models can represent available water resources (Elliott et al., 2014; Jägermeyr et al., 2017), water limitations to agricultural production may well be underestimated. For example, the potential for irrigation, commonly assumed to play an important role in ensuring food security, could be more limited than models assume (Box 4.3).

With higher levels of warming, risks to water-dependent energy production increase substantially across regions (van Vliet et al., 2017). While there are increasing potentials of ~2% to 6% for hydropower production by 2080 (*medium confidence*), risks to thermoelectric power production increase for most regions (*high confidence*), for example, with potentially near doubling risks to European electricity production from 1.5°C to 3°C (Tobin et al., 2018). Shifting to a higher share of renewable sources less dependent on water resources for energy production could substantially reduce the vulnerability of this sector (4.5.2).

Increasing hydrological extremes also have consequences for the maintenance and further improvement of the provision of Water, Sanitation and Hygiene (WaSH) services (*medium confidence*). Risks related to the lack or failure of WaSH services under climate change include increased incidence and outbreaks of water-related diseases, physical injuries, stress, exacerbation of the underlying disease, and risk of violence, which is often gendered (4.5.3). Although globally, the regional potential infestation areas for disease-carrying vectors could be five times higher at 4°C than at 2°C (Liu-Helmersson et al., 2019), climate projections suggest up to 2.2 million more cases of *E. coli* by 2100 (2.1ºC increase) in Bangladesh (Philipsborn et al., 2016), up to an 11-fold and 25-fold increase by 2050 and 2080, respectively (2-4ºC increase), in disability-adjusted life years associated with cryptosporidiosis and giardiasis in Canada (Smith et al., 2015), and an additional 48,000 deaths in children under 15 years of age globally from diarrhoea by 2030 (WHO, 2014).

Increasing water demand in conjunctions with changing precipitation patterns will pose risks to urban water security by mid-century, with water demand in nearly a third of the world's largest cities potentially exceeding surface water availability by 2050 (RCP6.0) (Flörke et al., 2018) and the global volume of domestic water withdrawal projected to increase by 50 to 250% (Wada et al., 2016) (4.5.4). Globally, climate change will exacerbate existing challenges for urban water services, driven by further population growth, the rapid pace of urbanization and inadequate investment, particularly in less developed economies with limited governance capacity (*high confidence*).

Risks to freshwater ecosystems increase with progressing climate change, with freshwater biodiversity decreasing proportionally with increasing warming if 1.5°C is exceeded (*medium evidence, high agreement*). Risks include range shift, a decline in species population, extirpation as well as extinction (4.5.5).

The potential for climate change to influence conflict is highly contextual and depends on various socio-economic and political factors. However, water-specific conflicts between sectors and users may be exacerbated for some regions of the world (*high confidence*) (4.5.7).

Human migration takes many forms and can be considered a consequence and impact of climate change and an adaptation response (4.5.8). Projections indicate a potentially substantial increase in internal and international displacement due to water-related climate risks (Missirian and Schlenker, 2017; Rigaud et al., 2018). In the context of water-related adaptation, short-term migration as an income diversification approach is commonly documented. However, permanent relocation and fundamental changes to livelihoods are more transformational and yet can be associated with tangible and intangible losses (Mechler et al., 2019). In the context of climate-induced hydrological change, increased vulnerability among migrants and the risk of trapped populations poses significant additional risks. However, quantifications that disentangle different climate drivers and show specific risks emanating from hydrological change are unavailable (Rigaud et al., 2018).

Hydrological change, especially increasing extreme events, pose risks to the cultural uses of water of Indigenous Peoples, local communities and traditional peoples (*high confidence*), with implications for the physical of these groups (*high confidence*). Increasing risks are documented across groups and regions, however, partly due to the unquantifiable nature of these risks, the lack of research funding for the social dimensions of climate change, particularly in the Global South, and the systemic underrepresentation of marginalized groups in scientific research, quantitative projections are limited (4.5.8).

Adaptation is already playing an integral part in reducing climate impacts and prepare for increasing climate risk, and it will grow in importance evermore with increasing risks at higher levels of warming. Remaining sub-sections describe these adaptation responses.

[START BOX 4.2 HERE]

Box 4.2: Observed Risks, Projected Impacts and Adaptation Responses to Water Security in Small Island States

AR5 and SR1.5 recognized the exceptional vulnerability of islands, especially concerning water security and potential limits to adaptation that may be reached due to freshwater resources (Klein et al., 2014; Hoegh-Guldberg et al., 2018; Roy et al., 2018).

Small islands are already regularly experiencing droughts and freshwater shortages (*high confidence*) (Holding et al., 2016; Pearce et al., 2018; Gheuens et al., 2019; MacDonald et al., 2020). Freshwater supply systems vary from household or small community systems such as rainwater harvesting systems and private wells to large public water supply systems using surface, groundwater and, in some cases, desalinated water (Alsumaiei and Bailey, 2018b; Falkland and White, 2020). In many cases, communities rely on more than one water source, including a strong reliance on rainwater and groundwater (Elliott et al., 2017; MacDonald et al., 2020). Groundwater resources in freshwater lenses (FWLs) are essential in providing access to freshwater resources, especially during droughts when the collected rainwater is insufficient (Barkey and Bailey, 2017; Bailey et al., 2018). lead to greater risks of water-borne diseases, with significant effects on nutrition (Elliott et al., 2017; Savage et al., 2020), and improper sanitation poses additional risks to the limited groundwater resources (MacDonald et al., 2017). Drought events have also severely affected freshwater lenses (FWL) recharge (Barkey and Bailey, 2017), with extraction rates further threatening available groundwater volumes (Post et al., 2018). In conjunction with sea-level rise, this poses serious risks to groundwater salinization (Alsumaiei and Bailey, 2018b; Storlazzi et al., 2018; Deng and Bailey, 2019). In addition, FWLs are threatened by climate change due to changes in rainfall patterns, extended droughts and wash over events caused by storm surges and SLR (*high confidence*) (see Chapter 15) (Chui and Terry, 2015; Alsumaiei and Bailey, 2018a; Alsumaiei and Bailey, 2018b; Post et al., 2018; Storlazzi et al., 2018; Deng and Bailey, 2019). After small-scale wash over events, the FWLs have been shown to recover to pre-wash over salinity levels within a month (Oberle et al., 2017).

Due to wash over events exacerbated by sea-level rise (SLR) and lens thinning due to pumping, recovery time for FWLs is projected to take substantially longer (Oberle et al., 2017; Alsumaiei and Bailey, 2018a; Storlazzi et al., 2018). Projections indicate that atolls may be unable to provide domestic freshwater resources due to the lack of potable groundwater by 2030 (RCP8.5+ice- sheet collapse), 2040 (RCP8.5), or 2060s (RCP4.5) (Storlazzi et al., 2018). Projections of future freshwater availability in Small Islands further underline these substantial risks to island water security (Karnauskas et al., 2016; Karnauskas et al., 2018). Population growth, changes in rainfall patterns and agricultural demand are projected to increase water stress in Small Islands (Gohar et al., 2019; Townsend et al., 2020). While some islands are projected to experience an increase in rainfall patterns, this may refer to shorter intense rainfall events, thereby increasing the risk of flooding during the wet season, while not decreasing their risk of droughts during dry periods (Aladenola et al., 2016; Gheuens et al., 2019). In addition, projected shifts in the timing of the rainfall season might pose an additional risk for water supply systems (Townsend et al., 2020).

Observed adaptation during drought events includes community water-sharing (Bailey et al., 2018; Pearce et al., 2018) as well as using alternative water resources such as water purchased from private companies (Aladenola et al., 2016), desalination units (Cashman and Yawson, 2019; MacDonald et al., 2020) or accessing deeper or new groundwater resources (Pearce et al., 2018). Rainwater harvesting to adapt the water supply system in the Kingston Basin in Jamaica was able significantly alleviate water stress, for example. Still, it would not fill the total supply gap caused by climate change (Townsend et al., 2020). Likewise, groundwater sustainability with increasing climate change in Barbados cannot be ensured without aquifer protection, leading to higher optimized food prices if no additional adaptation measures are implemented (Gohar et al., 2019). The potential of using multiple water sources is rarely assessed in future water supply projections in Small Islands (Elliott et al., 2017). In the Republic of Marshall Islands, more than half of all interviewed households have already had to migrate once due to a water shortage (MacDonald et al., 2020). In Cariacou, Grenada, increases in migration rates have been observed following drought events (Cashman and Yawson, 2019). with long-term cross border and internal migration shown to be having significant impacts on well-being, community-cohesion, livelihoods and people-land relationships (Yates et al., 2021).

In sum, small islands are already regularly experiencing droughts and freshwater shortages (*high confidence*). For atoll islands, freshwater availability may be severely limited as early as 2030 (*low confidence*). The effects of temperature increase, changing rainfall patterns, sea level rise and population pressure, combined with limited options available for water-related adaptation leave small islands partially water insecure currently, with increasing risks in the near-term and at warming above 1.5°C (*high confidence*).

[END BOX 4.2 HERE]

4.6.2 Adaptation in the Agricultural Sector

AR5 reported a range of available hard and soft adaptation options for water-related adaptation in the agricultural sector. However, the evidence on the effectiveness of these adaptation responses, now and in the future, was not assessed (Noble et al., 2014; Porter et al., 2014). Assessing the feasibility of different irrigation measures as adaptation, SR1.5 (de Coninck et al., 2018) found mixed evidence, depending on the applied methodology.

There is *high confidence* that water-related adaptation is occurring in the agricultural sector (Acevedo et al., 2020; Ricciardi et al., 2020), and water-related adaptation in the agricultural sector makes up the majority of documented local, regional and global evidence of implemented adaptation (*high confidence*) (4.7.1, Figure 4.23 and Figure 4.24, Table 4.8). However, while there is increasing evidence of adaptation and its benefits across multiple dimensions, the link between adaptation benefits and climate risk reduction is unclear due to methodological challenges (*medium confidence*) (4.7.1). On the other hand, while it is methodologically possible to measure the effectiveness of future adaptation in reducing climate risks, here the main limitation is that not all possible range of future adaptations can be modelled given the limitations of climate and impact models (*high confidence*) (4.7.2). Furthermore, findings on current adaptation are constrained by what is documented in peer-reviewed articles. At the same time, there may be a range of options implemented on the ground by local governments or as a part of corporate social responsibility that is not published in peer-reviewed publications.

Water and soil conservation measures (e.g. reduced tillage, contour ridges, or mulching) are frequently documented as adaptation responses to reduce water-related climate impacts (Kimaro et al., 2016; Traore et al., 2017). This measure features in all continents' top four adaptation responses except Australasia (Figure 4.27). Especially for rain-fed farming, which currently is the norm in most of Africa, large parts of Central and South America and Europe, water and soil conservation measures and various components of conservation agriculture are some of the most frequently used adaptation responses (Jat et al., 2019). This measure is deemed to have economic benefits and benefits for vulnerable communities who adopt this measure (*high confidence*) and benefits in terms of water-saving and positive ecological and socio-cultural benefits (*medium confidence*). However, this measure can be sometimes maladaptive (*low evidence, medium agreement*) and can have mitigation co-benefits (*low evidence, high agreement*) (Figure 4.29). Furthermore, water and soil management related measures show high potential efficacy in reducing impacts in a 1.5°C world, with declining effectiveness at higher levels of warming (Figure 4.28 and Figure 4.29)

Changes in cropping patterns, the timing of sowing and harvesting, crop diversification towards cash crops, and the adoption of improved crop cultivars that can better withstand hazards like floods and drought are among the most used adaptation responses by farmers. This is among the top two measures in Asia and Africa (Figure 4.27). Extra income allows households to re-invest in improved agricultural techniques and improved cultivars (Taboada et al., 2017; Khanal et al., 2018b). Beneficial outcomes are documented in terms of increases in incomes and yields and water-related outcomes (*medium confidence*, from *robust evidence, but medium agreement*), but benefits to vulnerable communities are not always apparent on the whole (Figure FAQ4.4.1). Changes in cropping patterns and systems are also among those adaptation options assessed for their potential to reduce future climate impacts, though effectiveness is shown to be limited (Brouziyne et al., 2018; Paymard et al., 2018). Assessments of the future effectiveness of crop rotation systems for adaptation show a continued reduction in required irrigation water use, though studies of effectiveness beyond 2°C global mean temperature increase are not available (Kothari et al., 2019; Yang et al., 2019b) (Figure 4.28 and Figure 4.29).

Conservation agriculture and climate-smart agriculture (includes improved cultivars and agronomic practices) have proven to increase soil carbon, yields and technical efficiency (Penot et al., 2018; Salat and Swallow, 2018; Ho and Shimada, 2019; Makate and Makate, 2019; Okunlola et al., 2019). Some water-related measures in conservation agriculture include allowing for shading and soil moisture retention, with the co-benefit of reducing pest attacks (Thierfelder et al., 2015; Raghavendra and Suresh, 2018; Islam et al., 2019a). Especially for traditional food grains in smallholder agriculture, improved practices such as modern varieties or integrated nutrient management can play an important role in making production more resilient to climate stress (Handschuch and Wollni, 2016). This measure is also among the top four most frequent adaptation measures in all continents except Australia and North America (Figure 4.27). In addition, this measure is shown to have positive economic benefits (*high confidence*) and also benefits on other parameters (*medium confidence*) (Figure FAQ4.4.1). Such approaches are also among those most frequently assessed for their effectiveness in addressing future climate change but show limited effectiveness across warming levels (Figure 4.28 and Figure 4.29).

The use of non-conventional water sources, i.e. desalinated and treated waste-water, is emerging as an important component of increasing water availability for agriculture (DeNicola et al., 2015; Martínez-Alvarez et al., 2018b; Morote et al., 2019). While desalination has a high potential in alleviating agricultural water stress in arid coastal regions, proper management and water quality standards for desalinated irrigation water are essential to ensure continued or increased crop productivity. In addition to the energy intensity (4.7.6), risks of desalinated water include lower mineral content, higher salinity, crop toxicity, and soil sodicity (Martínez-Alvarez et al., 2018b). Similarly, waste-water reuse can be an important contribution to buffer against the increasing variability of water resources. However, waste-water guidelines that ensure the adequate treatment to reduce adverse health and environmental outcomes due to pathogens or other chemical and organic contaminants will be essential (Angelakis and Snyder, 2015; Dickin et al., 2016) (Box 4.5; 4.6.4).

Indigenous Knowledge and local knowledge are crucial determinants of adaptation in agriculture for many communities globally. Indigenous Peoples have intimate knowledge about their surrounding environment and are attentive observers of climate changes. As a result, they are often best placed to enact successful adaptation measures, including shifting to different crops, changing cropping times or returning to traditional varieties (Mugambiwa, 2018; Kamara et al., 2019; Nelson et al., 2019) (4.8.4).

Migration and livelihood diversification is often an adaptation response to water-related hazards and involves securing income sources away from agriculture, including off-farm employment, temporary or permanent migration, and these are particularly important in Asia and Africa (Figure 4.27). Income and remittances are sometimes re-invested, for instance, for crop diversification (Rodriguez-Solorzano, 2014; Musah-Surugu et al., 2018; Mashizha, 2019). While there is extensive documentation on the benefits of migration, the quality of studies is such that links between migration and subsequent benefits are not clear, making our conclusion of benefits from this measure as having *medium confidence*. On the other hand, there is more rigorous evidence on the maladaptive nature of migration as an adaptation measure (Figure FAQ4.4.1). However, adverse climatic conditions, especially droughts, have been found to reduce international migration, as resources are unavailable to consider this option (Nawrotzki and Bakhtsiyarava, 2017), resulting in limits to adaptation (Ayeb-Karlsson et al., 2016; Brottem and Brooks, 2018; Ferdous et al., 2019). In addition, it is difficult to model this option in future climate adaptation models.

Policies, institutions, capacity building, are important adaptation measures in agriculture and often have beneficial outcomes, with quality of studies precludes a high degree of certainty about those impacts (Figure FAQ4.4.1). Access to credits, subsidies or insurance builds an important portfolio of reducing reliance on agricultural income alone (Rahut and Ali, 2017; Wossen et al., 2018). Training and capacity building are essential tools to ensure effective adaptation in agriculture, increasing food security (Chesterman et al., 2019; Makate and Makate, 2019), through better understanding the implementation of available responses reduce exposure to climate impacts. In addition, public regulations, including water policies and allocations and incentive instruments, availability of appropriate finance play an essential role in shaping and enabling (4.8.5, 4.8.6, 4.8.7), but also limiting (4.8.2), water-related adaptation for agriculture (see also Chapter 17).

Water stressed regions already rely on importing agricultural resources, thus importing water embedded in these commodities (D'Odorico et al., 2014). Virtual water trade will continue to play a role in reducing water-related food insecurity (Cross-Chapter Box INTERREG in Chapter 16) (Pastor et al., 2014; Graham et al., 2020b).

While an increasing body of literature documents water-related adaptation in the agricultural sector, both in reducing current climate impacts and addressing future climate risk, knowledge gaps remain about assessing the effectiveness of such measures to reduce impacts and risks. Additional considerations on co-benefits of trade-offs for overall sustainable development are not always sufficiently considered in the available literature.

In sum, water-related adaptation in the agricultural sector is widely documented, with irrigation, agricultural water management, crop diversification and improved agronomic practices among the most common adaptation measures adopted (*high confidence*). However, the projected future effectiveness of available water-related adaptation for agriculture decreases with increasing warming (*medium evidence, high agreement*).

[START BOX 4.3 HERE]

Box 4.3: Irrigation as an Adaptation Response

Irrigation has consistently been used as a crop protection and yield enhancement strategy and has become even more critical in a warming world (Siebert et al., 2014). Approximately 40% of global yields come from irrigated agriculture, with a doubling of irrigated areas over the last 50 years and now constituting around 20% of the total harvested area (FAO, 2018b; Meier et al., 2018; Rosa et al., 2020b). Thus, irrigation is one of the most frequently applied adaptation responses in agriculture and features centrally in projections of adaptation at all scales. Expansions of irrigated areas over the coming century are projected, leading to shifts from rain-fed to irrigated agriculture in response to climate change (Malek and Verburg, 2018; Huang et al., 2019; Nechifor and Winning, 2019). However, there are regional limitations to this expansion due to renewable water resource limitations, including water quality issues (Zaveri et al., 2016; Turner et al., 2019). Depending on the specific spatial, temporal and technological characteristics of irrigation expansion, up 35% of current rain-fed production could sustainably shift to irrigation with limited negative environmental effects (Rosa et al., 2020b).

Irrigation increases resilience and productivity relative to rain-fed production by reducing drought and heat stress on crop yields and by lowering ET demand by cooling canopy temperatures (Siebert et al., 2014; Tack et al., 2017; Li and Troy, 2018; Zaveri and B. Lobell, 2019; Agnolucci et al., 2020; Rosa et al., 2020b). Large-scale irrigation also affects local and regional climates (Cook et al., 2020b). While cooling effects, including reduction of the extreme heat due to irrigation, have been observed (Qian et al., 2020; Thiery et al., 2020), increases in humid heat extremes because of irrigation with potentially detrimental health outcomes have also been reported (Krakauer et al., 2020; Mishra et al., 2020). For the heavily irrigated North China Plain, a night-time temperature increase overcompensated daytime cooling effects, leading to an overall warming effect (Chen and Jeong, 2018). In addition, modification of rainfall patterns has been linked to irrigation (Alter et al., 2015; Kang and Eltahir, 2019; Mathur and AchutaRao, 2020). For example, increases in extreme rainfall in Central India in recent decades has been linked to the intensification of irrigated paddy cultivation in northwest India (Devanand et al., 2019).

Different irrigation techniques are associated with significant differences in irrigation water productivity (Deligios et al., 2019) and replacing inefficient systems can reduce average non-beneficial water consumption by up to 76% while maintaining stable crop yields (Jägermeyr et al., 2015). Several adjustments can improve water use efficiency, including extending irrigation intervals, shortening the time of watering crops or reducing the size of the plot being irrigated (Caretta and Börjeson, 2015; da Cunha et al., 2015; Dumenu and Obeng, 2016). Deficit irrigation is an important mechanism for improving water productivity (Zheng et al., 2018) and increasing regional crop production under drying conditions (Malek and Verburg, 2018). Access to irrigation can also play a role in alleviating poverty, contributing to reducing vulnerability and risks (Balasubramanya and Stifel, 2020). However, the diversity of irrigation related techniques and the consequent differences in effect and water-use intensity is often underreported (Vanschoenwinkel and Van Passel, 2018).

The use of water-saving technologies like laser levelling, micro-irrigation, efficient pumps and water distribution systems (Kumar et al., 2016); increasing irrigation efficiency (Wang et al., 2019a) through improved agronomic practices (Kakumanu et al., 2018) and economic instruments like water trading in developed countries like Australia (Kirby et al., 2014) are known to reduce water application rates and increase yields, and "save" water at the plot level, but may exacerbate basin-scale water scarcity (van der Kooij et al., 2013; Zhou et al., 2021).

Asia accounts for 69-73% of the world's irrigated area. However, irrigation currently plays a relatively minor role in most Africa, except in the contiguous irrigated area along the Nile basin and North Africa and South Africa (Meier et al., 2018). In India, long-term data (1956-1999) on the irrigated area shows that farmers adjust their irrigation investments and crop choices in response to medium-run rainfall variability (Taraz, 2017). (da Cunha et al., 2015) report that farmers' income tends to be higher on irrigated lands in Brazil. In Bangladesh, farmers invest a part of their increased incomes in improving irrigation access (Delaporte and Maurel, 2018). The severity of drought increases the likelihood of farmers adopting supplementary irrigation in Bangladesh (Alauddin and Sarker, 2014). In Vietnam, irrigation improvement had the highest positive impact on crop yield among all farm-level adaptive practices (Ho and Shimada, 2019). In South Africa, access to irrigation was one of the most important predictors of whether or not farmers would adopt a whole suite of other adaptation responses (Samuel and Sylvia, 2019).

Irrigation is also associated with adverse environmental and socio-economic outcomes, including groundwater over-abstraction, aquifer salinization (Foster et al., 2018; Pulido-Bosch et al., 2018; Quan et al., 2019; Blakeslee et al., 2020); land degradation (Singh et al., 2018). Further, while irrigation expansion is one of the most commonly proposed adaptation responses, there are limitations to further increases in water use, as many regions are already facing water limitations under current climatic conditions (Rockström et al., 2014; Steffen et al., 2015; Kummu et al., 2016).

Projections of the future effectiveness of irrigation indicate a varying degree of effectiveness depending on the region and specific type and combination of approaches used. At the same time, overall residual impacts increase at higher levels of warming (4.7.1.2). Uncertainties in regional climate projections and limitations in the ability of agricultural models to fully represent water resources are important limitations in our understanding of the potential of further irrigation expansion (4.5.1) (Greve et al., 2018).

In light of the volume of irrigated agriculture globally, and the projected increase in water requirements for food production, increasing water productivity and thus improving the ratio of water used per unit of agricultural output, is necessary globally to meet agricultural water demand (4.5.1) (Jägermeyr et al., 2015; Jägermeyr et al., 2017). For example, assuming a doubling of global maize production by 2050 increased water productivity could reduce total water consumption compared to the baseline productivity by 20 to 60% (Zheng et al., 2018). Under economic optimization assumptions, shifts towards less water-intensive and less climate-sensitive crops would be optimal in terms of water use efficiency and absolute yield increases; however, this could pose risks to food security as production shifts away from main staple crops (Nechifor and Winning, 2019). Shifting currently rain-fed production areas to irrigation will be an important element in ensuring food security with increasing temperatures, though investment in storage capacities to buffer seasonal water shortage will be essential to ensure negative environmental impacts are minimised (Rosa et al., 2020b).

[END BOX 4.3 HERE]

4.6.3 Adaptation in Energy and Industrial Sectors

While AR5 (Arent et al., 2014) had looked at demand and supply changes in the energy sector due to climate change, none of the AR5 chapters had assessed adaptations in the energy sector *per se*. A modeling study by (van Vliet et al., 2016b) demonstrated that increasing the efficiency of hydropower plants by up to 10% could offset the impacts of decreased water availability in most regions by mid-century, under both RCP2.6 and RCP8.5 scenarios (*medium confidence*). Changing hydropower operation protocol and plant design can be effective adaptation measures, yet may be insufficient to mitigate all future risks related to increased floods and sediment loads (Lee et al., 2016).

(van Vliet et al., 2016b) projected that even a 20% increase in efficiency of thermoelectric power plants might not be enough to offset the risks of water stress by mid-century (*medium confidence*). Therefore, thermoelectric power plants will need additional adaptation measures such as changes in cooling water sources and alternative cooling technologies (van Vliet et al., 2016c). In China, many coal-fired power plants in water-scarce North China have adopted air cooling technologies (Zhang et al., 2016a). In Europe, wet/dry cooling towers (Byers et al., 2016) and seawater cooling (Behrens et al., 2017) have been the preferred options. Overall, freshwater withdrawals for adapted cooling systems under all scenarios are projected to decline by -3% to -63% by 2100 compared to the base year of 2000 (Fricko et al., 2016) (*medium confidence*).

Diversifying energy portfolios to reduce water-related impacts on the energy sector is another effective adaptation strategy with high mitigation co-benefits. A modelling study from Europe shows that for a 3°C scenario, an energy mix with an 80% share of renewable energy can potentially reduce the overall negative impacts on the energy sector by a factor of 1.5 times or more (Tobin et al., 2018). In addition, hydropower can also play a role in compensating for the intermittency of other renewable energies (François et al., 2014). For example, integrating hydro, solar, and wind power in energy generation strategies in Grand Ethiopian Renaissance Dam can potentially deliver multiple benefits, including decarbonization, compliance with environmental flow norms, and reduce potential conflicts among Nile riparian countries (Sterl et al., 2021). Furthermore, reducing the share of thermoelectric power with solar and wind energy (Tobin et al., 2018; Arango-Aramburo et al., 2019; Emodi et al., 2019) can be synergistic from both climate and water perspectives, as solar and wind energy has lower water footprints (*high confidence*).

Indigenous Peoples, mountain communities, and marginalized minorities often bear the brunt of environmental and social disruptions due to hydropower. As a consequence, hydropower operators face resistance prior to and during construction. Benefit sharing mechanisms help redistribute some of the gains from hydropower generation to the communities in the immediate vicinity of the project. For instance, sharing of hydropower revenues and profits to fund local infrastructure and pay dividends to local people has been practiced in Nepal and in some countries of the Mekong basin to enhance the social acceptability of hydropower projects (Balasubramanya et al., 2014; Shrestha et al., 2016) (*low confidence*).

Most water-intensive industries are increasingly facing water stress, making the reuse of water an attractive adaptation strategy (see Box 4.5). For example, Singapore, where the share of industrial water use is projected to grow from 55% in 2016 to 70% in 2060, is increasing its NEWater (highly treated wastewater) supply share from 30% to 55% to meet the growing demand of industrial and cooling activities (PUB, 2016). In addition, the mining industry has also adopted water adaptations measures, such as water recycling and reuse; using brackish or saline sources; and working with regional water utilities to reduce water extraction and improve water use efficiency (Northey et al., 2017; Odell et al., 2018).

In summary, energy and industrial sector companies have undertaken several adaptation measures to reduce water stress, with varying effectiveness levels. However, residual risks will remain, especially at higher levels of warming (*medium confidence*).

4.6.4 Adaptation in Water, Sanitation and Hygiene (WaSH) Sector

AR5 pointed to adaptive water management techniques (*limited evidence, high agreement*) (Field et al., 2014b), while SR1.5 documented the need for reducing vulnerabilities and promoting sustainable development and disaster risk reduction synergies (*high confidence*) (IPCC, 2018a). WaSH has also been identified as a low regrets adaptation measure (Cutter et al., 2012).

Access to appropriate, reliable WaSH protects against water-related diseases, particularly after climate hazards such as heavy rainfalls and floods (Carlton et al., 2014; Jones et al., 2020). WaSH interventions have been demonstrated to reduce diarrhoea risk by 25-75% depending on the specific intervention (Wolf et al., 2018) (*high confidence*). Conversely, inadequate WaSH is associated with an estimated annual loss of 50 million Daily Adjusted Life Years (Prüss-Ustün et al., 2019), of which 89% of deaths are due to diarrhoea, and 8% of deaths from acute respiratory infections (Chapter 7 WGII 7.3.2), making universal access to WaSH (i.e., achievement of SDG 6.1, 6.2), a critical adaptation strategy (*high confidence*). However, not all WaSH solutions are suited to all climate conditions (Sherpa et al., 2014; Howard et al., 2016) so health outcome improvements are not always sustained under changing climate impacts (Dey et al., 2019) (*medium evidence, high agreement*). As such, WaSH infrastructure also needs to be climate-resilient (Smith et al., 2015; Shah et al., 2020). In addition to new WaSH infrastructure design and implementation, expansion and replacement of existing infrastructure offer opportunities to implement climate-resilient designs and reduce greenhouse emissions (Boholm and Prutzer, 2017; Dickin et al., 2020) (*medium evidence; high agreement*).

Effective adaptation strategies include protecting source water and managing both water supply and demand. Source water protection (Shaffril et al., 2020) has proven effective in reducing contamination. Improved integrated (urban) water resources management (Kirshen et al., 2018; Tosun and Leopold, 2019), governance (Chu, 2017; Miller et al., 2020), and enhanced ecosystem management (Adhikari et al., 2018b) lead to policies and regulations that reduce water insecurity and, when developed appropriately, reduce inequities (*medium confidence*). Supply (source) augmentation, including dams, storage, and rainwater/fog harvesting, can increase the supply or reliability of water for drinking, sanitation, and hygiene (DeNicola et al., 2015; Pearson et al., 2015; Majuru et al., 2016; Poudel and Duex, 2017; Lucier and Qadir, 2018; Goodrich et al., 2019) (*high confidence*). For example, rainwater harvesting in an Inuit community increased water for hygiene by 17%, reduced water retrieval efforts by 40%, and improved psychological and financial health (Mercer and Hanrahan, 2017). However, climate change impacts will affect amounts of rainwater available. A recent study concluded that domestic water demand met through rainwater harvesting generally improves under climate change scenarios for select communities in Canada and Uganda, with the exception of drier summers in some areas of Canada (Schuster-Wallace et al., 2021). Further, it is important to recognize that many of these interventions require financial investments that make them inaccessible to the poorest (Eakin et al., 2016). Demand for water can be decreased through reductions in water loss from the system (e.g., pipe leakage) (Orlove et al., 2019) and water conservation measures (Duran-Encalada et al., 2017) (*medium confidence*).

During periods of water insecurity, people often implement maladaptive strategies (Magnan et al., 2016), i.e., strategies that can increase the risk of adverse health impacts, increase exposure to violence, or cause malnutrition (Kher et al., 2015; Pommells et al., 2018; Collins et al., 2019a; Schuster et al., 2020) (*medium evidence, high agreement*). Examples include walking further, using less safe water sources, prioritizing drinking and cooking over personal/household hygiene, or reducing food/water intake. Conversely, some rebalancing of gender roles can occur when women and girls cannot source sufficient water, with men building additional water supply or storage infrastructure or fetching water (Singh and Singh, 2015; Magesa and Pauline, 2016; Shrestha et al., 2019b). Some adaptation strategies create unintended health threats such as increased odds (1.55) of mosquito larvae in water storage pots (Ferdousi et al., 2015), which could have even more significant impacts in the future given projected range expansion for vectors as a result of climate change (Liu-Helmersson et al., 2019). Other unintended consequences include pathogen contamination (Gwenzi et al., 2015) and time or financial tradeoffs (Schuster et al., 2020) (*medium evidence, high agreement*). Wastewater reuse for irrigation may have adverse health impacts if wastewater is not treated (Dickin et al., 2016). Conversely, especially where women are responsible for domestic and productive water management, adaptive agricultural water strategies, such as water-efficient irrigation or low-water crops, mean that less water from finite water supplies are used for agriculture, leaving more water locally available for domestic purposes (see section 4.6.2). These co-benefits across sectors become important community water stress adaptations (Chinwendu et al., 2017), with water savings from one use leading to more water available for other uses. This can reduce domestic water burdens and, therefore, gender inequities (4.8.3) (*limited evidence, high agreement*). Further analyses of co-benefits, particularly employing a gender lens, are required to improve adaptation strategies (McIver et al., 2016).

In summary, ensuring access to climate-resilient WaSH infrastructure and practices represents a key adaptation strategy that can protect beneficiaries against water-related diseases induced by climate change (*high confidence*). Better management of water resources, supply augmentation, and demand management are important adaptation strategies (*high confidence*). Reliable, safe drinking water reduces adverse physical and psychological impacts of climate-related water stress and extreme events (*robust evidence, medium agreement*). WaSH infrastructure expansion and replacement provide opportunities to redesign and increase resilience in rural and urban contexts (*limited evidence, high agreement*).

[START BOX 4.4 HERE]

Box 4.4: COVID-19 Amplifies Challenges for WaSH Adaptation

While COVID-19 is an airborne disease (see Cross-Chapter Box COVID in Chapter 7), public health responses to the COVID-19 pandemic and the associated socio-economic and environmental impacts of these measures intersect with WaSH (Armitage and Nellums, 2020a). Notably, COVID-19 and climate change act as compound risks in the context of water-induced disasters, exacerbating existing threats to sustainable development (Neal, 2020).

The principal WaSH response to COVID-19 relates to hand hygiene, an infection control intervention that requires access to sufficient, clean and affordable water beyond cooking, hydration, and general sanitation needs, as outlined in SDG6 (Armitage and Nellums, 2020a). However, despite significant progress, more than 800 million people in Central and Southern Asia, and 760 million in sub-Saharan Africa, lack basic hand-washing facilities in the home (UNICEF, 2020). Notably, one in four healthcare facilities in select low- and middle-income countries lack basic water access, and one in six lack hand-washing facilities (WHO, 2019) (4.3.3). Moreover, household water insecurity also impacts marginalised and minority groups in the Global North (Deitz and Meehan, 2019; Rodriguez-Lonebear et al., 2020; Stoler et al., 2021).

Compound disasters have arisen due to either the co-occurrence of drought, storms or floods and COVID-19. COVID-19 acts as a stress multiplier for women and girls in charge of water collection and minorities and disabled people who are not engaged in water management (Phillips et al., 2020; Rodriguez-Lonebear et al., 2020). Across the world, existing inequalities deepened due to lockdowns, which further limited access to clean water and education for women and girls, and reinstated gendered responsibilities of child, elderly and sick care, which had been previously externalised (Cousins, 2020; Neal, 2020; Zavaleta-Cortijo et al., 2020). Accordingly, COVID-19 has further steepened the path to reach SDGs 2, 3, 4, 5, and 11 (Lambert et al., 2020; Mukherjee et al., 2020; Neal, 2020; Pramanik et al., 2021). In addition, the pandemic exacerbated food insecurity in drought-affected eastern and southern Africa (Phillips et al., 2020; Mishra et al., 2021). As the twin risk of COVID-19 and hurricanes on the US Gulf Coast (Pei et al., 2020; Shultz et al., 2020) and cyclone Amphan in Bangladesh (Pramanik et al., 2021) showed, increased hand-washing, additional WaSH and evacuation and shelter infrastructures proved essential for preventing further spread of COVID-19 (Baidya et al., 2020; Ebrahim et al., 2020; Guo et al., 2020; Mukherjee et al., 2020; Pei et al., 2020; Shultz et al., 2020; Pramanik et al., 2021). Moreover, while immediate steps can be taken during disaster response to minimise climate-attributable loss of life, climate adaptation requires long-term strategies that intersect with pandemic preparedness (Phillips et al., 2020).

Public health responses to COVID-19 geared towards infection control and caring for the sick can trigger increased water demand where population numbers and density are high (Mukherjee et al., 2020; Sivakumar, 2021). As COVID-19 has highlighted the importance of WaSH (4.3.3), this pandemic could also result in long-term positive outcomes in community resilience, improved infection control, and health protection while addressing longer-term environmental challenges of climate change (Phillips et al., 2020).

[END BOX 4.4 HERE]

4.6.5 Adaptation in Urban and Peri-Urban Sectors

AR5 reported that although case studies of the potential effectiveness of adaptation measures in cities are growing, not all considered how adaptation would be implemented in practice (Jiménez Cisneros et al., 2014). Furthermore, AR5 concluded that more attention had been given to adaptations that help ensure sufficient water supplies than to increasing the capacity of sewage and drainage systems to adapt to heavier rainfall or sea-level rise (Revi et al., 2014).

Since AR5 knowledge on urban adaptation has advanced, even though there is still a limited documentation of urban of water adaptation in urban context as compared to other adaptation responses (Figure 4.23.) Majority of the case studies on urban documentation are also from developed countries, with case studies on adaptation in the urban sector being most common in Europe and Australasia (Figure 4.24). Water-related urban and peri-urban climate change adaptation can involve 'hard'-engineering structures (grey), managed or restored biophysical systems (green and blue), or hybrid approaches that combine these strategies (Ngoran and Xue, 2015; Palmer et al., 2015) (Figure 4.21, also see Figure 4.22 for types of urban adaptation options).

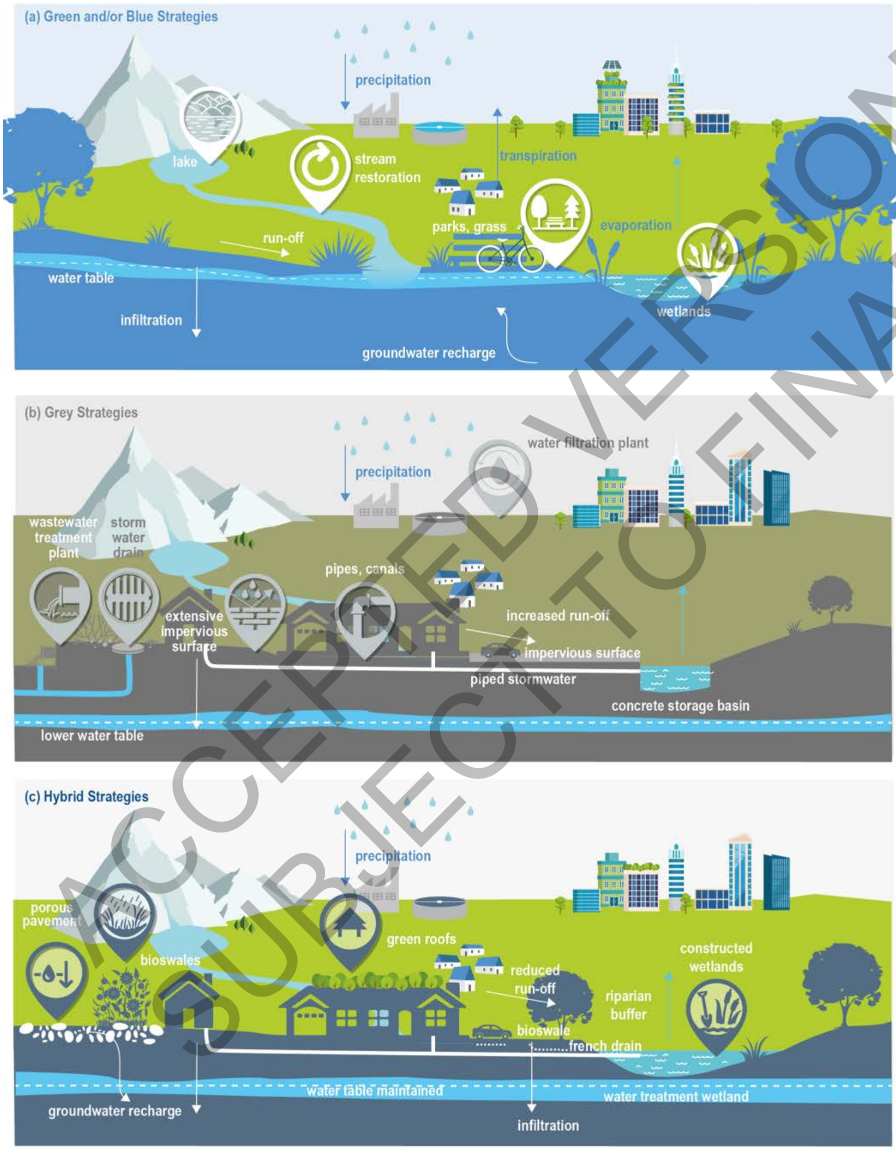

Figure 4.21: Strategies for Urban Water Adaptation a) Green and blue strategies of urban water adaptation prioritise ecosystem restoration, such as wetlands restoration. b) Grey water strategies are hard engineering approaches to urban water adaptation, including infrastructure such as pipes and canals, with extensive areas of impervious surfaces. c) Hybrid approaches combine green, blue, and grey adaptation strategies, such that ecosystem functions are complemented by engineered infrastructure, such as constructed wetlands, green roofs, and riparian buffers. Green and blue, and hybrid approaches are variously classified in terms of circular economy, water sensitive urban design, nature-based solutions (NBS), integrated urban water management, and ecological infrastructure. Adapted from (Depietri and McPhearson, 2017).

In most regions, hybrid adaptation approaches are underway. For example, sustainable urban drainage systems (SUDS) are a common adaptation measure that can reduce flooding and improve stormwater quality while reducing the urban heat island effect (e.g. (Chan et al., 2019; Loiola et al., 2019; Song et al., 2019; Huang et al., 2020; Lin et al., 2020)) (Box 4.6; 12.5.5.3.2; 12.7.1). Municipal, catchment and local community plans to minimise water-related climate risks are another form of adaptation (Stults and Larsen, 2018). Plans involve supply augmentation (Chu, 2017; Bekele et al., 2018), as well as floodplain management, land-use planning, stakeholder coordination, and water demand management (Andrew and Sauquet, 2017; Flyen et al., 2018; Robb et al., 2019; Tosun and Leopold, 2019), with some US cities including strategies to address social inequalities that climate change may exacerbate (Chu and Cannon, 2021).

Such adaptation measures are concentrated in more developed countries (Olazabal et al., 2019). For example, about 80% of European cities with more than 500,000 inhabitants have either mitigation and/or adaptation plans (Reckien et al., 2018). In contrast, a survey of cities with more than one million inhabitants found 92% of Asian cities, 89% African cities, and 87% of Latin American cities did not report adaptation initiatives (Araos et al., 2016) (12.5.8.1). Autonomous adaptation measures (e.g., elevating housing and drainage maintenance) are pursued to reduce flood risk in urban Senegal (Schaer, 2015), Kenya (Thorn et al., 2015), Brazil (Mansur et al., 2018), and Guyana (Mycoo, 2014) (Box 4.7; 9.8.5.1; 12.5.5.3; FAQ 12.2).

Further studies are required to ascertain the effectiveness of adaptation measures implemented since AR5, particularly for the growing populations of informal and peri-urban settlements. For example, in urban Africa, such informal settlements are sites of political contestation as residents resist municipal relocation strategies for flood alleviation (Douglas, 2018). In addition, the growing complexity of challenges facing urban water management, such as climate change, urbanisation and environmental degradation, warrants a transformative shift away from prevailing siloed approaches of water supply, sanitation and drainage to more integrated systems that enhance adaptive capacity (Ma et al., 2015; Franco-Torres et al., 2020).

In summary, although water-related adaptation is underway in the urban, peri-urban and municipal sectors of some nations, governance, technical, and economic barriers remain in implementing locally-informed strategies, particularly in developing countries (*high confidence*).

[START BOX 4.5 HERE]

Box 4.5: Reduce, Remove, Re-use and Recycle (4Rs): Wastewater Re-use and Desalination as an Adaptation Response

Circular economies can increase the available sustainable adaptation space by moving away from a linear mode of production of "extract-produce-use-discard" to a '4Rs' closed loop to reduce pollution at the source, remove contaminants from wastewater, re-use treated wastewater, and recover valuable by-products ((UN Water, 2017)}, see WGIII 11.3.3).

It is estimated that 380 billion m^3 of wastewater is produced annually worldwide, which equals about 15% of agricultural water withdrawals. The recovery of nitrogen, phosphorus and potassium from wastewater can offset 13.4% of the global agriculture demand for these nutrients (Jiménez and Asano, 2008; Fernández-Arévalo et al., 2017). Recycling human waste worldwide could satisfy an estimated 22% of the global demand for phosphorus (UN Water, 2017). It has been estimated that some 36 million ha worldwide (some 12% of all irrigated land) re-use urban wastewater, mainly for irrigation. However, only around 15% is adequately treated (Thebo et al., 2017), thus the need to invest in sustainable, low-cost wastewater treatment to protect public health. The irrigation potential of this volume of wastewater stands at 42 million ha. Wastewater production is expected to increase globally to 574 billion m^3 by 2050, a 51% increase compared to 2015, mainly due to a growing urban population (Qadir et al., 2020). Water re-use with treated wastewater for potable and nonpotable purposes can be practised in a manner that is protective of public health and the environment (WHO, 2006; WHO, 2017). For example, when implemented with sufficient treatment standards, the use of recycled water for the irrigation of crops is protective of public health (Blaine et al., 2013; Paltiel et al., 2016), as was determined by an appointed panel of experts in the state of California (Cooper et al., 2012). However, there are several barriers to the adoption of wastewater re-use, these include technical barriers and public health aspects related to microbiological and pharmaceuticals risks (Jiménez and Asano, 2008; Jaramillo and Restrepo, 2017; Saurí and Arahuetes, 2019). These are currently being addressed by strengthening regulatory standards, with, e.g., 11 out of 22 Arab States adopting legislation permitting the use of treated wastewater (WHO, 2006; US EPA, 2017; WHO, 2017; EC, 2020). Benefits of wastewater re-use usually outweigh the costs (Stacklin, 2012; Hernández-Sancho et al., 2015; UN Water, 2017).

Desalination is particularly important in arid and semi-arid climates, coastal cities, and small island states (Box 4.2). There are 16,000 operational desalination plants globally, with a daily desalinated water production of 95 million m^3 per day in 2017 (IDA, 2020). In 2012 desalinated water was equivalent to 0.6% of the global water supply and 75.2 TWh of energy per year was used to generate desalinated water i.e. about 0.4% of the worldwide electricity consumption (IRENA, 2012). Unfortunately, only 1% of total desalinated water uses renewable sources (IRENA, 2012; Amy et al., 2017; Balaban, 2017; Martínez-Alvarez et al., 2018a; Jones et al., 2019) (4.7.6). Desalination has already helped to meet urban and peri-urban water supply, particularly during annual or seasonal drought events, with half of the world's desalination capacity in the Arab region (UN Environment, 2019; UN Water, 2021). In addition, seawater desalination could help address water scarcity in 146 (50%) large cities (including 12 (63.2%) megacities) (He et al., 2021). Desalination is also being adopted for irrigation. For example, in the island of Gran Canary (Spain), 30% of the agricultural surface area is irrigated with desalinated water to irrigate high-value crops (Burn et al., 2015; Martínez-Alvarez et al., 2018a; Monterrey-Viña et al., 2020). The expected growth of desalination, if not coupled with renewable energy (RE), causes a projected 180% increase in carbon emissions by 2040 (GCWDA, 2015; Pistocchi et al., 2020). There have been advances in large scale and on-farm renewable desalination (Abdelkareem et al., 2018). Using renewable energy to decarbonize desalination has meant that the projected global average levelised cost of water has decreased from 2.4 €/m^3 (2015) to approximately 1.05€/m^3 by 2050, considering unsubsidized fossil fuel costs (Caldera and Breyer, 2020). Desalination will be maladaptive if fossil fuel is used (Tubi and Williams, 2021).

In summary, a resilient circular economy is central to deliver access to water, sanitation, wastewater treatment, desalination, and water re-use as viable adaptation options compatible with the Paris agreement, while safeguarding ecological flows according to the SDG6 targets for climate-resilient development *(medium evidence, high agreement).*

[END BOX 4.5 HERE]

4.6.6 Adaptation for Communities Dependant on Freshwater Ecosystems

AR5 concluded that some adaptation responses in the urban and agricultural sectors could negatively impact freshwater ecosystems (*medium confidence*) (Settele et al., 2014).

Adaptation measures to cope with changes in ecosystems, including freshwater ecosystems, include Ecosystem-based Adaptation (EbA) interventions and gained wide recognition at the global policy level (Reid, 2016; Barkdull and Harris, 2019; Piggott-McKellar et al., 2019b).These have been implemented in many locations around the world, yet, challenges remain, including improving the evidence base of their effectiveness, scaling up of these interventions, mainstreaming across sectors and receiving more adaptation finance (*medium confidence*).

A systematic review of 132 academic papers and 32 articles from non-peer-reviewed literature (Doswald et al., 2014) provided a comprehensive global overview of EbA, which showed that EbA interventions were used in various ecosystems, including inland wetlands (linked to 30 publications). An investigation of EbA effectiveness by (Reid et al., 2019), where nine case studies covering South Asia, Africa and South America were associated with freshwater systems, concluded that EbA enabled the enhancement of the adaptive capacity or resilience to climate change, particularly for the more vulnerable groups in the community. An assessment of the potential for EbA in three sub-basins of the Murray-Darling Basin, Australia, concluded that EbA can augment catchment management practices but that there were also institutional challenges

(Lukasiewicz et al., 2016). In urban settings, EbA has been associated with ecological structures for reducing risks, including the use of urban wetlands (Barkdull and Harris, 2019). EbA is a subset of Nature based Solutions (NbS) that is rooted in climate change adaptation and covers both mitigation (Pauleit et al., 2017) (4.6.5, Box 4.6). Although adaptation measures for freshwater ecosystems have been implemented in many places (Shaw et al., 2014; Lukasiewicz et al., 2016; Karim and Thiel, 2017; Milman and Jagannathan, 2017; FAO, 2018a; Piggott-McKellar et al., 2019b), the evidence base for the effectiveness of these measures to cope with changes in freshwater ecosystems needs improvement. These measures also require further financial support, mainstreaming across sectors, and the scaling up of individual measures (*medium confidence*).

In summary, adaptation measures to cope with changes in freshwater ecosystems have been implemented in many locations around the world. However, challenges remain, including improving the evidence base of their effectiveness, scaling up these interventions, mainstreaming across sectors and receiving more adaptation finance (*medium confidence*).

[START BOX 4.6 HERE]

Box 4.6: Nature Based Solutions for Water-related Adaptation

In the context of climate change-induced water insecurity, NbS are an adaptation response that relies on natural processes to enhance water availability, water quality and mitigates risks associated with water-related disasters (IUCN, 2020).

Until recently, NbS has been considered mainly for mitigation (Kapos et al., 2020; Seddon et al., 2020). Yet, NbS increases the low-cost adaptation options that expand the adaptation space due to its multiple co-benefits (Cross-Chapter Box NATURAL in Chapter 2). Furthermore, a meta-review of 928 NbS measures globally shows that NbS largely addresses water-related hazards like heavy precipitation (37%) and drought (28%) }(Kapos et al., 2020).

Natural infrastructure (green and blue) uses natural or semi-natural systems, e.g., wetlands, healthy freshwater ecosystems, etc., to supply clean water, regulate flooding, enhance water quality, and control erosion (6.3.3.1 to 6.3.3.6.). Grey infrastructure can damage biophysical and hydrological processes, seal soils, and bury streams. Compared with grey physical infrastructure, natural infrastructure is often more flexible, cost-effective, and can provide multiple societal and environmental benefits simultaneously (McVittie et al., 2018; UN Water, 2018; IPBES, 2019). There is increasing evidence and assessment methods on the role of NbS for climate change adaptation and disaster risk reduction at different scales (Chausson et al., 2020; Seddon et al., 2020; Cassin and Matthews, 2021) (4.6.5).

At the landscape scale, there is evidence that impacts from fluvial and coastal floods can be mitigated through water-based NBS like detention /retention basins, river restoration, and wetlands (Thorslund et al., 2017; Debele et al., 2019; Huang et al., 2020). Several examples show the effectiveness of floodplain restoration, natural flood management and making room for the river measures (see FAQ 2.5, (Hartmann et al., 2019; Mansourian et al., 2019; Wilkinson et al., 2019)) (*medium evidence, high agreement*). Likewise, the use of managed aquifer recharge (MAR) in both urban and rural settings will be crucial for groundwater-related adaptation (Zhang et al., 2020a).

At the urban and peri-urban scale, the use and effectiveness of NbS is a crucial feature to build resilience in cities for urban stormwater management and heat mitigation (Depietri and McPhearson, 2017; Carter et al., 2018; Huang et al., 2020; Babí Almenar et al., 2021) (*high confidence*). NbS have been used for stormwater management by combining water purification and retention functions (Prudencio and Null, 2018; Oral et al., 2020). NbS have also been used to mitigate impacts from high impact extreme precipitation events by integrating large scale NBS investment plans into urban planning in cities like New York and Copenhagen, highlighting the importance of blended finance and investment (including insurance) to mainstream NbS investments (Liu and Jensen, 2017; Rosenzweig et al., 2019; Lopez-Gunn et al., 2021). According to the

CDP database, one in three cities use NBS to address climate hazards, and this trend is growing (Kapos et al., 2020).

NbS are cost-effective and can complement or replace grey solutions (Cross-Chapter Box FEASIB in Chapter 18, 3.2.3), (Chausson et al., 2020)). Moreover, estimates of NbS are increasingly based on integrated economic valuations that incorporate co-design with stakeholders to incorporate local knowledge (Pagano et al., 2019; Giordano et al., 2020; Hérivaux and Le Coent, 2021; Palomo et al., 2021) (*medium evidence, high agreement*). Yet, the performance of NbS themselves may be limited at higher GWLs (Calliari et al., 2019; Morecroft et al., 2019).

More knowledge is needed on the long term benefits of NbS, particularly to hydro-meteorological hazards (Debele et al., 2019). There is still *low evidence* for slow onset events, including the applicability of NbS to manage highly vulnerable ecosystems and in agriculture (Sonneveld, 2018),

In summary, there is growing evidence on NBS effectiveness as an adaptation measure and critical role for transformative adaptation to address climate change water-related hazards and water security (*medium evidence, high agreement*). Moreover, several NBS– as, e.g. natural (blue and green) and grey infrastructure can help address water-related hazards, e.g., coastal hazards, heavy precipitation, drought, erosion and low water quality (*high confidence*).

[END BOX 4.6 HERE]

4.6.7 Adaptation Responses for Water-related Conflicts

AR5 concluded with *high confidence* that challenges for adaptation actions (though not water) are particularly high in regions affected by conflicts (Field et al., 2014a). Although climate-conflict linkages are disputed (4.3.6), the potential for synergies between conflict risk reduction and adaptation to climate change exists (Mach et al., 2019). For example, discourses around climate-conflict inter-linkages can present opportunities for peace-building and cooperation (Matthew, 2014; Abrahams, 2020). Indeed, adaptation efforts are needed in the context of conflict, where the pre-existing vulnerability undermines the capacity to manage climatic stresses. In addition, adaptive capacity depends on contextual factors such as power relations and historical, ethnic tensions (Petersen-Perlman et al., 2017; Eriksen et al., 2021), which need to be adequately considered in the design of adaptation strategies.

Some adaptation options, such as water conservation, storage and infrastructure, voluntary migration, planned relocation due to flood risk/sea-level rise, and international water treaties, can reduce vulnerability to climate change and conflicts. However, on the other hand, these adaptation options sometimes may have unintended consequences by increasing existing tensions (Milman and Arsano, 2014); displacing climate hazards to more vulnerable and marginalized groups (Milman and Arsano, 2014; Mach et al., 2019), e.g. pastoralists (Zografos et al., 2014); favouring some over others, e.g. industry over agriculture (Iglesias and Garrote, 2015), upstream countries over downstream countries (Veldkamp et al., 2017), men over women (Chandra et al., 2017). Such unintended consequences may happen when adaptation measures intended to reduce vulnerability produce maladaptive outcomes by rebounding or shifting vulnerability to other actors (Juhola et al., 2016). For example, in the Mekong River basin, the construction of dams and water reservoirs contributes to the adaptation efforts of the upstream southeast Asia countries while increasing current/future vulnerability to floods and droughts in downstream countries and can emerge as a cause of conflict (Earle et al., 2015; Ngô et al., 2016).

Furthermore, adaptation in the context of water-related conflicts is also constrained by economic, institutional, political, competing for development (Anguelovski et al., 2014) and gender considerations (Sultana, 2014; Chandra et al., 2017), which need to be taken into account when designing adaptation plans/measures.

4.6.8 Adaptations Through Human Mobility and Migration

AR5 noted that whether migration is adaptive or maladaptive depends on the context and the individuals involved, however it did not focus specifically on hydrological changes-induced migration (Noble et al., 2014). Migration is often regarded as a transformational adaptation strategy in response to climate-induced hydrological changes (Gemenne and Blocher, 2017) but rarely as the primary or only adaptation measure ((Wiederkehr et al., 2018; de Longueville et al., 2020), Cross-Chapter Box MIGRATE in Chapter 7). Migration is among one of the top five adaptation responses documented in Asia and Africa (Figure 4.27) and confers several benefits to migrants yet maladaptations are also documented (Figure 4.29). This strategy is not available to everyone. Vulnerable populations exposed to hydrological changes may become trapped due to a lack of economic and social capital required for migration (Adams, 2016; Zickgraf, 2018) *(medium confidence)*.

Spontaneous migration, undertaken without outside assistance, has shown the potential to improve the resilience of migrants and communities (Call et al., 2017; Jha et al., 2018a) but may also lead to increased vulnerability and insecurity in some instances (Adger et al., 2018; Linke et al., 2018a; Singh and Basu, 2020). Migration is not a viable strategy for everyone, but age, gender and socio-economic status play a significant role in encouraging or inhibiting the chances of successful migration (Maharjan et al., 2020; Bergmann et al., 2021; Erwin et al., 2021). Migration has increased vulnerability among women and female-headed households (Patel and Giri, 2019) but has also triggered gender positive processes, e.g., increased female school enrolment (Gioli et al., 2014) *(medium confidence)*. Remittances, i.e., transfers of money from migrants to beneficiaries in sending areas, may reduce vulnerability and increase adaptive capacity to climate-induced hydrological changes (Ng'ang'a et al., 2016; Jha et al., 2018b) *(medium confidence)*. Managed retreat refers to the planned and assisted moving of people and assets away from risk areas, such as government- or community-led resettlement (Hino et al., 2017; Maldonado and Peterson, 2018; Tadgell et al., 2018; Arnall, 2019). Such initiatives may reduce exposure to risk (Lei et al., 2017). However, they often fail to include affected populations in the process and may lead to greater impoverishment and increased vulnerability (Wilmsen and Webber, 2015) *(medium confidence)*.

More research on how to ensure migration becomes a successful adaptation strategy is needed (McLeman et al., 2016). In addition, impacts on women, youth and marginalized groups (McLeman et al., 2016; Miletto, 2017) and immobility issues need more attention (Zickgraf, 2018).

In summary, measures that facilitate successful migration and inclusive resettlement may facilitate adaptation to climate-induced hydrological changes *(medium confidence)*.

4.6.9 Adaptation of the Cultural Water Uses of Indigenous Peoples, Local Communities and Traditional Peoples

AR5 reported that religious and sacred values inform actions taken to adapt to climate change (Noble et al., 2014). Neither AR5 nor SR1.5 reviewed adaptation of Indigenous, local and traditional uses of water. SROCC highlighted the context-specific adaptation strategies of vulnerable communities in coastal, polar and high mountain areas, reporting that adaptive capacity and adaptation limits are not only physical, technical, institutional and financial, but also culturally-informed (Hock et al., 2019b; Meredith et al., 2019; Oppenheimer et al., 2019).

There is *high confidence* that some Indigenous Peoples, local communities, and traditional peoples could and are adapting to climate-driven hydrological changes and their impacts on culturally-significant sites, species, ecosystems, and practices in polar, high mountain and coastal areas, where sufficient funding, decision-making power and resourcing exist (e.g., (Golden et al., 2015; Bunce et al., 2016; Anderson et al., 2018). However, there is also *high confidence* that there are significant structural barriers and limits to their adaptation, and that the outcomes of some adaptation strategies can be uneven and maladaptive (*medium evidence, high agreement*) (4.7.4; 4.8.3). These barriers include the lack of recognition of Indigenous sovereignty and exclusion of Indigenous Peoples from decision-making institutions (Ford et al., 2017; Labbé et al., 2017; Eira et al., 2018; McLeod et al., 2018; MacDonald and Birchall, 2020) (14.4.4.2.2; 13.8.1.2). At the same time, the rate and scale of climate change can impede the ability of vulnerable communities to turn their adaptive capacity into effective adaptation responses (Ford et al., 2015; Herman-Mercer et al., 2019).

There is *high confidence* that local people are adapting to the cultural impacts of climate-driven glacier retreat and decline in snow cover and ice in polar and high mountain areas. However, there is also *high confidence* that such adaptation can be detrimental and disrupt local cultures. For example, in the Peruvian Andes, concerns about water availability for ritual purposes has led to restrictions on pilgrims' removal of ice and limiting the size of ritual candles to preserve the glacier (Paerregaard, 2013; Allison, 2015). Relatedly, some local people have questioned the cosmological order, and re-oriented their spiritual relationships accordingly (Paerregaard, 2013; Carey et al., 2017). In Siberia (Mustonen, 2015) and northern Finland (Turunen et al., 2016), community-led decisions among herders favour alternative routing, pasture areas, and shifts in nomadic cycles in response to changing flood events and permafrost conditions (Box 13.2). However, loss of grazing land and pasture fragmentation pose adaptation limits, and some strategies such as supplementary feeding and new technologies may further affect cultural traditions of herding communities (Risvoll and Hovelsrud, 2016; Jaakkola et al., 2018).

There is *high confidence* that relocation (managed retreat) is an adaptation response for communities in areas impacted by, or at risk of, inundation and other hydrological changes (15.3.4.7; 15.5.3). However, relocation can be culturally, socially, financially, politically and geographically constrained due to the importance of cultural relationships with traditional, customary or ancestral lands (*high confidence*) (Albert et al., 2018; Narayan et al., 2020; Yates et al., 2021). Among Pacific islands, for example, the prospect of migration raises concerns about the loss of cultural identity and Indigenous Knowledge (IK) and practices, which can impact emotional well-being (Yates et al., 2021).

As cultural beliefs influence risk perception, there is *medium confidence* that some cultural understandings can foster a false sense of security among Indigenous Peoples, local communities and traditional peoples regarding climate-driven hydrological changes. For example, some members of the Rolwaling Sherpa community in Nepal believe that mountain deities protect them from glacial lake outburst floods (GLOFs) (Sherry and Curtis, 2017)(4.2.2). Elsewhere, such as in the islands of Fiji and St. Vincent, cultural beliefs can diminish human agency because change is viewed as inevitable and beyond human intervention (Smith and Rhiney, 2016; Currenti et al., 2019). Yet such cultural beliefs are not necessarily maladaptive, as they potentially support other resilience factors, such as IK and local knowledge (4.8.5; (Ford et al., 2020)), as well as cultural connections and social ties (Yates et al., 2021).

In sum, although some Indigenous Peoples, local communities and traditional peoples can and are adapting to climate-driven hydrological changes, and their impacts on and risks to culturally significant practices and beliefs (*medium confidence*), these strategies are constrained by structural barriers and adaptation limits (*high confidence*).

[START BOX 4.7 HERE]

Box 4.7: Flood-related Adaptation Responses

Floods, due to their rapid onset and destructive force, require specific adaptation measures. Historically, to address flood damages and risk protection, retreat and accommodation were most common, emphasizing protecting and retreating (Wong et al., 2014; Bott and Braun, 2019). Figure 4.22 identifies five major adaptation strategies from a meta-review of water-related adaptation responses that helps in protecting, retreating and accommodating (4.7.1).

Globally, structural measures for flood protection through hard infrastructure are the most common measures as they directly manage flood hazards by controlling flow through streams and prevent water overflow (Andrew and Sauquet, 2017; Duží et al., 2017). These measures include dikes, flood control gates, weirs, dams, storage and proper waste management (Barua et al., 2017; Egbinola et al., 2017). Infrastructure measures require high maintenance, such as dredging clearing channels and overpasses (Egbinola et al., 2017). A negative aspect of protective infrastructural measures is that, while they eliminate the hazard up to a certain magnitude (Di Baldassarre et al., 2013), they also generate an illusion of no risk by diminishing frequent floods (Duží et al., 2017; Logan et al., 2018). In addition, specific engineering solutions that might be introduced from other localities without proper contextual adjustments may lead to maladaptation (Mycoo, 2014; Pritchard and Thielemans, 2014). Nature-Based Solutions (NbS, Box 4.6) have shifted infrastructure measures from purely grey onto mixed engineering and environmental measures. Examples include Sustainable Urban Drainage Systems (SUDS), which aid in decreasing flow peaks and are affordable, aesthetically pleasing and socially acceptable while also reducing heat and hence the production of storms (Chan et al., 2019) (4.6.5).

Non-structural or soft measures for flood adaptation include human actions that generate capacities, information and, therefore, awareness of floods (Du et al., 2020). Soft measures aim to integrate flood resilience within city management and planning (Wijaya, 2015; Andrew and Sauquet, 2017; Abbas et al., 2018). Social support between members of a community and economic mechanisms such as loans or remittances are soft measures that promote recovery or resilience to floods (Barua et al., 2017; Musah-Surugu et al., 2018; Bott and Braun, 2019). Communities with heightened awareness and knowledge of floods are probably going to elect political leaders that will affect flood protection and policies that include adaptation (Abbas et al., 2018). Soft measures can be an anchoring factor for policies that promote early warning systems, infrastructure, flood resilient housing and environmental restoration (Andrew and Sauquet, 2017; Abbas et al., 2018). However, soft measures, especially at large scale, may also lead to maladaptation as lack of synchronization between international, national and local levels (Hedelin, 2016; Lu, 2016; Jamero et al., 2017), and can further be hampered by bureaucracy (Pinto et al., 2018).

Early warning systems (EWS) are defined as integrated systems of hazard monitoring, forecasting and prediction, disaster risk assessment, communication, and preparedness activities systems to enable individuals, communities, governments, businesses to take timely action to reduce disaster risks in advance of hazardous events (UNISDR, 2021). By this definition, EWS are directly dependent on soft and hard infrastructure measures that increase capacity and reduce hazard (Abbas et al., 2018). Aside from the capacity dependent on soft measures and the monitoring infrastructure, communication at all scales, from national weather services to local leaders, needs to be effective for prompt action (Devkota et al., 2014). In many cases, early warning systems might be the only option to reduce flood casualties (Kontar et al., 2015).

Accommodating floods has gained popularity as the effects of climate change become more apparent, and notable hydroclimatic events exceed the limitations of protective measures (Pritchard and Thielemans, 2014). NbS measures like wetland restoration can act as modern infrastructure protection with clear mitigation co-benefit and provides opportunities for accommodating floods. For example, initiatives such as Room for the River consider flood safety combined with other values such as landscape, environment and cultural values (Zevenbergen et al., 2015). A popular ecosystem-based adaptation measure has been wetland restoration, which can control flood peaks, serve as storage ponds in addition to restoring the environment (Pinto et al., 2018; Saroar, 2018). However, its effectiveness under different conditions is yet to be assessed (Wamsler et al., 2016). Flood resilient housing is another form of accommodating and living with floods. These comprise mostly of elevated homes or different flood protection measures considering vegetation around the house to make those flood resilient (Ling et al., 2015; Abbas et al., 2018; Ferdous et al., 2019).

Despite different degrees of effectiveness, no flood adaptation measure is uniquely effective to eliminate flood risk. Adaptation to floods needs to be considered at a local level, considering the types of floods, community's capacities and available livelihoods (Fenton et al., 2017a). Ideally, flood adaptation strategies need to include short term actions linked to long term goals, be flexible, consider multiple strategies and interlink investment agendas of stakeholders (Zevenbergen et al., 2015). Most importantly, flood adaptation and management options have been proven effective to reduce loss of human lives, but not entirely at sustaining livelihoods and reducing infrastructure damages (Rahman and Alam, 2016; Bower et al., 2019; Ferdous et al., 2019).

[END BOX 4.7 HERE]

4.7 Benefits and Effectiveness of Water-Related Adaptations, Their Limits and Trade-offs

The previous section documented adaptation responses in water use sectors we assess in this chapter (4.6), and noted that in many instances, effectiveness of those responses is not clear. While, there are thousands of case studies of implemented adaptation responses (observed adaptation) to water insecurity, there is a lack of synthesized understanding about the effectiveness and benefits of adaptation (Berrang-Ford et al., 2021a) and whether or not those benefits also translate into climate risk reduction (Singh et al., 2021). In contrast, literature on the effectiveness of future projected adaptation in reducing climate risks is limited in number. Yet, even then, the findings are not synthesized across various options to make an overall assessment of the effectiveness of future projected adaptation. In this section, we draw on two meta-review protocols (see SM4.2 for a description of each protocol) and assess the benefits of current adaptation and effectiveness of future projected adaptation in reducing climate risks. We also assess limits to adaptation and trade-offs and synergies between adaptation and mitigation.

4.7.1 Current Water-related Adaptation Responses, Benefits, Co-benefits and Maladaptation

AR5 (Jiménez Cisneros et al., 2014) concluded that developing countries needed a larger share of adaptation investments for anticipatory adaptation in the water sector (*medium evidence, high agreement*) and that adaptive water management measures were critical in addressing climate-related uncertainty. (Noble et al., 2014) listed various examples of adaptation options, and water-related adaptation featured prominently in almost all categories. They also discussed the challenges of developing metrics for measuring adaptation outcomes; and stressed the importance of transformational adaptation instead of incremental adaptation. Finally, SR 1.5 (de Coninck et al., 2018) made one of the first attempts to systematically assess the feasibility of adaptation options (Singh and Basu, 2020).

4.7.1.1 Current Water-related Adaptation Responses

We define an adaptation response as a water-related adaptation if the hazard is water-related (e.g., floods, droughts, extreme rainfall events, groundwater depletion, melting and thawing of cryosphere (Figure 4.25); or the adaptation intervention is water-related (e.g., irrigation, rainwater harvesting, soil moisture conservation etc.). Adaptation responses were implemented across all water use sub-sectors assessed in this chapter (4.6, Figure 4.23). Given the overall interest in assessing adaptations that documents outcomes, we limited our analysis to a set of 359 unique articles that measures outcomes of adaptation across pre-defined outcome categories (SM4.2, Table SM4.5, (Berrang-Ford et al., 2021a; Mukherji et al., 2021). A total of 1054 adaptation responses were documented in the 359 case studies; these were categorized into 16 categories (Figure 4.22). These adaptation responses are not always specific to long term climate change impacts (that is, changes in annual mean fluxes) but rather respond to changes in variability in the water cycle and specific water hazards. Adaptation to internal variability is needed to increase the resilience to projected water cycle changes because water cycle changes primarily manifest as changes in variability (Douville et al., 2021).

There is *high confidence* that a significant share of water-related adaptations is occurring in the agriculture sector. Agriculture accounts 60-70% of total water withdrawals (Hanasaki et al., 2018; Burek et al., 2020; Müller Schmied et al., 2021) and supports the livelihoods of a large majority of people in the developing countries. Within the agriculture sector, there is *high confidence* in the quality and quantity of evidence of adaptation responses such as improved cultivars and agronomic practices, on-farm irrigation and water management and water and soil moisture conservation, and *medium confidence*, derived from *robust evidence*, and *medium agreement* for other most other adaptation responses (Figure 4.23 and Figure 4.24). Most of these adaptation case studies are from Asia and Africa, and agriculture is the pre-dominant sector where most of these adaptation responses are being implemented (*high confidence*) (4.6.2). However, the sectoral nature of adaptation responses varies across continents. Agriculture is the most important sector in all continents, except Europe and Australasia, where the most adaptation occurs in the urban sector (*high confidence*) (Figure 4.24).

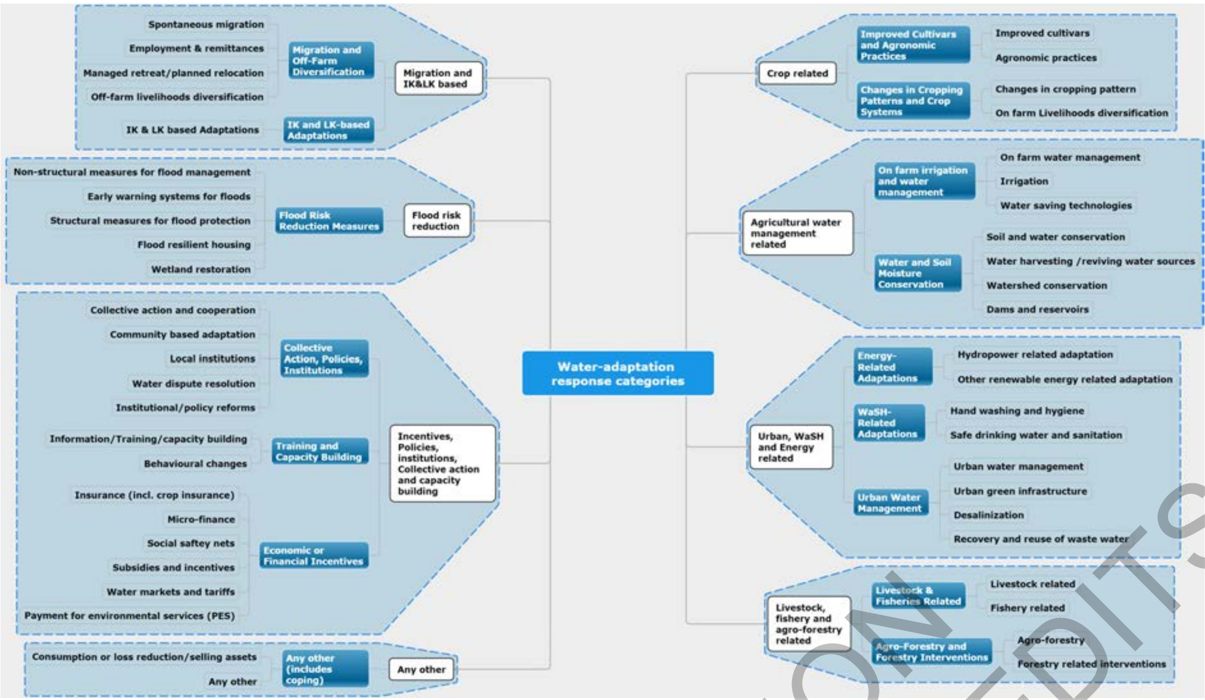

Figure 4.22: Decision tree, documenting the classification of water-related adaptation responses across 48 subcategories, into16 intermediate and 8 larger categories. We use the 16 intermediate categories of adaptation responses for further analysis in this section.

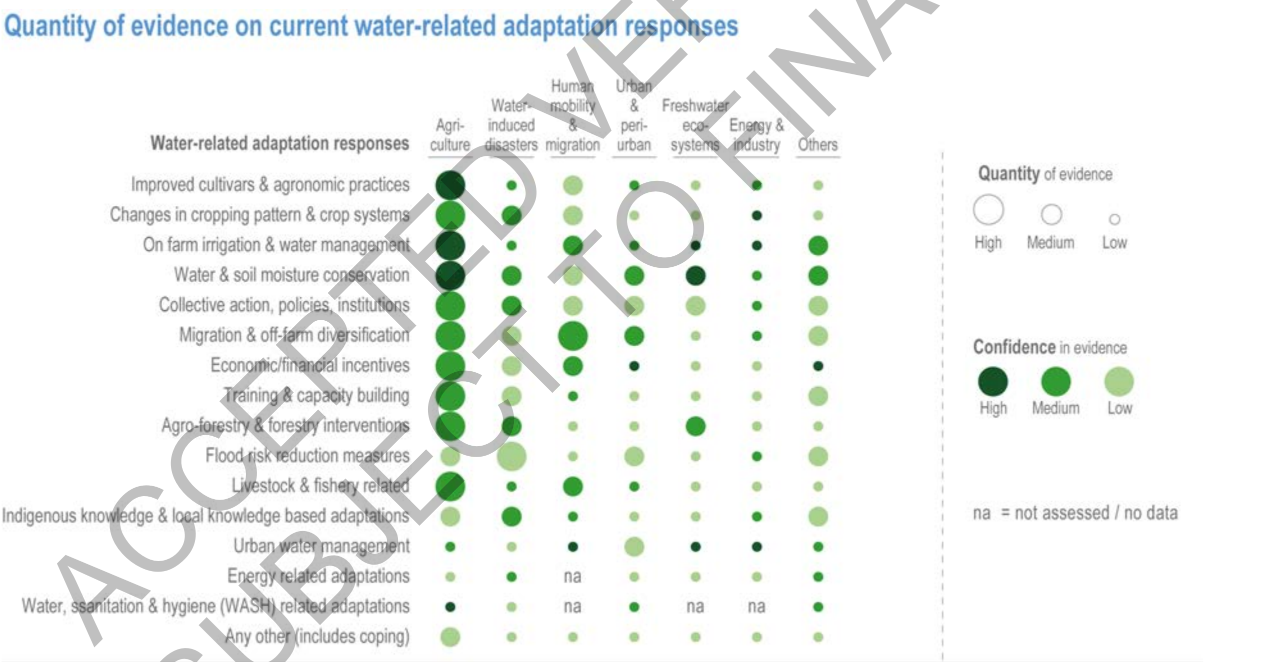

Figure 4.23: Sectoral distribution of documented water-related adaptation responses (observed adaptation) across the 16 categories derived from Figure 4.22. The quantity of evidence is derived from the number of papers in a particular adaptation response category where High >40 papers, Medium: 10-40 papers; Low <10 papers. Confidence in evidence relates to the way the article links outcomes of adaptation with the adaptation response. Category 1: studies causally link adaptation outcomes to the adaptation response by constructing credible counterfactuals; Category 2: studies correlate responses and outcomes without causal attribution; Category 3: studies describe adaptation outcomes without making any causal or correlation claims between adaptation outcomes and adaptation responses. *High confidence*: more than 67% of the studies fall in categories 1 and 2; *medium confidence*: 50-67% of the studies are in categories 1 and 2, and *low confidence* is less than 50% of studies are in categories 1 and 2.

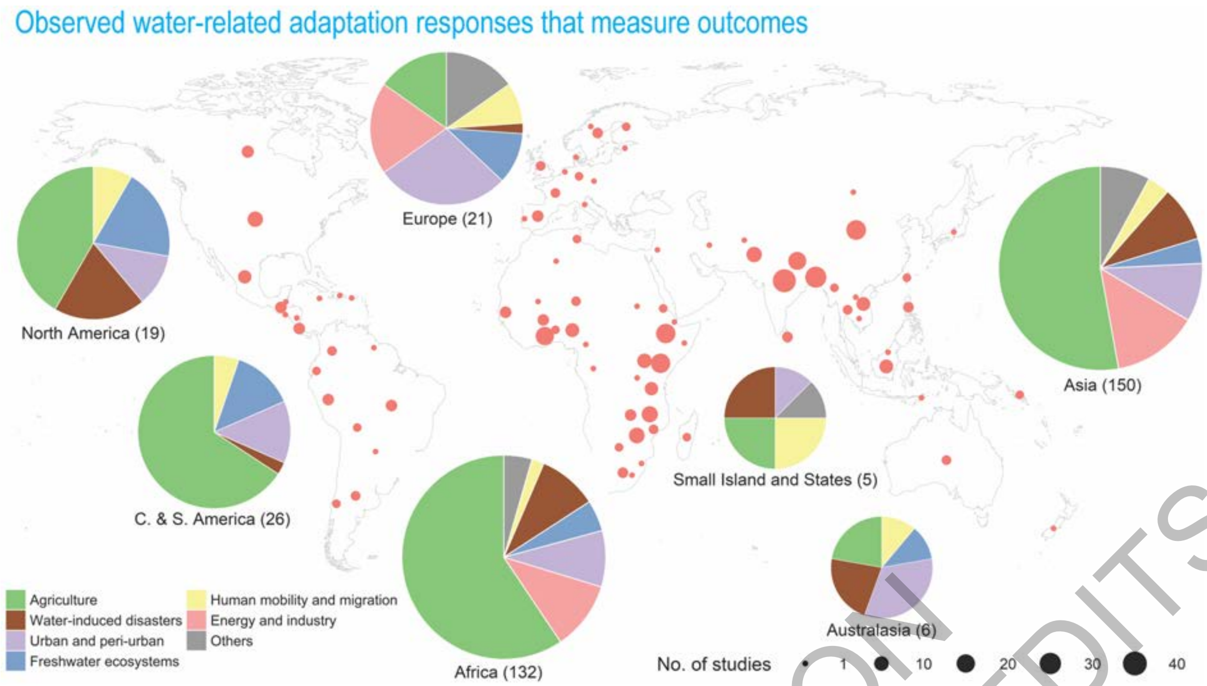

Figure 4.24: Location of case studies on water-related adaptation which measure adaptation outcomes (n=359) and their sectoral distribution across all regions. Circles denote the number of case studies in a particular location in the continent. The pie chart shows the sectors in which adaptation is taking place. The sectors correspond to water use sectors described in sections 4.3, 4.5 and 4.6 of this chapter.

The top four adaptation responses in terms of frequency of documentation are changes in the cropping pattern and crop systems (145 responses), improved crop cultivars and agronomic practices (139 responses), irrigation and water management practices (115 responses) and water and soil conservation measures (102 responses). These top four responses provide several benefits such as higher incomes and yields, better water use efficiencies and related outcomes (*high confidence*) (Table 4.9 and Figure 4.27). However, those benefits are incremental, that is, it helps improve crop production and incomes, at least in the short run, but may not automatically lead to transformative outcomes and climate risk reductions (Pelling et al., 2015; Fedele et al., 2019). One way to move from incremental to transformative adaptation could be to invest gains from incremental adaptation in education and capacity building to improve overall adaptive capacity (Vermeulen et al., 2018). Responses such as migration, including spontaneous and planned relocation, are also relatively well documented (*medium confidence*), as are responses such as collective action, training and capacity building and economic and financial measures for increasing adaptive capacities (*medium confidence*). These categories of adaptation can potentially lead to transformative outcomes, such as a shift to livelihoods that are less exposed to climate hazards. However, transformative pathways are not always straightforward (Pahl-Wostl et al., 2020) (Table 4.8).

Table 4.8: Illustrative examples of case studies of water-related adaptation responses where outcomes were measured (n=359). These cases include instances where adaptation benefits were positive, negative, or neutral. Examples also include studies with or without causal and correlation links between adaptation response and outcomes (categories 1, 2 and 3 studies as described in caption of Figure 4.23. The purpose of the table is to provide a list of illustrative examples to showcase the wide range of adaptation responses that are being implemented. Table 4.9 zooms into examples where adaptation had positive benefits on any of the selected parameters described in 4.7.1.2.

Name of the adaptation response (number of documented responses that category)	Description of adaptation response	Sources
Changes in the cropping pattern and crop systems (145 responses)	Changes in cropping pattern; e.g., the introduction of sugarcane and rice in Costa Rica; crop diversification in Ethiopia and Zimbabwe; crop diversification in Tanzania.	(Singh et al., 2014; Warner et al., 2015; Asmare et al., 2019; Lalou et al., 2019; Makate et al., 2019)
	Changes in the timing of sowing and harvesting, e.g., in China; India and Pakistan	(Yu et al., 2014; Macchi et al., 2015)
	On-farm diversification, e.g., an integrated crop-livestock system in France	(Havet et al., 2014)
Improved crop cultivars and agronomic practices (139 responses)	Improved crop cultivars, e.g., short-duration paddy varieties in Nepal; saline tolerate rice cultivar in Bangladesh; drought-tolerant maize varieties in Malawi, Nigeria, Zimbabwe, Uganda	(Kabir et al., 2016; Wossen et al., 2017; Khanal et al., 2018a; Makate et al., 2019)
	Improved agronomic practices, e.g., conservation agriculture to conserve soil moisture in Malawi, Tanzania; climate-smart agricultural practices in Zambia; alternate wetting and drying and direct seeding of rice in India.	(Thierfelder et al., 2015; Kimaro et al., 2016; Traore et al., 2017; Kakumanu et al., 2019)
Irrigation and water management practices (115 responses)	Irrigation, e.g., construction of local irrigation infrastructure in Chile; funding of community wells in Canada; drilling of borewells in Thailand; irrigation in Ethiopia; spate irrigation in Sudan; night-time irrigation scheduling to reduce evaporative demand in the UK	(Hurlbert and Pittman, 2014; Ferchichi et al., 2017; Rey et al., 2017; Pak-Uthai and Faysse, 2018; Fadul et al., 2019; Lemessa et al., 2019; Lillo-Ortega et al., 2019; Torres-Slimming et al., 2020)
	On-farm water management and water-saving technologies, e.g., use of surface pipes for irrigation water conveyance in China; drip irrigation in China; and use of water-saving measures in India	(Hong and Yabe, 2017; Tan and Liu, 2017; Deligios et al., 2019; Rouabhi et al., 2019)
Water and soil conservation (102 responses)	On-farm water and soil conservation measures, e.g., in Burkina Faso; terraces and contour bunds in Ethiopia.	(West Colin et al., 2016; Kosmowski, 2018)
	Water harvesting through on sand dams in Kenya; in-situ and ex-situ water harvesting in Uganda and India	(Ngigi et al., 2018; Sullivan-Wiley and Short Gianotti, 2018; Kalungu et al., 2021)
	Watershed conservation programs, e.g., in Ethiopia.	(Siraw et al., 2018)
	Revival of water bodies; e.g., creation of artificial lakes in Portugal.	(Santos et al., 2018)
Collective action, policies and institutions (95 responses)	Collective action and cooperation; e.g., grassroots-level collective action for conflict resolution in Guatemala; collective decision to reduce water withdrawals during drought in Japan.	(Hellin et al., 2018; Tembata and Takeuchi, 2018)
	Community-based adaptation in Bangladesh, community-based management of rangelands in Mongolia.	(Fernández-Giménez et al., 2015; Roy, 2018)
	Local institutions, e.g., multi-stakeholder platforms for disaster risk reduction and agriculture in Peru; and several African countries; Adaptation Learning Program.	(Mapfumo et al., 2017; Lindsay, 2018)
	Water dispute resolution; e.g., water conflict mitigation in Costa Rica.	(Kuzdas et al., 2016)

	Institutional and policy reforms; e.g., local water and land use planning instruments in Australia; the Dutch Delta Program in the Netherlands; implementation of EU Flood Directives in Sweden.	(Fallon and Sullivan, 2014; Zevenbergen et al., 2015; Hedelin, 2016)
Migration and off-farm diversification (92 responses)	Spontaneous migration, e.g., voluntary relocation in the Solomon Islands and rural to urban migration in Ethiopia and Pakistan.	(Birk and Rasmussen, 2014; Iqbal et al., 2018)
	Employment and remittances, e.g., in Senegal.	(Romankiewicz et al., 2016)
	Planned relocation; e.g., the Massive Southern Shaanxi Migration Program in China; resettlement of flood-prone communities in Bangladesh.	(Islam et al., 2014; Lei et al., 2017)
	Off-farm diversification; e.g., migration to towns and engaging in off-farm labour wage-earning in Niger, Ghana Bangladesh; shifting to non-pastoral livelihoods in Ethiopia.	(Mussetta et al., 2016; Basupi et al., 2019)
Livestock and fishery-related (63 responses)	Livestock related, e.g., livestock species diversification in Ethiopia and Kenya; insuring livestock in Pakistan; changes in range management practices in the USA	(Opiyo et al., 2015; Yung et al., 2015; Wako et al., 2017; Rahut and Ali, 2018)
	Fishery related, e.g., non-destructive fishery gears and techniques in Ghana and Tanzania	(Yang et al., 2019a)
Training and capacity building (57 responses)	Information, training and capacity building; e.g., climate information services in Kenya and Senegal; Training contributed new learning about digging canals to avoid prolonged water logging in the Philippines; soil conservation training program in Ethiopia.	(Bacud, 2018; McKune et al., 2018; Chesterman et al., 2019)
Agro-forestry and forestry-related responses (56 responses)	Agro-forestry related measures in India, Kenya, Nigeria, Farmer-Managed Natural Regeneration FMNR in Ghana	(Weston et al., 2015; Pandey et al., 2017; Fuchs et al., 2019; Okunlola et al., 2019)
	Forestry related; e.g., Coastal afforestation by planting salinity-resistant trees in Bangladesh, in Colombia.	(Pandey et al., 2016; Barrucand et al., 2017; Barua et al., 2017)
Economic and financial incentives (54 responses)	Insurance; rice crop insurance program in Indonesia; agricultural insurance program in South Africa.	(Dewi et al., 2018; Elum et al., 2018)
	Micro-finance and credit programs, e.g., in Bangladesh.	(Fenton et al., 2017b)
	Social safety nets; e.g., food-based safety net programs in Brazil, food for work programs in Ethiopia.	(Mesquita and Bursztyn, 2017; Sain et al., 2017; Tesfamariam and Hurlbert, 2017; Gao and Mills, 2018)
	Subsidies and incentives, e.g., farm input subsidy program in Malawi; financing programs in Canada to help producers with resources to improve/maintain the quality of soil, water, biodiversity for drought mitigation.	(Hurlbert, 2014; Kawaye and Hutchinson, 2018)
	Water markets and tariffs; e.g., urban water tariffs in Zaragoza, Spain; informal groundwater markets in China.	(Kayaga and Smout, 2014; Zhang et al., 2016b)
	Payment for ecosystems services, e.g., in Mexico.	(Newsham et al., 2018)
IK and LK based adaptations (41 responses)	Use of traditional knowledge of Konda Reddy's in India to shift agro-forestry practices; and among *Khasia* and Tripura communities in Bangladesh; use of local ecological knowledge is by small-scale fisher-farmers in the Amazon floodplains, Brazil; traditional water sharing system "*bethma*" in Sri Lanka; Indigenous methods of water harvesting in India	(Sarkar et al., 2015; Burchfield and Gilligan, 2016; Kodirekkala, 2018; Ahmed and Atiqul Haq, 2019)
	Non-structural measures for flood management; e.g., changes in day-to-day practices in Indonesia; place-specific social structures in the UK.	(Petzold, 2018; Bott and Braun, 2019)

Flood risk reduction measures include (40 responses)	Structural measures for flood management; improvement of the drainage system in Indonesia; flood walls in Beira, Mozambique; dredging and construction of culverts in Nigeria.	(Bahinipati and Patnaik, 2015; Wijaya, 2015; Egbinola et al., 2017; Spekker and Heskamp, 2017)
	Early warning systems; e.g., flood forecasting in Nepal, Indonesia, Nigeria.	(Ajibade and McBean, 2014; Devkota et al., 2014; Sari and Prayoga, 2018)
	Flood resilient housing; e.g., houses on stilts in Guyana, in Pakistan, Vietnam, Philippines.	(Mycoo, 2014; Ling et al., 2015; Abbas et al., 2018)
	Wetland restoration; e.g., in USA and Netherlands.	(Zevenbergen et al., 2015; Pinto et al., 2018)
Urban water management (22 responses)	Urban water management, e.g., incorporating low impact development and urban design features for sustainable urban drainage systems in Spain and Malaysia; demand management and tariff reforms in several European countries.	(Flyen et al., 2018; Rodríguez-Sinobas et al., 2018; Stavenhagen et al., 2018; Chan et al., 2019)
	Green infrastructure; e.g., ecological stormwater management and re-naturalization processes in Sweden; pavement watering in France, Ghana, India, Kenya, Bangladesh	(Hendel and Royon, 2015; Wamsler et al., 2016; Tauhid and Zawani, 2018; Birtchnell et al., 2019)
	Desalinization for water supplies in Spain	(Martínez-Alvarez et al., 2016; Morote et al., 2019)
Energy related adaptations (8 responses)	Hydropower related; e.g., hydropower benefit sharing in the Mekong basin and Nepal	(Balasubramanya et al., 2014; Suhardiman et al., 2014; Shrestha et al., 2015)
	Other renewable energy-related, e.g., "Raising Water and Planting Electricity project" in Taiwan	(Lin and Chen, 2016)
WaSH related adaptations (5 responses)	Hand washing and hygiene, e.g., provision of latrines and washing hands with soap in Bangladesh	(Dey et al., 2019)
	Safe drinking water and sanitation; e.g., piped water supply, China	(Su et al., 2017)
Any other including coping strategies (20 responses)	Reduction in consumption, selling off assets etc.; e.g., selling of household property and livestock in Nigeria; consumption smoothing in Ghana; reducing consumption in Nepal	(Musah-Surugu et al., 2018; Rai et al., 2019)

Droughts, followed by precipitation variability and extreme precipitation, are the two most common hazards against which adaptation responses are forged. The other three top hazards are general climate impacts, heat-related hazards and inland and riverine flooding (Figure 4.25). The majority of the adaptation responses across all categories were introduced by individuals and households, followed by the civil society, and hence autonomous (Figure 4.26). The private sector (defined as profit-making companies and distinct from individual farmers and households) has played a relatively minor role in initiating adaptation responses. However, the low participation of the private sector in initiating adaptation responses could be partly an artefact of the nature of documentation.

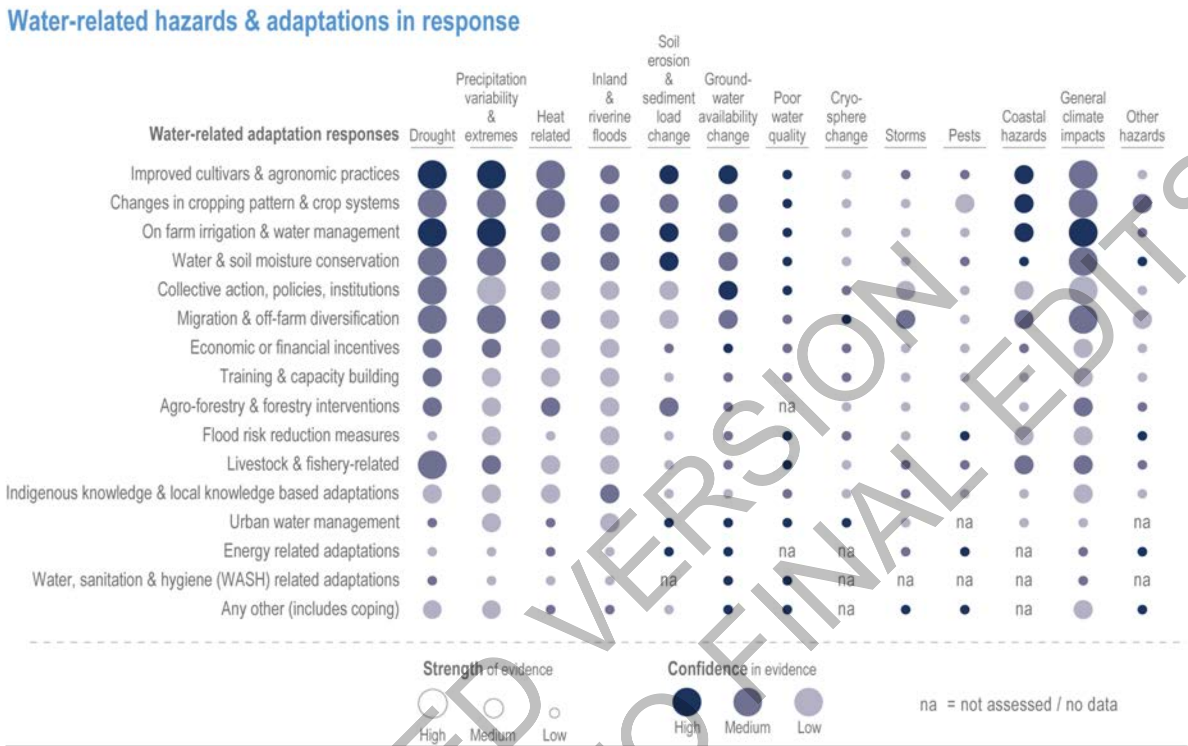

Figure 4.25: Water-related adaptations and climate hazards against which adaptation responses are forged. Evidence and confidence are derived in the same way as in Figure 4.23.

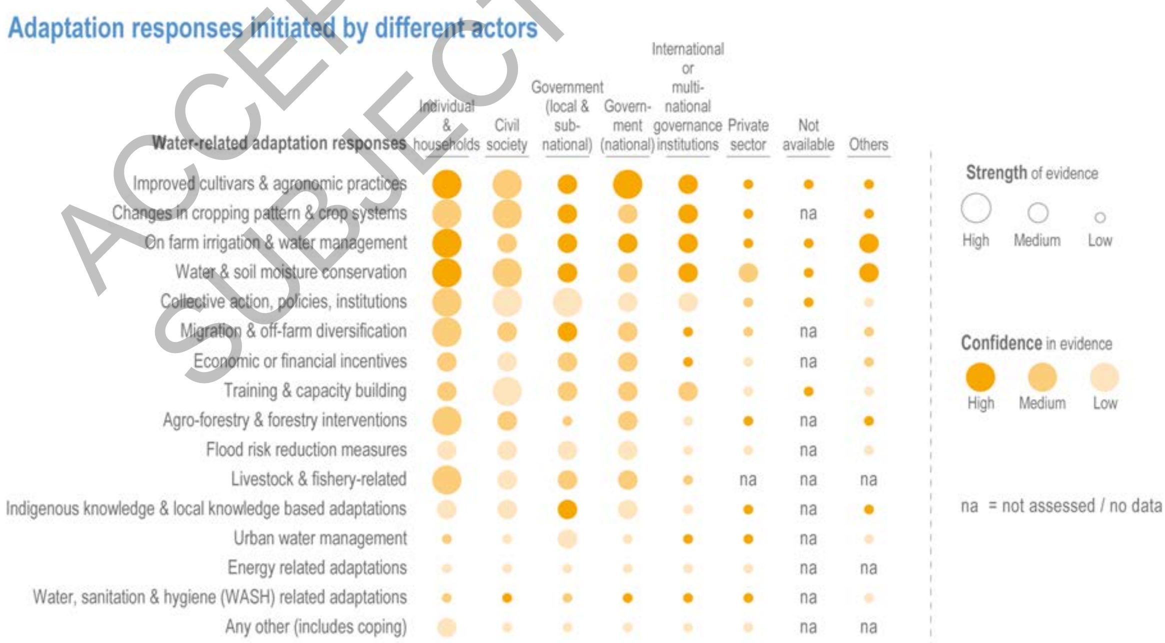

Figure 4.26: Water-related adaptations and their initiators. Initiator of adaptation is defined broadly, and includes the entities who initiates a response, implements that response, or engages in that response in any way, including leading, financing or enabling. Evidence and confidence are derived in the same way as in Figure 4.23.

4.7.1.2 Benefits, Including Co-benefits of Water-related Adaptation Responses and Resulting Maladaptation

There is no consensus in the literature about ways of measuring the effectiveness of current adaptation responses in reducing climate-related impacts (Singh et al., 2021). However, various methodologies, including feasibility assessment, has been deployed (Williams et al., 2021). Given the methodological challenges in defining and measuring the effectiveness of adaptation in reducing climate risks, in this section, we focus on outcomes of water-related adaptation across several dimensions. A total of 359 studies were identified to contain sufficiently *robust evidence* of documented adaptation outcomes to form the basis of this assessment (SM4.2, Table SM4.5, (Berrang-Ford et al., 2021a; Mukherji et al., 2021)). Positive outcomes denote benefits of adaptation, while negative outcomes may mean that adaptation wasn't effective in bringing any benefits or that it was maladaptive (Schipper, 2020).

We assess outcomes across five indicators: a) economic and financial indicators, such as improvements in crop yields and resulting incomes; increase in profits, higher savings, or lesser losses from hazards; b) impacts on vulnerable people, e.g. on women, children; Indigenous Peoples; c) water-related impacts, e.g. improved water use efficiency, water saving, reduction in water withdrawals and application; d) ecological and environmental impacts such as lesser energy use, better soil structures, and better thermal comfort.; e) institutional and socio-cultural impacts such as improved social capital and stronger communities of practice, equity; and strengthening of local institutions or national policies. Of these 359 studies, 319 documented beneficial outcomes across one or more indicators, while the remaining 40 presented no beneficial outcomes. Illustrative examples are shown in Table 4.9, while the distribution of these responses with positive outcomes are shown in Figure 4.27, and indicates that economic benefits of adaptation are more common in developing countries, while benefits along ecological dimensions are more common in the developed countries,

Table 4.9: Illustrative examples of adaptation responses and their benefits across different outcome indicators. All these studies are either category 1 or category 2 studies in that the link between adaptation response and the outcome is either causal or correlated with one another. These benefits notwithstanding, links of adaptation benefits to climate and associated risk reduction are not always clear. Some of these adaptation responses can have beneficial outcomes in one of the five parameters but can have maladaptive outcomes in others.

Hazard	Adaptation responses	Outcome category	Adaptation outcome	Reference
Droughts, floods, and general climate impacts in Nepal	Improved crop cultivars, agronomic practices, irrigation, soil water conservation measures	Economic and financial outcomes	Farming households that adapted produced about 33% more rice than households that did not adapt after controlling for all heterogeneity.	(Khanal et al., 2018a)
Increased rainfall variability in India	Farmer's training on agronomic measures, e.g., alternate drying and wetting AWD, modified system of rice intensification MSRI and direct-seeded rice DSR		The capacity building and water-saving increased crop yields by 960kg/ha, 930 kg/ha and 770 kg/kg through the adoption of AWD, MSRI and DSR, respectively. The three practices have increased farmers' income and decreased the cost of cultivation by up to US$169/ha.	(Kakumanu et al., 2019)
Droughts and changes in the seasonality of rainfall in Pakistan	Adjusting sowing time of wheat		Household income and wheat yields were higher for households who adjusted the sowing time to cope with climate risks than those who did not, after controlling for other factors.	(Rahut and Ali, 2017)

Droughts in North China Plains	Irrigation		Adding one extra irrigation could increase wheat yield by up to 12.8% in a severe drought year.	(Wang et al., 2019a)
Soil degradation; extreme rainfall events high run-off causing erosion in Mali	Soil and water conservation using contour ridges and improved millet and sorghum cultivars		Millet grain yield in 2012-14 was statistically higher in contour ridge terrace plots than the control, with yield differences ranging from 301kg/ha in 2012 to 622 kg/ha in 2013. Improved varieties produced on average 55% more yield than the local ones.	(Traore et al., 2017)
Drought, floods, hailstorm and erratic rainfall, Ethiopia	On-farm agricultural water management		The net revenue from adopting a combination of agricultural water management and modern seeds or inorganic fertilizer is significantly higher by 7600 and 1500 Birr/ha respectively than adopting modern seeds or inorganic fertilizer alone. Birr is the Ethiopian currency.	(Teklewold et al., 2017)
Droughts and general climate impacts, South Africa	Crop insurance and irrigation		Farmers who insured their farm business, and had access to irrigation, had relatively higher net revenue than those who did not, but this link is not causal. Instead, it shows causality could go either way, including those farmers who were better off getting their business insured.	(Elum et al., 2018)
Droughts and floods in Kenya	Migration		Remittance income enables uptake of costlier adaptation measures such as a change in livestock species, which also have higher returns for households. Therefore, the study was not causal in its inference.	(Ng'ang'a et al., 2016)
Droughts in Nigeria	Drought-tolerant varieties		Per capita, food expenditure of those who adopted drought-tolerant maize was significantly lower than those who did not after controlling for everything else and causal inference.	(Wossen et al., 2017)
General climate impacts, including rainfall variability in Brazil	Agro-forestry systems as land use in rural municipalities		The land value in the municipalities with agro-forestry was higher than that of the municipalities where the agro-forestry scheme was not implemented.	(Schembergue et al., 2017)
Water quality deterioration due to floods in Bangladesh	Water, sanitation and health WaSH program	Outcomes for vulnerable people	Children: Prevalence of childhood diarrhoea reduced by 35% in midline prevalence 8.9% and by 73% in end line prevalence 3.6% compared to baseline prevalence 13.7%. Inferences are causal.	(Dey et al., 2019)
Droughts in Zimbabwe	Adoption of drought-tolerant maize varieties by smallholder farmers		Smallholder farmers: Smallholder farmers practising conservation agriculture CA were as likely to adopt drought-tolerant maize varieties as other farmers and thus benefit from increased yields and incomes.	(Makate et al., 2019)
General climate impacts, including	Crop diversification		Poor households: Crop diversification mainly benefits the most vulnerable households; the impact on the poorest group ranges from double to triple the impact on the wealthiest group.	(Asfaw et al., 2018)

droughts in Niger				
Droughts and general climate impacts in Malawi and Zimbabwe	Conservation agriculture; drought-tolerant maize and improved legume varieties		Female farmers: Yield and income effects on the adoption of conservation agriculture and improved varieties of maize and legumes were both positive for men and women	(Makate et al., 2019)
Historically widespread and severe droughts in Ethiopia in 1999, 2002, 2003, 2005 and 2008.	Government safety net program called Productive Safety Net Program PSNP		Poor households: PSNP transfers reduce chronic poverty level from 15.7% to 10.6% and increase the never poor share from 11.5% to 15.8%.	(Gao and Mills, 2018)
Droughts in Kenya	Water harvesting structures, e.g., sand dams	Water-related outcomes	Sand dams increase groundwater storage in riverbanks by up to 40%, which is maintained throughout the year	(Ryan and Elsner, 2016)
Millennium drought in Australia	Water trading		Irrigation application rates fell in the dairy industry from 4.2 million litres/ha in 2000–2001 to 3.5 million litres/ha in 2005–2006	(Kirby et al., 2014)
Droughts, floods, and soil erosion and sediment load in a river basin in France	Agreement signed between water and electricity utilities and farmers		Agreement between water and electricity utilities to compensate farmers for reducing water use resulted in a decrease in water demand from 310 Mm^3 in 1997 to 220 Mm^3 in 2012 in the Durance Valley irrigation system in France	(Andrew and Sauquet, 2017)
Drought in India	The reducing area under irrigated rice crop		Reduced rice irrigation resulted in over 60 mm/ha of water savings compared to irrigated rice crops on that land.	(Hochman et al., 2017b)
Floods due to cyclonic storms and tidal inundation in Bangladesh	Planting of vetiver grass for stabilizing coastal embankments	Ecological and environmental outcomes	Households who planted vetiver grass around their homestead and nearby road managed to save their houses and assets from the recent cyclonic storm and tidal inundation	(Barua et al., 2017)
General climate impacts, including rainfall variability in Brazil	Agro-forestry systems as land use in rural municipalities		Trees planted as a part of the agro-forestry program provide thermal comfort to both animals and humans	(Schembergue et al., 2017)
Drought in 2015 in Ethiopia	Contour ridge terraces as soil water conservation measure		Contour ridge terraces primarily controlled water run-off and soil erosion and acted as a buffer during the 2015 Ethiopian drought	(Kosmowski, 2018)
Drought and rainfall variability in Pakistan	Climate-smart agricultural practices	Institutional and socio-cultural outcomes	Farmers who adopted climate-smart practices also tended to form a better relationship with local extension agents and reached out to them more frequently. Again, however, causality might as well lie the other way round.	(Imran et al., 2019)
Droughts, Mexico	Strengthening of local water users' associations through external assistance programs		Local water user's associations were able to reduce water abstractions during years of severe droughts.	(Villamayor-Tomas and García-López, 2017)

Rainfall variability in Niger	Community-based adaptation and through adaptation learning programs	More robust social networks where women were able to take important decisions.	(Vardakoulias and Nicholles, 2015)

Figure 4.27: Top panel: location of case studies of water-related adaptation responses (996 data points from 319 studies). In these 996 data points, at least one positive outcome was recorded in one of the five outcome indicators. These outcome indicators are economic/financial, outcomes for vulnerable people, ecological/environmental, water-related, and socio-cultural and institutional. Middle panel: the top six documented adaptation options per region as a fraction of the total of reported studies, with grey bars containing the share of all other adaptation responses. In most instances, the top six adaptation categories include nearly 3/4th of the studies. Bottom panel: The spider diagrams show

the number of studies reporting beneficial outcomes for one or more dimensions for the top six adaptation options identified in each region. Due to a small number of studies in small island states, a spider diagram was not generated for the Small Island States.

Co-benefits are defined as mitigation benefits resulting from an adaptation response (Deng et al., 2017). Around a quarter of papers that documented positive adaptation outcomes also reported mitigation co-benefits. Agro-forestry, community forests and forest-based adaptations are the most oft-cited examples of mitigation co-benefits ((Bhatta et al., 2015; Etongo et al., 2015; Weston et al., 2015; Pandey et al., 2017; Sain et al., 2017; Sánchez and Izzo, 2017; Wood et al., 2017; Adhikari et al., 2018a; Hellin et al., 2018; Aniah et al., 2019; Quandt et al., 2019), also see Box 5.11). Other examples include mitigation benefits of climate-smart agricultural practices that reduce input intensity and helps in carbon sequestration (Arslan et al., 2015; Somanje et al., 2017); retrofitting buildings in urban areas with energy-efficient devices for lowering electricity bills and emissions (Fitzgerald and Lenhart, 2016) and re-use of treated wastewater for irrigation and urban uses (Morote et al., 2019) (Box 4.5, 4.7.6,).

Not all adaptation responses reduce risks, and some may have long term maladaptive outcomes, even if they are beneficial in the short term. Maladaptation often stems from poor planning and implementation of adaptation responses and because of not addressing the root causes of vulnerability (Schipper, 2020; Eriksen et al., 2021). Of the 319 case studies where adaptation response was found to have some beneficial outcomes, around 1/3rd of them also mentioned the possibility of maladaptation. Migration can often have maladaptive outcomes because migration can exacerbate the inherent vulnerabilities of migrants (4.6.8). For example, slum dwellers in cities may earn higher incomes, but their quality of life worsens (Ayeb-Karlsson et al., 2016). In some instances, even wage rates in migration hotspots can remain low due to the high volume of the migrant population (Fenton et al., 2017b); as such, it does not help buffer consumption against rainfall shocks (Gao and Mills, 2018). Migration also has gendered impacts, with girls from migrating families being taken out of school (Gioli et al., 2014) or interrupting children's education overall (Warner and Afifi, 2014). In planned relocation from vulnerable urban slums, relocation sites can be far from job sites and increase social conflicts (Tauhid and Zawani, 2018).

Adaptation responses that focus on improving incomes through production intensification can have maladaptive outcomes. An oft-cited example of this is groundwater over-use as a result of irrigation intensification. There is widespread evidence of groundwater over-use in many countries in Africa (Mapfumo et al., 2017) and in the Middle East and North Africa (Petit et al., 2017; Daly-Hassen et al., 2019); in Asia (Burchfield and Gilligan, 2016; Zhang et al., 2016b; Kattumuri et al., 2017), in Spain (Petit et al., 2017) and Australia (Kirby et al., 2014) (4.2.6, 4.6.2, Box 4.3). Intensification based approaches also increase costs of cultivation (Mussetta et al., 2016; Wang and Chen, 2018; Quan et al., 2019), can lead to more use of fertilizers and herbicides (Thierfelder et al., 2015; Sujakhu et al., 2016; Khanal et al., 2018a; Yamba et al., 2019). Diversification away from food crops can also compromise domestic food security (Kloos and Renaud, 2014; Brüssow et al., 2017).

Even interventions that have positive carbon co-benefits like forestry and agro-forestry can have maladaptive consequences on land and water resources, especially if inappropriate species (Etongo et al., 2015) with higher water demands are grown (Krishnamurthy et al., 2019) (4.7.6).

In summary, current adaptation responses have benefits across several dimensions. In developing countries, most adaptation measures improve economic outcomes (*high confidence*). Adaptation responses also have benefits in terms of water outcomes and environmental and ecological parameters, and these benefits are more commonly manifested in developed countries (*high confidence*). Of the papers assessed for water-related adaptation, roughly 1/4th reported adaptation co-benefits (*high confidence*). In contrast, 1/3rd of studies reported maladaptive outcomes, now or in the future (*high confidence*), underscoring the importance of looking at synergies and trade-offs. Despite many adaptation case studies, there is a knowledge gap in understanding if the benefits of adaptation also translate into a reduction of climate impacts, and if so, to what extent, and under conditions (*high confidence*). In view of this critical knowledge gap, our assessment is limited to benefits of current adaptation responses.

4.7.2 Projections of Future Effectiveness of Adaptation Responses

Several adaptation options have been shown to have beneficial effects on societally relevant outcomes under current climate conditions (4.7.1.2) and will remain critical to adapt to future climate change. However, there is limited quantitative information on the future viability of available responses to reduce projected climate impacts effectively. However, the context-specific nature of adaptation on the ground and the uncertainties associated with future climate outcomes, both in terms of policy decisions around mitigation and model-inherent uncertainties, make long-term projections of adaptation effectiveness of limited use for decision-making on the ground. However, such projections are still needed to understand the efficacy of current technical and managerial solutions to reduce climate risk. Consequently, an increasing body of literature focuses on the effectiveness of specific interventions to reduce projected climate risks in a local to regional setting.

This section provides a quantitative aggregate assessment of effectiveness of projected water-related climate adaptations at different levels of GWLs (SM4.2). Effectiveness is defined as the potential of a given adaptation measure to address projected changes in climate and return the system under analysis to baseline conditions. If the measure cannot fully compensate for the projected climate risk, residual risks remain, defined as the fraction of risk remaining after adaptation. For example, in many regions, projected temperature-driven yield loss can be reduced by shifting to or increasing irrigation. However, yields often do not always fully return to baseline conditions without climate change, leaving residual risk after adaptation. Assessed option are limited to technical solutions, which have quantitative entry-points to global climate impact models.

Most adaptation projections focus on water-related interventions in the agricultural sector, including irrigation-related responses, shifting planting dates, changing crops and cultivars, and water and soil conservation. Sectoral projections of adaptation effectiveness are limited in forestry and agro-forestry related responses, flood protection measures (excluding here options that are solely related to effects of sea-level rise), urban water-related adaptation as well as energy-related responses. The majority of assessed studies focus on comparing different variations of one or several response options in terms of timing or duration, for example, a shift in planting dates of 10 days and 20 days, relative to present-day practice and provide results for a range of scenarios and (or) timeframes.

A total of 45 studies were identified for this assessment, based on their quantitative assessment of the effects of adaptation on projected impacts (SM4.2 for the method of future projected effectiveness assessment). From each study, the distinct combinations of specific variations of adaptations, scenarios and timeframes assessed were considered as individual data points, providing a total of 450 unique data points for the assessment (Table SM4.6). The study-specific temperature increase was classified relative to the 1850-1900 baseline for each data point, based on the model and scenario specifications provided and grouped into outcomes at 1.5°C, 2°C, 3°C and 4°C. The effectiveness is assessed based on the fraction of risk that an option can reduce. Co-benefits are defined as a situation where outcomes improve relative to baseline conditions, whereas maladaptive outcomes describe a situation where risks increase after adaptation has been implemented.

Several studies assess the future effectiveness of improved cultivars and agronomic practices, such as changing fertilizer application or switching to drought-resistant crops (5 studies; 85 data points). Results show a range of effectiveness levels across regions and warming levels and vary depending on the tested response options (Qin et al., 2018) (Figure 4.29), with moderate to small effectiveness, large residual impacts or potential maladaptive outcomes as well as decreasing effectiveness with increasing warming (Figure 4.28) (*high confidence*). For studies testing results across a range of scenarios, approaches show increasingly mixed (Qin et al., 2018) and limited effects (Amouzou et al., 2019) with higher warming, with overall reductions across warming levels for most tested responses (Qin et al., 2018).

Changes in cropping patterns and crop systems (Figure 4.28) (5 studies; 31 data points) indicate limited potential to reduce projected climate risks, with the majority of studies providing results of up to 1.5°C of warming and limited evidence for higher warming levels. At 1.5°C, effectiveness in Africa is mostly insufficient, with substantial maladaptive potential (Brouziyne et al., 2018). Over Asia, effectiveness is mostly small at 1.5°C with substantial residual impacts, further reducing to insufficient effectiveness at large residual risks at 4°C (Figure 4.28 Projected effectiveness) (*robust evidence; medium agreement*) (Boonwichai et al., 2019; Dai et al., 2020; Mehrazar et al., 2020). Amongst the options related to changes in cropping patterns and crop systems, shifting planting dates is projected to retain moderate to high residual risks under some specifications in Iran (Paymard et al., 2018) and Morocco (Brouziyne et al., 2018), while high effectiveness is reported for similar specifications in Thailand (Boonwichai et al., 2019), Australia (Luo et al., 2016), Morocco ((Brouziyne et al., 2018) and Iran (Mehrazar et al., 2020). Of the assessed adaptation options, changes in cropping patterns and cropping systems appear least effective in reducing climate risk, with decreasing effectiveness at higher levels of warming.

Studies assessing the future effectiveness of irrigation related responses (Figure 4.28) focus on a range of specific approaches, including increasing irrigation efficiency, deficit irrigation, irrigated area expansion or shifting from rain-fed to irrigated agriculture, as well as specific types of irrigation (21 studies; 103 data points). As a frequently implemented option with direct entry points to agricultural models, this option provides the most robust set of data points across regions and warming levels. For all regions, a reduction in effectiveness is apparent from 1.5°C to higher levels of warming, leading to increased residual risk with increasing warming (*high confidence*). Irrigation can increase yield relative to present-day, showing co-benefits for some regions, though the share of co-benefits decreases with higher warming (*high confidence*) (Figure 4.28). However, since many of these studies rely on global agricultural models and these do not fully represent the actual availability of water, further expansion of irrigation at the scale assumed in those studies may not be realistic (4.3.1.2. 4.3.1.3) (Elliott et al., 2014).

A wide range of water and soil management-related options (Figure 4.28), including mulching, no tilling, or contour farming, has been assessed for future effectiveness (8 studies; 49 data points). Results underline the context-specific nature and need to carefully adjust the specific options to a regional setting, with variations of options leading to effective outcomes or residual impacts within individual studies (Qiu et al., 2019) and across regions and warming levels.

Similar to observed adaptation, studies assessing combinations of the agricultural adaptation options outlined above (11 studies; 36 data points) show the highest effectiveness across agricultural adaptation outcomes and generally project moderate to high effectiveness with the potential for co-benefits (Figure 4.28). Though maladaptive outcomes are also documented, residual risks are limited, also at higher levels of warming. Therefore, developing integrated plans of synergistic options linked to adequate monitoring and evaluation approaches and designed to adjust to changing conditions continuously is desirable to minimize climate risk and ensure food security (Babaeian et al., 2021).

Globally, agro-forestry related adaptation (4 studies; 18 data points) is moderate to highly effective, with the potential for substantial co-benefits at 1.5° and 2°C of warming, with a sharp decline in effectiveness at 3°C and 4°C and a substantial increase in residual risk and maladaptive outcomes (Figure 4.28).

Flood risk related adaptation (4 studies; 47 data points) is associated with the potential for substantial co-benefits relative to present-day flood risk, indicating a current adaptation gap larger than for other impact areas. These co-benefits decline with increasing warming. Limits to the tested options become increasingly apparent at 3°C and 4°C of warming, where residual risks increase for most assessed cases (Figure 4.28).

Adaptation projections for urban water risks as well as the energy sector are limited to one study each, with one data point for urban adaptation (Rosenberger et al., 2021) and 80 data points for different variations of adaptation outcomes across regions and scenarios for the energy sector (van Vliet et al., 2016c). Sustainable stormwater management, focusing on a combination of nature-based solutions, is shown to be highly effective and yields co-benefits at 3°C. However, these results were gained in a specific case study setting in a European city with limited generalizability (Figure 4.28).

The assessment of adaptation in the hydropower and thermo-electric power-generation sector indicates high effectiveness and co-benefits across all regions for 1.5°C, with decreasing effectiveness and increasing residual risks for 2°C and 3°C of warming and highest reductions in effectiveness for Central and South America (Figure 4.28).

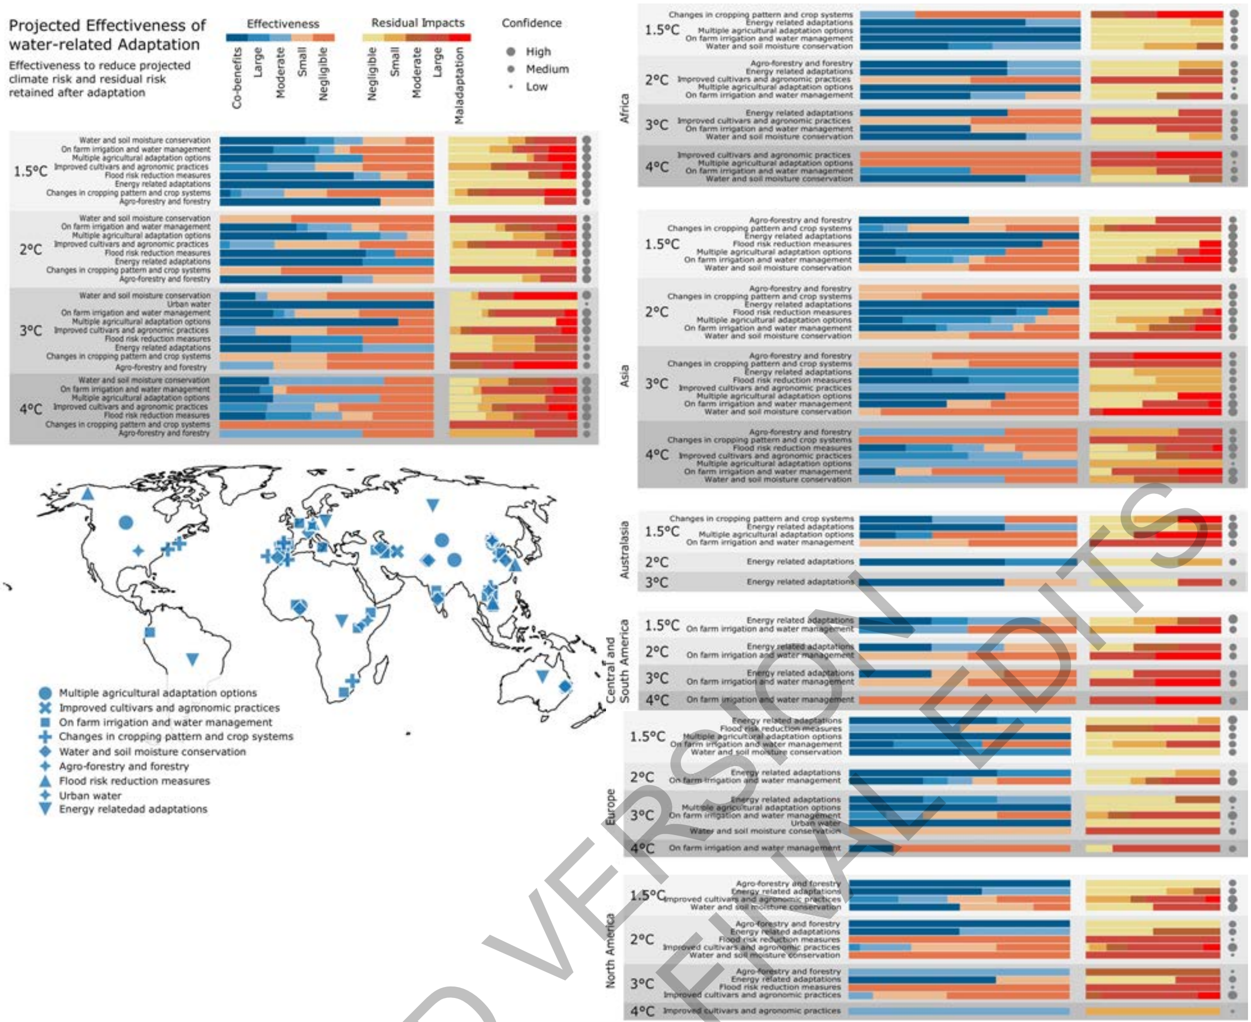

Figure 4.28: Projected effectiveness of adaptation options in returning the system to a study-specific baseline state relative to the projected climate impact; and level of residual risk retained after adaptation, relative to baseline conditions. Regional summaries are based on IPCC regions. Warming levels refer to the global mean temperature (GMT) increase relative to a 1850-1900 baseline. For each data point, the study-specific GMT increase was calculated to show effectiveness at 1.5°C, 2°C, 3°C and 4°C. Based on the ability of an implemented option to return the system to its baseline state, the effectiveness is classified based on the share of risk the option can reduce: Large (>80%); Moderate (80-50%); Small (<50-30%); Insufficient (<30%). Where the system state is improved relative to baseline, Co-benefits are identified. Residual impacts show the share of remaining impacts after adaptation has been implemented: Negligible (<5%); Small (5 to <20%); Moderate (20 to <50); Large (50% and more). Where risks increase after adaptation, data points are shown as maladaptation. All underlying data is provided in Table SM4.6.

Quantitative projections of future adaptation depend on available impact models to analyze the effect of specific adaptation interventions. However, since not all possible future adaptation responses can be incorporated in climate impact models, this is a major limitation to assessing the full scope of options available in the future. For example, many frequently implemented measures showing effective outcomes, such as behavioral and capacity building focused responses or migration and off-farm diversification (4.7.1.2), are not incorporated in quantitative water-related climate impact projection models. In addition, projections of future adaptation depend on currently available technologies or approaches, but new methods and technologies will probably emerge. Thus, improving the representation of adaptation in future projections is a significant knowledge gap that remains to be addressed.

Whether specific adaptation responses are shown to be effective and even lead to co-benefits or are associated with residual impacts is highly contextual, location and crop-specific. In addition, the specific climate-impact-scenario combinations play an important role in determining assessed outcomes.

In practice, responding to increasing climate risk will need to be context-specific and sufficiently agile to respond to ever-changing realities on the ground. The adaptive pathways approach underline that a sequence of different options responding to climate change over time may be most effective (Babaeian et al., 2021). In addition, impact models generally underestimate or underrepresent climate extremes (Schewe et al., 2019), limiting the ability of the present analysis to reflect adaptation requirements to extremes, which are likely to push systems to their limits (4.7.4). While currently known structural adaptation responses can reduce some of the projected risks across sectors and regions, residual impacts remain at all levels of warming, and effectiveness decreases at higher levels of warming. Adaptation generally performs more effectively at 1.5°C, though residual damages are projected at this warming level across sectors and regions (*high confidence*). A range of options also shows the potential for further increasing negative effects (maladaptation) across sectors, regions, and warming levels, further underlining the need for contextualized approaches.

4.7.3 Comparing Current and Future Water-related Adaptation Responses

Water-related adaptation is being observed across sectors and regions (4.6), and beneficial outcomes are documented across different dimensions (4.7.1). A limited set of frequently documented adaptation responses is also represented in quantitative projections of adaptation effectiveness (4.7.2, Figure 4.29). However, due to the largely different assessment methodologies for measuring beneficial outcomes for current adaptations and effectiveness to reduce impacts for future adaptations, comparing current and future adaptation outcomes is not straightforward. For current adaptation responses, beneficial outcomes may or may not translate to climate risk reduction, making risk reduction potential of observed adaptation a significant gap in our current understanding. The large diversity of outcomes across regions and assessed options becomes apparent for future adaptation options, with the group of 'inconclusive' outcomes indicating a large spread of results across regions. This underlines the contextual nature of adaptation and boundary conditions for implementation that can determine the success of adaptation outcomes, now or in the future.

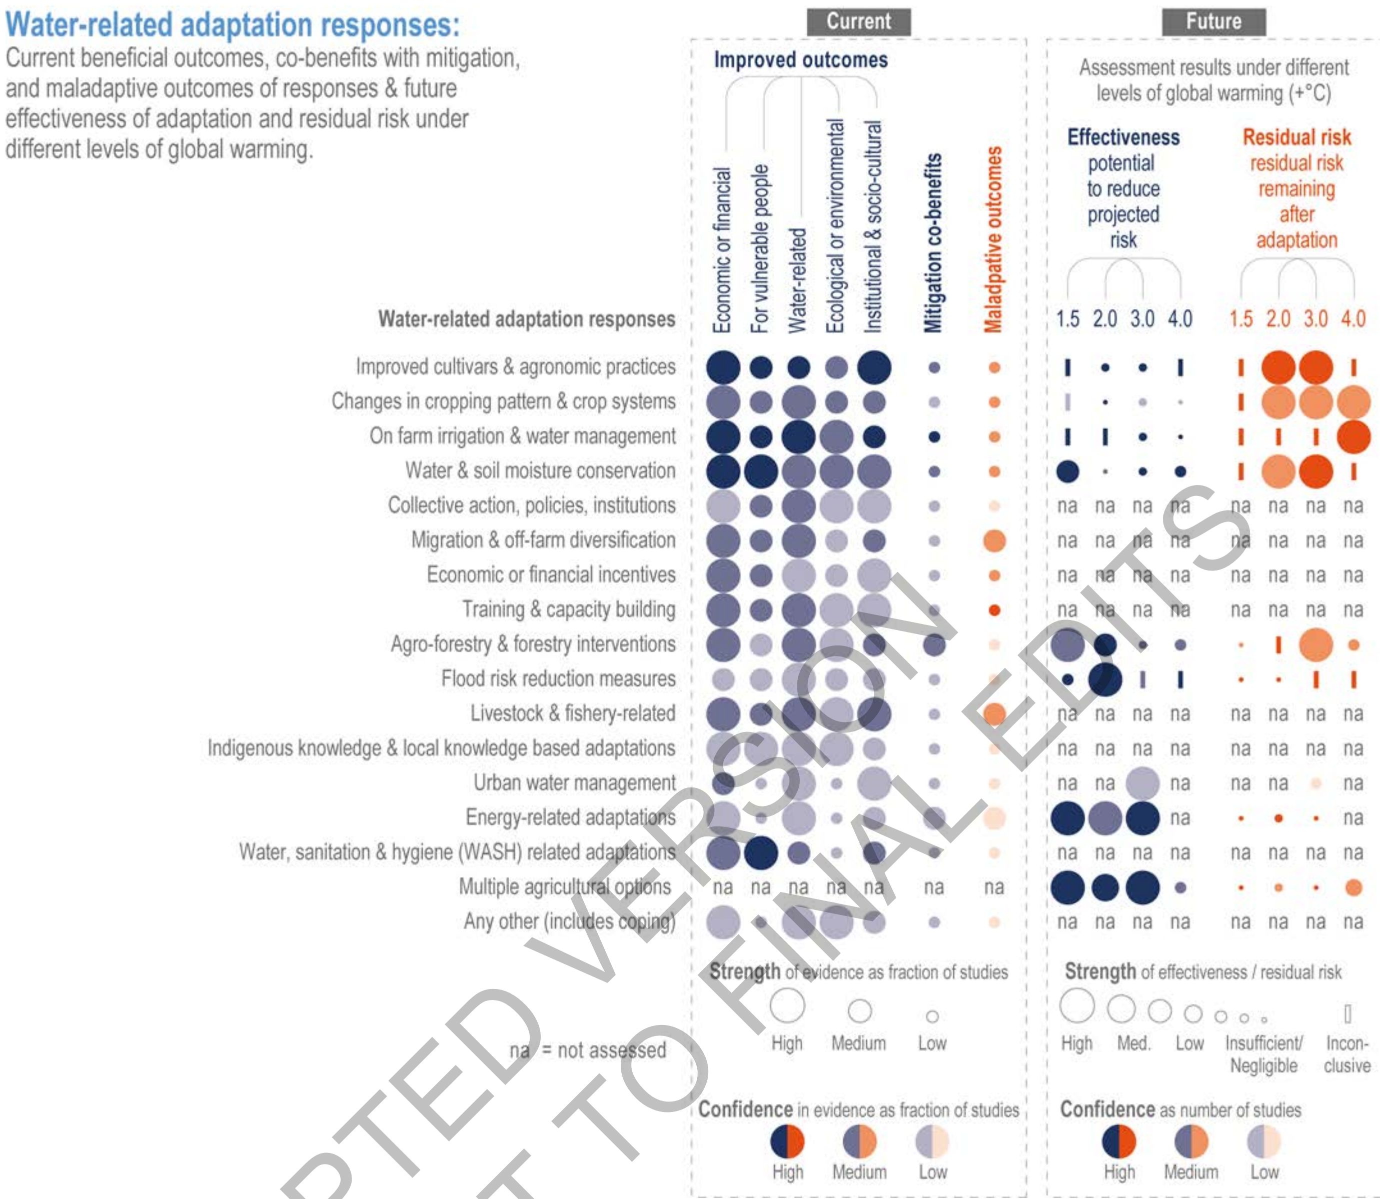

Figure 4.29: Panel on the left side shows observed benefits of adaptation. Observed outcomes are reported across five dimensions of benefits, co-benefits as well as maladaptation outcomes. Benefits are measured across five dimensions. Strength of evidence is high if >80% of adaptation responses in that category has at least one beneficial outcome; medium if between 50-80% of adaptation responses in that category has at least one beneficial outcome, and low if <50% of adaptation responses have at least one beneficial outcome. Confidence in evidence relates to the way the article links outcomes of adaptation with the adaptation response. Category 1: studies causally link adaptation outcomes to the adaptation response by constructing credible counterfactuals; Category 2: studies correlate responses and outcomes without causal attribution; Category 3: studies describe adaptation outcomes without making any causal or correlation claims between adaptation outcomes and adaptation responses. *High confidence*: more than 67% of the studies fall in categories 1 and 2; *medium confidence*: 50-67% of the studies are in categories 1 and 2, and *low confidence* is less than 50% of studies are in categories 1 and 2. The panel on the right-hand side shows the effectiveness of future adaptations. Future outcomes are assessed in terms of their effectiveness to reduce climate impacts at 1.5°C, 2°C, 3°C and 4°C of global temperature increase relative to 1850-1900. Effectiveness is defined as the fraction of adaptation that the option is able to reduce; residual risks is the fraction of risk remaining after adaptation. If>66% of assessed data points agree on the effectiveness class, a response-temperature combination is shown as belonging to that class. Where results diverge, the result is inconclusive, with studies showing high and low effectiveness across regions and studies. Confidence is based on the number of data points available for each response-temperature combination with *high confidence*: 5 or more data points; *medium confidence*: 2-4 datapoints; *low confidence*: 1 datapoint. Also, see Figure 4.28 for further explanations and Tables SM4.5 and SM4.6 provide underlying data.

Documented implemented adaptations show several beneficial outcomes, with most studies (319 of 356) documenting positive rather than negative outcomes. However, there may be a positive reporting bias in the literature, as positive outcomes are more likely to be reported than negative ones. Also, positive outcome in one parameter does not preclude negative outcomes in others, so maladaptation is still possible even when an adaption has some positive benefits (4.7.1.2). In addition, much of the adaptation happening on the ground may not be published in peer-reviewed publications and, therefore, not covered by the literature assessed in this report. Further, there is limited knowledge about the effectiveness of current adaptation in reducing climate-related risks due to documentation and methodological challenges elaborated in 4.7.1.2 (SM4.2).

In contrast, evaluating the effectiveness for future projected adaptations is methodologically possible (4.7.2, and SM4.2), but every adaptation that is happening now cannot be modelled for the future. Therefore, projections of future adaptation effectiveness are limited to those options that can be incorporated into (global) quantitative climate impact models. Unfortunately, an extensive range of options, such as capacity building or training, migration and employment, which are essential building blocks in the portfolio of available (water-related) adaptation options, are currently not quantitatively represented in adaptation projections. In addition, the future will probably bring further development in technical solutions, which are currently also not modelled. While implementing the modelled technical options may be feasible in general, several barriers and constraints (4.7.4) and enabling conditions, which influence adaptation action in practice, are not included in current modelling studies. Therefore, the modelling studies may present optimistic assessments of adaptation effectiveness for the future.

Adaptations that are beneficial now (e.g., crop and water-related ones) are also projected to be effective to varying extents in reducing future risks, with the degree of effectiveness strongly depending on future GWLs. For example, beyond a certain level of warming (2°C and upwards), the effectiveness of most options is projected to reduce, and residual impacts are projected to increase. Reduction in the effectiveness of future adaptation at higher global warming levels underscores the need for limiting warming to 1.5°C, as space for adaptation solution starts to shrink beyond that for most options for which future projections exists (*high confidence*).

To sum up, there are two significant knowledge gaps in our understanding of water-related adaptations. First, the nature of literature on current adaptation makes it challenging to infer their effectiveness in reducing climate risks, even though the benefits of adaptation are clear (*high confidence*). Second, not all adaptation responses that are possible in the future can be modelled because of inherent limitations to what can be modelled. Thus, advancement in tools and metrics for measuring the effectiveness of current adaptation in reducing climate risks and suitable downscaled climate and impact models that incorporate economic, social, cultural and management aspects for an extensive range of future adaptation options is needed.

4.7.4 Limits to Adaptation and Loss and Damage

The core constraints identified in AR5 (Klein et al., 2014) for freshwater-related adaptation were lack of governance, financial resources and information, while water availability was singled out as a core constraint to diversifying options for water-dependent sectors. SR1.5 showed that increasing aridity and decreased freshwater availability, including limited groundwater supply in fossil aquifers in conjunction with rising sea levels may pose hard limits to adaptation for Small Islands (Roy et al., 2018). SR1.5 also shows that water-related risks can be reduced substantially by limiting warming to 1.5°C (*high confidence*) (Hoegh-Guldberg et al., 2018), thereby also reducing the potential to reach hard limits to adaptation. SROCC highlighted that several barriers and limits to adapt to reduced water availability in mountain areas, such as lack of finance and technical knowledge (Hock et al., 2019b). The SRCCL further highlighted the critical importance of water-related climate change adaptation, and potential limits to adaptation in the land sector, when extreme forms of desertification lead to a complete loss of land productivity *(high confidence)* (Mirzabaev et al., 2019).

Institutional constraints, including path-dependency and lengthy decision-making processes, remain major limitations to successful adaptation globally *(high confidence)* (Barnett et al., 2015; Oberlack, 2017), as well as for the water sector (Kingsborough et al., 2016; Oberlack, 2017; Azhoni and Goyal, 2018). For example, a lack of institutional support has limited the ability of farmers to implement adaptation, even if information about the benefits is acknowledged (Nambi et al., 2015). A lack of inter-sectoral coordination and communication within institutions and conflicting interests between water sectors limit the potential for integrated policies. For all water related adaptation options, which have shown to be effective in one or more dimensions (4.7.1.2), governance and institutional constraints were identified to be the most commonly encountered to a moderate or significant extent (Figure 4.30). Water-energy-food-nexus approaches can help overcome these inter-sectoral barriers (Box 4.8) (Rasul and Sharma, 2016; Ernst and Preston, 2017). In addition, trade-offs between different policy goals must be considered to ensure the broader significance of the implemented adaptation strategies, such as water quality implication of adaptation efforts in the agricultural or energy sectors (4.7.6) (Fezzi et al., 2015).

The lack of financial and technological resources constrains adaptation implementation (Castells-Quintana et al., 2018; Iglesias et al., 2018) and were identified as significant or moderate across all water-related adaptation responses, with significant constraints especially present in options related to the agricultural sector (Figure 4.30). For example, financial resources were significant constraints to implementing Climate Smart Agriculture in Guatemala, a relevant adaptation strategy to improve food security, resilience, and low emission development (Sain et al., 2017).

While financial barriers played an important role in adopting new technologies at the farm level in Spain, acceptance, common understanding and awareness were amongst the most frequently identified barriers across different adaptation options (Esteve et al., 2018). Limitations in knowledge and understanding of complex processes, feedback effects and interconnections in the water sector pose challenges to effective adaptation and adaptation decision-making (Kundzewicz et al., 2018). Such constraints are identified as moderate across the range of options assessed in this chapter (Figure 4.30). For tropical and mountainous regions and the African continent, in particular, significant uncertainties in available data and a lack of reliable climate projections remain one of the biggest obstacles in long-term adaptation planning (Antwi-Agyei et al., 2015), especially in the water sector (Watson et al., 2017; Azhoni and Goyal, 2018; Hirpa et al., 2018; González-Zeas et al., 2019). There is also often a discrepancy between the level of awareness among different stakeholders, for example, between affected farmers whose agency is limited by the lack of knowledge by local authorities (Chu, 2017).

For some regions of the world, such as Small Islands (Karnauskas et al., 2016; Karnauskas et al., 2018) (Box 4.2) and the Mediterranean (Cross-Chapter Paper 4) (Schleussner et al., 2016), aridity increases have the potential to pose hard adaptation limits. In mountain and polar regions, changes in the cryosphere (4.2.2, 4.4.2) may limit water availability for irrigation systems that depend on melt-water (4.5.1) (Qin et al., 2020). Biophysical limits may also be reached through impacts of hydrological extremes, such as crop loss as a consequence of extreme precipitation events (Huggel et al., 2019; van der Geest et al., 2019). Such limits are reported to a limited to moderate extent across all adaptation options assessed (Figure 4.30). However, knowledge gaps remain about physical and biological constraints to adaptation in the water sector. Climate impacts, such as droughts in East Africa or glacier melt in the cryosphere, indicate that biophysical limits to adaptation may exist, even under current climate conditions (Figure 4.31) (Warner and van der Geest, 2013; Huggel et al., 2019; van der Geest et al., 2019). A lack of investment in relevant infrastructure, such as dikes for example, as well as maladaptive effects of certain measures could increase existing risks and exacerbate impacts (van der Geest et al., 2019).

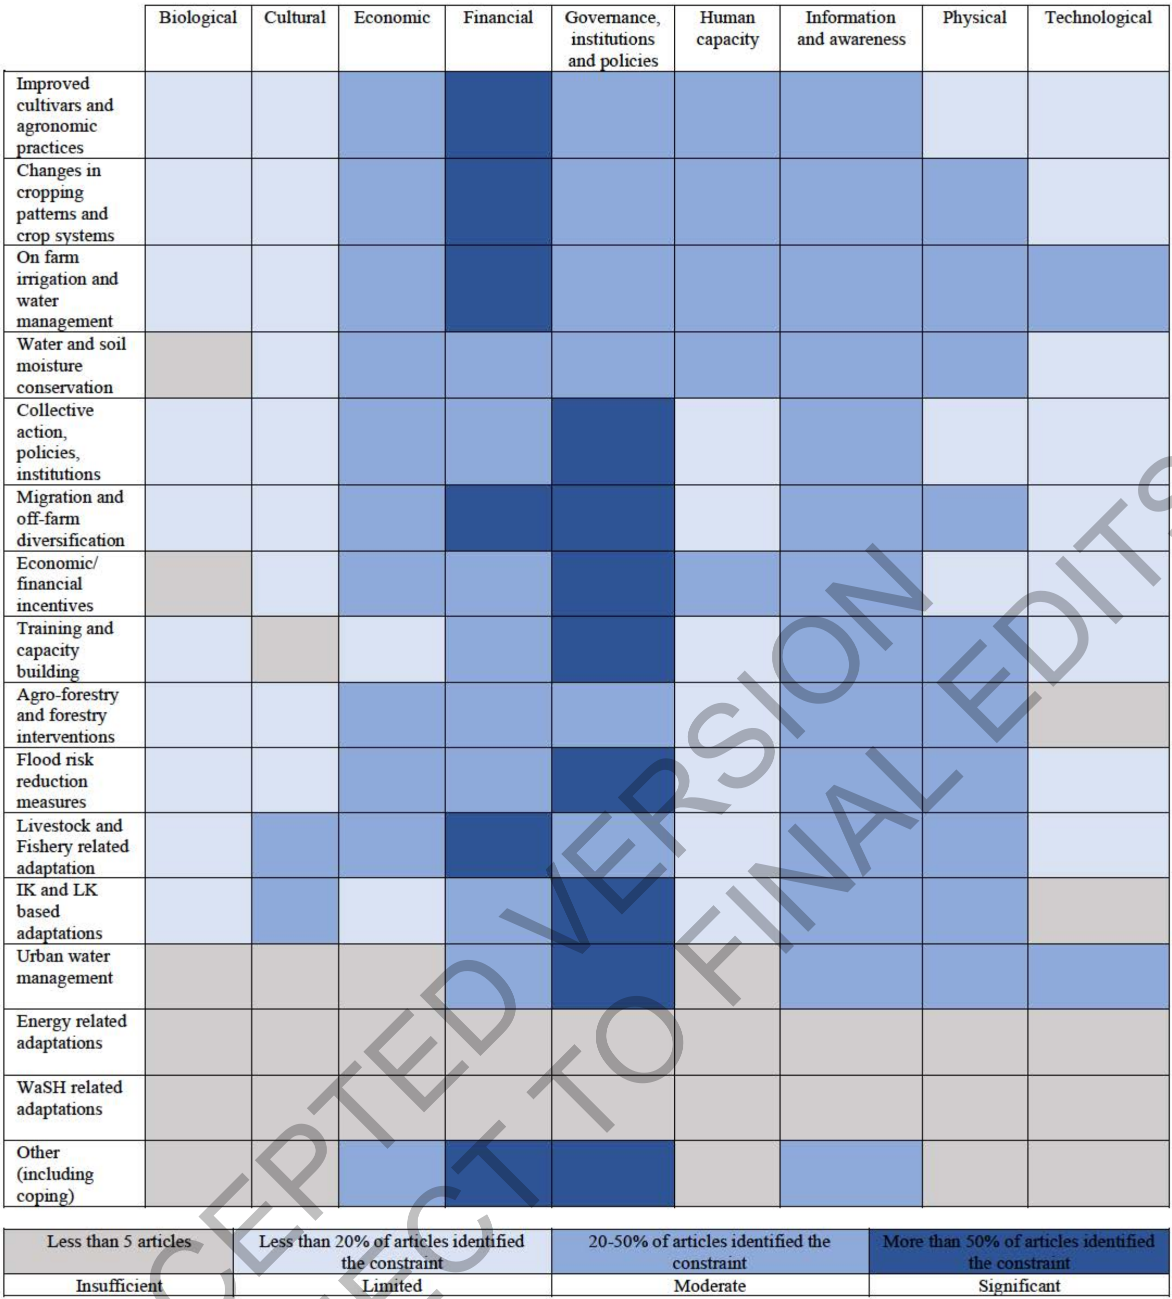

Figure 4.30: Adaptation constraints manifest across a range of dimensions and here are assessed based on a meta-review of water-related adaptation (4.7.1, SM4.2, and Table SM4.5). Where less than five articles are available for assessment, data is insufficient to assess the extent to which a constraint is present. Where less than 20% of the articles reporting on the respective adaptation option identify the presence of a constraint, it is classified as 'limited', where 20 to 50% report on a specific constraint it is considered as 'moderate'. Where more than 50% of articles report on the presence, the constraint is considered 'significant'. This assessment is based on the available peer-reviewed literature assessing adaptation benefits in the water sector - in practice, these or other constraints may still be significant, but have not have been identified in peer-review sources.

Integrated approaches, such as linking land-use and water policies (Mehdi et al., 2015), inter-institutional networks (Azhoni et al., 2017), nexus approaches (Box 4.8) (Conway et al., 2015) as well as consideration of linkages to the SDGs (4.8) (Gunathilaka et al., 2018) are crucial to overcoming constraints in water adaptation. In addition, monitoring and evaluating the effectiveness of adaptation measures, policies and actions can contribute to knowledge, awareness and data to support adaptation implementation in the future (4.7.1; 4.8) (Klostermann et al., 2018). Although the information on climate change adaptation that has beneficial impacts, including enabling conditions and success factors specific to the water sector, is emerging, significant knowledge gaps remain (4.7.1.2) (Gotgelf et al., 2020). Further understanding the constraints and limits that exist with regard to adaptation in the water sector is becoming urgent in light of increasing slow (e.g., droughts) and rapid (e.g., floods) onset impacts associated with climate change.

Taking action towards adaptation critically determines the outcomes and impacts of climate change processes across space and time. Where efforts to reduce risk do not effectively occur, losses and damages occur as a consequence of climate change, some of which can have irreversible and existential effects (van der Geest and Warner, 2015; Page and Heyward, 2016; Thomas and Benjamin, 2018a; Mechler et al., 2019). Water-related impacts that occurred despite implemented adaptation have been documented across all world regions (*high confidence*) (Figure 4.31).

	Hazard	Adaptation	Loss and Damage
A	Temperature increase, permafrost thawing	Outmigration	**Loss of livelihoods, ecosystems and infrastructure**
B	Drought	Crop-livestock integration, soil fertility management, crop variety, migration	**Loss of food security**
	Drought, climate variability	Pastoralism (moving cattle to regions with abundant pasture)	**Loss of food security**
C	Hurricanes, storms, droughts	Using savings, borrowing, government assistance	**Loss of income sources, loss of access to finance, depletion of assets, health problems, damage to housing and agriculture**
D	Landslides	Diversify livelihoods, physical barriers, house adjustments, migration	**Loss of life, loss of property and infrastructure**
	Changing monsoon patterns	Irrigation channels, water sharing mechanisms, crop diversification	**Loss of access to water and loss of crops**
	Floods, cyclones, surges, coastal flooding	Physical protection, creating buffers, build safety nets	**Loss of livelihoods, harvest failure and damage to infrastructure**
E	Floods, storms and drought	irrigation, diversification of crops, regeneration of degraded forests, animal husbandry	**Loss of food security, crops, income, livelihoods and land**
	Floods, landslides, typhoons	Food relief, temporary shelter and loaning money	**Loss of livelihoods, infrastructure and ecosystems**
F	Freshwater scarcity, aridity, cyclones, El Nino, flooding	Seasonal work and outmigration, early warning systems	**Loss of life, livelihoods, homes, crops, contamination of drinking water, displacement**
G	Changes in glacier runoff, permafrost thawing, GLOFs	Outmigration, new livelihoods (e.g. tourism)	**Loss of cultural heritage, loss of income, loss of lives**

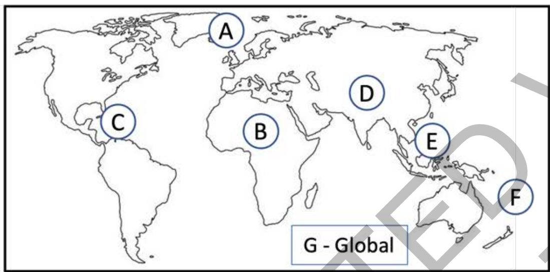

Figure 4.31: Examples of regional studies where experienced negative impacts despite or beyond implemented adaptation have been documented. Panels indicate the climate hazard that leads to the need for adaptation, the adaptation option implemented and the recorded impacts per region (A – Arctic (Landauer and Juhola, 2019), B – Africa (van der Geest et al., 2019), C – Caribbean (Lashley and Warner, 2015), D – South Asia (Kusters and Wangdi, 2013; van der Geest and Schindler, 2016; Bhowmik et al., 2021), E – Southeast Asia (Acosta et al., 2016; Beckman and Nguyen, 2016), F - Pacific the Small Island States (Gawith et al., 2016; Handmer and Nalau, 2019), G – Global effect: Mountain Cryosphere (Huggel et al., 2019)). Presented examples are limited to the available peer-reviewed literature that focuses explicitly on impacts that have been documented despite documented evidence that adaptation in relation to water hazards had previously been implemented. Section 4.3 provides a full assessment of observed impacts across sectors and regions.

Advances in climate change attribution (4.2; SM4.3; Figure 4.20) show the direct effects of anthropogenic climate change, also with regard to climate extremes. These advances also provide the basis for climate litigation (Marjanac and Patton, 2018) to hold countries/companies accountable for climate change impacts, for example, concerning risks of glacial lake outburst in Peru (Frank et al., 2019).

A further increase in the frequency and/or intensity of water-related extremes (4.4) will also increase consequent risks and associated losses and damages (4.5), primarily for exposed and vulnerable communities globally (Bouwer, 2019). After assessing the future potential of currently available technologies to reduce projected water-related climate impacts, there is evidence that residual impacts will remain after adaptation for most adaptation options and levels of warming, with increasing residual risks at higher warming levels (4.7.2). Financial, technical and legal support will be needed when hard limits are transgressed and loss and damage occurs (Mechler et al., 2020). Knowledge gaps remain regarding quantified information on limits and constraints to adaptation in the water sector.

In summary, institutional constraints (governance, institutions, policy), including path dependency and financial and information constraints, are the main challenge to adaptation implementation in the water sector (*high confidence*). Water-related losses and damages that manifest despite or beyond implemented adaptation have been observed across world regions, primarily for exposed and vulnerable communities (*high confidence*). Hard limits to adaptation due to limited water resources will emerge for Small Islands (*medium evidence, high agreement*) and regions dependent on glacier- and snowmelt (*medium evidence, high agreement*).

4.7.5 Costs of Adaptation and Losses due to Non-Adaptation

Estimating adaptation costs for climate change impacts on the various water use sectors is vital for decision-making, budgeting, and resource allocation (Chambwera et al., 2014). However, in AR5, studies on adaptation costs for water were deemed to have 'limited coverage' and mainly focused on 'isolated case studies'; costs in agriculture were 'extremely limited' (Chambwera et al., 2014).

One estimate on observed losses due to climate change from the United Kingdom notes that almost 50% of freshwater thermal capacity is lost on extreme high-temperature days, causing losses in the range of average GBP 29-66 million/year (Byers et al., 2020). However, global estimates of current losses because of climate change impacts on water resources remain few. Most of the evidence is focused on projected damages rather than actual ones (World Bank, 2016; Rozenberg and Fay, 2019).

Without adaptation, water-related impacts of climate change are projected to reduce global GDP by 0.49% in 2050 under SSP3, with significant regional variations for the Middle East (14%); Sahel (11.7%); Central Asia (10.7%), and East Asia (7%) (World Bank, 2016). In Asia, water-related impacts of climate change on all sectors of the economy are projected to reduce GDP by 0.9% (in high-income Asia) to 2.7% (in low-income Asia) by 2050 without adaptation or mitigation. Under the A1B scenario, real GDP is projected to fall by 0.78% by 2030 in South Asia (Ahmed and Suphachalasai, 2014). In Sub-Saharan Africa, damages from floods in 2100 are projected at 0.5% of GDP under a 2ºC temperature rise without adaptation; and will be non-uniformly spread across countries (Markandya, 2017; Dottori et al., 2018). In Europe, annual damages due to coastal flooding are projected at €93 billion by 2100 under RCP 8.5-SSP3 (Ciscar et al., 2018). Global direct damages from fluvial floods are projected to rise to €1250 billion per year under a 3ºC global warming level and SSP5 socio-economic scenario (Dottori et al., 2018). A model-based study of selected water-related sectors like fluvial and coastal flooding, agricultural productivity of major crops, hydroelectric power generation, and thermal power generation provides much conservative estimates of GDP loss (Takakura et al., 2019). The study shows that without adaptation, loss of global GDP could be 0.094% under RCP8.5 and SSP5 and 0.013% under RCP2.6 and SSP1 scenarios in 2090 (2080-2099), with regional values for Africa (0.017 to 0.286%), Asia (0.015 to 0.104%), Australasia (-0.012 to 0.003%), North America (-0.002 to 0.005%) and South and Central America (0.011 to 0.055%) (Takakura et al., 2019). So, while there is general agreement about negative impacts on GDP due to water-related risks in the future, the magnitude of GDP loss estimates varies substantially and depends on various model assumptions (*high confidence*). Updating costs while improving the modelling of uncertainties is essential for evidence-based decision-making (Ginbo et al., 2020).

Costs of water-related infrastructure in adaptation have received attention at the global and regional level to bridge the 'adaptation gap' (Hallegatte et al., 2018; UNEP, 2018; Dellink et al., 2019; GCA, 2019). For example, (Rozenberg and Fay, 2019) estimated that subsidizing capital costs to extend irrigation to its full potential would cost 0.13% of the GDP per year of low-and middle-income countries between 2015 and 2030. The coastal and riverine protection cost was between 0.06% to 1% of these countries' GDP per year over the same period. Projected economic damage due to coastal inundation was US$ 169–482 billion in 2100 under RCP8.5-SSP3 without adaptation, but US$ 43-203 billion cost to raise dike height will reduce 40% of the total damage (Tamura et al., 2019). Hard infrastructure for river floods, costing $4-9 billion per year, can reduce damage by US $22-74 billion per year (Tanoue et al., 2021). Damages are estimated to be up to six-time larger than the cost of implementing efficient adaptation measures (H2020., 2014). (GCA, 2019) reported that investing US$1.8 trillion globally, e.g., in early warning systems, climate-resilient infrastructure; dryland crop production; mangrove protection; and improving the resilience of water resources between 2020 and 2030 could generate US$ 7.1 trillion in benefits.

Comparatively, less attention has been paid to low-regret options, especially at the national and local levels. Conservation agriculture and integrated production systems, early-warning systems, restoration of wetlands, and zoning are postulated to have lower investment and lock-in costs than engineering-based options (Mechler, 2016; Cronin et al., 2018; Johnson et al., 2020). However, they require regular maintenance and high technical and human capacity, which are likely to vary by scale, location, and context (Chandra et al., 2018; Khanal et al., 2019; Mutenje et al., 2019; Rahman and Hickey, 2019). Global studies suggest improvements in returns on adaptation investments by delivering better services and reducing water wastage through appropriate water pricing and regulations (Damania et al., 2017; Bhave et al., 2018). For example, under scenarios SSP1 and SSP3, water pricing and regulation are projected to reverse losses in expected 2050 global GDP of 0.49% to gains of 0.09%. GDP losses are projected to drastically reduce in the Middle East, eliminated in the Sahel and Central Africa, and reversed into gains in Central Asia and East Africa, with benefits concentrated in worst-affected regions (World Bank, 2016). More local and national studies are needed to identify low regret options and their benefits and actual costs (Blackburn and Pelling, 2018; Abedin et al., 2019; Brown et al., 2019; Momblanch et al., 2019; Page and Dilling, 2020) (*limited evidence, high agreement*).

In summary, climate change impacts on water resources are projected to lower GDP in many low-and middle-income countries without adequate adaptation measures (*high confidence*). However, estimating the exact quantum of future GDP loss due to water-related impacts of climate change is fraught with several methodological challenges. Adaptation measures that focus on reducing water-related impacts of climate change will help stem losses further. Still, more work needs to be done on actual benefits and costs of adaptation strategies and residual impacts and risks of delaying adaptation action (*medium confidence*). In addition, better evidence on the costs and benefits of low-regret solutions, such as water pricing, increasing water use efficiency through technology and service improvements, and enhanced support for autonomous adaptation, is also needed for informed decision-making (*high confidence*).

4.7.6 Trade-offs and Synergies between Water-related Adaptation and Mitigation

In AR5, there was *medium evidence* and *high agreement* that some adaptation and mitigation measures can lead to maladaptive outcomes, such as a rise in GHG emissions, while further exacerbating water scarcity leading to increased vulnerability to climate change, now or in the future (Noble et al., 2014). In addition, SR1.5 (Hoegh-Guldberg et al., 2018; IPCC, 2018a) and SRCCL (IPCC, 2019b) reiterated the challenge of trade-offs that may undermine sustainable development. Conversely, adaptation, when framed and implemented appropriately, can synergistically reduce emissions and enhance sustainable development.

Different mitigation pathways can either increase or decrease water withdrawals or water consumption (or both, or either) depending on the specific combination of mitigation technologies deployed (*high confidence*) (Fricko et al., 2016; Jakob and Steckel, 2016; Mouratiadou et al., 2016; Fujimori et al., 2017; Parkinson et al., 2019). For example, the impacts of climate change mitigation on future global water demand depend largely on assumptions regarding socioeconomic and water policy conditions and range from reduction of 15,000 km^3 to an increase of more than 160,000 km^3 by the end of century (Mouratiadou et al., 2016). This section assesses some of the mitigation and adaptation measures from a water trade-off and synergy lens.

Solar pumps for irrigation are increasingly introduced where conventional energy is not available (Senthil Kumar et al., 2020) or supply is intermittent or expensive (Shah et al., 2018), e.g., in Africa (Schmitter et al., 2018), Europe (Rubio-Aliaga et al., 2016) and South Asia (Sarkar and Ghosh, 2017). Solar pumps can replace diesel and electric pumps (Rajan et al., 2020), potentially reduce 8-11% of India's carbon emissions (~45.3–62.3 MMT of CO_2) attributable to groundwater pumping while also boosting agricultural productivity (Gupta, 2019). However, in the absence of incentives to deter groundwater over-exploitation (Shah et al., 2018), solar pumps may exacerbate groundwater depletion (Closas and Rap, 2017; Gupta, 2019) (*low evidence, medium agreement*).

In many places, treatment and reuse of wastewater from urban residential and industrial sources may be the principal supply option under acute water scarcity (US EPA, 2017) and help reduce other freshwater withdrawals (Tram Vo et al., 2014; Diaz-Elsayed et al., 2019). While reuse may recover valuable nutrients, capture energy as methane, and save water, effluent containing heavy metals may degrade land and surface and groundwater quality and pose a salinization risk in semi-arid regions (*medium evidence, high agreement*). Agricultural reuse of poor-quality wastewater will become increasingly necessary, but treatment is energy-intensive and may contribute to further GHG emissions (Qadir et al., 2014; Salgot and Folch, 2018) (Box 4.5).

Desalination of seawater or brackish water is an adaptation measure in many coastal water-scarce regions (Hanasaki et al., 2016; Jones et al., 2019). Solar desalination is developing rapidly, and it lessens the carbon footprint of conventional, fossil-fuel-powered desalinization plants (Pouyfaucon and García-Rodríguez, 2018) (also see Box 4.5). However, the desalinization process is energy-intensive (Caldera et al., 2018); it ejects brine that is difficult to manage inland, has high salinity and other contaminants (Wilder et al., 2016) (*medium evidence, high agreement*) (Box 4.5).

Negative-emission technologies, such as direct air capture (DAC) of CO_2, could reduce emissions up to 3GtCO_2/year by 2035, equivalent to 7% of 2019 global emissions. However, they can increase net water consumption by 35 km^3/year in 2050 (Fuhrman et al., 2020) under the low-overshoot emissions scenario. According to other estimates, capturing 10Gt of CO_2 could translate to water losses between 10-100 km^3, depending on the technology deployed and climatic conditions (temperate vs. tropical) (Chapter 12, WGIII). Some DAC technologies that include solid sorbents also produce water as a by-product, but not in quantities that can offset total water losses (Beuttler et al., 2019; Fasihi et al., 2019)(*medium confidence*).

Developing countries are projected to witness the highest increase in future energy demand under 2°C global warming leading to significant increases in water use for energy production (Fricko et al., 2016) (4.5.2). Results from a simulation study on retrofitting coal-fired power plants built after 2000 with carbon capture and storage (CCS) technologies show an increase in global water consumption, currently at 9.66 km^3/year, by 31% to 50% (to 12.66 km^3/year and 14.47 km^3/year, respectively) depending on the cooling and CCS technology deployed, and hence are best deployed in locations which are not water scarce (Rosa et al., 2020c) (*medium confidence*). In Asia, the near-term mitigation scenario with high CCS deployment increases the average regional water withdrawal intensity of coal generation by 50-80% compared to current withdrawals (Wang et al., 2019b). Carbon can be 'scrubbed' from thermo-electric power-plant emissions and injected for storage in deep geological strata (Turner et al., 2018), but this can lead to pollution of deep aquifers (Chen et al., 2021) and have health consequences (*low confidence*).

Bio-energy crop with carbon capture and storage (BECCS) involves CO_2 sequestration as biofuel or forest bioenergy (Creutzig et al., 2015). BECCS has profound implications for water resources (Ai et al., 2020), depending on factors including the scale of deployment, land use, and other local conditions. Evaporative losses from biomass irrigation and thermal bioelectricity generation are projected to peak at 183 km^3/year in 2050 under a low overshoot scenario (Fuhrman et al., 2020). (Senthil Kumar et al., 2020) projected that while BECCS strategies like irrigating biomass plantations can limit global warming by the end of the 21st century to 1.5°C, this will double the global area and population living under severe water stress compared to the current baseline. Both BECCS (Muratori et al., 2016) and DAC can significantly impact food prices via demand for land and water (Fuhrman et al., 2020). The direction and magnitude of price movement will depend on future carbon prices, while vulnerable people in the Global South will be most severely affected (*medium evidence, high agreement*).

Afforestation and reforestation are considered one of the most cost-effective ways of storing carbon. An additional 0.9 billion ha of canopy cover in suitable locations could store 205 Gt of carbon (Bastin et al., 2019), but this estimate is deemed unrealistic. Aggressive afforestation and reforestation efforts can result in trade-offs between biodiversity, carbon sequestration, and water use (Smith et al., 2008). In northern China, ecological restoration by regreening drylands resulted in several environmental and social benefits (Mirzabaev et al., 2019) but also led to increased freshwater use in some pockets (Zhao et al., 2020). Afforestation and reforestation with appropriate broad-leaf species in temperate Europe (Schwaab et al., 2020) can offer water quality and quantity-related benefits, mitigate extreme heat, and buffer against drought (Staal et al., 2018). A global assessment on forest and water showed that forests influence the overall water cycle, including downstream water availability via rainfall-runoff dynamics and downwind water availability via recycled rainfall effects (Creed and van Noordwijk, 2018). The study concluded that afforestation and reforestation should be concentrated (Ellison et al., 2017) in water-abundant locations (to offset downstream impacts) and where transpiration can potentially be captured downwind as precipitation (Creed et al., 2019) (Cross-Chapter Box NATURAL in Chapter 2). Overall, extensive BECCS and afforestation/reforestation deployment can alter the water cycle at regional scales (*high confidence*) (Cross-Chapter Box 5.1 in Chapter 5, WGI, (Canadell et al., 2021)).

On the other hand, demand-side mitigation options, such as dietary changes to more plant-based diets, reduced food waste (Aleksandrowicz et al., 2016; Springmann et al., 2018; Kim et al., 2020), can reduce water use (*medium evidence, high agreement*).

In summary, many adaptation and mitigation measures have synergistic or maladaptive consequences for water use, depending on associated incentives, policies, and governance that guide their deployment. Many mitigation measures have a considerable water footprint (*high confidence*), which must be managed in socially and politically acceptable ways to reduce the water intensity of mitigation while increasing synergies with sustainable development (*medium evidence, high agreement*).

[START BOX 4.8 HERE]

Box 4.8: Water-Energy-Food (WEF) Nexus Approaches for Managing Synergies and Trade-offs

WEF nexus is an approach that recognizes that water, energy, and food are linked in a complex web of relationships in the hydrological, biological, social, and technological realms (D'Odorico et al., 2018; Liu et al., 2018b; Märker et al., 2018). For instance, agricultural production requires significant energy inputs due to intensive groundwater pumping (Siddiqi and Wescoat, 2013; Gurdak, 2018; Putra et al., 2020). Similarly, hydropower production often has trade-offs with irrigation, affecting food production, carbon emission, and forest protection (Meng et al., 2020). New technologies, such as desalination plants for urban water supply against future climate change and drought, are also very energy-intensive (Caldera et al., 2018) (Box 4.5). Quantifying the complex interdependencies among food, energy, and water is critical to achieving the SDGs; and reducing trade-offs (Liu et al., 2018a; Liu et al., 2018b; UN, 2019). A key benefit of the nexus approach is to leverage the interconnection of WEF and achieve the most efficiency in the overall systems. Hence, this approach allows for widening the set of salient stakeholders and, therefore solution possibilities, that may otherwise not be possible in single domain efforts and helps connect these stakeholders to achieve synergistic goals (Ernst and Preston, 2017; Mercure et al., 2019).

The WEF nexus approach thus opens up possibilities for strategic interventions across sectors through a better understanding of trade-offs (Albrecht et al., 2018). Policies and strategies aiming to cope with climate change may amplify rather than reduce negative externalities and trade-offs within the nexus: low carbon transition, the shift to non-conventional water resources, and agricultural intensification, all implemented to mitigate and adapt to climate change, are not always nexus-smart. Hence, a nexus approach that integrates management and governance across these three sectors can enhance WEF security by minimizing trade-offs and maximizing synergies between sectors. At the same time, renewable energy offers the opportunity to decouple water and food production from fossil fuel supply, leading to several advantages from both a socio-economic and environmental point of view (Cipollina et al., 2015; Pistocchi et al., 2020). WEF nexus approaches can achieve overall system efficiency when maximizing the use and recovery of water, energy, nutrients, and materials (Pistocchi et al., 2020; Tian et al., 2021). These types of holistic system thinking of WEF show promising strategies to catalyze transformative changes. Suppose the specific types and extent of WEF linkages in a region are well understood. In that case, it becomes possible to intervene through one element to cause an effect on another connected component that may have proven difficult for direct intervention (Mukherji, 2020).

Several challenges remain for sound operationalization of the nexus, notably insufficient data, information, and knowledge in understanding the WEF inter-linkages and lack of systematic tools to address trade-offs involved in the nexus and to generate future projections (Liu et al., 2017a; Liu et al., 2018b). There are recent signs of progress in developing models and tools for addressing the nexus trade-offs, e.g., the bioenergy–water nexus (Ai et al., 2020). There is a need to move beyond viewing the WEF nexus as a way of problem identification to seek integrated solutions to interconnected problems.

[END BOX 4.8 HERE]

4.8 Enabling Principles for Achieving Water Security, Sustainable and Climate Resilient Development Through Systems Transformations

Sustainable development is a global policy priority and commitment, as is keeping temperatures well below 2°C as per the Paris Agreement. Water is central to almost all SDGs (Box 4.1). Water is explicitly referred to in SDG6 (clean water and sanitation) and SDG11 (sustainable communities and cities) (UN, 2015) (4.1). SDG1 (no poverty) is statistically linked to SDG6 (clean water and sanitation) (Pradhan, 2019), since reducing poverty can help increase adaptive capacity in line with the Paris Agreement adaptation goals (see Chapter 1 and Chapter 18). SDG2 (zero hunger) cannot be achieved without access to adequate water for agriculture. Meeting SDG 3 (health and wellbeing) will rely on access to basic infrastructure like water and sanitation ((Delany-Crowe et al., 2019), see Cross-Chapter Box HEALTH in Chapter 7, 4.3.3, 4.3.5), while SDG 7 (affordable and clean energy), will need water for hydropower production under changing climate (Berga, 2016; Byers et al., 2016) (4.5.2). Meeting SDG11 (sustainable cities and communities) will require reducing the impacts from water related disasters.

Water is also fundamental to all systems transitions, namely, transitions in energy, industrial, land and ecosystem and urban systems. Within energy and industrial system transitions, water stress for electricity generation has already caused impacts (4.3.2). Therefore, water efficiency measures are increasingly applied in both energy and industrial systems with benefits for mitigation and adaptation (4.6.3). Water is inextricably entwined with land and ecosystems transitions, with forested areas and ecosystems being integral components of the water cycle, regulating streamflow, fostering groundwater recharge and contributing to atmospheric water recycling (Takata and Hanasaki, 2020) (4.2). However, mitigation action of large afforestation, can have negative water impacts (Cross-Chapter Box 1 in Chapter 5 of WGI repor, 4.7.6), making it imperative to consider water footprint of land and forest-based mitigation (Muricho et al., 2019; Seddon et al., 2020) (4.7.6). Sustainable forest management and nature-based solutions (NbS) are promising alternatives for good water management (Muricho et al., 2019; Seddon et al., 2020). Water will also play a crucial role in sustainable urban transitions. Cities are already facing water related impacts (4.3.4), which are projected to intensify with every degree of global warming (Flörke et al., 2018; Nazemi and Madani, 2018) (4.5.4). Mitigation and adaptation measures in urban spaces, such as green infrastructure (Liu and Jensen, 2018), sustainable water supply management through recycling of wastewater and storm water runoff (Box 4.5), and NbS like sponge cities are fundamentally about water (Box 4.6).

Thus, water remains central to achieving SDGs, and will play a fundamental role in systems transitions needed for climate resilient development. We outline a set of seven enabling principles that are needed to achieving water security, and will also help in achieving SDGs and facilitate systems transitions.

4.8.1 Appropriate Technologies

AR5 concluded that successful adaptation across all sectors depends on access to technology, and technology transfer can play an essential role in building up adaptive capacity (Noble et al., 2014). SR1.5 discussed the role of efficient irrigation technologies in adaptation (de Coninck et al., 2018).

Technologies that reduce carbon emissions by promoting the efficient use of water can support successful adaptation (Biagini et al., 2014), provided they do not have adverse distributional outcomes (*medium evidence, high agreement*). Water management in agriculture has long seen the use of technology. For example, the use of technology to improve access to water, e.g., through the diffusion of groundwater pumps in the 1970s in South Asia, had several livelihood benefits but made agriculture more carbon-intensive (Zaveri et al., 2016). More recently, technology has been used to improve water use efficiency in agriculture through the adoption of drip and sprinkler irrigation (Zhuo and Hoekstra, 2017; Grafton et al., 2018); and the use of the Internet of Things (IoT) (Keswani et al., 2019). In addition, innovations to re-use water through various wastewater recovery technologies (Diaz-Elsayed et al., 2019; Capodaglio, 2020); and to create potable water through desalinization (Caldera et al., 2018); and re-use of wastewater in agriculture (Salgot and Folch, 2018) are also on the rise (Box 4.5). Solar technologies are increasingly used for irrigation, wastewater recovery, desalinization, and water harvesting (Algarni et al., 2018; Pouyfaucon and García-Rodríguez, 2018; Tu et al., 2018; Zhao F. et al., 2020). Machine learning and artificial intelligence technologies (Doorn, 2021) have started being used in many water-use sectors, such as urban (Nie et al., 2020); wastewater management (Abdallah et al., 2020; Ben Ammar et al., 2020), and agricultural water management, but mostly in high-income countries mostly on an experimental basis (Tsang and Jim, 2016; González Perea et al., 2018). Technology is being increasingly used in hydrological sciences for measurements and monitoring (SM4.1), as well as for creating comprehensive hydrometeorological warning systems (Funk et al., 2015). Lack of technology and knowledge transfer, especially related to remote sensing, is an adaptation barrier in states with less resources (Funk et al., 2015).

Adoption of technologies depends on the availability of finance (4.8.2). The effectiveness of technology in reducing climate-related risks depends on its appropriateness to the local context (Biagini et al., 2014; Mfitumukiza et al., 2020) and other factors, including institutional and governance frameworks (*high confidence*). Water technologies can also have unintended outcomes leading to maladaptation in some cases. For example, efficient irrigation technologies like drip and sprinkler irrigation, while reducing water application rates per unit of land, can increase overall water extraction by increasing total land under irrigation (van der Kooij et al., 2013; Grafton et al., 2018; Mpanga and Idowu, 2021). Water-related technologies can also have adverse distributional outcomes when gains from technology adoption accrue disproportionately to a small section of the population; for example, only rich and male farmers can adopt high-cost technologies like solar irrigation pumps (Gupta, 2019) (*medium confidence*).

In summary, technology is an important part of water adaptation response, and outcomes of technology adoption are mediated through other societal factors, including institutions, governance frameworks, and equity and justice issues (*medium evidence, high agreement*).

4.8.2 Adequate and Appropriate Financing

Although AR5 did not explicitly mention finance for water-related adaptation actions, it considered urban adaptation (Revi et al., 2014) and risk financing (Arent et al., 2014). SR1.5 (de Coninck et al., 2018) discussed governance and finance limitations, while SRCCL discussed finance in adapting to floods and droughts (Hurlbert et al., 2019).

Mitigation garners the significant share of committed climate finance. For example, of the total US$ 15.4 billion climate finance commitments through Green Bonds, 79% accrued to mitigation and the rest to adaptation (World Bank, 2017). However, within adaptation finance, water garners a significant share of adaptation funds, with 13% of the Adaptation Fund's investments were for water management, 12% for coastal management, and 10% for disaster risk reduction (Adaptation Fund, 2018). Similarly, within the urban adaptation landscape, which got ~3% to 5% of total adaptation finance flows of US$ 30.8 billion tracked in 2017-18 (Richmond et al., 2021), water and wastewater management projects received the largest share of urban adaptation finance (US$ 761 million annually) followed by disaster risk management (US$ 323 million) (Richmond et al., 2021). However, more frequent tracking of public financing is required, with a greater focus on transparency and accountability (Ciplet et al., 2018; Khan et al., 2020) and justice and social equity (Emrich et al., 2020) (also see Cross-Chapter Box FINANCE in Chapter 17).

Private financing remains a minor source of adaptation financing (World Bank, 2019). Around 39% of green bonds issued in 2017 were for water, wastewater, and solid waste management (World Bank, 2017). In 2018, US$100.5 billion of water-themed bonds were issued, mainly in Europe (63%), the Asia Pacific (19.6%), and North America (14.9%) (Filkova et al., 2018; World Bank, 2019). Such financing focuses on returns and scale (Cholibois, 2020), and as such, local needs, especially those of the poor, may not be adequately represented (Manuamorn et al., 2020; Williams, 2020) (*medium confidence).*

COVID-19 will probably affect adaptation financing in water. Countries will be fiscally stretched to finance public investments domestically and through international development aid (Barbier and Burgess, 2020). However, investments in flood and drought management (Phillips et al., 2020) and water and sanitation (Armitage and Nellums, 2020b; Bhowmick et al., 2020) are critical for building resilience against pandemics, are also crucial elements of adaptation in water. Therefore, integrated approaches that achieve both goals need to be deployed (Barbier and Burgess, 2020; Newell and Dale, 2020) (Box 4.4., Cross-Chapter Box COVID in Chapter 7).

In summary, water garners a significant share of public and private adaptation funds (*high confidence*). However, current COVID-related cuts in adaptation financing may further impede developing countries' ability to invest in adequate water adaptation.

4.8.3 Gender, Equity and Social Justice

SR 1.5 acknowledged that the adaptative capacity of a population was going to reduce with each degree of warming and that vulnerability to climate change was due to gender, race and level of education, which can compound existing and future vulnerabilities (IPCC, 2018a).

Gender, class, race, age, physical ability and educational level determine access to water, financial and societal resources, potentially adverting climate-induced water hazards, reducing vulnerability and facilitating adaptation. However, insufficient attention has been given to the role of improving equity in access to water (Abedin et al., 2019; Eakin et al., 2020). Not all water adaptation strategies are accessible to the poorest, who may turn to maladaptive strategies if their access to water is negatively affected (Eakin et al., 2016). Consequently, there have been calls for mainstreaming equity considerations into adaptation (Blackburn and Pelling, 2018) *(medium evidence, high agreement)*. It has been shown that people living in poverty, racial minorities and those ageing are more vulnerable to climate-induced water hazards and that their adaptive capacity is limited (Szewrański et al., 2018; Winsemius et al., 2018; Nyantakyi-Frimpong, 2020; Erwin et al., 2021). Among these categories, gender is the one that has been most analyzed in the context of water and climate change.

Women’s water rights are hampered by societal patriarchal norms that prevent women from accessing water and participating in water management. Gender power relations effectively limit women’s decision-making power, mobility and access to resources, including water, which makes them more vulnerable to climate-related hazards (Caretta and Börjeson, 2015; Djoudi et al., 2016; Sultana, 2018; Yadav and Lal, 2018). In most societies in developing countries, women and girls are in charge of fetching water. The necessity of water collection takes away time from income-generating activities and education (*high confidence*) (Fontana and Elson, 2014; Kookana et al., 2016; Yadav and Lal, 2018). In addition, the distances women and girls would have to walk as a result of growing water scarcity due to climate change may increase (*limited evidence, high confidence*) (Becerra et al., 2016) (4.3.3, 4.5.3). Numerous studies substantiate a male bias in information access, employment opportunities, resource availability, and decision-making in water-related adaptation measures (Huynh and Resurreccion, 2014; Sinharoy and Caruso, 2019).

Although women are often depicted as victims of climate change-induced water scarcity (Huynh and Resurreccion, 2014; Djoudi et al., 2016; Gonda, 2016; Yadav and Lal, 2018), they are also proactive adaptation actors (Singh and Singh, 2015) (Cross-Chapter Box GENDER in Chapter 18). Notably, women are not a homogenous group, and local gender roles are not immutable or generalizable (Carr and Thompson, 2014; Djoudi et al., 2016; Gonda, 2016; Sultana, 2018). Coping responses and adaptation mechanisms to climate change are profoundly gendered. Women and men approach the diversification of agricultural and pastoral livelihoods differently in response to climate change (Caretta and Börjeson, 2015; Kankwamba et al., 2018; Singh et al., 2018; Basupi et al., 2019). For example, reliance on women’s self-help groups and associations has proven successful in ensuring women’s participation in decision-making in adaptation interventions as a response to climate change-induced shifting precipitation patterns and increasing droughts (Chu, 2017; Mersha and van Laerhoven, 2018; Phuong et al., 2018; Walch, 2019). Studies feature water harvesting, crop diversification, cash transfer programs, and food subsidies as adaptation measures that enhance gender equality. Adaptation to climate change in these instances promoted gender equality because it allowed women to reap the benefits of these new measures in terms of economic and health wellbeing (Tesfamariam and Hurlbert, 2017; Lindoso et al., 2018; Walch, 2019).

Meanwhile, adaptation interventions such as drip irrigation, the adoption of more labor-intensive crops, and livelihood diversification through male out-migration have proven to increase women’s burden (Caretta and Börjeson, 2015; Kattumuri et al., 2017). Hence, a lack of gender-sensitive analysis before implementing water management projects can lead to maladaptation and increase gender vulnerability (Phan et al., 2019; Eriksen et al., 2021) (*high confidence)*.

Acknowledging and understanding the implications of climate-related water adaptation policies in terms of equity and justice is a prerequisite for ensuring their legitimacy and inclusiveness and promotes social justice (Carr and Thompson, 2014; Djoudi et al., 2016; Jost et al., 2016; Sultana, 2018). Furthermore, integrating the principle of gender inclusivity in adaptation is morally and ethically appropriate and effective because women hold much of the local and traditional knowledge in many agricultural communities and can fruitfully provide insights on how to design and implement adaptation responses (Fauconnier et al., 2018; James, 2019).

In summary, there is *high confidence* that the effects of climate change-induced water insecurity are not evenly felt across populations. Particularly vulnerable groups are women, children, disabled and Indigenous Peoples, whose ability to access adequate water is limited and varies across race, ethnicity and caste. Equity and justice are central to climate change adaptation and sustainable development, as the world's poorest people and countries feel the adverse impacts of a changing climate most acutely. These groups can become even more vulnerable due to adaptation actions that are not equitable.

4.8.4 Inclusion of Indigenous Knowledge and Local Knowledge

AR5 concluded that there is *robust evidence* that mutual integration and co-production of local and traditional and scientific knowledge increase adaptive capacity and reduce vulnerability (Adger and Pulhin, 2014). SROCC stated with *medium confidence* that Indigenous Knowledge (IK) and local knowledge (LK) provide context-specific and socio-culturally relevant understandings for effective climate change responses and policies (Abram et al., 2019). SRCCL found that IK and LK contribute to enhancing resilience against climate change and combating desertification (*medium confidence*). The combination of IK and LK with new sustainable land management techniques, SRCCL stated with *high confidence*, can contribute to raising resilience to the challenges of climate change and desertification (Mirzabaev et al., 2019).

There is *high confidence* that adaptation efforts benefit from the inclusion of IK and LK (Mustonen et al., 2021). IK and LK can inform how climate change impacts and risks are understood and experienced. Holders of IK and LK can also help to develop place-based and culturally appropriate adaptation strategies that meet their expectations (Comberti et al., 2019; Martinez Moscoso, 2019) (Cross-Chapter Box INDIG in Chapter 18).

There is *high confidence* that genuine partnerships with Indigenous Peoples and local communities can assist in decolonising approaches to freshwater management (Arsenault et al., 2019; Wilson et al., 2019), which recognise the importance of knowledge that is not grounded on the technocratic division between nature and society (Goldman et al., 2018). There is also *high confidence* that Indigenous-led freshwater management can facilitate culturally inclusive decision-making and collaborative planning processes at the local and national levels (Somerville, 2014; Harmsworth et al., 2016; Parsons et al., 2017). However, market-based models of water rights regimes can impede the ability of Indigenous Peoples to exercise their rights and deploy traditional ecological knowledge regarding freshwater protection (Nursey-Bray and Palmer, 2018) (*medium evidence, high agreement*).

Community-led actions and restoration measures are helping to ameliorate climate impacts and provide "safe havens" to affected freshwater species (*high confidence*). For example, the Skolt Sámi of Finland have introduced adaptation measures to aid survival of culturally-significant Atlantic salmon stocks in the Näätämö watershed. Atlantic salmon had declined as northern pike, which preys on juvenile salmon, expanded its range in response to warmer water temperatures. Indigenous co-management measures included increasing the catch of pike and documenting important sites (such as lost spawning beds) to ensure ecological restoration encourages further habitat and increased salmon reproduction (Pecl et al., 2017; Mustonen and Feodoroff, 2018).

Community-led applications of IK and LK in conjunction with external knowledge and funding can improve water security (*high confidence*). For example, Borana pastoralists in Ethiopia (Iticha and Husen, 2019) and Ati and Suludnon people (Philippines) (Nelson et al., 2019) utilise both IK and technical information for weather forecasting, while Calanguya people (Philippines) collaborated with local government and NGOs to diversify crops and protect the watershed (Gabriel and Mangahas, 2017). With assistance from municipalities, Indigenous Peoples are rehabilitating springs and traditional water wells in Bangladesh hill tracts (Sultana et al., 2019) and Micronesia (McLeod et al., 2019). In response to changing cryosphere conditions in the Peruvian Andes, Indigenous Quechua farmers use IK and technical information in community-led research to preserve biocultural knowledge and emblematic crops (Sayre et al., 2017). In Galena, Alaska (USA), a flood-preparedness and response program have benefitted from the long-term cooperation between emergency management and tribal officials (Kontar et al., 2015) (12.5.3.2 Main concepts and approaches). IK and LK can enhance the visibility of Indigenous Peoples and local communities that are excluded from official decision-making processes. In southwest Burkina Faso, for example, Indigenous Peoples are using IK and LK to balance (and sometimes resist) official technical estimates of water availability, which enhances their political visibility and enables them to address water scarcity (Roncoli et al., 2019).

There are structural and institutional challenges in knowledge co-production between holders of IK and LK and "technical" knowledge. These challenges include issues of water rights, language, and extractive research practices (Ford et al., 2016; Simms et al., 2016; Stefanelli et al., 2017; Arsenault et al., 2019), and colonial uses of IK and LK (Castleden et al., 2017), which can produce distrust among holders of IK and LK (David-Chavez and Gavin, 2018). In addition, some IK is sacred and cannot be shared with outsiders (Sanderson et al., 2015).

In summary, IK and LK are dynamic and have developed over time to adapt to climate and environmental change in culturally specific and place-based ways (*high confidence*). Ethical co-production between holders of IK and LK and technical knowledge is a key enabling condition for successful adaptation measures and strategies pertaining to water security, as well as other areas (*medium evidence, high agreement*). Knowledge co-production is a vital and developing approach to the water-related impacts of climate change that recognises the culture, agency and concerns of Indigenous Peoples and local communities. It is critical to developing effective, equitable and meaningful strategies for addressing the water-related impacts of global warming (Cross-Chapter Box INDIG in Chapter 18).

4.8.5 Participative, Cooperative and Bottom-up Engagement

Participation, cooperation and bottom-up engagement are critical to optimal adaptation *(medium evidence-high agreement).* There is *high confidence* that many of the countries and social groups most threatened by climate change have contributed the least to global emissions and do not have not the resources to adapt. Effective participation of these actors in climate change adaptation planning in the water sector can contribute to more just adaptation actions *(high confidence).*

There is *medium evidence*, *high agreement* that optimal adaptation depends critically on inter-state cooperation (Banda, 2018), which in turn requires trust and norms of reciprocity among all those involved (Ostrom, 2014). Reciprocity is central to international cooperation on climate change, where actors are more inclined to cooperate when they perceive that the expected outcome will be fair in terms of costs and benefits of implementation (Keohane and Oppenheimer, 2016). Indeed, cooperation at the international level is less probable to occur if participants do not trust each other's (Hamilton and Lubell, 2018). In climate-related water adaptation, transboundary cooperation is essential, as 60% of global freshwater resources contained in 276 river and lake basins are shared between countries (Timmerman et al., 2017). Yet, more than 50% of the world 310 international river basins lack any type of cooperative framework (McCracken and Meyer, 2018).

SDG 6 on water and sanitation includes a specific indicator (6.5.2) to assess cooperation over transboundary waters. While the methodology for measuring this indicator is debated, it is clear that its composition will influence international and national water policy and law (McCracken and Meyer, 2018) and possibly help build an environment of trust among riparian states. Moreover, although the 2030 Agenda for Sustainable Development (A/RES/70/1) makes it clear that without the participation of local communities (e.g., SDG 6, target 6. B) and women (e.g., SDG5, target 5.5.), the SDGs will not be met, the involvement of these actors in formal water governance processes and water management is still limited (Fauconnier et al., 2018). This is due partly to the absence, in many regions of the world, of adequate legal, regulatory and institutional frameworks for effective stakeholder's participation, partly to the influence of local social and cultural contexts, which can discourage inclusive water governance (Andajani-Sutjahjo et al., 2015; Dang, 2017). Yet, inclusion and effective participation in bottom-up decision-making processes of those disproportionately affected by climate change – including women and Indigenous Peoples - is particularly important to ensure the legitimacy and inclusiveness of the decision-making process and the design of socially just adaptation actions (Shi et al., 2016). Moreover, incentives for bottom-up and participative decision-making in the water sector can facilitate effective stakeholder engagement (OECD, 2015), which helps build public confidence and trust in water governance.

4.8.6 Polycentric Water Governance

SR1.5 concluded with *high confidence* that cooperation and coordinated actions at various governance levels are vital to ensuring participation, transparency, capacity-building and learning among different actors (IPCC, 2018a). According to SRCCL, adaptive governance builds on multi-level and polycentric governance (Hurlbert et al., 2019), where efforts taken by multiple actors across different scales provide learning opportunities for all (Hurlbert, 2018).

Polycentrism is characterized by the absence of a unique centre of authority. Therefore, the legitimacy of the decisions taken by multiple decision-makers at different levels of water governance derives from the perceived fairness of the decision-making process (Baldwin et al., 2018) and the inclusion of women, Indigenous Peoples and young people (Iza, 2019) (*medium confidence*). Evidence-based approaches can also enhance the legitimacy of polycentric governance (Boelens et al., 2015; Arriagada et al., 2018) by generating knowledge to support localized and multileveled decision-making, as in the case of water user communities in Peru (Buytaert et al., 2014; Buytaert et al., 2016).

The advantages of polycentric approaches to climate governance include improved communication, inclusiveness, consensus and better outcomes (Ostrom, 2014; Cole, 2015; Keohane and Victor, 2016; Morrison et al., 2017; Tormos-Aponte and García-López, 2018) (*high agreement*). However, polycentric governance systems require cross-scale information sharing, coordination and democratic participation to work appropriately (Pahl-Wostl and Knieper, 2014; Carlisle and Gruby, 2017; Morrison et al., 2017; Biesbroek and Lesnikowski, 2018; Frey et al., 2021) (*high confidence*). For example, efficient information sharing has been necessary to implement groundwater governance in transboundary contexts (Albrecht et al., 2017).

Empirical studies that examined the potential of polycentric governance to address water challenges in the face of climate change showed that polycentrism could encourage and support participatory, decentralized and deliberative adaptation. These, in turn, can produce better environmental outcomes and improve water governance outcomes (*high confidence*). Polycentric water governance can be an effective enabler for adaptation when it ensures interconnectedness with multiple public and private actors across the different sectors (e.g. irrigation users, domestic users, industrial users, watershed institutions, etc.) and across different levels (e.g. local, regional and national governments) to help come up with well-coordinated water adaptation responses (*high confidence*) (Pahl-Wostl and Knieper, 2014; McCord et al., 2017; Baldwin et al., 2018; Hamilton and Lubell, 2018; Kellner et al., 2019).

Questions remain about the extent to which polycentrism can result in either greater climate justice or exacerbate existing inequalities due, for example, to existing power inequalities which may affect the performance and effectiveness of a polycentric system (Pahl-Wostl and Knieper, 2014; Morrison et al., 2017; Hamilton and Lubell, 2018; Okereke, 2018). For instance, historical inequities and injustices due to settler colonialism and top-down water policies, governance and laws (Collins et al., 2017; Arsenault et al., 2018; Johnson et al., 2018; Robison et al., 2018) have resulted in long-term water insecurity in many Indigenous communities in North America (Simms et al., 2016; Medeiros et al., 2017; Conroy-Ben and Richard, 2018; Diver, 2018; Emanuel, 2018) (*high confidence*) (4.6.9). Additionally, studies highlight that power dynamics can undermine the success of those initiatives. For example, in the Sao Paulo water crisis, polycentric governance did not fully realize its potential when it was guided by authoritarian governance favouring political interests over social, territorial and environmental justice (Frey et al., 2021). Likewise, in the Thau basin (France), the most important and influential actors shaped policy measures in response to climate change, thus limiting the potential for radical changes in water use (Aubin et al., 2019).

In summary, polycentric governance can enable improved water governance and effective climate change adaptation (*medium confidence*). However, it can also exacerbate existing inequalities as long as less powerful actors, such as women, Indigenous Peoples and young people, are not adequately involved in the decision-making process *(high confidence).*

4.8.7 Strong Political Support

According to AR5 (Jiménez Cisneros et al., 2014), barriers to adaptation in the water sector include lack of institutional capacity, which, together with political support, constitutes one of the feasibility dimensions towards limiting global warming to 1.5°C (de Coninck et al., 2018). As the IPCC SROCC (IPCC, 2019a) and SRCCL (Shukla et al., 2019) suggest, limited institutional support can challenge adaptation efforts in water management.

Climate adaptation planning approaches can be constrained by several economic, institutional, developmental and political barriers (Anguelovski et al., 2014; Eisenack et al., 2014), including strong political support, that is, the lack of collective willingness to take action. Despite the ongoing accumulation of scientific evidence as to the seriousness of the impact of climate change on water resources, state action has not always been effective. There are now a rising number of case laws addressing the state's failure to implement adaptation policies and resultant climate change litigation (Setzer and Vanhala, 2019; Peel and Osofsky, 2020), including in the water sector, as in the leading case Leghari v Federation of Pakistan (2015 WP. No. 25501/201), in which a farmer sued the national government for failure to carry out national climate change policies impacting on the constitutional right to life (Preston, 2016).

The 2015 Paris Agreement made a significant impact on the status quo, with almost all the countries agreeing to limit global warming to 2°C or less. The preparation of NDCs under the Paris Agreement contributed positively to national climate policies and helped focus on the centrality of water in adaptation planning (Röser et al., 2020). 92% of countries that mention adaptation in NDCs also include water (GWP, 2018). Low-income countries make specific reference to rainfed or irrigated agriculture and livestock. In contrast, middle and high-income countries include developing management, governance mechanisms and increased disaster risk reduction in their NDC pledges (GWP, 2018). Floods were the critical climate hazards identified in the adaptation components of NDCs, followed by droughts (85 out of countries for floods and 80 out of 137 for drought). Also, the water sector was identified as the top priority sector for adaptation actions in the NDCs for 118 out of 137 countries, followed closely by the agricultural sector with 100 out 137 (GWP, 2018) based on data from (UNFCCC, 2017). Many developing countries have included quantitative targets for adaptation in the water sector (Pauw et al., 2018). Similarly, water-related impacts and adaptation often feature prominently in NAPs (DEFRA, 2018).

Evidence suggests that adaptation failure in the water sector is due to policy and regulatory failures (Keohane and Victor, 2016; Oberlack and Eisenack, 2018; Javeline et al., 2019) reflecting political myopia (Muller, 2018; Empinotti et al., 2019; Pralle, 2019) (*high confidence*).

International donors and supranational/transnational legislation (e.g. EU law) can support the capacity of national and sub-national governments to act and remove possible barriers to the effective implementation of climate change adaptation policies in the water sector, including obstacles posed due to lack of financial support for the developing countries (Massey et al., 2014; Tilleard and Ford, 2016; Biesbroek et al., 2018; Rahman and Tosun, 2018) (*medium confidence*).

[START FAQ4.1 HERE]

FAQ4.1: What is water security, and how will climate change affect it?

Water is essential for all societal and ecosystems needs. Water security is multi-dimensional and not just about water availability. Water needs to be available in sufficient quantity and quality and needs to be accessible in an acceptable form. Accordingly, a situation of water security indicates the availability and accessibility of sufficient clean water to allow a population to sustainably ensure its livelihoods, health, and socio-economic development and political stability. Many socio-economic factors, such as population *growth and food consumption patterns, play an important role in determining water security. Still, climate change is increasingly shown to be an important contributor to water insecurity worldwide, with some regions more at risk than others.*

Climate change can affect these different dimensions of water security in different ways. Most directly, climate change is affecting the overall availability of water across regions and during important seasons. More extended periods of dry spells and droughts are already affecting water availability, especially in the arid areas of India, China, the USA and Africa. Other extremes, such as heavy precipitation and flooding, can affect water quality, making water unsafe for drinking, for example. In coastal regions and small islands, the combined effects of higher sea levels and more intense storms affect water security by increasing the salinization of groundwater resources. Indirect effects of climate change on water security include impacts on infrastructure for the provision and recovery of water resources, which can affect the safe access to adequate water resources, both in terms of quality and quantity.

In terms of assessing the extent of water scarcity, studies estimate that currently, between 1.5 and 2.5 billion people live within areas exposed to water scarcity globally. These numbers are projected to increase continuously, with estimates of up to 3 billion at 2°C and up to 4 billion at 4°C by 2050. Many socio-economic factors, such as population growth and food consumption patterns, determine water scarcity. Still, climate is increasingly shown to be an important component that drives scarcity across the world. Water scarcity is often a seasonal occurrence, and climate change is projected to increase seasonal extremes. Often consecutive years with drier conditions lead to a long-term decrease in groundwater tables, affecting water availability directly and soil moisture in the longer term.

As an essential component of water security, climate change will affect water quality in different ways. Drier conditions lead to a reduction in water availability, causing a potential increase in the concentration of contaminants. Increasing runoff and floods can wash pollutants into water bodies. With climate change projected to increase the variability of rain over space and time, such impacts on water quality are becoming increasingly likely. Higher temperatures add to deteriorating water quality by reducing oxygen levels.

Another critical component to ensure secure access to water resources is adequate water infrastructure for access, disposal and sanitation. Unfortunately, increasing extremes due to climate change, especially floods and increasing storm activity, have great potential to damage such infrastructure, especially in developing world regions, where infrastructure is much more susceptible to damage and pollution.

There are substantial differences in the distribution of risks across regions, with some areas facing a much higher risk burden than others. Also, projections of the potential impacts of climate change on water security vary across regions. However, patterns of projected water-related extremes are emerging more clearly globally with increasing confidence.

[END FAQ4.1 HERE]

[START FAQ4.2 HERE]

FAQ4.2: Which places are becoming wetter and which are becoming drier, and what risks do these bring to people?

Due to climate change, substantial numbers of people are now living in climates with average precipitation levels significantly different to the average over the 20th century. Nearly half a billion people are living in unfamiliar wet conditions, mostly in mid- and high-latitudes, and over 160 million people are living in unfamiliar dry conditions, mostly in the tropics and sub-tropics. In addition to changes in average precipitation, precipitation patterns over time are also changing, as well as river flows. Societal impacts and increased risks from both wetter and drier conditions are starting to emerge.

Some parts of the world are becoming wetter and some are becoming drier, in terms of either changes in precipitation and/or the water available in the soil, in rivers, or underground. Soil moisture, river water and groundwater are affected by changes in precipitation and also by changes in evaporation, which is affected by temperature and by uptake by vegetation.

All these factors are affected by climate change. Rising temperatures drive higher evaporation, which dries the landscape, although this can be offset in some areas by reduced uptake of water from the soil by plants in response to rising CO_2 concentrations. A warming climate brings more precipitation overall, although changes in global wind patterns mean that some areas are seeing less precipitation.

As a result, substantial numbers of people are now living in climates with average precipitation levels significantly different to the average over the 20th century. Nearly half a billion people are living in unfamiliar wet conditions, mostly in mid- and high-latitudes, and over 160 million in unfamiliar dry conditions, mostly in the tropics and sub-tropics (Figure FAQ4.2.1).

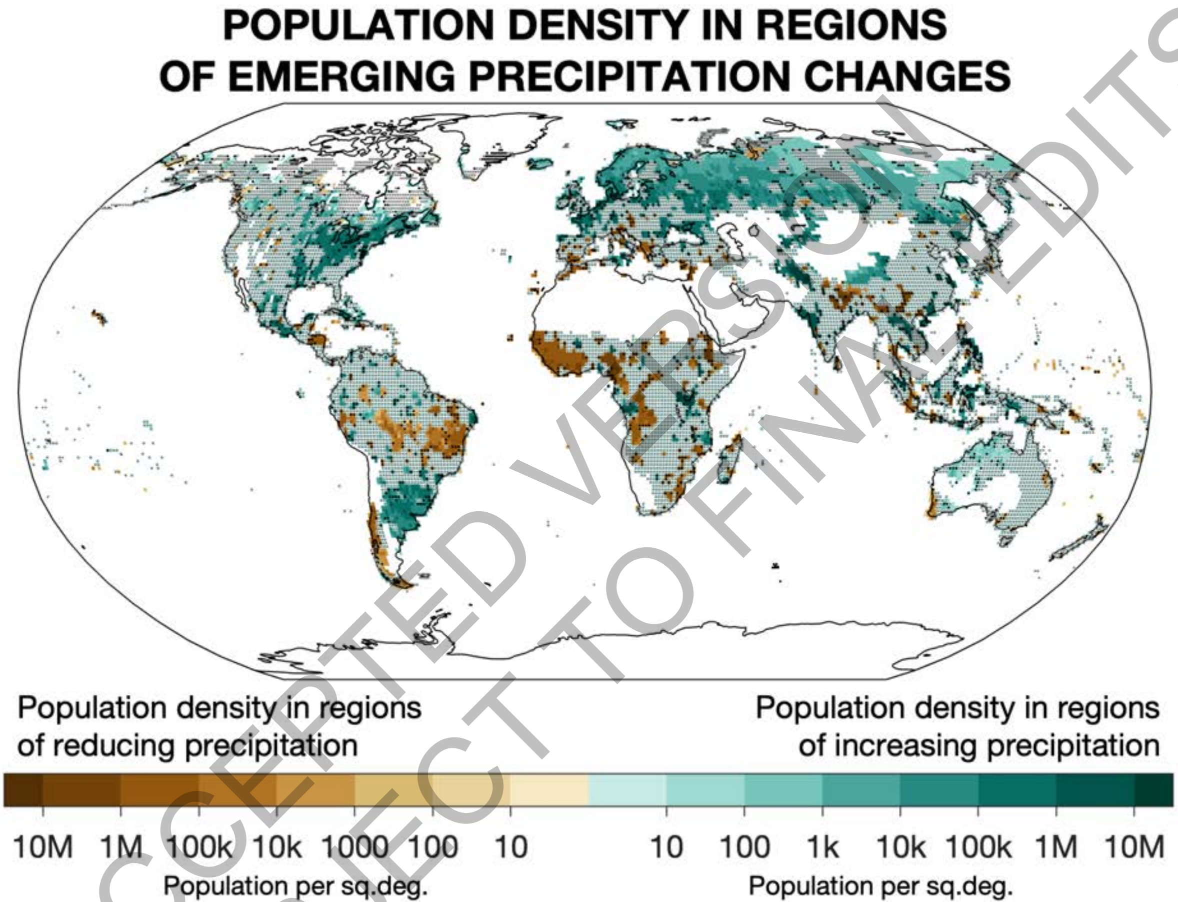

Figure FAQ4.2.1: Numbers of people seeing increases and decreases in precipitation.

In addition to changes in average precipitation, the patterns over time are also changing, such as the length of dry spells and the amount of precipitation falling in heavy events. Again, these changes vary across the world due to shifting wind patterns. Approximately 600 million people live in places with longer dry spells than in the 1950s, mostly in West Africa, south Asia and parts of South America. Approximately 360 million people experience shorter dry spells, in North America, northern Asia and other parts of South America.

In contrast, far more people (about 600 million people) are seeing heavier precipitation than less heavy precipitation (80 million). A more widespread increase in heavy precipitation is expected in a warming world, where the warmer atmosphere takes up more moisture and hotter ground drives more intense storms.

River flows are also changing in many parts of the world, often due to changes in precipitation, although direct human impacts are also important. Generally, the most widespread increased river flows are seen high latitudes, while decreasing flows are seen in mid- and low- latitudes, although there are major exceptions to these trends and data is sparse in many regions (Figure FAQ4.2.2).

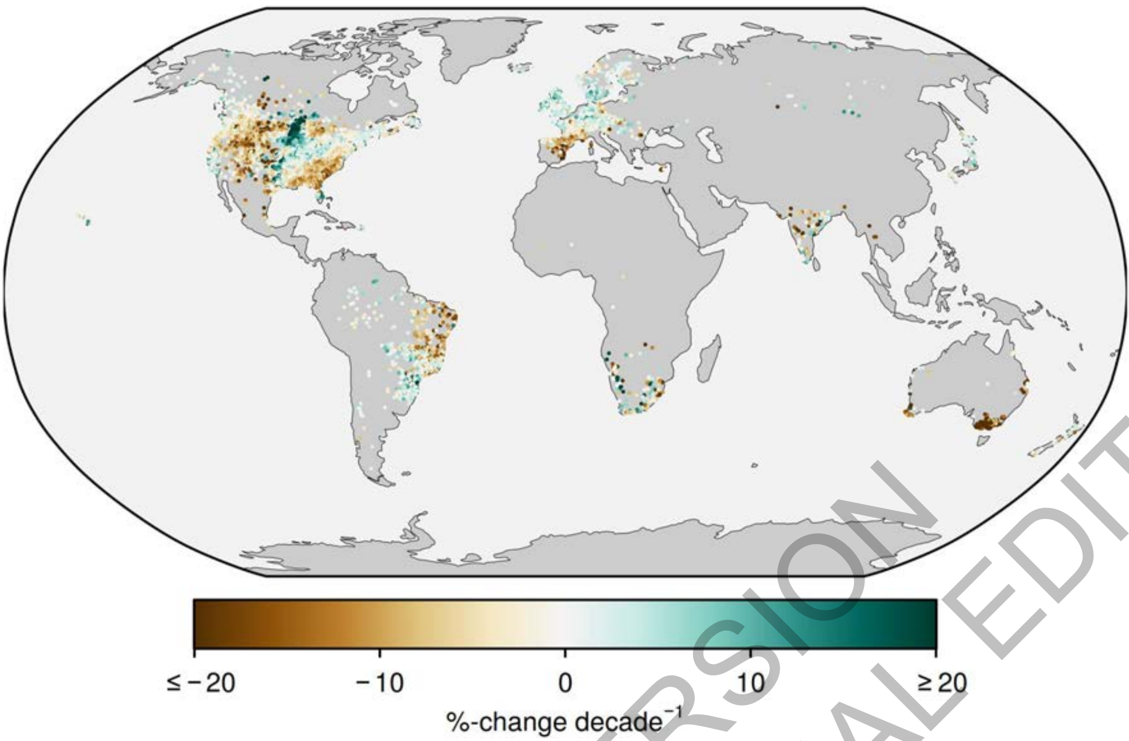

Figure FAQ4.2.2: Observed changes in mean river flows from 1971-2010

Some of these changes are starting to have impacts on society. For example, increasing rainfall in the USA has led to increased crop yields. Heavy rainfall and long periods of rainfall lead to flooding, causing deaths, injuries, infrastructural damage, spread of disease, disruptions to employment and education, psychological trauma, and territorial displacement. The weather conditions associated with many recent major flooding events were made *more likely* by climate change, although non-climatic factors remain the dominant driver of increased flooding.

Drier soils have made heatwaves more severe. A drying of the landscape has increased the length of the fire season across much of the world, contributing to unprecedented severity of wildfires in recent years. In recent years, several major drought events with impacts on agriculture were made *more likely* by climate change.

Overall, the general picture is of increased average precipitation and/or longer periods of precipitation in the mid and high latitudes, but decreased precipitation and/or longer times between precipitation across much of the tropics and sub-tropics. Where heavy precipitation is changing, this is mostly towards increasing intensity. Societal impacts and increased risks from both wetter and drier conditions are starting to emerge.

[END FAQ4.2 HERE]

[START FAQ4.3 HERE]

FAQ4.3: How will climate change impact the severity of water-related disasters, such as droughts and floods?

Climate change will lead to populations becoming more vulnerable to floods and droughts due to an increase in the frequency, magnitude, and total area affected by water-related disasters. Floods and droughts will also affect more people in the course of this century as a result of population growth and increased urbanization, especially if warming cannot be limited to 1.5°C. The impact of floods and droughts *are expected to increase across all economic sectors, resulting in negative outcomes for the global production of goods and services, industry output, employment, trade, and household consumption. Floods will pose additional risks to people's lives and health through inundation, facilitating the further spread of waterborne diseases. At the same time, droughts can have adverse health impacts due to the limited availability of food and water for drinking and hygienic purposes. All losses, both in terms of lives and in economic terms, will be more limited in a 1.5°C than in a 3°C warmer world.*

Anthropogenic land-use changes and climate change will exacerbate the intensity, frequency and spatial extent of floods and droughts, leading to populations becoming more vulnerable. According to projections, these increases in extreme events will be more significant with higher levels of global warming. However, the location and severity of floods and droughts are context-dependent and complex phenomena.

The processes that lead to droughts include lack of or less frequent precipitation, increased evapotranspiration, and decreased soil moisture, snow cover, runoff, and streamflow. For example, warming temperatures may result in higher evapotranspiration, in turn leading to drier soils. In addition, reduced soil moisture diminishes the amount of water filtering into rivers in both the short and long term while also increasing the aridity that can foster the conditions for fire. Moreover, decreased snow cover represents less runoff supply to downstream areas during warmer seasons. Depending on this process and the propagation of a meteorological drought onto further systems, a drought can be defined as hydrological, agricultural or ecological. Agricultural drought threatens food production through crop damage and yield decreases, and consequent economic impacts and, therefore, can be the most impactful to humans. Geographically the likelihood of agricultural drought is projected to increase across most of southern Africa, Australia, the majority of Europe, the southern and western United States, Central America and the Caribbean, north-west China, parts of South America, and the Russian Federation; but due to increased precipitation, it is projected to decline in, Southeastern South America, Central Africa, central Canada, western India and the south of the Arabian Peninsula.

Flood hazard natural processes usually result from increases in heavy precipitation events, but they can also be caused by saturated soils, increased runoff and land-use changes. A warming climate usually causes greater energy for the intense upward motion for storm formation and increases evapotranspiration, which leads to heavier precipitation. Many places around the world will experience more than average rainfall, which may increase soil moisture. Wetter soils saturate faster during precipitation events, resulting in increased runoff that can muddy the waters and lead to floods. Anthropogenic land-use changes, such as urbanization, deforestation, grasslands, and agricultural extension, can also reduce the amount of water infiltrating the soil and leading to frequent flooding. Floods are expected to increase in Asia, the U.S., and Europe, particularly in areas dependent on glaciers' water where melting will lead to earlier spring floods. Additionally, fluvial floods are projected to be more frequent in some regions in central Africa and northern high latitudes and less frequent in the southern areas of North America, southern South America, the Mediterranean, parts of Australia and southern parts of Europe.

Globally, socioeconomic development will lead to heightened societal hazards. Due to population growth and increased urbanization, floods and droughts will affect more people in the course of this century, especially if warming cannot be limited to 1.5°C. All losses, both in lives and in economic terms, will be more limited in a 1.5°C than in a 3°C warmer world. The impacts of floods and droughts are expected to increase across all economic sectors, from agriculture to energy production, resulting in negative outcomes for our global production of goods and services, industry output, employment, trade and household consumption. Landslides, sinkholes and avalanches arising from heavy rainfall events will increasingly threaten infrastructure and agricultural production. In cities, increased flood frequency could disrupt waste management systems, resulting in the clogging of waterways. In addition, unprecedented flood magnitudes could overwhelm hydraulic infrastructure, affecting the energy, industry, and transportation sectors. An expansion in inundation area, coupled with urban sprawl, would increase flood damage. Floods will pose additional risks to people's lives and health through inundation, facilitating the spread of waterborne diseases. At the same time, drought can have adverse health impacts due to the limited availability of food and water for drinking and hygienic purposes. Although there are no agreed-upon projections for migration and displacement due to water-related disasters, it is known that drought and desertification cause harvest failures, which may lead subsistence farmers to relocate to urban areas. Whether temporary or permanent, displacement is often mired with diminished safety, loss of social ties, and a weakened sense of place and cultural identity.

Finally, vulnerable groups such as people living in poverty, women, children, Indigenous Peoples, uninsured workers, and the elderly will be the most affected by water-related disasters.

[END FAQ4.3 HERE]

[START FAQ4.4 HERE]

FAQ4.4: Globally, agriculture is the largest user of water. How will climate change impact this sector, and how can farmers adapt to these changes?

Climate-induced changes in the global hydrological cycle are already impacting agriculture through floods, droughts and increased rainfall variability, which have affected yields of major crops such as maize, soybeans, rice and wheat. These changes are projected to continue in a warmer world, which will cause yields of rain-fed crops to decline and reduce the amount of water available for irrigation in water-stressed regions. Farmers already use adaptation and coping strategies to manage agricultural water use. Some of the most important adaptation responses are the application of irrigation, on-farm water and soil conservation; changing cropping patterns; adopting improved cultivars, and improved agronomic practices. In many parts of the world, farmers increasingly use Indigenous Knowledge and local knowledge to inform their decisions of what to grow, when to grow, and how much to irrigate. To offset the risks of market-related volatility coupled with climate change, farmers also adopt economic and financial instruments such as index-based crop insurance. Training and capacity building programs and social safety nets are other forms of adaptation that farmers are using to respond to these changes.

Worldwide, and especially in developing countries, agriculture (including crop cultivation and livestock and fisheries) is the largest water user, accounting for 50% to 90% of all water use. Moreover, a substantial part of the water used in agriculture is "consumptive" use, which means that the water is "consumed" for crop growth and is not immediately available for other uses. This is different from other sectors, such as energy production, where only a fraction of the water is "consumed", and other downstream users can re-use the rest. Agriculture also accounts for a large share of employment in developing countries, with 60 to 80% of the rural population dependent on agriculture for their livelihoods. Agriculture provides food security for all. This makes farmers and agriculture particularly vulnerable to climate change.

Climate-induced changes in the global hydrological cycle are already impacting agriculture through floods, droughts and increased rainfall variability. For example, loss in yields has been reported for major crops such as maize (by 4.1%), soybeans (by 4.5%), rice (by 1.8%) and wheat (by 1.8%) due to changes in precipitation between 1981 to 2010. In addition, drought has affected both the area under cultivation and the yields of major crops. According to one estimate, globally, there has been a loss of 9 to 10% of total cereal production due to droughts and other weather extremes. Similarly, floods are one of the significant reasons for crop losses worldwide. Climate change-induced losses in livestock and fisheries have also been documented. In some parts of the world, especially in cold temperate zones, agro-climatic zones have become more conducive to yield growth in crops like maize and soybean due to increases in summer precipitation. Yet, negative impacts far outweigh positive impacts.

Projected impacts on agriculture due to changes in water availability are also severe. For example, yields of rain-fed crops such as maize are projected to decline by 1/5th to 1/3rd by the end of the century. In contrast, many areas which currently support multiple crops may become unsuitable for rain-fed farming or support only one crop in a year. Irrigation, which is often one of the most effective adaptive strategies against water-induced stress, is also projected to be affected by a reduction of the amount of water available for irrigation in some parts of the world that are already water-stressed or as a result of groundwater depletion in places such as India, North China, and the north-western United States. Overall, future droughts and floods will pose a major risk to food security, and agriculture and impacts will be more severe on countries and communities that are already food insecure.

Given that farmers are already dealing with variability in the amount and timing of rainfall. In many places, demand for agricultural water is greater than supply, and farmers are using many adaptations and coping strategies to meet water demands for their crops, fish and livestock. Some of the most popular adaptation responses around crops and water include:

- changing cropping patterns to less water-intensive crops, and changes in the timing of sowing and harvesting to respond to unfamiliar trends in the onset of rains;
- adoption of improved cultivars, such as drought and flood-resistant seed varieties;
- improved agronomic practices, including conservation agriculture that helps reduce water application rates;
- irrigation and water-saving technologies such as efficient irrigation and on-farm water management techniques;
- on-farm water and soil moisture conservation.

Most of these measures are beneficial across multiple indicators (water saving, increased incomes etc.), however, whether they also reduce climate related risks is not well understood and remains a knowledge gap. Irrigation and changes in crop choices and cultivars are also shown to be effective for future adaptation, especially at 1.5°C global warming levels, but much less effective at 2°C and 3°C when these responses will not mitigate a large part of the climate risk. Most of these adaptation measures mentioned above are autonomous. However, some, such as improved seeds and cultivars, are supported by national agricultural research agencies, international research coalitions such as the CGIAR, and private seed companies. In many parts of the world, farmers are also increasingly using Indigenous Knowledge and local knowledge to inform these decisions of what to grow, when to grow, and how much to irrigate.

Given the predominance of market economies worldwide, most farmers also depend on the market to sell their produce, and market fluctuations affect their incomes. In addition, market-related volatility coupled with climate change is a source of increased risk for farmers. Several economic and financial instruments are being used with varying levels of success to offset some of these interlinked impacts. Index-based crop insurance is one such instrument that compensates farmers for losing crops due to hazards such as floods and droughts. However, several limitations in their implementation remain.

In cases of severe droughts and floods, which have debilitating impacts on already poor and vulnerable populations, national governments provide social safety programs, such as food or cash-for-work programs, which are shown to be successful in reducing risks for the most vulnerable people, even though there are often concerns with targeting efficiency. Providing training and capacity building of farmers to adopt new farming practices and technologies to manage risk better are also known to be effective when the training is conceptualized, targeted and implemented in consultation with farmers. Planned adaptation practices include managing weather and market risks through insurance products, social safety nets for vulnerable populations, and providing the right mix of training and capacity building. These adaptation practices are generally implemented by civil society, governments and the private sector.

Figure FAQ4.4.1: Water-related adaptation responses in agriculture sector: benefits, co-benefits with mitigation, and possible maladaptation

[END FAQ4.4 HERE]

[START FAQ4.5 HERE]

FAQ4.5: Which principles can communities implement to sustainably adapt to the ways that climate change is impacting their water security?

For communities to sustainably adapt to climate impacts on water security, their participation, cooperation, and bottom-up engagement are critical in all stages of decision-making processes. In addition to enhancing the legitimacy of the decision-making process, the community's involvement can increase the equitability *and effectiveness of the adaptation approach. As water insecurity disproportionately affects marginalised social groups, their participation in water governance and implementation can help improve their water security. Combining and integrating local, Indigenous and traditional ecological knowledge with Western understandings of climate change can enhance the effectiveness of adaptation measures and strategies while ensuring that the adaptation is equitable and just. Improving water security is fundamental to achieving many of the 17 Sustainable Development Goals (SDGs).*

For decades, communities worldwide have already been adapting to climate change-induced hydrological changes to maintain their livelihood and safety. Adaptation is a multi-faceted process that is implemented differently depending on the sector affected by changes in the hydrological cycle and the region where these changes happen. For instance, farmers in the semi-arid areas might adapt to changing rain patterns through irrigation (see also FAQ4.4). At the same time, urban dwellers can adopt measures such as rainwater harvesting and other nature-based solutions. Several principles have been documented as crucial for achieving sustainable adaptation as they support communities in becoming more resilient to climate change. However, these principles can be implemented singularly or in tandem, and it is essential to acknowledge that long-term adaptation success is context-specific. Therefore, it is critical to involve local communities in co-designing effective adaptation responses.

For communities to sustainably adapt to climate impacts on water security, participation, cooperation, and bottom-up engagement are critical in all stages of the decision-making processes, from planning to full implementation. Many of the countries and social groups most threatened by climate change have contributed least to global warming and do not have access to adequate resources to adapt. Effective participation of these actors in water-related climate change adaptation planning can contribute to more equitable adaptation actions. The involvement of the most vulnerable in the design of adaptation responses makes it more probable that these solutions will suit their needs and have therefore a higher change of being effective to be effective. Accessible, inclusive and well-coordinated efforts to enhance water security will improve the legitimacy of water governance and work synergistically with reducing inequalities (UN Sustainable Development Goal, SDG 10) and encouraging more sustainable communities (SDG 11). Communities can also be involved in sector-specific adaptation responses. These are often water-related and help ensure that climate action (SDG13) is well aligned with clean water and sanitation (SGD6).

The participation of traditionally excluded groups such as women and marginalised communities and Indigenous people and ethnic minorities contributes to more equitable and socially just adaptation actions. Water insecurity disproportionately affects these marginalised groups, and their participation in water governance and implementation can help alleviate this burden.

Recognising the importance of Indigenous Knowledge and Local Knowledge in improving water security is vital to ensuring that decisions and solutions align with the interests of Indigenous and local peoples and benefit their communities culturally and economically. Furthermore, the effectiveness of adaptation measures and strategies improves when local, Indigenous Knowledge and traditional ecological knowledge is combined and integrated with technical understandings of climate change.

The climate adaptation plans led by national governments and local authorities will only be accepted and adequately implemented when supported by the community. Therefore, strong political and societal support is necessary to ensure effective policy changes, whether local or national. Significantly, access to financial assistance from private and public sources expands the range of strategies that communities can consider for enhancing their water security.

These principles are also conducive to the achievement of the United Nations Sustainable Development Goals. Actions that reduce climate risk and enhance water security can positively interact with sustainable development objectives (synergies). Therefore, improving water security is fundamental to achieving many of the 17 Sustainable Development Goals (SDGs).

Executive Summary

Current Impacts

Climate change impacts are stressing agriculture, forestry, fisheries, and aquaculture, increasingly hindering efforts to meet human needs (*high confidence*[1]). Human-induced warming has slowed growth of agricultural productivity over the past 50 years in mid- and low-latitudes (*medium confidence*). Crop yields are compromised by surface ozone (*high confidence*). Methane emissions have negatively impacted crop yields by increasing temperatures and surface ozone concentrations (*medium confidence*). Warming is negatively affecting crop and grassland quality and harvest stability (*high confidence*). Warmer and drier conditions have increased tree mortality and forest disturbances in many temperate and boreal biomes (*high confidence*), negatively impacting provisioning services (*medium confidence*). Ocean warming has decreased sustainable yields of some wild fish populations (*high confidence*). Ocean acidification and warming have already affected farmed aquatic species (*high confidence*). {5.2.1, 5.4.1, 5.5.1, 5.6.1, 5.7.1, 5.8.1, 5.9.1}

Warming has altered the distribution, growing area suitability and timing of key biological events, such as flowering and insect emergence, impacting food quality and harvest stability *(high confidence)*. It is *very likely*[2] that climate change is altering the distribution of cultivated, wild terrestrial, marine and freshwater species. At higher-latitudes warming has expanded potential area but has also altered phenology (*high confidence*), potentially causing plant-pollinator and pest mismatches (*medium confidence*). At low-latitude temperatures have crossed upper tolerance thresholds more frequently leading to heat stress (*high confidence*). {5.4.1, 5.7.4, 5.8.1, Cross-Chapter Box MOVING PLATE this Chapter , 5.12.3.4}

Climate-related extremes have affected the productivity of all agricultural and fishery sectors, with negative consequences for food security and livelihoods (*high confidence*). The frequency of sudden food production losses has increased since at least mid-20th century on land and sea *(medium evidence, high agreement)*. Droughts, floods, and marine heatwaves contribute to reduced food availability and increased food prices, threatening food security, nutrition, and livelihoods of millions *(high confidence)*. Droughts induced by the 2015-2016 El Niño, partially attributable to human influences (*medium confidence*), caused acute food insecurity in various regions, including eastern and southern Africa and the dry corridor of Central America (*high confidence*). In the northeast Pacific, a recent 5-year warm period impacted the migration, distribution, and abundance of key fish resources (*high confidence*). Increasing variability in grazing systems has negatively affected animal fertility, mortality, and herd recovery rates, reducing livestock keepers' resilience (*medium confidence*). {WGI AR6 Sections 11.2-11.8, 5.2.1, 5.4.1, 5.4.2, 5.5.2,5.8.1, 5.9.1, 5.12.1, 5.14.2, 5.14.6, Cross-Chapter Box MOVING PLATE this Chapter}

Climate change impacts everybody, but vulnerable groups, such as women, children, low-income households, Indigenous or other minority groups and small-scale producers, are often at higher risk of malnutrition, livelihood loss, rising costs and competition over resources (*high confidence*). Increasing competition for land, energy, and water, exacerbates impacts of climate change on food security (*high confidence)*. {5.4.2.2, 5.5.2.6; 5.8.2.2, 5.9.2.1, 5.12.2, 5.12.3.1; 5.12.3.2; 5.12.3.3; 5.13.1, 5.13.3, 5.13.4}

Projected Impacts

Climate change will make some current food production areas unsuitable (*high confidence*). Current global crop and livestock areas will increasingly become climatically unsuitable under a high emission scenario (*high confidence*) (e.g.,10% by 2050, over 30 % by 2100 under SSP-8.5 vs below 8% by 2100 under SSP1-2.6). Increased, potentially concurrent climate extremes will periodically increase simultaneous losses

---

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*. This Report also uses the term 'likely range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

in major food-producing regions (*medium confidence*). {WGI Section 11.8, 5.2.2, 5.4.1, 5.4.3, 5.5.2, 5.5.3, Cross-Chapter Box MOVING PLATE in Chapter 5 this Chapter, Section 5.12.4}

Impacts on food availability and nutritional quality will increase the number of people at risk of hunger, malnutrition and diet-related mortality (*high confidence*). Climate change will increase the number of people at risk of hunger in mid-century, concentrated in Sub-Saharan Africa, South Asia and Central America (*high confidence*) (e.g. between 8 million under SSP1-6.0 to 80 million people under SSP3-6.0). Increased CO_2 concentrations will reduce nutrient density in some crops (*high confidence*). Climate change will increase loss of years of full health[3] by 10% in 2050 under RCP8.5 due to undernutrition and micronutrient deficiencies (*medium evidence, high agreement*). {5.2.2, 5.4.2, 5.4.3, 5.12.1.2, 5.12.4; Cross-Chapter Box MOVING PLATE this Chapter}

Climate change will increasingly expose outdoor workers and animals to heat stress, reducing labour capacity, animal health, and dairy and meat production (*high confidence*). The number of days with climatically stressful conditions for outdoor workers will increase by up to 250 workdays per year by century's end in some parts of South Asia, tropical sub-Saharan Africa and parts of Central and South America under SSP5-8.5, with negative consequences such as reduced food productivity, higher costs and prices (*medium confidence*). From early-to end-century, cattle, sheep, goats, pigs and poultry in the low latitudes will face 72-136 additional days per year of extreme stress from high heat and humidity under SSP5-8.5. Meat and milk productivity will be reduced (*medium confidence*). {5.5.3.4; 5.12.4}

Climate change will further increase pressures on terrestrial ecosystem services supporting global food systems (*high confidence*). Climate change will reduce the effectiveness of pollinator agents as species are lost from certain areas, or the coordination of pollinator activity and flower receptiveness is disrupted in some regions (*high confidence*). Greenhouse gas emissions will negatively impact air, soil, and water quality, exacerbating direct climatic impacts on yields (*high confidence)*. {5.4.3, Box5.3, Box5.4, 5.5.3.4; 5.7.1, 5.7.4, 5.10.3}

Climate change will significantly alter aquatic food provisioning services and water security with regional variances (*high confidence*). Climate change will reduce marine fisheries and aquaculture productivity, altering the species that will be fished or cultured, and reducing aquaculture habitat in tropical and sub-tropical areas (*high confidence*).. Global ocean animal biomass will decrease by 5 to 17% under RCP2.6 and 8.5 respectively from 1970 to 2100 with an average decline of 5% for every 1°C of warming, affecting food provisioning, revenue value and distribution, (*medium confidence*). Global marine aquaculture will decline under warming and acidification from 2020 to 2100, with potential short-term gains for temperate finfish and overall negative impacts on bivalve aquaculture from habitat reduction (50-100% for some countries in the Northern Hemisphere) (*medium confidence*). Changes in precipitation, sea level, temperature, and extreme climate events will affect food provisioning from inland and coastal aquatic systems (*high confidence*). Sea-level rise and altered precipitation will increase coastal inundation and water conflicts between water-dependent sectors, such as rice production, direct human use, and hydropower (*medium confidence*). {5.8.3, 5.9.3, 5.13, Cross-Chapter Box SLR in Chapter 3}.

The occurrence and distribution of pests, weeds and diseases, including zoonoses, in agricultural, forest and food systems (terrestrial and aquatic) will be altered and their control will become costlier (*medium confidence*). Changes in the rates of reproduction and distribution of weeds, insect pests, pathogens and disease vectors will increase biotic stress on crops, forests, and livestock, and will increase the risk of biodiversity loss and ecosystem degradation (*medium evidence, high agreement*). Risks will increase for climate-driven emerging zoonoses (*medium evidence, high agreement*). {5.4.1.3, 5.9.4, Cross-Chapter Box MOVING PLATE this Chapter}

Forest production systems will have variable responses to climate change across regions, with negative effects being more predominant in tropical forests (*high confidence*). In temperate and boreal regions, some productivity gains are projected, but tree mortality will increase in some areas (*high confidence*). In tropical forests, change in species composition and forest structure will lower production *(medium confidence*). Some models project a possible increase in global wood supply and lowering of average wood

[3] Disability-Adjusted Life Years or DALYs.

prices, but they do not account for the negative impacts of extreme events and thus possibly overestimate the wood supply (*medium confidence*). {5.6.2}

Climate change will negatively impact food safety (*high confidence*). Higher temperatures and humidity will favour toxigenic fungi, plant and animal-based pathogens, and harmful algal blooms (HABs) (*high confidence*). More frequent and intense flood events and increased melting of snow and ice will increase food contamination (*high confidence*). Incidence and severity of harmful algal blooms and water-borne diseases will increase, as will indirect effects from infrastructure damage during extreme events (*high confidence*). {5.4.3, 5.5.2.3, 5.8.1, 5.8.2, 5.8.3, 5.9.1, 5.11.1, 5.11.3, 5.12.3; Cross-Chapter Box ILLNESS in Chapter 2}

Adaptation

Many autonomous adaptation options have been implemented in both terrestrial and aquatic systems, but on-farm adaptations are insufficient to meet SDG2 (*high confidence*). Autonomous responses include livestock and farm management, switching varieties/species and altered timing of key farm activities such as planting or stocking (*high confidence*). However, because of limited adaptive capacities and non-climatic compounding drivers of food insecurity, SDG2 will not be met (*high confidence*). {Table 5.1, 5.4.4; 5.5.4, 5.9.4, 5.10.4; 5.12.4}

Various adaptation options are currently feasible and effective at reducing climate impacts in different socio-cultural, economic, and geographical contexts (*high confidence*) but some lack adequate economic or institutional feasibility or information on limits (*medium confidence*). Feasible and effective options include cultivar improvements, community-based adaptation, agricultural diversification, climate services, adaptive eco-management in fisheries and aquaculture. There is *limited evidence, medium agreement* on the institutional feasibility or cost effectiveness of adaptation activities, and the limits to such adaptations. {5.4.4, 5.5.4, 5.6.3, 5.8.4, 5.9.4, 5.10.4, 5.11.4, 5.12.4, 5.14.1}

Ecosystem-based approaches such as diversification, land restoration, agroecology, and agroforestry have the potential to strengthen resilience to climate change with multiple co-benefits but trade-offs and benefits vary with socio-ecological context (*high confidence*). Ecosystem-based approaches support long-term productivity and ecosystem services such as pest control, soil health, pollination and buffering of temperature extremes (*high confidence*), but potential and trade-offs vary by socio-economic context, ecosystem zone, species combinations and institutional support (*medium confidence*). {5.4.4.4, 5.6.3, 5.10.4, 5.14.1, Cross-Chapter Box NATURAL in Chapter 2; Cross-Working Group Box BIOECONOMY this Chapter}

Bio-based products as part of a circular bioeconomy have potential to support adaptation and mitigation, with sectoral integration, transparent governance and stakeholder involvement key to maximizing benefits and managing trade-offs (*high confidence*). A sustainable bioeconomy relying on bioresources will need to be supported by technology innovation and international cooperation and governance of global trade to disincentivize environmental and social externalities (*medium confidence*). {Cross-Working Group Box BIOECONOMY this Chapter}

Sustainable resource management in response to distribution shifts of terrestrial and aquatic species under climate change is an effective adaptation option to reduce food and nutritional risk, conflict and loss of livelihood (*medium confidence*). Adaptive transboundary governance and ecosystem-based management, livelihood diversification, capacity development and improved knowledge-sharing will reduce conflict and promote the fair distribution of sustainably-harvested wild products and revenues (*medium confidence*). Other options include shared quotas and access rights considering trade-offs, shifting livelihoods to follow target species, new markets for emerging species, and technology {Cross Chapter Box MOVING PLATE this Chapter, 5.8.4, 5.14.3.4}

Implemented adaptation in crop production will be insufficient to offset the negative effects of climate change (*high confidence*). Currently available management options have the potential to compensate global crop production losses due to climate change up to ~2-°C warming, but the negative impacts even with adaptation will grow substantially from the mid-century under high temperature change scenarios (*high* *confidence*). Regionally, the negative effects will prevail sooner where current temperatures are already higher as in lower latitudes (*high confidence)*. {5.2.2, 5.4.3, 5.4.4, 5.8.4, 5.9.4, 5.14.2.4}

Supportive public policies will enhance effectiveness and/or feasibility of adaptation in ecosystem provisioning services (*medium confidence*). Policies that support system transitions include shifting subsidies, removing perverse incentives, regulation and certification, green public procurement, investment in sustainable value chains, support for capacity-building, access to insurance premiums and payments for ecosystem services, social protection, among others (*medium confidence*). {5.4.4.3; 5.4.4.4; 5.10.4.4; 5.12.6; 5.13.4; 5.14.1.3; 5.14.2.4; Box 5.13, Cross-Working Group Box BIOECONOMY in Chapter 2}.

Harnessing youth innovation and vision alongside other SDGs such as gender equity, Indigenous knowledge, local knowledge, urban and rural livelihoods, will support effective climate change adaptation to ensure resilient economies in food systems (*high confidence*). Adaptation strategies that address power inequities lead to co-benefits in equity outcomes and resilience for vulnerable groups (*medium confidence*). Indigenous knowledge and local knowledge facilitate adaptation strategies for ecosystem provisioning, especially when combined with scientific knowledge using participatory and community-based approaches (*high confidence*). {5.4.4.3, Table 5.6, 5.6.3, 5.8.4, 5.9.2, 5.9.4.1, 5.9.5, 5.10.2.2, 5.12.7, 5.12.8, 5.13.4, 5.13.5, 5.14.1.1, 5.14.1.2, 5.14.1.4,5.14.2.1, Box 5.13, 5.14.2.2 }

Policy decisions related to climate change adaptation and mitigation that ignore or worsen risks of adverse effects for different groups and ecosystems increase vulnerability, negatively affect capacity to deal with climate impacts, and impede sustainable development (*medium confidence with robust evidence, medium agreement*). Lacking sufficient stakeholder participation, large-scale land acquisitions have had mostly negative implications for vulnerable groups and climate change adaptation (*high confidence*). Policy and program appraisal of adaptation options that consider the risks of adverse effects across different groups at different scales and use inclusive rights-based approaches help avoid maladaptation (*medium confidence*). Successful forest adaptation involves recognition of land rights and cooperation with Indigenous Peoples and other local communities who depend on forest resources (*high confidence*). {5.6.3; 5.12.3, 5.13.1; 5.13.2; 5.14.2.1}

Financial barriers limit implementation of adaptation options in agriculture, fisheries, aquaculture and forestry and vastly more public and private investment is required (*high confidence)*. Public-sector investment in adaptation of agriculture, forestry and fisheries has grown four-fold since 2010 but adaptation costs will be much higher to meet future adaptation needs (*medium confidence*). Expanding access to financial services and pooling climate risks will enable and incentivize climate change adaptation (*medium confidence*). {5.14.3, 5.14.5., Cross-Chapter Box FINANCE in Chapter 17}.

Climate-resilient development pathways offer a way forward to guide climate action in food system transitions, but operationalisation is hampered by limited indicators and analyses (*medium confidence*). Robust analyses are needed that detail plausible pathways to move towards more resilient, equitable and sustainable food systems in ways that are socially, economically and environmentally acceptable through time (*high confidence*). Appropriate monitoring and rapid feedback to food system actors will be critical to the success of many current and future adaptation actions (*high confidence*). {5.14.4}

5.1 Introduction

5.1.1 Scope of the Chapter

This chapter assesses the scientific literature produced after AR5 dealing with past, current, and future climate change effects on managed ecosystems that provide provisioning and cultural services. It spans low and high intensity production systems for food, feed, fibre, and other ecosystem products.

Climate change has already had global impacts, including high income countries. Special emphasis is placed on the assessment of vulnerabilities of particular groups that are context- and location-specific, such as Indigenous Peoples and other minorities, women and small-scale food producers. The report builds on the IPCC AR5 and recent Special Reports. This chapter combines food systems, fibre, wood, and other products from ecosystems previously detailed in separate chapters of AR5, with an increased focus on ecosystem services, including the long-term sustainability of the global food system (Figure 5.1). The chapter focuses on key climate risks, implementation and outcomes of adaptation solutions for different groups as well as limits to adaptation.

5.1.2 Starting Point: AR5 and Recent IPCC Special Reports

AR5 Chapter 7 reported with *high confidence* that food production systems were being negatively impacted by climate change, including both terrestrial and aquatic food species (Porter et al., 2014). Increased temperatures will have large negative impacts on the food production system under 2°C warming by late 20th century, with temperatures exceeding 4°C posing even greater risk to global food security (Porter et al., 2014). Adaptation options are needed to reduce the risk from climate change, but there was limited information of their effectiveness.

The 1.5°C Special Report concluded that climate-related risks to food security will rise under 1.5°C and will increase further under 2°C or higher. Above 1.5°C, currently available adaptation options will be much less effective and site-specific limits to adaptation will be reached for vulnerable regions and sectors. There was *high confidence* that limiting warming to 1.5°C will result in smaller net reductions in yields of major crops affecting food availability and nutrition, and that rising temperatures will adversely affect livestock via changes in feed quality, fertility, production, spread of diseases and water availability.

The SRCCL expanded beyond the 1.5°C report to provide more in-depth information on climate change interactions with food security, desertification, and degradation. There was *high confidence* that climate risks, both for slow changes and extreme events, are interlinked with ecosystem services, health, and food security, often cascading and potentially reinforcing effects. Climate change already affects all dimensions of food security, namely availability, access, utilization, and stability, by disrupting food production, quality, storage, transport, and retail. These effects exacerbate competition for land and water resources, leading to increased deforestation, biodiversity reduction and loss of wetlands. With *high certainty*, limiting global warming would lower future risks related to land, such as water scarcity, fire, vegetation shifts, degradation, desertification and food insecurity and malnutrition, particularly for those most vulnerable today: small-scale food producers in low-income countries, Indigenous communities, women, and the urban poor. SRCCL assessed a range of adaptation pathways to increase food resilience.

The SROCC identified climate change impacts of warming, deoxygenation and acidification of the ocean and reductions in snow, sea ice and glaciers as having major negative impacts on fisheries and crops watered from mountain runoff, agriculture. These impacts affect food provisioning of food and directly threatening livelihoods and food security of vulnerable coastal communities and glacier-fed river basins. Climate change impacts on fisheries will be particularly high in tropical regions, where reductions in catch are expected to be among the largest globally, leading to negative economic and social effects for fishing communities and with implications for the supply of fish and shellfish (*high confidence*). While specific impacts will depend on the level of global warming and mitigative action to improve fisheries and aquaculture management, some current management practices and extraction levels may not be viable in the future.

5.1.3 Chapter Framework

This chapter is taking a food systems approach similar to the food security chapter in SRCCL (Mbow et al., 2019), with close attention to food system linkages, interactions and impacts on ecosystem services and biodiversity (Steffen et al., 2015; Raworth, 2017; Gerten et al., 2020). Climate change directly affects food systems, and the impacts on terrestrial or aquatic food production will become increasingly negative, although regionally some changes may be beneficial in the near future (Porter et al., 2014). Current food system trajectories are leading to biodiversity loss, land and aquatic ecosystem degradation without delivering food security and nutrition, sustainable and healthy livelihoods to many (Steffen et al., 2015). Addressing climate change in isolation ignores these interconnections, which is why the chapter considers integrated adaptation solutions to allow humanity to thrive in the long term. At the same time, social foundations of equality, justice and political participation are crucial in order to move toward a safe operating space for humanity (Raworth, 2017). The SDGs provide the most comprehensive set of metrics of humanity's progress in achieving equitable and thriving socio-ecological systems. Therefore, while the focus of this chapter is climate change impacts, vulnerability and adaptation of food systems, feed, fibre and other ecosystem products, other environmental and social challenges are considered concomitantly.

Food system and natural systems interact via political, economic, social, cultural, and demographic factors in complex ways, leading to food security and sustainability outcomes. The food system has a supply (production) and demand (consumption) side, connected via processing, trade and retail, with loss and waste streams all along the food chain. Natural ecosystems provide multiple services (regulating, supporting, provisioning, cultural) to the food system. Food security and nutrition strongly depend on the driving forces connecting food and natural systems while at the same time positively or negatively influencing them. Climate change frequently exacerbates the effects of other drivers of change, further limiting the environment within which humanity can safely operate and thrive. The chapter assesses how climate change affects the four pillars of food security and nutrition and how these effects can be mediated by various factors, including our adaptation responses, social equity, underlying ecosystem services and governance (Figure 5.1). Adaptation solutions are a major emphasis of this chapter, including many ecosystem-based adaptation options (Table 5.1), which fall under the broader umbrella of nature-based solutions (Seddon et al., 2020).

Ecosystem-based adaptation, defined as the "use of ecosystem management activities to increase the resilience and reduce the vulnerability of people and ecosystems to climate change" (Campbell et al., 2009), has at its core the recognition that there are unexploited synergies in agricultural systems that can increase productivity and resilience. These can result from increasing biodiversity, adding organic matter to soils, integrating livestock and aquatic species, including aquaculture, into farming practices, broadening landscape practices to exploit crop-forestry synergies, supporting beneficial insect populations, and altering pest management practices that have unintended negative consequences. In addition, the chapter considers socio-economic strategies to build resilience in the food system, strengthening local and regional economies, building on Indigenous and local knowledge, addressing social inequity, inclusive, participatory and democratic governance of food systems (HLPE, 2019; Wezel et al., 2020).

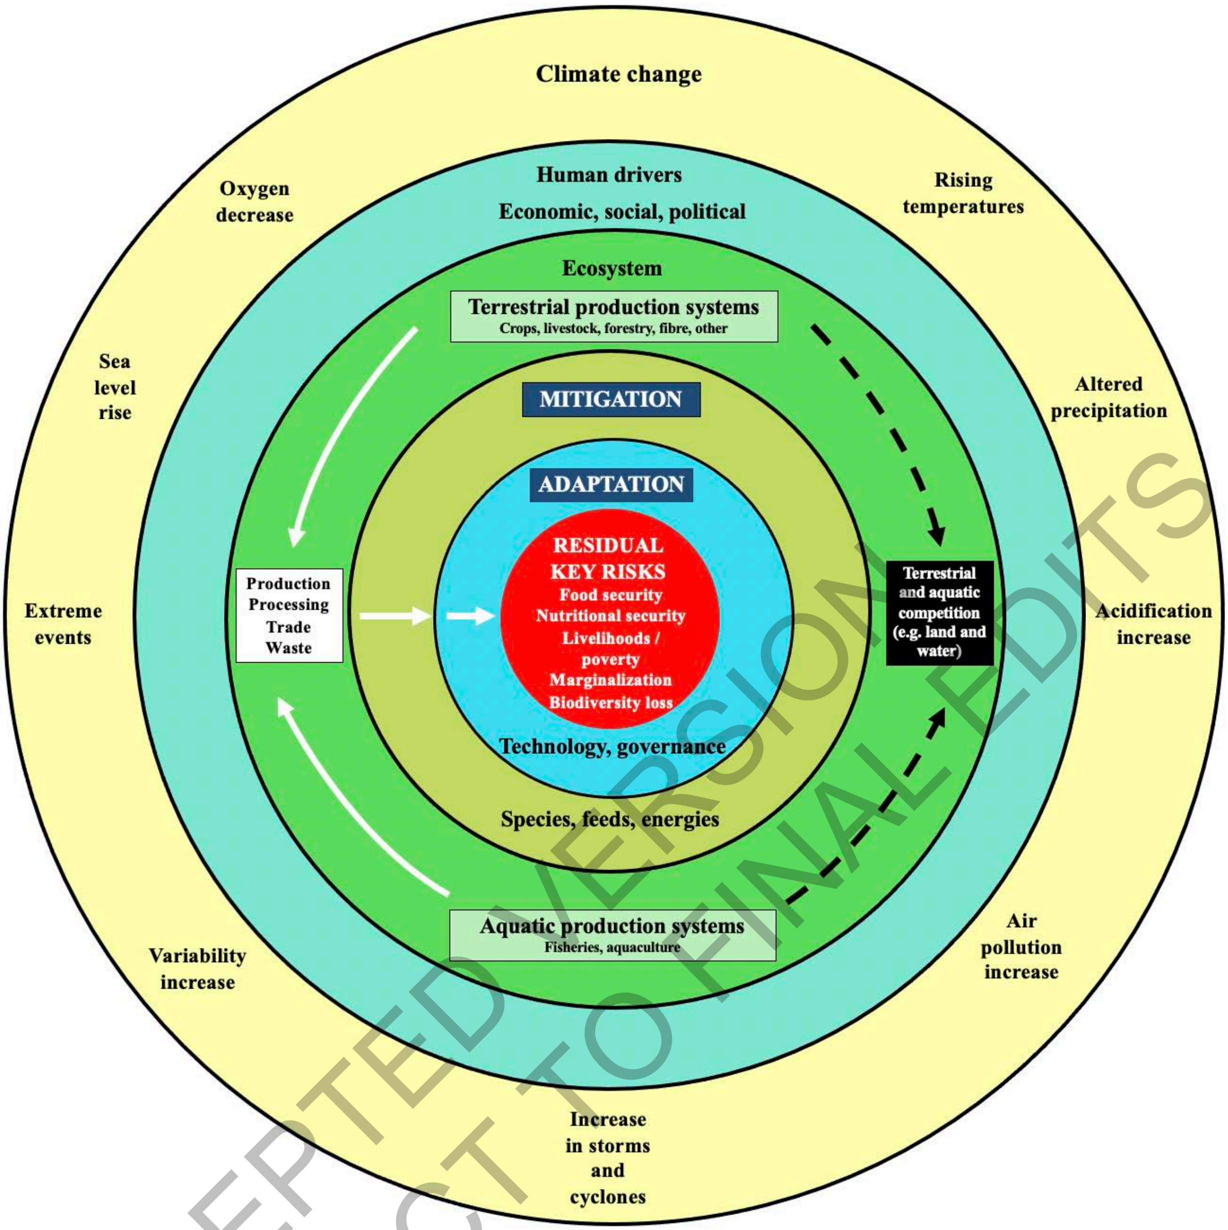

Figure 5.1: Conceptual framework of Chapter 5

Table 5.1: Adaptation strategies assessment in food, fibre, and other ecosystem provisioning services.

Adaptation strategies/options	Systems	Benefits	Constraints or enablers	Confidence	Relevant sections
• **Ecosystem-based integrated approaches such as agroecology that increase soil organic matter, enhance soil and water conservation, and diversify food production systems** • **Certain types of urban agriculture**	Crops	• Improve resilience of food systems • Provide mitigation measures and co-benefits in health, ecosystem services and other sustainable development goals	Secure tenure arrangements are often critical for delivering successful ecosystem-based adaptation.	*High*	(5.4.4.5, 5.6.3, 5.12.3, Cross-Chapter Box NATURAL in Chapter 2, 5.14.3.6, 5.14.3.11; Cross-Chapter Box HEALTH in Chapter 7)

		• Improve productivity and yield stability			
• **Increasing agroecosystem diversification through -expanding crop, animal, fish and other species genetic diversity -varying spatial and temporal arrangements including mixed planting, crop rotations, integrated crop, livestock and agroforestry systems**	Crops, Livestock, Aquaculture, Mixed, Agroforestry systems	• Increase resilience, productivity, and sustainability of farming systems under climate change.	Policies and technologies that support diversification at landscape and farm levels: programs that reward farmers for diversification practices, reduced incentives for intensified monocultures, extension support and market infrastructure for diverse crops, and productivity research on a greater variety of crops with support for post-harvest processing and regional markets	*High*	(5.4.4.4, 5.14.3.1, 5.14.3.6)
• **Changing the relative emphasis on crops and livestock** • **Changing crop varieties and livestock breeds and species**	Crops-livestock mixed system particularly in the tropics and subtropics	• Increase resilience	Gender inequalities can act as a risk multiplier	*Medium*	(5.5.4; 5.10.4)
• **Indigenous and local knowledge including participatory plant breeding or community-based adaptation**	Crops, Forestry, Fisheries	• Increase resilience and sustainability of food, fibre, forest, and small-scale fisheries production	Indigenous knowledge and local knowledge can facilitate adaptation when combined with scientific knowledge and utilized in management regimes.	*High*	(5.4.4.5, 5.6.3, 5.14.3)
• **Land restoration** • **Agroforestry** • **Silvo-pasture**	Forestry	• Improve resilience and productivity	Partnerships between key stakeholders such as researchers, forest managers, Indigenous and local forest dependent communities will facilitate sustainable forest management	*Medium*	(5.6.3)

• **Improved management practices that consider fish stocks and the ecosystem (ecosystem-based management, adaptive management, co-management, adaptive eco-management, and active adaptive management)** • **Adopting complementary productive activities to reduce economic dependence on fisheries** • **Developing capacity** • **Improving information flows in adaptive co-management transboundary resource management** • **Gear or vessel modifications**	Fisheries	• Promote sustainable harvesting and fair distribution of wild fish products and revenues • Proactive dynamic fisheries management and diversification based on scientific, Indigenous and local knowledge will facilitate adaptive fisheries planning and reduce conflict (national and international) over resources.		*Medium*	(5.14.3.4; Cross-Chapter Box MOVING PLATE this Chapter)
• **Adaptation options that incorporate ecological knowledge and risk into management decisions in the near- and long-term**	Aquacultur e	• Enhance sustainable aquaculture production	Governance that recognizes unexploited biological and socioeconomic food system synergies and equity would lead to positive adaptation strategy development and implementation, but options may be limited for those most at risk due to technological cost and low financial access	*High*	(5.14.3.5)
• **Effective linkage of freshwater aquatic food provisioning management to the adaptation plans of other water-using sectors, considering trade-offs of production with community nutritional needs**	Freshwater fisheries and aquaculture systems,	• Reduce the risk of food insecurity and livelihood loss for those reliant on freshwater for inland fisheries and aquaculture	Changing precipitation patterns will increase competition for limited freshwater supplies.	*Medium*	(5.8.4, 5.9.4.)

• **Agricultural production systems that integrate crops, livestock, forestry, fisheries, and aquaculture**	Mixed system	• Increase food production per unit of land • Reduce climate risks • Reduce GHG emission • Confer buffering capacity • Increasing household resilience though the benefits and challenges depend on local context.	Uncertainties exist concerning the scalability of integrated systems; their uptake face particular barriers around risk, land tenure, social inclusion, information and management skill, and the nature and timing of benefit flows.	*High*	(5.10.4)
• **Investments in improved humidity and temperature control in storage facilities for perishable items, and changes in public policy that control international trade and domestic market transactions**	Post-harvest	• Improve food utilization and access and thereby resilience to climate change.	The extent to which adaptation activities beyond harvest are cost-effective, and the limits to such adaptation, are location-specific and largely unknown	*Medium*	(5.11.4)
• **Integrated multisectoral food system adaptation approaches that address food production, consumption, and equity issues.** • **Nutrition and gender sensitive agriculture programs, adaptive social protection and disaster risk management are examples.**	Production and post-harvest	• Protect vulnerable groups against livelihood risks; • Enhance responsiveness to extreme events	Differentiated responses based on food security level and climate risk can be effective.	*Medium*	(5.12.4)
• **Rights-based approaches, including legislation, gender transformative approaches to agriculture, recognition of rights to land, seeds, fishing areas and other natural resources, and community-based adaptation.**	Production and post-harvest	• Improved food security and nutrition for marginalized groups; • Increased resilience through capacity-building of marginalized groups; • Address questions of access to resources for marginalized groups.	Focus on meaningful participation in governance, design, and implementation of adaptation strategies of those groups who are vulnerable including gender. Can be conflicts and tradeoffs, such as between addressing land rights or traditional fishing grounds.	*Medium*	(5.12.4)

• **Climate services**	Production	• Can support decision-makers i agriculture by providing tailored information that can inform the implementation o specific adaptatio options	For some high- and medium-income countries, evidence suggests that climate services have been underutilized. In low-income countries, use of climate services can increase yields, incomes and promote changes in farmers' practices, but *low confidence* that climate services are delivering on their potential, whether they are being accessed by the vulnerable, and how these services are contributing to food security and nutrition.	*Medium*	(5.14.1)

5.2 Observed Impacts and Key Risks

5.2.1 Detection and Attribution of Observed Impacts

Detection and attribution of climate change impacts on the food system remain challenging because many non-climate drivers are involved (Porter et al., 2014), but have been improved by recently developed climate model outputs tailored for impact attribution (Iizumi et al., 2018; Moore, 2020; Ortiz-Bobea et al., 2021).

Climate change has caused regionally different, but mostly negative, impacts on crop yields, quality, and marketability of products (*high confidence*) (see Section 5.4.1 for observed impacts). There is *medium evidence and high agreement* that the effects of human-induced climate warming since the pre-industrial era has had significantly negative effects on global crop production, acting as a drag on the growth of agricultural production (Iizumi et al., 2018; Moore, 2020; Ortiz-Bobea et al., 2021). One global study using an empirical model estimated the negative effect of anthropogenic warming trends from 1961 to 2017 to be on average 5.3 % for three staple crops (5.9% for maize, 4.9% for wheat, and 4.2 % for rice) (Moore, 2020). Another study using a process-based crop model found a yield loss of 4.1% (0.5-8.4%) for maize and 4.5% (0.5-8.4%) for soybean between 1981 and 2010 relative to the non-warming condition, even with CO_2 fertilisation effects (Iizumi et al., 2018). Human-induced warming trends since 1961 have also slowed down the growth of agricultural total factor productivity by 21% (Ortiz-Bobea et al., 2021). Regionally, heat and rainfall extremes intensified by human-induced warming in West Africa have reduced millet and sorghum yields by 10-20%, and 5-15 %, respectively (Sultan et al., 2019).

Methane emissions significantly impact crop yields by increasing temperatures as a GHG and surface ozone concentrations as a precursor (*medium confidence*) (Shindell, 2016; Van Dingenen, 2018; Shindell et al., 2019). Shindell (2016) estimated a net yield loss of 9.5±3.0% for four major crops due to anthropogenic emissions (1850-2010), after incorporation of the positive effect of CO_2 (6.5±1.0%) and the negative effects of warming (10.9±3.2%) and tropospheric ozone elevation (5.0±1.5%). Although these estimates were not linked with historical yield changes, more than half of the estimated yield loss is attributable to increasing temperature and ozone concentrations from methane emissions, suggesting the importance of methane mitigation in alleviating yield losses (*medium confidence*) (Section 5.4.1.4).

Climate change is already affecting livestock production (*high confidence)* (Section 5.5.1). The effects include direct impacts of heat stress on mortality and productivity, and indirect impacts have been observed on grassland quality, shifts in species distribution and range changes in livestock diseases (Sections 5.5.1.1 – 5.5.1.3). Quantitative assessment of observed impacts is still limited.

In aquatic systems, more evidence has accumulated since AR5 on warming-induced shifts (mainly poleward) of species (*high confidence*) (Section 5.8.1, Cross-Chapter Box MOVING PLATE this Chapter), causing significant challenges for resource allocation between different countries and fishing fleets. Quantitative assessments of climate change impacts on production are still limited, but (Free et al., 2019) estimated a 4.1% global loss of the maximum sustainable yield of several marine fish populations from 1930 to 2010 due to climate change. The effects of climate change on aquaculture are apparent but diverse, depending on the types and species of aquaculture (*high confidence*) (Section 5.9.1). Temperature increases, acidification, salt intrusion, oxygen deficiency, floods, and droughts have negatively impacted production via reduced growing suitability, mortalities, or damages to infrastructure (Section 5.9.1).

The impacts of climate change on food provisioning have cascading effects on key elements of food security, such as food prices, household income, food safety and nutrition of vulnerable groups (Peri, 2017; Ubilava, 2018; 5.11, 5.12). Climate extreme events are frequently causing acute food insecurity (Section 5.12.3, FSIN, 2021). There is growing evidence that human-induced climate warming has amplified climate extreme events (Seneviratne et al., 2021), but detection and attribution of food insecurity to anthropogenic climate change is still limited by a lack of long-term data and complexity of food systems (Phalkey et al., 2015; Cooper et al., 2019). A recent event attribution study by Funk (2018) demonstrated that anthropogenic enhancement of the 2015/16 El Niño increased drought-induced crop production losses in Southern Africa. Human-induced warming also exacerbated the 2007 drought in southern Africa, causing food shortages, price spikes, and acute food insecurity in Lesoto (Verschuur et al., 2021).

5.2.2 Key Risks

Key risks in this chapter are grouped into those related to food security, food safety and dietary health, livelihoods of people in related sectors and ecosystem services (Table 16.9). Determining when a risk is considered severe is challenging to quantify because of the complexity of the food system, uncertainty about the effects and ethical challenges.

Current levels of food insecurity are already high in some parts of the world, and often exacerbated by short-term food shortages and price spikes caused by weather extremes partly linked to climate change (Sections 5.2.1, 5.12.3, 16.5.2). Climate change will increase malnourished populations through direct impacts on food production and have cascading impacts on food prices and household incomes, all of which will reduce access to safe and nutritious food (*high confidence)* (Figure 5.2, 5.12).

Extreme climate events will become more frequent and force some of the current food production areas beyond the safe climatic space for production (*high confidence*) (Sections 5.4.3, 5.5.2). Globally, 10% of the currently suitable area for major crops and livestock are projected to be climatically unsuitable in mid-century and 31-34% by the end of the century under SSP5-8.5 (Kummu et al., 2021). Adverse effects of climate change on food production will become more severe when global temperatures rise by more than 2°C (Sections 5.4.4.1, 5.12.4.1). One study estimated that the heat stress from projected 3°C warming above baseline (1986-2005) would reduce labour capacity by 30-50% in Sub-Saharan Africa and southeast Asia, leading to an 5% increase in crop prices because of higher labour cost and production losses, thereby undermining food availability, access, and livelihood (de Lima et al., 2021). Thiault et al. (2019) projected that by 2100 climate change under RCP8.5 could have negative impacts on both agriculture and marine fisheries productivity in countries where 90% of the world population live. A global analysis of shellfish aquaculture estimated that habitat suitability will decline beyond 2060 globally, but much sooner in some Asian countries (Stewart-Sinclair et al., 2020; 5.9.1). These negative effects in the second half of the century will be much less under RCP2.6.

Climate change impacts will increase the number of people at risk of hunger in 2050 ranging from 8 million people under SSP1 to 80 million people under SSP3 scenarios (RCP6.0), compared to a world with no climate change (Mbow et al., 2019). Estimates also vary depending on the adaptation and mitigation assumptions (Hasegawa et al., 2018; Janssens et al., 2020). Geographically, nearly 80% of the population at risk of hunger are projected to occur in Africa and Asia (Nelson et al., 2018). Projections of risk of hunger beyond 2050 are limited, but it will grow from the mid-century toward the end of the century, with more people at risk under RCP8.5 compared to RCP4.5 (Richardson et al., 2018). Regional disparity is projected to increase, particularly under a high emission scenario.

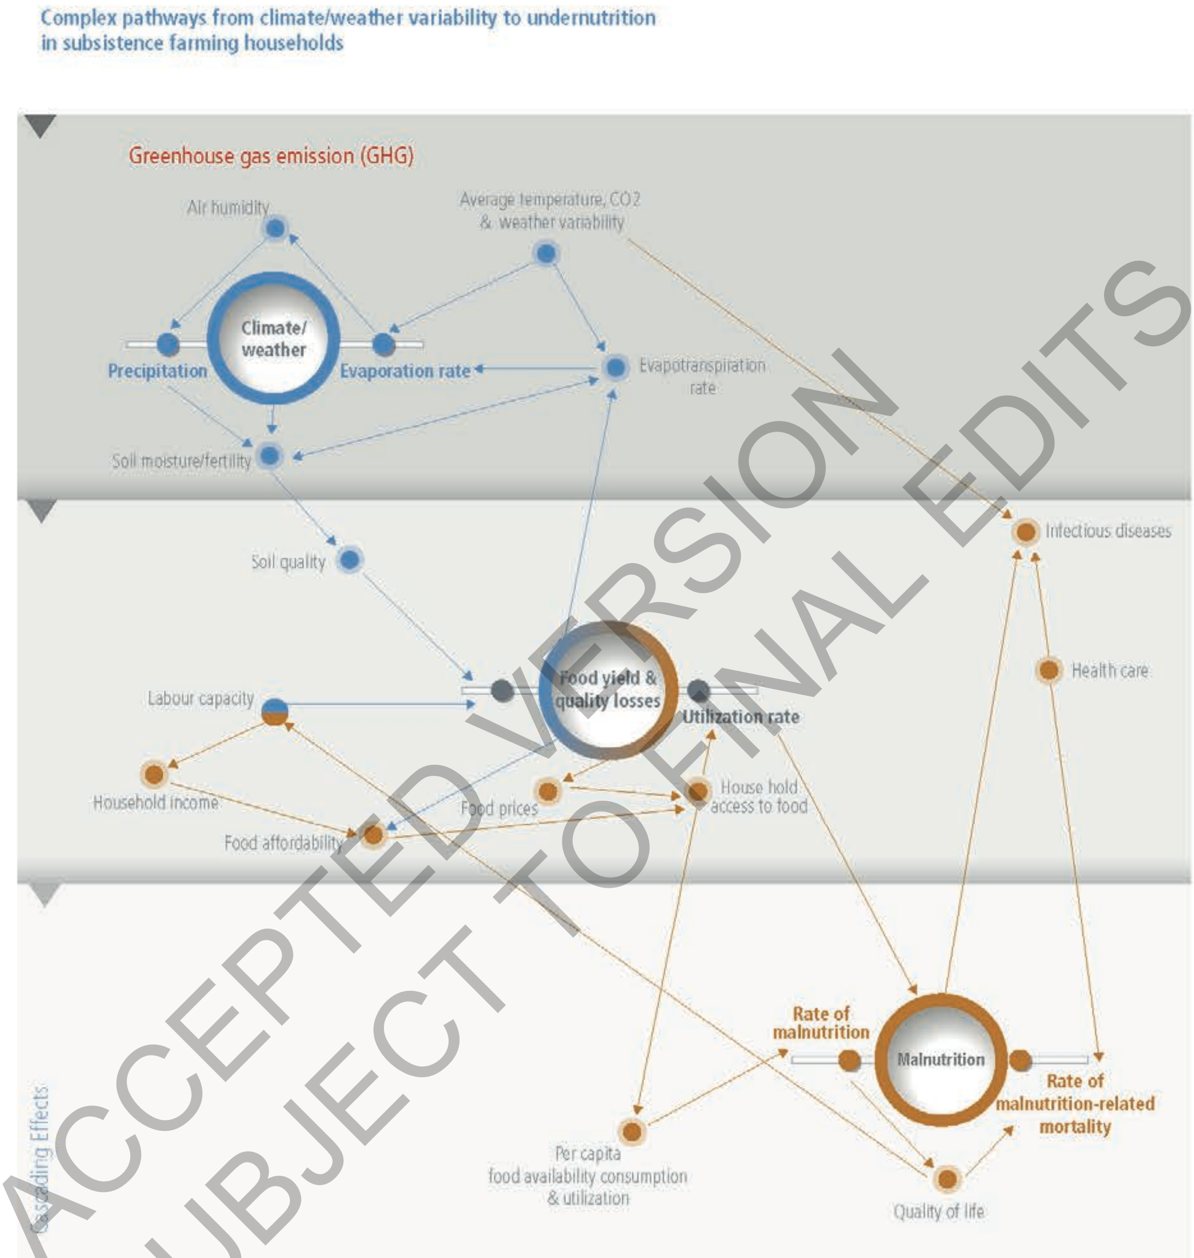

Figure 5.2: Complex pathways from climate/weather variability to malnutrition in subsistence farming households. The factors involved in and the probable impacts of weather variables on crop yields (blue arrows) and of production on malnutrition (red arrows). Adapted and revised from (Phalkey et al., 2015)

Climate change will increase the costs and management challenges of providing safe food. The safety challenges arise from contamination caused by increased prevalence of pathogens, harmful algal bloom, and toxic inorganic bioaccumulation (*high confidence*) (Sections 5.8, 5.9, 5.11, 5.12). Micronutrient deficiency is prevalent across many regions and will continue to be a problem at least during the first half of the century (Nelson et al., 2018), with significant implications for human health (Section 5.12.4).

Food security and healthy balanced diets will also be undermined by reduced livelihoods and health of people in agriculture and food-related sectors (Sections 5.12.3, 5.12.4), diminished ecosystem services provided by pollinators, the soil biome (Section 5.4.3), and water systems, and climate-mitigation related policies that solely focus on reducing GHG emissions without considering their potential to increase competition with food production for scarce land and water (Section 5.13.3).

5.3 Methodologies and Associated Uncertainties

Chapter text draws on previous IPCC reports, other reports (i.e., HLPE, FAO, IPBES, and Traffic), and literature published since 2014. This section highlights key trends in research topics and methods since AR5.

5.3.1 Methodologies for Assessing Impacts and Risks

Since AR5, there are more examples of observed impacts from past climate change in cropping systems (Section 5.4.1), pastoral systems (Section 5.5.1), forests (Section 5.6.1), fisheries (Section 5.8.1) and in mixed farming systems (Section 5.10.1). These assessments of observed impacts make use of historical data on climate, production area and yield to attribute the role of climate in driving changes in suitability, production, yield, food quality or Total Factor Productivity (Ortiz-Bobea et al., 2021). Observations across the global food-systems have been analysed (Cottrell et al., 2019), with the advantage that unexpected impacts due to changes in seasonality and biotic interactions can be detected. Quantitative analysis is only possible in places with adequate historical data, in many cases studies rely on qualitative assessments, often drawing on farmers perceptions of climate impacts.

Projecting future climate impacts relies on modelling that combines climate data with data from experimental studies testing how species respond to each climate factor. In cropping and forest systems, a network of experimental studies with plants exposed to elevated CO_2 concentrations, ozone and elevated temperature provides data on the fundamental responses to climate and atmospheric conditions (i.e., free-air carbon dioxide enrichment (FACE) and temperature free-air controlled enhancement (T-FACE) systems). FACE results have been combined and assessed more extensively since AR5 (Bishop et al., 2014; Haworth et al., 2016; Kimball, 2016; Ainsworth and Long, 2021; SM5.3). Field-based FACE studies have several advantages over more enclosed testing chambers, although results from more controlled experiments and coordination between different methods continue to give new insights into crop responses to climate change and variability (Drag et al., 2020; Ainsworth and Long, 2021; Sun et al., 2021). Experimental results have limitations and can be difficult to scale up (Porter et al., 2014; Haworth et al., 2016), but generally the conclusions follow known plant responses (Lemonnier and Ainsworth, 2018). As highlighted in AR5, there is a scarcity of FACE infrastructure in the tropics and subtropics (Leakey et al., 2012; Lemonnier and Ainsworth, 2018; Toreti et al., 2020). One area that has been further investigated is the negative impact of elevated CO_2 on crop nutritional value, which has important implications for human nutrition (Scheelbeek et al., 2018; Smith and Myers, 2018; Toreti et al., 2020; Ainsworth and Long, 2021). Increasingly, experimental studies seek to examine the interaction between climatic factors such as temperature, drought and ozone, or the responses of understudied food-systems, crop species, cultivars, and management interventions (Kimball, 2016; Ainsworth and Long, 2021). The use of experimental data to improve projections has also expanded in other systems. There has been an increased focus on the impact of warming on livestock health and productivity (5.5.2). Aquatic system studies have incorporated projected impacts on physiology, distribution, phenology, and productivity (5.8.3).

Modelling approaches differ widely and serve different purposes (Table 5.2; Porter et al., 2014; Jones, 2017a). The use of process-based and statistical modelling alongside remote sensing and other spatial data has grown. Projections increasingly draw on a combination of modelling approaches and coordinated efforts for model intercomparisons and ensemble techniques, using standardized emission scenarios (RCPs). For major crops, models of global yield impacts from CO_2 concentration, air temperature and precipitation, have been refined and compared (Challinor et al., 2014; Iizumi et al., 2017; Ruane et al., 2017; Zhao et al., 2017; Rojas et al., 2019). Despite advances since AR5, modelling is still constrained by limited data from field experiments (Ruane et al., 2017). Increasingly, studies attempt to incorporate effects of elevated CO_2, ozone, and climate extremes (Barlow et al., 2015; Schauberger et al., 2019a; Vogel et al., 2019), as well as attempts to incorporate more complex interactions with soil and crop management (Basso et al., 2018; Smith et al., 2020b). However, only a few models consider crop protein content and other quality factors (Nuttall et al., 2017; Asseng et al., 2019). Some models take account of the impacts of climate on the timing of key biological events (phenology) in the target species, however incorporating biotic interactions with pests, pathogens, and pollinators remains a challenge (Table 5.2; Sections 5.4.1, 5.4.2).

In addition to productivity projections, research also draws on climate suitability estimates (Table 5.2). These compare the known climate suitability of species and habitats with projected climate conditions across different locations. Such projections are useful especially for incorporating movement of pests and pathogens but cannot be applied in isolation if non-climate constraints are not considered. As different research groups use different assumptions and data inputs, more coordination is needed if suitability projections are to be compared globally (SM5.3).

Increasingly, projections look across different disciplines and across multiple components of the food-system, including livestock, fisheries and mixed farming systems (Campbell et al., 2016; Mbow et al., 2019). Major timber species have been modelled, with projected impacts on productivity, duration of rotation and distribution (i.e., climate suitability) (Albert et al., 2018). Livestock systems are influenced by plant productivity projections via their feedstock, e.g., rangeland cattle impacted by changes in net primary production (NPP) (Boone et al., 2018). Direct climate impacts on animals are also projected, using indices based on direct observations (Section 5.5.3). Since AR5, Fish-MIP has allowed for global intercomparisons and ensemble projections of marine fisheries (Fisheries and Marine Ecosystem Model Intercomparison Project), and projections capturing interactions from multiple food systems (e.g., Inter-Sectoral Impact Model Intercomparison Project (ISI–MIP); Sections 5.8, 5.10).

Global simulations have uncovered important differences between regions (Deryng et al., 2016; Blanchard et al., 2017). Efforts to coordinate and combine regional and global modelling studies allow for greater insight into regional differences in climate change impacts, e.g., the Coordinated Global and Regional Assessments (CGRA) performed by the Agricultural Model Intercomparison and Improvement Project (AgMIP) (Blanchard et al., 2017; Müller et al., 2017; Rosenzweig et al., 2018; Ruane et al., 2018; Lotze et al., 2019). Increasingly, multi-model intercomparisons are used to evaluate global gridded crop models' performance and sensitivity to temperature, water, nitrogen, and CO_2 within AgMIP, with the focus mostly on major annual crops (Valdivia et al., 2015; Ruane et al., 2017; Müller et al., 2021a). Differences in model type, structures and input data can result in large variation in projections, particularly for the response of crops to elevated CO_2 and temperature (5.4.3.1), methods for quantifying and minimizing this uncertainty have been developed, but improvement is still needed (Li et al., 2014b; Asseng et al., 2015; Zhao et al., 2017; Folberth et al., 2019; Tao et al., 2020; Müller et al., 2021a; Ruane et al., 2021). The use of multi-model intercomparisons has widened the range of uncertainties but has increased the robustness of impact assessments (Asseng et al., 2013; Challinor et al., 2014; Zhao et al., 2017). Model outputs are strongly influenced by decisions over which factors to include, e.g., including drought impacts can result in positive yield projections switching to neutral or negative values (Gray et al., 2016; Jin et al., 2018). Models are also limited in their ability to incorporate socio-economic drivers and extreme events (Porter et al., 2014; Campbell et al., 2016; Ruane et al., 2017; Jagermeyr and Frieler, 2018; Webber et al., 2018; Schewe et al., 2019).

For long-term projections and integrated assessments, a large component of uncertainty remains the ability to represent socio-economic responses to climate change and the degree to which these will mitigate or exacerbate climatic changes (Valdivia et al., 2015; Prestele et al., 2016; Arneth et al., 2019). This includes the potential adaptation responses of food producers. Models that incorporate alternative socio-economic responses offer one solution (e.g., AgMIP) (Nelson et al., 2014; Von Lampe et al., 2014; Wiebe et al., 2015; Rosenzweig et al., 2018; van Zeist et al., 2020). Another approach is the use of solution-oriented scenarios to compare the effectiveness of adaptation options (Le Mouël and Forslund, 2017; Arneth et al., 2019), or to quantify the time period in which adaptation responses will become essential (Challinor et al., 2016; Rojas et al., 2019). Others point to the necessity of managing food systems within the context of uncertainty (Campbell et al., 2016).

Table 5.2: A comparison of modelling approaches and their application in climate change impact projections. Model types are categorised by: food system, with labels representing the food systems from this chapter where each model type is used (**[CROP]**, **[TREE]**, **[LIVES]**, **[FISH]**, **[MIX]**, **[FOOD]**); scale over which each model type is usually applied (local [()], regional [( )], global [( )], or a combination of these); and sensitivity to climate change where the

colour intensity indicates the ability of each model type to incorporate each of the listed factors. After (Van Wijk et al., 2014; Kanter et al., 2018; Thornton, 2018). Integrated assessment models are discussed in the main text.

		Description	Applications for each food-system	Scale	Sensitivity to climate change factors and responses: Climate	CO2	Biotic	Adaptation	System responses
Empirical	Agroclimatic indices	Use simple equations to link agricultural performance to key climate factors, such as drought or heat stress, or summarising agricultural requirements using multiple environmental descriptors.	Comparing regions; matching crops to regions; early warning systems: e.g. Agro-ecological zones, Ecocrop, Palmer Drought Severity Index **{CROP}**.	(( ))					
	Statistical models	Use quantitative associations between agricultural performance and climate, based on past observations. Can include projections for biotic factors such as pest and disease.	Productivity and production area projections; annual climate variability; attribution: e.g. Traditional: regression, statistical emulators **{CROP} {TREE} {LIVES} {FISH}**; e.g. Spatial suitability models /niche models: MaxEnt, CLIMEX, Ecocrop **{CROP} {TREE} {FISH}**.	(( ))					
Process-based (dynamic simulation models)	Vegetation focused	Use combinations of land-surface energy and soil water balance models to simulate the growth of crop species along with natural vegetation, typically using plant and crop functional types.	Productivity projections; interactions with non-climate variables (e.g. CO2): e.g. PEGASUS, Agro-IBIS, DayCent, LPJmL, LPJ-GUESS, ORCHIDEE **{CROP} {TREE}**.	( )					
	Species focused	Use mechanistic models based on the known responses of species to key environmental descriptors over time. Typically based on detailed information for a particular species within a region, but also applied to mixed systems such as agroforestry and globally.	Productivity projections; matching tree species to locations; species interactions; interactions with non-climate variables (e.g.CO2); adaptation projections: e.g. point-based versions: APSIM, AquaCrop, DayCent, DSSAT, EPIC, Infocrop, SARRA-H, STICS **{CROP}** IBIS **{TREE}** LIVSIM, RUMINANT **{LIVES}** Fish-MIP **{FISH}** Yield-SAFE, WaNuLCAS, Hi-sAFe **{MIX}**; e.g. global gridded version: pDSSAT, pAPSIM, GEPIC, GLAM, MCWLA, PEGASUS, SARRA-O **{CROP}**.	(( ))					
Integrated models	Optimization methods	Mathematical representations of systems with regard to key indicators, constraints, and objectives. Allows prioritisation of different climate change response options using the defined indicators.	Adaptation projections; food security projections; livelihood projections; trade-offs; live cycle assessment: e.g. Global Timber Model **{TREE}** CSAP toolkit, FarmDESIGN **{CROP} {MIX} {FOOD}**	()					
	Economic (Econometric, Economic surplus,	Used to integrate the broad impacts of climate change with other economic drivers, to quantify the economic costs and assess the value of adaptation/mitigation interventions.	Adaptation projections; food security projections; livelihood projections: e.g. GFPM **{TREE}** FUND 3.8, DICE 2010, IMPACT **{FOOD}**	( )					
	Household and village models	Use detailed site-specific data to generate rules that describe the current behaviour of stakeholders such as households or villages. Can be integrated with other model approaches to consider climate response and adaptation interventions.	Adaptation projections (case specific); behavioural responses; trade-offs; participatory monitoring: e.g. DECUMA, PALM, MPMAS, MIDAS, TOA-MD **{LIVES} {MIX} {FOOD}**	(())					

5.3.2 Methodologies for Assessing Vulnerabilities and Adaptation

Methods for monitoring vulnerability and adaptation are under-researched but have increased since AR5. Increasingly, projections move from individual crops, to assessing risks across the food systems and the relative vulnerability of different systems (Campbell et al., 2016; Gil et al., 2017; Lipper et al., 2017; Richardson et al., 2018). Adaptation options can be considered as parameters in integrated models, such as those used in ISI-MIP, while others use systematic assessments of case studies, e.g., the application of agent-based household models to assessments of adaptation in livestock systems (Section 5.5.4). Quantitative studies are less common than qualitative assessments and there is a need to combine modelling and qualitative approaches more effectively (Beveridge et al., 2018a; Vermeulen et al., 2018).

The food system is dynamic with changes in management practices driven by many factors including climate adaptation (Iizumi, 2019; Iizumi et al., 2021a). Adaptation potential, such as expected advances in crop breeding, are often not explicitly accounted for in modelling studies, but more recent studies do quantify the potential for adaptation (Iizumi et al., 2017; Tao et al., 2017; Aggarwal et al., 2019; Minoli et al., 2019). To account for this complexity, case studies rely on data derived from the perception and practices of stakeholders who are engaged in adaptation (usually autonomous adaptation) (Hussain et al., 2016; Lipper et al., 2017; Ankrah, 2018; Sousa-Silva et al., 2018). Case studies use a range of different indicators to monitor climate response options, making quantitative comparisons more difficult (Gil et al., 2017; Vermeulen et al., 2018). However, systematic comparisons have provided valuable insights (Descheemaeker et al., 2018; Shaffril et al., 2018; Aggarwal et al., 2019; Bene et al., 2019), e.g., the sustainable livelihood framework has been applied widely to diverse aquatic systems (Bueno and Soto, 2017; Barange and Cochrane, 2018) and the Livelihood Vulnerability Index is well used across systems (Section 5.14). Coordinated efforts such as the AgMIP also provide systematic assessments (Blanchard et al., 2017; Lipper et al., 2017; Antle et al., 2018). Nonetheless, the full effectiveness of different adaptation options is difficult to assess given that many impacts have not yet occurred (due to the cumulative nature of impacts and the inertia in the climate system (Stocker et al., 2013; Zickfeld et al., 2013).

Transformation of the food system that addresses all dimensions of ecosystem services is discussed in this chapter, including risk management and the communication of uncertainties (Section 5.14). The focus is on flexible approaches to risk and uncertainty, assessing trends, drivers, and trade-offs under different future scenarios (Campbell et al., 2016).

5.4 Crop-based Systems

Crops such as cereals, vegetables, fruit, roots, tubers, oilseeds, and sugar account for about 80 % of the dietary energy supply (FAO, 2019f). Crops are a significant source of food and income for about 600 million farms in the world, 90 % of which are family farms (Lowder et al., 2019). Previous assessment reports focused on yields of staple crops such as maize, wheat and rice, but studies are emerging on climate change impacts on other crops.

5.4.1 Observed Impacts

5.4.1.1 Observed impacts on major crops

AR5 Chapter 7 stated with confidence that warmer temperatures have benefited agriculture in the high latitudes, and more evidence has been published to support the statement. Typical examples include pole-ward expansion of growing areas and reduction of cold stress in East Asia and North America (Table SM5.1).

Recent warming trends have generally shortened the life cycle of major crops (*high confidence*) (Zhang et al., 2014; Shen and Liu, 2015; Ahmed et al., 2018; Liu et al., 2018c; Tan et al., 2021). Some studies, however, observed prolonged crop growth duration despite the warming trends (Mueller et al., 2015; Tao et al., 2016; Butler et al., 2018; Zhu et al., 2018b) due to shifts in planting dates and/or adoption of longer-duration cultivars in mid to high latitudes. Conversely, in mid-to-low latitudes in Asia, a review study found that farmers favoured early maturing cultivars to reduce risks of damages due to drought, flood and/or heat (Shaffril et al., 2018), suggesting that region-specific adaptations are already occurring in different parts of the world *(high confidence)*.

Global yields of major crops per unit land area have increased 2.5 - 3-fold since 1960. Plant breeding, fertilisation, irrigation, and integrated pest management have been the major drivers, but many studies have found significant impacts from recent climate trends on crop yield (*high confidence*) (Figure 5.3; See Section 5.2.1 for the change attributable to anthropogenic climate change).

Climate impacts for the past 20-50 years differ by crops and regions. Positive effects have been identified for rice and wheat in Eastern Asia, and for wheat in Northern Europe. The effects are mostly negative in Sub-Saharan Africa, South America and Caribbean, Southern Asia, Western and Southern Europe. Climate factors that affected long-term yield trends also differ between regions. For example, in Western Africa, 1°C-warming above preindustrial climate has increased heat and rainfall extremes, and reduced yields by 10-20% for millet, and 5-15 % for sorghum (Sultan et al., 2019). In Australia, declined rainfall and increased temperatures reduced yield potential of wheat by 27%, accounting for the low yield growth between 1990 and 2015 (Hochman et al., 2017). In Southern Europe, climate warming has negatively impacted yields of almost all major crops, leading to recent yield stagnation (Moore and Lobell, 2015; Agnolucci and De Lipsis, 2020; Brás et al., 2021).

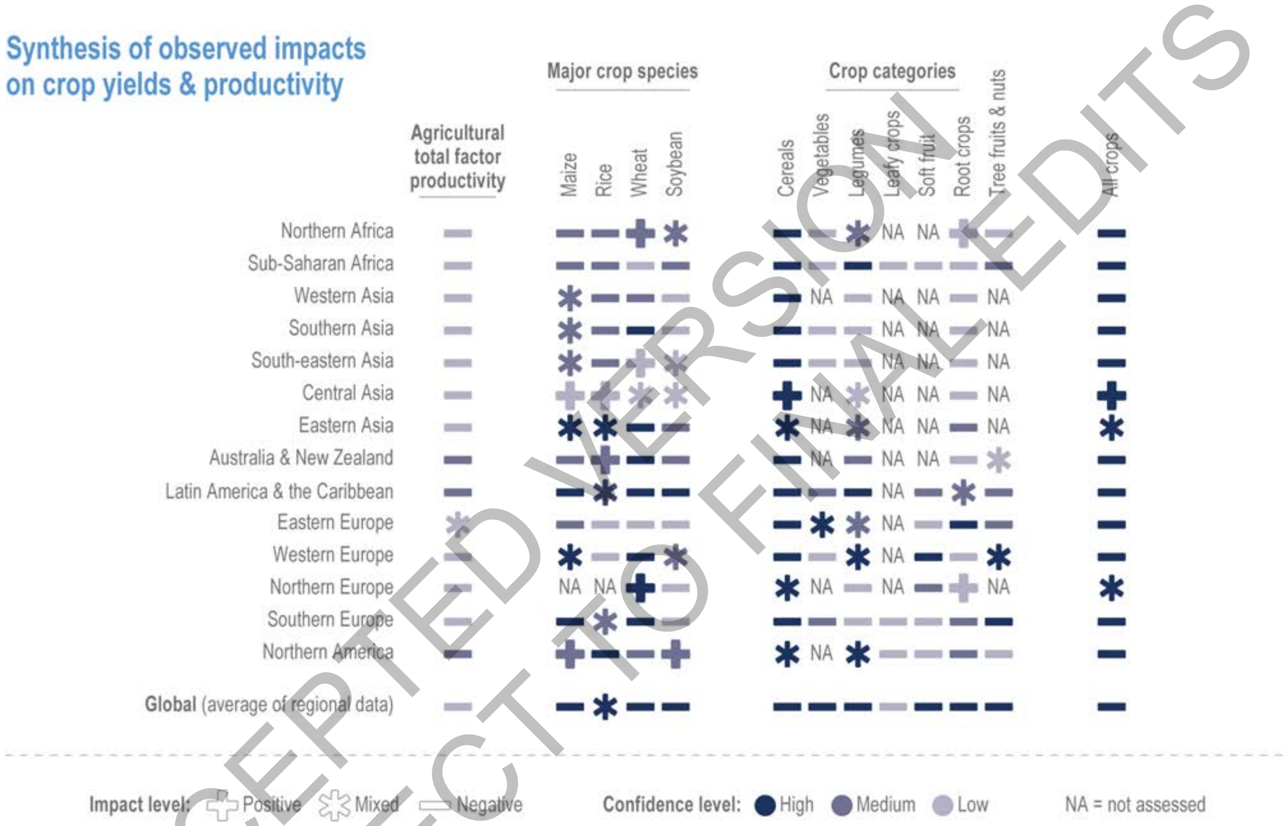

Figure 5.3: Synthesis of literature on observed impacts of climate change on productivity by crop type and region. The figure draws on >150 articles categorised by: agriculture total factor productivity including literature estimating all agricultural outputs in a region; major crop species including literature assessing yield changes in the four major crops; crop categories including productivity changes (yield, quality, and other perceived changes) in a range of crops with different growth habits. The assessment uses literature published since AR5, although the timespan often extends prior to 2014. The direction of the effect and the confidence are based on the reported impacts and attribution, and on the number of articles. See SM5.1 and SM5.2 for details.

Ortiz-Bobea et al. (2021) analysed agricultural Total Factor Productivity (TFP), defined as the ratio of all agricultural outputs to all agricultural inputs, and found that while TFP has increased between 1961 and 2015, the climate change trends reduced global TFP growth by a cumulative 21% over a 55-year period relative to TFP growth under counterfactual non-climate change conditions. Greater effects (30- 33%) were in Africa, Latin America and the Caribbean (Figure 5.3).

Climate variability is a major source of variation in crop production (Ray et al., 2015; Iizumi and Ramankutty, 2016; Frieler et al., 2017; Cottrell et al., 2019)(Table SM5.1). Weather signals in yield variability are generally stronger in productive regions than in the less productive regions (Frieler et al., 2017), where other yield constraints exist such as pests, diseases, and poor soil fertility (Mills et al., 2018;

5.2.2). Nevertheless, yield variability in less productive regions has severe impacts on local food availability and livelihood (*high confidence*) (FAO, 2021).

Climate-related hazards that cause crop losses are increasing (*medium evidence, high agreement*) (Cottrell et al., 2019; Mbow et al., 2019; Brás et al., 2021; FAO, 2021; Ranasinghe et al., 2021). Drought-related yield losses have occurred in about 75% of the global harvested area (Kim et al., 2019b) and increased in recent years (Lesk et al., 2016). Heatwaves have reduced yields of wheat (Zampieri et al., 2017) and rice (Liu et al., 2019b). The combined effects of heat and drought decreased global average yields of maize, soybeans, and wheat by 11.6, 12.4, and 9.2% (Matiu et al., 2017). In Europe, crop losses due to drought and heat have tripled over the last five decades (Brás et al., 2021), pointing to the importance of assessing multiple stresses. Globally, floods also increased in the past 50 years, causing direct damages to crops and indirectly reduced yields by delaying planting, which cost 4.5 billion USD in the 2010 flood in Pakistan and 572 million USD in the 2015 flood in Myanmar (FAO, 2021).

[START BOX 5.1 HERE]

Box 5.1: Evidence for Simultaneous Crop Failures due to Climate Change

Simultaneous yield losses across major producing regions can be a threat to food security but had not been quantified by the time of AR5. Large-scale sea surface temperature (SST) oscillations greatly influence global yield of major crops (*high confidence*) (Anderson et al., 2019b; Najafi et al., 2019; Ubilava and Abdolrahimi, 2019; Heino et al., 2020; Iizumi et al., 2021b) and food prices (Ubilava, 2018). Some studies showed that crop yields in different regions covaried with SST oscillations, suggesting occurrences of tele-connected yield failures (crop losses caused by related factors in distant regions; Table Box 5.1.1) (*medium confidence*). Evidence is still limited that synchronised crop failures are increasing with ongoing climate change.

Table Box 5.1.1: A summary of peer-review papers detecting synchronised yield losses

Regions/ Commodities	Period studied	Observed impacts	Climate driver	Evidence for multiple breadbasket failures	Evidence for increasing risks due to multiple breadbasket failures	Reference
Global breadbaskets for maize, rice, sorghum and soybean	1961-2013	Not only yields of each crop covaried in many countries, but also that of different crops, maize in particular, covaried with other crops.	Sea surface temperature anomalies (SST), atmospheric and oceanic indices, air temperature anomalies (AT) and Palmer Drought Severity Index (PDSI)	High	NA	Najafi et al. (2019)

Global breadbaskets for wheat, soybean, and maize		Climate modes (El Niño Southern Oscillation (ENSO), the Indian Ocean Dipole (IOD), tropical Atlantic variability (TAV), and the North Atlantic Oscillation (NAO)) account for 18, 7, and 6% of global maize, wheat, and soybean production variability. ENSO events sometimes offset yield reductions in some places by increases in other places (e.g., Soybean yields in the United States and southeast South America). Since 1961, ENSO in 1983 was the only climate mode that showed global synchronous crop failures.	Climate modes	Medium (1983)	NA	Anderson et al. (2019b)
Global breadbaskets for wheat, soybean, and maize		Climate modes induce yield variability in major breadbaskets. e.g. ENSO affects about half of maize and wheat areas. IOD and ENSO influence what in Australia. ENSO affects soybean in northern South America.	Climate modes	Medium	NA	Heino et al. (2020)
67 maize producing countries	1961-2017	SST anomalies from the 1980–2010 base period in the Niño3.4 region, a rectangular area bounded by 120◦W–170◦W and 5◦S–5◦ is used as a driver. Maize yields are tele-connected among the south-eastern tier of Sub-Saharan Africa, as well as Central America, South Asia, and Australia. A 1-degree increase in SST reduced maize yield by up to 20% in these countries.	Climate modes (Sea surface temperature), Precipitation	Medium	NA	Ubilava and Abdolrahimi (2019)
Global breadbasket (the United States, Argentina, Europe, Russia/Ukraine, China, India, Australia, Indonesia, and Brazil)	1967-2012	Likelihood of simultaneous climate risks increased from 1967-1990 to 1991-2012 in the global breadbasket (Lower 25th yield deviation percentile events at province level) for wheat, soybean maize, but not rice. Likelihood of simultaneous climate risks increased from 1967-1990 to 1991-2012 in China (Lower 25th yield deviation percentile events at province level)	Unspecified	medium	medium	Gaupp et al. (2020)

Global		Synchronous yield losses among major breadbaskets within each commodity, such as maize and soybean decreased between 1961 and 2008. In contrast, synchronous yield variation between crops has increased. Under a scenario of synchronization of all four crops, the global maximum production losses for rice, wheat, soybean, and maize are estimated to reach between −17% and −34%.	unspecified	medium	medium	Mehrabi and Ramankutty (2019)

[END BOX 5.1 HERE]

5.4.1.2 Observed impacts on other crops (vegetables, fruit, nut, and fibre)

The impact of climate change on these diverse crop types is under-researched and uncertain (Manners and van Etten, 2018; Alae-Carew et al., 2020), there are reports of positive impacts in some cases but overall, the observed impacts are negative across all crop categories (Figure 5.3).

Above-ground annual crops consumed as vegetables, fruits, or salad are essential for food security and nutrition (5.12). In temperate regions, climate change can result in higher yields (Potopová et al., 2017; Bisbis et al., 2018), while in subtropical/tropical regions, negative impacts from heat and drought take precedence (Scheelbeek et al., 2018). Different species have different sensitivities to heat and drought (Prasad et al., 2017; Scheelbeek et al., 2018) and to combinations of stresses (Zandalinas et al., 2018). Above-ground vegetables are especially vulnerable to heat and drought stress during pollination and fruit set, resulting in negitive impacts on yiled (Daryanto et al., 2017; Sita et al., 2017; Brás et al., 2021)and harvest quality (Mattos et al., 2014; Bisbis et al., 2018). Growers have already seen negative impacts from the expansion of pest and disease agents due to warming (Section 5.4.1.3; Figure 5.3).

Below-ground vegetables include starchy roots and tubers that form a regular diet in many parts of the tropics and sub-tropics. Warming and climate variability has altered the rate of tuber development with yield impacts varying by location, including yield increases in some cases (Shimoda et al., 2018; Ray et al., 2019). These crops are considered stress tolerant but are more sensitive to drought than cereals (Daryanto et al., 2017). Impacts on water supply are critical as root crops are water-demanding for long periods, and highly sensitive to drought and heat events during tuber initiation (Dua et al., 2013; Potopová et al., 2017; Brás et al., 2021).

Among perennial tree crops, only grapevine, olive, almond, apple, coffee, and cocoa have received significant research attention. Concerns about climate impacts on harvest quality are widespread (Figure 5.3) (Barnuud et al., 2014; Bonada et al., 2015). In higher-latitude regions, the primary concern is the effect of temperature variability on harvest stability, pests and diseases and phenology (including fulfilment of winter chill requirements and risks due to early emergence in spring), (El Yaacoubi et al., 2014; Ramírez and Kallarackal, 2015; Santos et al., 2017; Gitea et al., 2019). In lower-latitude regions, information is limited, but studies are focused on increased tree mortality and yield loss due to drought, heat, and impacts from variability in the timing of the wet and dry seasons (Glenn et al., 2013; Ramírez and Kallarackal, 2015); see Box 5.7). In fruit trees, warming and climate variability have already affected fruit quality, such as acidity and texture in apples, or skin colour in grape berries (Sugiura et al., 2013; Sugiura et al., 2018). The reliability and stability of harvests has been impacted by climate variability, changes in the distribution of pests and pathogens (Seidel, 2014; Bois et al., 2017), and by the mismatch of important phenological events (such as bud emergence and flowering) (Guo and Shen, 2015; Legave et al., 2015; Ito et al., 2018; Vitasse et al., 2018). Perennial crops are particularly vulnerable to these impacts as they are exposed throughout the year, with little potential for growers to adjust planting date or location. Negative impacts via disruption to phenology and pest dynamics are best studied in grapevine (see Box 5.2).

Among the fibre crops, cotton is particularly well studied. As cotton is heat tolerant and yield increases with extra plant growth, positive effects of increasing temperature are expected, but observed impacts have been mixed due to negative impacts on phenology and plant water status (Traore et al., 2013; Chen et al., 2015a; Cho and McCarl, 2017). Negative impacts of climate change due to proliferation of the pest cotton bollworm are widely reported (Ouyang et al., 2014; Huang and Hao, 2020).

The impacts of climate change on water availability (rainfall and irrigation supply) are an emerging issue. Increased occurrence of drought combined with limited access to irrigation water is already a key constraint, e.g., Californian almonds are predicted to increase their potential geographical range under climate warming (Parker, 2018), yet a trend of increasing drought has already resulted in trees being removed due to lack of access to irrigation water (Keppen and Dutcher, 2015; Kerr et al., 2018; Reisman, 2019).

5.4.1.3 Observed impacts on pests, diseases, and weeds

AR5 and SRCCL indicated that more frequent outbreaks and area expansion of pests and diseases are serious concerns under climate change but are under-researched because of the difficulties in assessing multi-species interactions (Porter et al., 2014; Mbow et al., 2019). High-quality historical and current observational data to detect changes in pests and diseases attributable to recent trends in climate are still limited.

Bebber (2013) found significant poleward expansions of many important groups of crop pests and pathogens since 1960, with an average shift of 2.7 km yr^{-1}. Different pest species populations respond differently to ongoing climate change, with some shifting, contracting, or expanding their current distribution range and others persisting or disappearing in their current range (*high confidence*). These asymmetric distribution changes can create novel species combinations or decouple existing ones (Pecl et al., 2017; Hobbs et al., 2018), but their consequences on future crop production and food security are hard to predict. Multi-species climate change experiments are rare (Bonebrake et al., 2018) but one study shows that under future climates, different pest assemblages of interacting species may alter levels of damage to crops compared to that by only one species (Crespo-Perez et al., 2015). Some studies highlight the importance of location-specific species interactions for more realistic projections of pest distribution, performance, and damage to crops, which in turn would allow more effective prevention and pest control strategies (Wilson et al., 2015; Carrasco et al., 2018).

Weeds are recognized as a primary constraint on crop production (Oerke, 2006), rangelands (DiTomaso et al., 2017) and forests (Webster et al., 2006). Climate change could favour the growth and development of weeds over crops with negative consequences for desired plants in managed systems (*medium evidence, high agreement*) (Peters et al., 2014; Ziska and McConnell, 2016). First, changes in temperature and precipitation alter the range, composition, and competitiveness of native and invasive weeds (Bradley et al., 2010). Second, rising concentrations of CO_2 enhance growth of C_3 species (~85% of plant species, including many weeds) (Ogren and Chollet, 1982; Ziska, 2003), and increase plant water use efficiency with potentially strong effects on invasive plant species establishment (Smith et al., 2000; Belote et al., 2004; Blumenthal et al., 2013).

Some invasive species within unmanaged areas will expand further, proliferate and be more competitive under climate change as they may benefit from increased resource ability (e.g., additional CO_2, enhanced precipitation) (Bradley et al., 2010; Kathiresan and Gualbert, 2016; Merow et al., 2017; Ramesh et al., 2017; Waryszak et al., 2018), which will make chemical weed-control more problematic (*medium evidence, high agreement*) (Waryszak et al., 2018; Ziska, 2020). The range of other invasive weeds may become static, or even decline (Bradley et al., 2016; Buckley and Csergo, 2017). A recent meta-analysis also supports that invasive plants respond more favourably to elevated CO_2 concentrations and elevated temperatures than native plants (Korres et al., 2016; Liu et al., 2017). Movement of invasive species into low fertility areas, however, could provide resource opportunities, especially if agriculture in those areas is limited (Randriambanona et al., 2019).

Rising CO_2 concentrations and climate change could reduce herbicide efficacy (*medium evidence, high agreement*). These reductions may be associated with physical environmental changes (precipitation, wind speed) that influence herbicide coverage (Ziska, 2016), as well as direct effects of CO_2 on plant biochemistry and herbicide resistance (Refatti et al., 2019). Increasing CO_2 levels and altered temperature and precipitation, are therefore projected to affect all aspects of weed biology (Peters et al., 2014; Ziska and McConnell, 2016), including establishment (Bradley et al., 2016), competition (Fernando et al., 2019), distribution, (Castellanos-Frías et al., 2016), and management (Waryszak et al., 2018).

A warmer climate increases the need for pesticides (Shakhramanyan et al., 2013; Ziska, 2014; Delcour et al., 2015; Zhang et al., 2018). Increases in temperature and CO_2 concentration may reduce pesticide efficiency by altering its metabolism, or accelerating detoxification (Matzrafi et al., 2016; Matzrafi, 2019). Intense rainfall also reduces persistence (Delcour et al., 2015). Invasive pests and pathogens impose an additional cost for the society (Bradshaw et al., 2016). Rapid and large-scale dispersal of pests is already a major threat to food security, as exemplified by the recent outbreak of desert locusts (see Box 5.8), indicating the importance of international cooperation. Taken together, the need for control of pests, disease and weeds will increase under climate change (*medium evidence, high agreement*). The use of toxic agricultural chemicals also has human health and environmental risks (Whitmee et al., 2015; IPBES, 2019). Surveillance for monitoring pest distribution and damages, climate-relevant pest-risk analysis, and climate-smart strategies for controlling pests with minimal impacts on human and environmental health are important tools in the face of climate change (IPPC Secretariat, 2021).

5.4.1.4 Observed impacts of ozone on crops

Tropospheric (i.e., the lowest 6–10 km of the atmosphere) ozone exacerbates negative impacts of climate change (*high confidence*) (Mattos et al., 2014; Chuwah et al., 2015; McGrath et al., 2015; Bisbis et al., 2018; Mills et al., 2018; Scheelbeek et al., 2018). Ozone is an air pollutant and short-lived greenhouse gas that affects air quality and global climate. It is a strong oxidant that reduces physiological functions, yield and quality of crops and animals. Surface ozone concentration has increased substantially since the late 19th century (Cooper et al., 2014; Forster et al., 2021; Gulev et al., 2021; Naik et al., 2021)and in some locations and times reaches levels that harm plants, animals, and human (*high confidence*) (Fleming et al., 2018).

Mills (2018) estimated global distributions of current yield losses of major crops due to ozone, pest and diseases, heat, and aridity (Figure 5.4). Ozone-induced yield losses in 2010-2012 averaged 12.4, 7.1, 4.4, and 6.1 % for soybean, wheat, rice, and maize, respectively. Spatial variation in yield losses is similar among different stresses; areas with a large loss due to ozone are also at high risk of yield losses due to pest and diseases and heat. Many vegetable crops are also susceptible to ozone, which will adversely impact quality and quantity (Mattos et al., 2014; Bisbis et al., 2018; Scheelbeek et al., 2018).

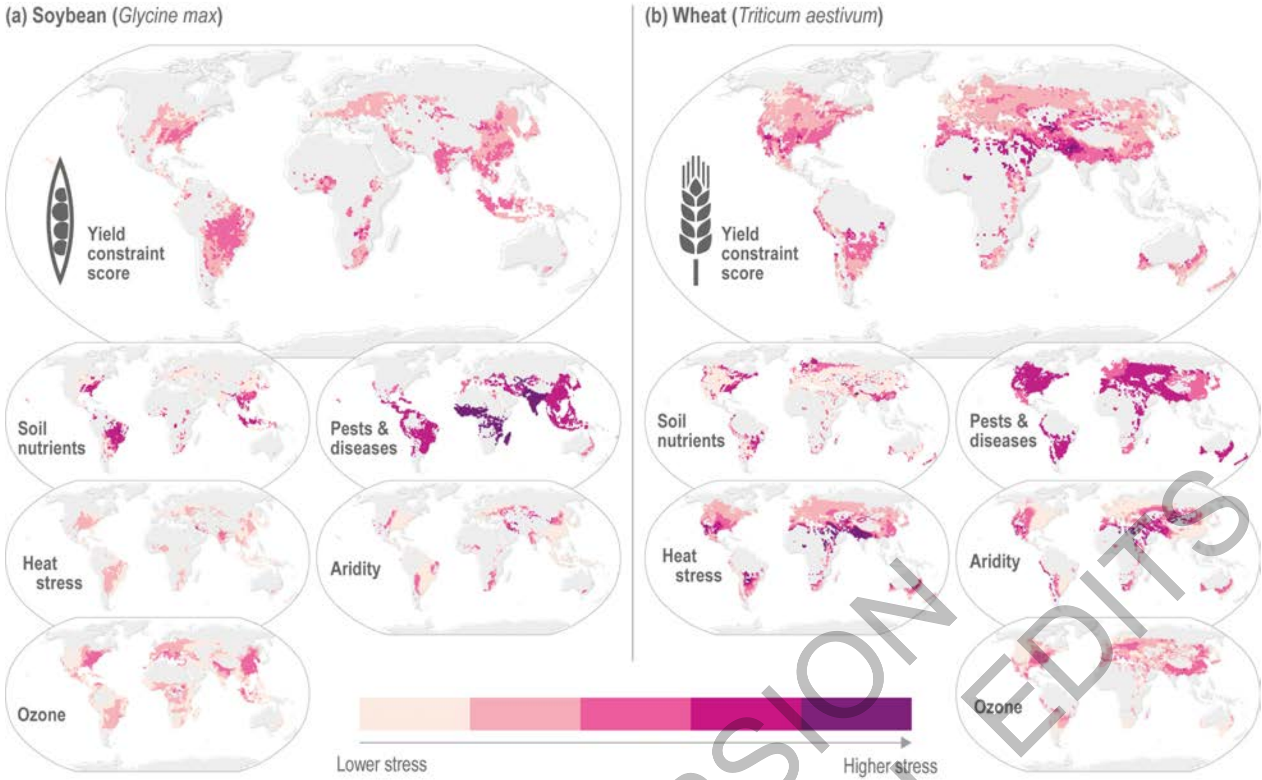

Figure 5.4: The global effects of five biotic and abiotic stresses on soybean and wheat. All data are presented for the 1 × 1° (latitude and longitude) grid squares where the mean production of soybean or wheat was >500 tonnes (0.0005 Tg). The effect of each stress on yield is presented as a Yield Constraint Score (YCS) on a scale of 1–5, where 5 is the highest level of stress from ozone, pests and diseases, heat stress and aridity (Mills et al., 2018). Data are available at Sharps et al.,(2020). See Annex I: Global to Regional Atlas for all four crops.

The estimated yield loss does not account for interactions with other climatic factors. Temperatures enhance not only ozone production but also ozone uptake by plants, exacerbating yield and quality damage. Burney (2014) estimated current yield losses due to the combined effects of ozone and heat in India at 36% for wheat and 20 % for rice. Schauberger et al. (2019a) found global yield losses, ranging from 2 to 10 % for soybean and 0 to 39 % for wheat with a model that accounts for temperature, water, and CO_2 concentration on ozone uptake.

5.4.2 Assessing Vulnerabilities within Production Systems

Since AR5, vulnerability assessment has become a pivotal component of risk analysis associated with climate hazards, climate change and climate variability (UNDRR, 2019). Vulnerability assessment can be sectoral or regional but involves social and ecological indicators. This section presents examples of vulnerability assessment to climatic hazards and social vulnerabilities.

5.4.2.1 Vulnerability to climatic hazards

Drought is a major risk component in cropping systems globally, with substantial economic loss (Kim et al., 2019b), livelihood impacts (Shiferaw et al., 2014; Miyan, 2015), and ultimately health risks such as malnutrition (Phalkey et al., 2015; Cooper et al., 2019). Vulnerability to drought can be estimated with a range of indicators (Hagenlocher et al., 2019). Meza (2020) showed that drought risks could be exacerbated or moderated by regional differences in vulnerability (Figure 5.5). For instance, high-level risks observed in southern Africa, western Asia, and central Asia result from high vulnerability (low coping capacity), whereas risk levels are relatively low despite the high exposure by relatively high adaptive capacity to drought in other regions.

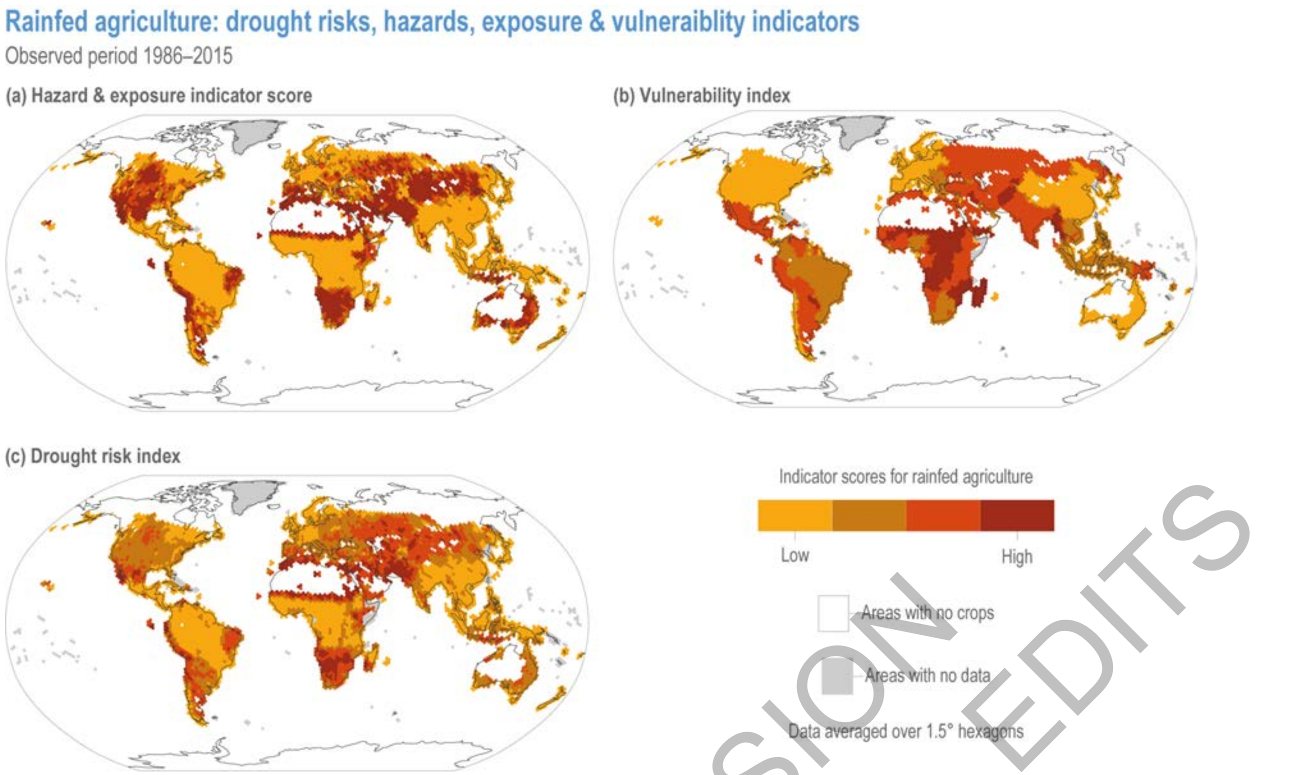

Figure 5.5: Hazard and exposure indicator score (a), vulnerability index (b) and drought risk index (c), for rainfed agricultural systems between 1986 and 2015. Drought hazard indicator is defined as the ratio of actual crop evapotranspiration to potential crop evapotranspiration, calculated for 24 crops. Vulnerability index is the country-scale weighted average of a total of 64 indicators including social and ecological susceptibility indicators, and coping capacity. Risk index is calculated by multiplying hazard/exposure indicator score and vulnerability index (Meza et al., 2020).

Regional-scale assessment also highlights the importance of adaptive capacity. For instance, rice and maize production in Viet Nam Mekong Delta has high exposure to multiple climate hazards such as flooding, sea-level rise, salinity intrusion, and drought (Parker et al., 2019). Risks can be moderated by a relatively high adaptive capacity because of infrastructure, resources, and high education levels (Parker et al., 2019). Another regional study demonstrated that erratic rains and high temperatures in southern and south-eastern Africa increased the vulnerability of agricultural soils, thereby exacerbating impacts of prolonged and frequent droughts (Sonwa et al., 2017a; See also Box 5.4).

Farm-scale assessment exemplifies context-sensitive vulnerability to climate hazards. Studies of coffee growers in Central America demonstrated that key vulnerability indicators varied greatly between regions and between farms, ranging from a lack of labour, postharvest infrastructure, conservation practices and transport that limits access to market, technical and financial assistance (Baca et al., 2014; Bouroncle et al., 2017). These region- and scale-specific vulnerability indicators assist in identifying ways to enhance resilience to climate hazards (*high confidence*).

5.4.2.2 Inequalities in cropping systems- other crops and regional disparities

While those working with major crops have benefited from the release of new cultivars, those growing other crops are typically reliant on a heritage cultivars or landraces. While Indigenous knowledge and local smallholder knowledge and practices play an important role in supporting agrobiodiversity which provides genetic diversity resistant to climate-related stresses, a global and national focus in international research, subsidies and support for a few crop species has contributed to an overall decline in agrobiodiversity (FAO, 2019e; Song et al., 2019) Similarly, there is a lack of agronomic innovation and research to service 'minor' crops (Moriondo et al., 2015; Manners and van Etten, 2018). Even some high value commodities grown outside high-income countries suffer from imbalances in the focus of available credit, research, and innovation (Section 5.4.4.3; Glover, 2014; Fischer, 2016; Farrell et al., 2018). There is a possibility that a lack of adaptive capacity and policy support will drive these growers to move away from these diverse crops, further reducing the resilience of food systems by increasing risk of crop loss from pests, disease and drought and potential loss of Indigenous or local knowledge (Section 5.13.5, Table Box 5.1.1). In the Andean Altiplano of Bolivia, for example, Indigenous farmers have traditionally managed a diverse set of native crops which are drought and frost-tolerant, using cultural practices of seed selection and exchange, but have faced an increase in pests and diseases and a decline of traditional crops due to climate change related stresses, out-migration and intensification drivers (Meldrum et al., 2018).

5.4.2.3 Gender and other social inequalities

Social inequalities such as gender, ethnicity, and income level, which vary by time and place and may overlap, can compound vulnerability to climate change for producers within cropping systems (*high confidence*) (Table 5.3, Arora-Jonsson, 2011; Djoudi et al., 2013; Carr and Thompson, 2014; Mbow et al., 2019; Rao et al., 2019a; Nyantakyi-Frimpong, 2020a). Rather than binary and static categories (i.e., men vs women), social vulnerabilities are dynamic and intersect; to understand vulnerability the specific socio-cultural identities, political and environmental context needs to be studied in relation to climate stress (Thompson-Hall et al., 2016; Rao et al., 2019a; Nyantakyi-Frimpong, 2020a).

Table 5.3: Examples of social inequalities in cropping systems that compound climate change vulnerability.

Social inequality	**How social inequality increases vulnerability to climate change in cropping systems**
Gender inequality can create and worsen social vulnerability to climate change impacts within cropping systems (*high confidence*) (Carr and Thompson, 2014; Sugden et al., 2014; Nyantakyi-Frimpong and Bezner-Kerr, 2015; Rao et al., 2019a; Ebhuoma et al., 2020; Nyantakyi-Frimpong, 2020a; see Cross-Chapter Box GENDER in Chapter 18).	• Men and women have different access to and decision-making control over resources such as seeds, systemic differences in land tenure and agricultural employment, and their responsibilities, workloads and response to climate stresses differ due to systemic gender inequities and socio-cultural norms, which intersect with other inequities (e.g., income level, ethnicity) to compound vulnerability (Rao et al., 2019a; Ebhuoma et al., 2020; Nyantakyi-Frimpong, 2020a). • In a study in northern Ghana, for example, poor widows with poor health had fewer resources to rely on during droughts than married women, particularly those married to local leaders; in contrast, due to gendered expectations, during floods low-income men suffered greater consequences (Nyantakyi-Frimpong, 2020a). • Adaptation strategies such as migration can compound that vulnerability, but importantly the specific gendered vulnerability intersects with other inequalities which are context specific (Sugden et al., 2014; Nyantakyi-Frimpong, 2020a; Cross-Chapter Box MIGRATE in Chapter 7).
Globally, **smallholder food producers** are more vulnerable than large-scale producers to climate change impacts (*high confidence*).	• In part because of limited policy, infrastructure and institutional support, low credit access, viable markets and limited political voice in policy debates (HLPE, 2013; Karttunen et al., 2017; Mbow et al., 2019; Nyantakyi-Frimpong, 2020a). • Smallholder producers' vulnerability may be increased by heavy reliance on one crop for income, particularly if the crop requires significant capital investments (*medium confidence*) (Toufique and Belton, 2014; Craparo et al., 2015; Ovalle-Rivera et al., 2015). • For example, smallholder coffee producers in southern Mexico and Central America are more vulnerable due to a range of factors, including unstable and low coffee prices, limited institutional support for small-scale producers, low negotiation capacity and access to markets, and heavy reliance on one crop for income (Economic Commission for Latin America and the Caribbean and System, 2014; Ovalle-Rivera et al., 2015; Ruiz Meza, 2015; Hannah et al., 2017; Bacon et al., 2021). Pest and disease outbreaks such as coffee leaf rust, extreme climatic events, ongoing conflict, poor governance, and low viability of livelihoods increased migration and high levels of food insecurity for this group (Robalino et al., 2015; Hannah et al., 2017; Donatti et al., 2019) which also varied by institutional and farm level responses, land size and income level (Quiroga et al., 2020; Bacon et al., 2021).
Farmworkers are another social group with heightened	• Farmworkers often experience job insecurity, food insecurity, poor working conditions, poverty, and social marginalization. Climate change impacts can compound their vulnerability, for example by worsening working conditions

vulnerability to climate change (*medium confidence*).	through increased temperatures and humidity (Section 5.12.3.1), or increase unreliability of work due to rainfall irregularity, flooding or drought, and can put them more at risk during climatic extreme events such as wildfires (Turhan et al., 2015; Greene, 2018; Mendez et al., 2020; Tigchelaar et al., 2020).

5.4.3 Projected Impacts

5.4.1.1 Advances in the characterisation of the effects of elevated atmospheric CO_2

Elevated CO_2 concentrations stimulate photosynthesis rates and biomass accumulation of C_3 crops, and enhance crop water use efficiency of various crop species including C_4 crops (*high confidence*) (Kimball, 2016; Toreti et al., 2020). Perennial crops and root crops may have a greater capacity for enhanced biomass under elevated CO_2 concentrations, although this does not always result in higher yields (Glenn et al., 2013; Kimball, 2016).

Recent FACE studies found that the effects of elevated CO_2 are greater under water-limited conditions (*medium confidence*) (Manderscheid et al., 2014; Fitzgerald et al., 2016; Kimball, 2016), which was generally reproduced by crop models (Deryng et al., 2016). However, drought sometimes negates the CO_2 effects (Jin et al., 2018).

There are significant interactions between CO_2, temperature, cultivars, nitrogen and phosphorous nutrients (Kimball, 2016; Toreti et al., 2020): Positive effects of rising CO_2 on yield are significantly reduced by higher temperatures for soybean, wheat and rice (*medium confidence*) (Ruiz-Vera et al., 2013; Cai et al., 2016; Gray et al., 2016; Hasegawa et al., 2016; Obermeier et al., 2016; Purcell et al., 2018; Wang et al., 2018). In aboveground vegetables, elevated CO_2 can in some cases reduce the impact of other climate stressors, while in others the negative impacts of other abiotic factors negate the potential benefit of elevated CO_2 (Bourgault et al., 2017; Bourgault et al., 2018; Parvin et al., 2018; Parvin et al., 2019). Significant variation exists among cultivars in yield response to elevated CO_2, which is positively correlated with yield potential in rice and soybean, suggesting the potential to develop cultivars for enhanced productivity under future elevated [CO_2] (Ainsworth and Long, 2021).

Elevated CO_2 reduces some important nutrients elements such as protein, iron, zinc, and some vitamins in the grains, fruit or vegetables to varying degrees depending on crop species and cultivars (*high confidence*) (Mattos et al., 2014; Myers et al., 2014; Dong et al., 2018; Scheelbeek et al., 2018; Zhu et al., 2018a; Jin et al., 2019; Ujiie et al., 2019). This is of particular relevance for fruit and vegetable crops given their importance in human nutrition (*high confidence*) (see Section 5.12.4 for potential impacts on nutrition; Nelson et al., 2018; Springmann et al., 2018). Recent experimental studies (Section 5.3.2), however, show some complex and counteracting interactions between CO_2 and temperature in wheat, soybean, and rice; heat stress negates the adverse effect of elevated CO_2 on some nutrient elements (Macabuhay et al., 2018; Kohler et al., 2019; Wang et al., 2019b). The CO_2 by temperature interaction for grain quality needs better quantitative understandings to predict food nutritional security in the future.

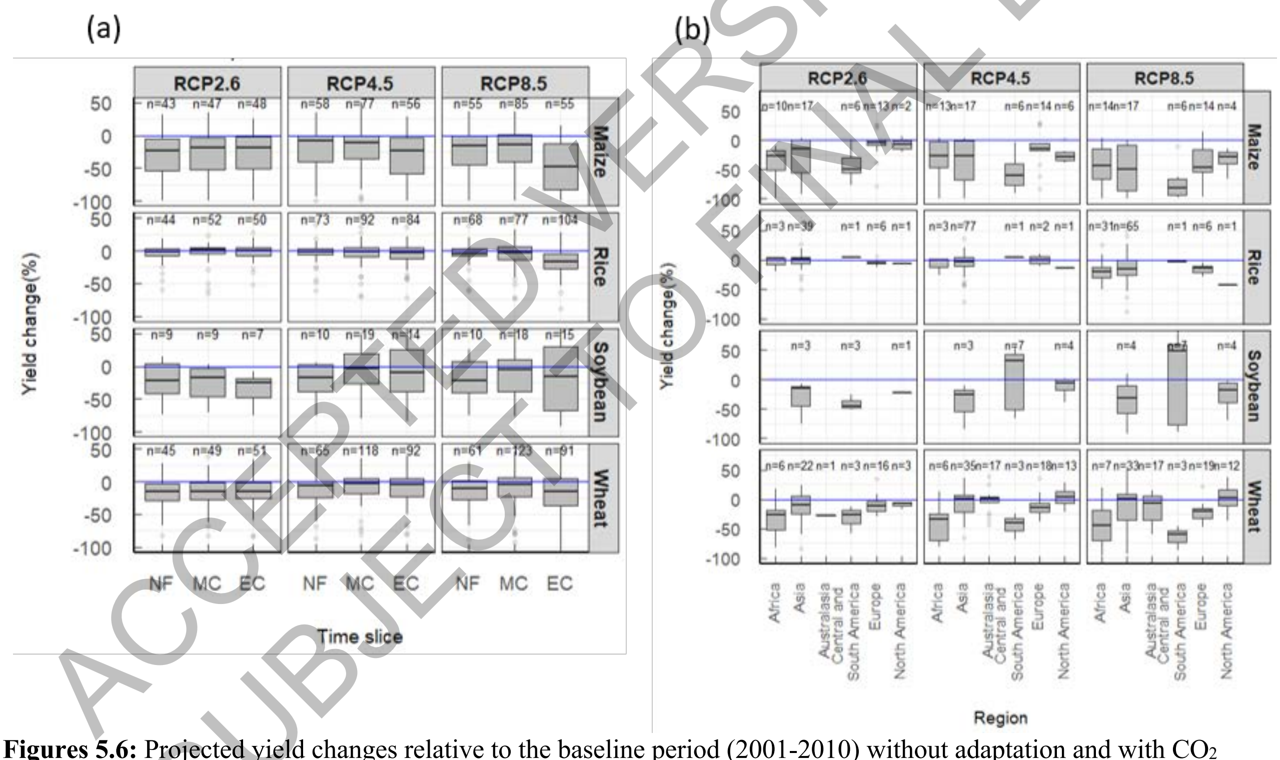
5.4.3.2 Projected impacts on major crop production

AR5 Chapter 7 estimated the crop yield reduction globally of about 1% per decade due to climate change (Porter et al., 2014), similar to that in the previous assessment reports (Porter et al., 2019). Additional research confirms that climate change will disproportionately affect crop yields among regions with more negative than positive effects being expected in most areas, especially in currently warm regions including Africa, Central and South America (*high confidence*).

A systematic literature search between 2014 and 2020 resulted in about 100 peer-reviewed papers that simulated crop yields of four major crops (maize, rice, soybean, and wheat) using CMIP5 data (Hasegawa et al., 2021b). Most studies focus on the relative change in crop yields due to climate change, but do not consider technological advances. Nevertheless, they provide useful insights into time-, scenario-, and warming-degree-dependent impacts of climate change.

The impact of climate change on crop yield without adaptation projected in the 21st century is generally negative even with the CO_2 fertilisation effects, with the overall median per-decade effect being −2.3% for maize, −3.3% for soybean, −0.7% for rice, and −1.3% for wheat, which are consistent with previous IPCC assessments (Porter et al., 2014). The effects vary greatly within each crop, timeframe, and RCP, but show a few common features across crops (Figure 5.6a**)**. Differences in the projected impacts between RCPs are not pronounced by mid-century. From then onward, the negative effect becomes more pronounced under RCP8.5, notably in maize. Rice yields show less variation across models than other crops presumably because simulations are mostly under irrigated conditions. A part of the uncertainty in the projection is due to regional differences (Figure 5. 6b). Negative impacts on cereals are projected in Africa and Central and South America at the end of the century, which agrees with the previous studies (Aggarwal et al., 2019; Porter et al., 2019).

The differences due to regions, RCPs, and timeframes are related to the current temperature level and degree of warming (Figure 5.7). The projected effects of climate change are positive where current annual mean temperatures (T_{ave}) are below 10 °C, but they become negative with T_{ave} above around 15 °C. At T_{ave}>20°C, even a small degree of warming could result in adverse effects. In maize, negative effects are apparent at almost all temperature zones. A new study using the latest climate scenarios (CMIP6) and global gridded crop model ensemble projected that climate change impacts on major crop yields appear sooner than previously anticipated, mainly because of warmer climate projections and improved crop model sensitivities (Jägermeyr et al., 2021).



Figures 5.6: Projected yield changes relative to the baseline period (2001-2010) without adaptation and with CO_2 fertilization effects (Hasegawa et al., 2021b). The box is the interquartile range (IQR) and the middle line in the box represents the median. The upper- and lower-end of whiskers are median 1.5 × IQR ± median. Open circles are values outside the 1.5 × IQR. (a) at different time periods (Near Future, NF, Baseline-2039; Mid Century, MC, 2040-2069; End of Century, EC, 2070-2100) under three representative concentration pathways (RCPs), and (b) at different regions at EC.

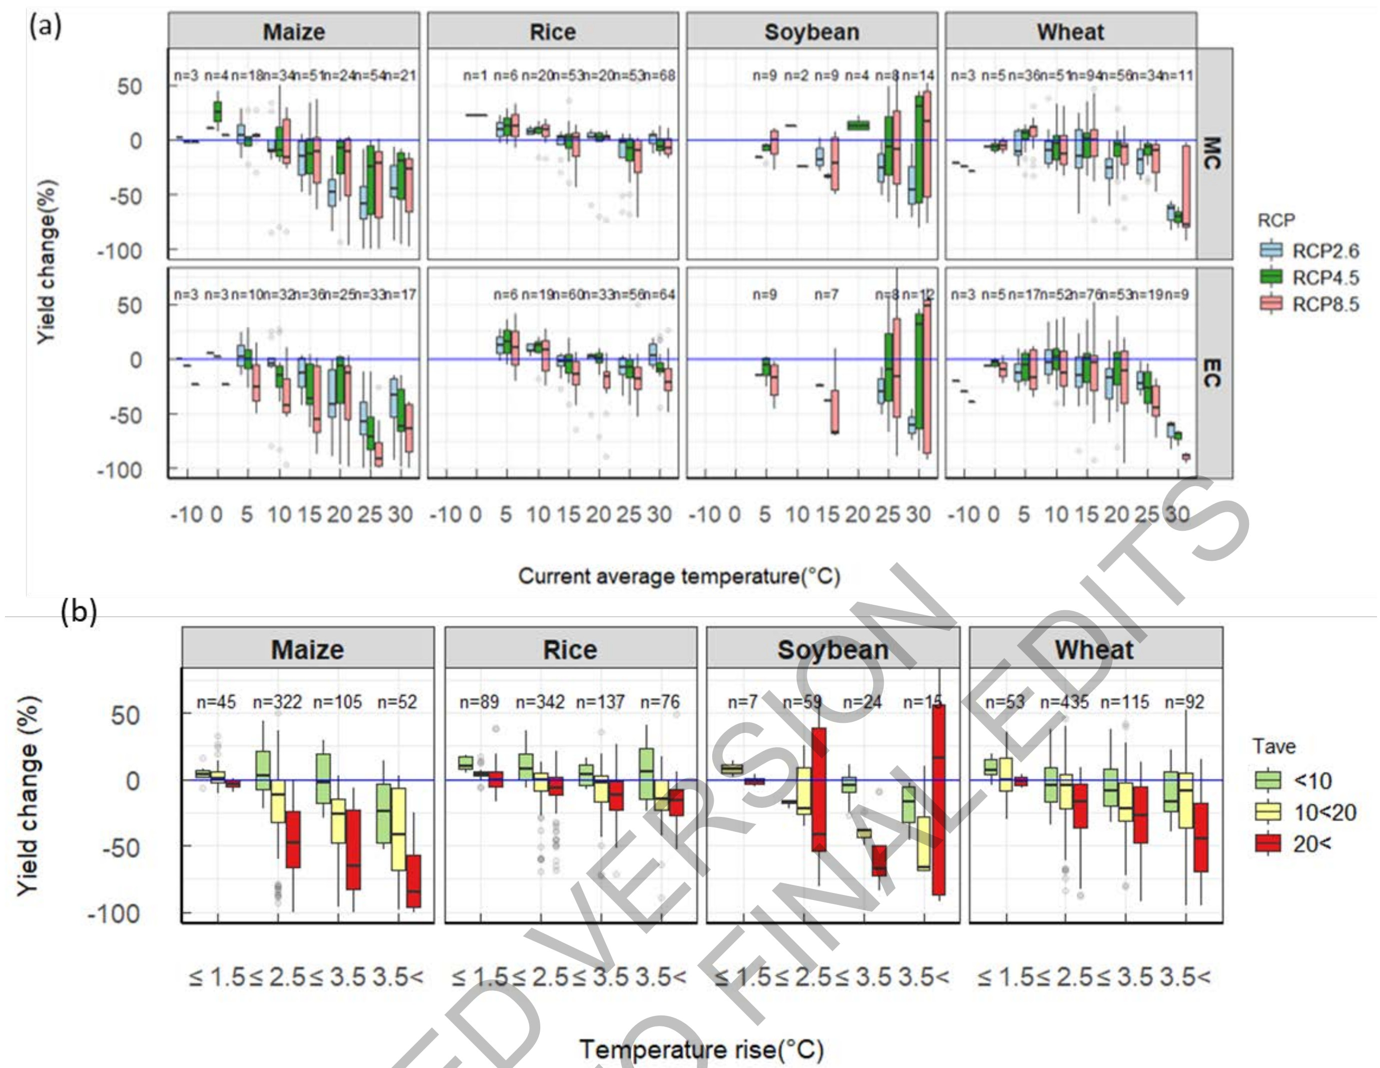


Figure 5.7: Projected yield changes relative to the baseline period (2001-2010) without adaptation and with CO_2 fertilization effects (Hasegawa et al., 2021b). (a) Mid-century (MC, 2040-2069) and end-century (EC, 2070-2100) projections under three RCP scenarios as a function of current annual temperature (T_{ave}), (b) as a function of global temperature rise from the baseline period by three T_{ave} levels. See Figure. 5.6 for legends.

As noted in Section 5.3.1, most simulations do not fully account for responses to pests, diseases, long-term change in soil, and some climate extremes (Rosenzweig et al., 2014), but studies are emerging to include some of these effects. For example, based on the temperature response of insect pest population and metabolic process, global yield losses of rice, maize, and wheat are projected to increase by 10 – 25 % per degree of warming (Deutsch et al., 2018). Rising temperatures reduce soil carbon and nitrogen, which in turn exacerbate the negative effects of + 3 °C warming on yield from 9 to 13 % in wheat and from 14 to 19 % in maize (Basso et al., 2018).

A few studies have examined possible occurrences of tele-connected yield losses (5.4.1.2) using future climate scenarios. Tigchelaar (2018) estimated that for the top four maize–exporting countries, the probability that simultaneous production losses greater than 10% occur in any given year increases from 0 to 7% under 2°C-warming and to 86% under 4 °C-warming. Gaupp (2019) estimated that risks of simultaneous failure in maize would increase from 6% to 40% at 1.5 °C and to 54% at 2 °C-warming, respectively, relative to the historical baseline climate. Large-scale changes in SST are the major factors causing simultaneous variation in climate extremes, which are projected to intensify under global warming (Cai et al., 2014; Perry et al., 2017). Consequently, risks of multi-breadbasket failures will also increase (*medium confidence*). Further examination is needed for the effects of spatial patterns of these extremes on breadbaskets in relation to SST anomalies under more extreme climate scenarios.

Future surface ozone concentration is highly uncertain (Fiore et al., 2012; Turnock et al., 2018); it is projected to increase under RCP8.5 and to decrease under other RCPs depending largely on different methane emission trajectories because methane is an important precursor of ozone. Methane, therefore, reduces crop yield both from climate warming and ozone increase (Avnery et al., 2013). Shindell (2016) estimated yield losses of four major crops (to be 25 ± 11% by 2100 under RCP8.5, as a net balance of the positive effect of CO_2 (15± 2%) and negative effects of warming (35 ± 10%) and ozone (4.0 ± 1.3%), and that 62% of the yield loss was attributable to methane. This points to the importance of reducing methane and other precursors of ozone as an effective adaptation strategy (*medium evidence, high agreement*).

5.4.3.3 Projected impacts on other crops

Yield projections for crops other than cereals indicate mostly negative impacts on production due to a range of climate drivers (*high confidence*), with yield reductions similar to that of cereals expected in tropical, subtropical and semi-arid areas (Mbow et al., 2019). Springmann et al. (2016), compared the projected global food availability for different food groups under the SSP2 2050 scenario and found reductions in availability were similar in cereals, fruit and vegetables, and root and tubers (with legumes and oilseed crops showing a smaller reduction).

Fruit and vegetables have not been subject to extensive or coordinated yield projections (Figure 5.8). Yield projections have been performed for individual crops and locations (Ruane, 2014; Adhikari et al., 2015; Awoye et al., 2017; Ramachandran et al., 2017); but more often crop suitability models have been used (SM5.3). Zhao(2019) introduced a modelling approach that could be used to generate yield projections for a wider range of annual crops. The discussion here also draws on reviews of more restricted experimental studies. Negative impacts of climate change on crop production are expected across many cropping systems (Figure 5.8). Apart from the direct effects of elevated carbon dioxide, most changes are expected to have negative effects on crop production. Changes in temperature and rainfall are most often mentioned as drivers of climate impacts, but expected changes in phenology, pests and diseases are also raising concerns. (Scheelbeek et al., 2018) synthesized projections for vegetables and legumes, based on their response to climate factors under experimental conditions; in most cases the magnitude of the changes is comparable to the RCP 8.5 2100 forecasts. Scheelbeek et al. (2018) projected yield changes of: +22.0% (+11.6% to +32.5%) for a 250 ppm increase in CO_2 concentration; −34.7% (−44.6% to −24.9%) for a 50 % reduction in water availability; −8.9% (−15.6% to −2.2%) for a 25 % increase in ozone concentration; −31.5% for a 4°C increase in temperature (in papers with a baseline temperature of >20°C). Overall, impacts are expected to be largely negative in regions where the temperature is currently above 20°C, while some yield gains are expected in cooler regions (provided that water availability and other conditions are maintained). Scheelbeek et al. (2018), did not consider changes in pest and disease pressure, which are projected to increase with warming (see SM5.3).

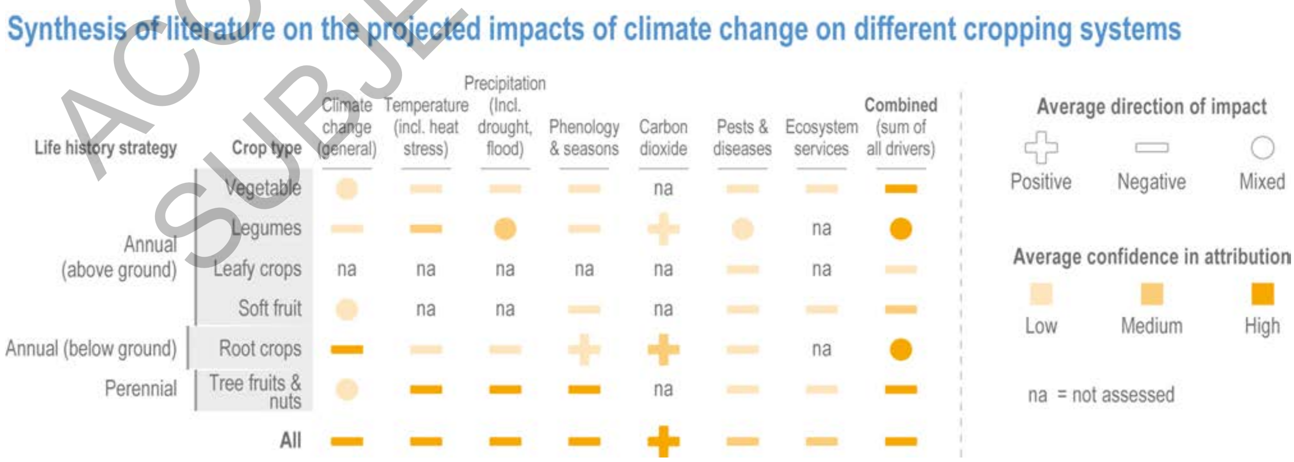

Figure 5.8: Synthesis of literature on the projected impacts of climate change on different cropping systems. The assessment includes projections of impacts on crop productivity over a range of emission scenarios and time periods. The projected impacts are disaggregated by the different climate and climate-related drivers. Impacts are reported as positive, negative or mixed. The assessment draws on >60 articles published since AR5. The confidence is based on the evidence given in individual articles and on the number of articles. See **SM5.2** information for details.

Systematic assessments of climate response for root crops as a group are lacking (Raymundo et al., 2014; Knox et al., 2016; Manners and van Etten, 2018). Climate suitability is projected to increase for tropical root crops (SM5.3) and some studies have found that root crops will be less negatively impacted than cereals, but there is no consensus on this (Brassard and Singh, 2008; Adhikari et al., 2015; Schafleitner, 2016; Manners et al., 2021). For potato, Raymundo et al. (2018) projected global yield reductions of 2-6% by 2055 under different RCPs, but with important differences among regions; tuber dry weight may experience reductions of 50 to 100% in marginal growing areas such as central Asia, while increases of up to 25% are expected in many high-yielding environments. Projections show yield increases of 6% per 100 ppm elevation in CO_2 but declines of 4.6% per °C and 2% per 10% decrease in rainfall (Fleisher et al., 2017). Jennings et al. (2020), projected an overall increase in global potato production, but only if widespread adoption of adaptation measures is achieved. Although increases in CO_2 could produce positive yield responses, the effects of temperature may offset these potential benefits (Dua et al., 2013; Raymundo et al., 2014). Warming offers the potential of longer growing seasons but can also have negative impacts through disrupted phenology and interactions with pests (Figure 5.8, Bebber, 2015; Pulatov et al., 2015).

Global yield modelling is lacking for woody perennial crops. Experimental studies suggest negative impacts on yields due to reduced water supply and increased soil salinity, as well as from warming and ozone (although evidence was limited for these) (Alae-Carew et al., 2020). Increasing CO_2 is expected to increase yields, but only where other factors, such as warming, do not become yield-limiting (Alae-Carew et al., 2020). Many local projections include large uncertainty because of a lack of observational data and reliable parametrization (Moriondo et al., 2015; Mosedale et al., 2016; Kerr et al., 2018; Mayer et al., 2019b). Most perennial crop models have found large negative impacts on yield and suitability, although CO_2 fertilisation and phenology are not always considered (Lobell and Field, 2011; Glenn et al., 2013). Perennial crops are often grown in dryland areas where rainfall or irrigation water can be critical (Mrabet et al., 2020). Valverde (2015) found that yield losses in the Mediterranean region were largely driven by reduced rainfall, with maximum estimated yield losses of 5.4% for grape, 14.9% for olive and 27.2% for almond under a relatively hot and dry scenario (by 2041–2070). Moriondo (2015) highlight the need for perennial crop models to incorporate phenology and extreme climate events. Equally challenging is the need to estimate the impact of biotic changes, particularly climate-driven movement of pests and diseases (Ponti et al., 2014; Bosso et al., 2016; Schulze-Sylvester and Reineke, 2019; Section 5.5.2.4).

For cotton, experimental studies suggest positive impacts from rising CO_2 and temperature (Zhang et al., 2017a; Jans et al., 2021), but projections show mixed impacts on yield, including large negative impacts in warmer regions due to heat, drought and the interaction of temperature with phenology (Yang et al., 2014; Williams et al., 2015; Adhikari et al., 2016; Rahman et al., 2018). Climate change is also expected to increase the demand for irrigation water, which will likely limit production (Jans et al., 2021). There are also concerns that fibre quality may deteriorate (e.g., air permeability of compressed cotton fibers) (Luo et al., 2016).

Higher temperatures and altered moisture levels are expected to present a food safety risk, particularly for above ground harvested vegetables (Figures 5.8; 5.10). Warmer and wetter weather is anticipated to increase fungal and microbial growth on leaves and fruit, while altered flooding regimes increase the risk of crop contamination (Liu et al., 2013; Uyttendaele et al., 2015). This is also true for perennial crops, e.g., warming and climate variability can increase fungal contamination of grapes including those associated with mycotoxins (Battilani, 2016; Paterson, 2018).

[START BOX 5.2 HERE]

Box 5.2: Case Study: Wine

Wine growing regions cover 7.4 million ha with a value of 35 billion USD in 2018 (OIV, 2019). Important regions (Italy, France, Spain, United States, Argentina, Australia, South Africa, Chile, Germany, China, Argentina) are located in areas where mean annual temperature roughly varies between 10 and 20 °C (Schultz and Jones, 2010; Mosedale et al., 2016).

Temperature is the primary determinant for vine development. Recent warming trends have advanced flowering, maturity, and harvest (*high confidence*) (Koufos et al., 2014; Cook and Wolkovich, 2016; Hall et al., 2016; Ruml et al., 2016; van Leeuwen and Destrac-Irvine, 2017; Koufos et al., 2020; Wang et al., 2020b; Wang and Li, 2020), and wine growing regions have expanded outside the normal temperature bounds of locally grown varieties (*limited evidence, high agreement*) (Kryza et al., 2015; Irimia et al., 2018). Milder winters have affected harvest in ice-wine growing regions (Pickering et al., 2015). Higher temperatures have mixed effects depending on site, but generally decreases grape quality (Barnuud et al., 2014; Morales et al., 2014; Sweetman et al., 2014; Kizildeniz et al., 2015; Kizildeniz et al., 2018). Warming increases sugar accumulation and decreases acidity (Leolini et al., 2019). Secondary metabolites are negatively affected (Biasi et al., 2019; Teslić et al., 2019). Developmental phases are projected to proceed faster in response to warming (*high confidence*) (Fraga et al., 2016a; Fraga et al., 2016b; García de Cortázar-Atauri et al., 2017; Costa et al., 2019; Molitor and Junk, 2019; Sánchez, 2019). However extreme high temperatures may have inhibitory effects on development (Cuccia et al., 2014).

In some cases, irrigation is required, and more frequent droughts are a key concern for yield and fruit quality (Morales et al., 2014; Bonada et al., 2015; Kizildeniz et al., 2015; Salazar-Parra, 2015; Kizildeniz et al., 2018; Funes et al., 2020). Water stress reduces shoot growth and berry size, and increases tannin and anthocyanin content (van Leeuwen and Darriet, 2016). However, controlled water stress produces positive impacts on wine quality, increasing skin phenolic compounds (van Leeuwen and Destrac-Irvine, 2017). The level of stress will depend on soil type, texture and organic matter content (Fraga et al., 2016a; Fraga et al., 2016b; Bonfante, 2017; García de Cortázar-Atauri et al., 2017; Leibar et al., 2017; Costa et al., 2019; Molitor and Junk, 2019; Sánchez, 2019). Increases in water demands with potential negative effects from increased soil salinity are among the most common effects of climate change in irrigated regions (*medium evidence, high agreement*) (Mirás-Avalos et al., 2018; Phogat et al., 2018).

Rising CO_2 will have mixed effects on vine growth and quality (*medium evidence, high agreement*) (Martínez-Lüscher et al., 2016; Edwards et al., 2017; van Leeuwen and Destrac-Irvine, 2017). Rising CO_2 concentrations will negatively affect wine quality by reducing anthocyanin concentration and colour intensity (Leibar et al., 2017).

Suitability responses to warming are region-specific. In regions where low temperature is a limiting factor, warming will enable growers to grow a wider range of varieties and obtain better-quality wines (*high confidence*) (Fuhrer et al., 2014; Mosedale et al., 2015; Mosedale et al., 2016; Meier et al., 2018; Jobin Poirier et al., 2019; Maciejczak and Mikiciuk, 2019). Subtropical and Mediterranean regions will experience major declines in fruit quality for high-quality wines (*high confidence*) (Resco et al., 2016; Lazoglou et al., 2018; Cardell et al., 2019; Fraga et al., 2019a; Fraga et al., 2019b; Teslić et al., 2019). These changes will also affect wine tourism (Nunes and Loureiro, 2016).

Impacts on suitability may reshape the geographical distribution of wine regions. Viability of the wine-growing regions will depend on the knowledge of local climatic variability (Neethling et al., 2019; Rességuier et al., 2020) and the implementation of adaptation strategies such as use of adapted plant material rootstocks, cultivars and clones, viticultural techniques (e.g., changing trunk height, leaf area to fruit weight ratio, timing of pruning), irrigation, enological interventions to control alcohol and acidity, as well as policy incentives and support (Callen et al., 2016; Ollat and Leeuwen, 2016; van Leeuwen and Destrac-Irvine, 2017; Merloni et al., 2018; Alikadic et al., 2019; del Pozo et al., 2019; Fraga et al., 2019b; Santillan et al., 2019; Morales-Castilla et al., 2020; Marín et al., 2021).

[END BOX 5.2 HERE]

[START BOX 5.3 HERE]

Box 5.3: Pollinators

Climate change will reduce the effectiveness of pollinator agents as species are lost from certain areas, or the coordination of pollinator activity and flower receptiveness is disrupted in some regions (*high confidence*)

(Potts et al., 2010; Gonzalez-Varo et al., 2013; Polce et al., 2014; Kerr et al., 2015; Potts et al., 2016; Settele et al., 2016; Giannini et al., 2017; Mbow et al., 2019). A modelling study estimates that complete removal of pollinators could reduce global fruit supply by 23%, vegetables by 16%, and nuts and seeds by 22%, leading to significant increases in nutrient-deficient population and malnutrition-related diseases (Smith and Haddad, 2015), highlighting the importance of this ecosystem service for human health.

Bees are an essential agricultural pollinator, widely recognized for their role in the fertilisation of many domesticated plants. The observed wide-spread decline in native bees and honeybee colony numbers, particularly in the U.S. and Europe, has been associated with a number of environmental stressors in addition to climate change, such as neonicotinoids and varroa mites, and has raised concerns regarding plant-pollinator networks, the stability of pollination services, global food production and the prevalence of malnutrition (Williams and Osborne, 2009; Potts et al., 2010; Chaplin-Kramer et al., 2014).

Any climatic influence on floral phenology or physiology could, potentially, alter bee biology. At present there is evidence that climate change induced asynchrony in pollen and pollinators can occur (Stemkovski et al., 2020). In addition, the nutritional composition of floral pollen may also affect the bee's health at the global level (*low evidence*). For example, the goldenrod (*Solidago* spp.), a ubiquitous pollen source for bees just prior to winter, has experienced a ~30% drop in protein since the onset of CO_2 emissions from the industrial revolution (Ziska et al., 2016).

Climate extremes could pose risks to pollinator when species tolerance is exceeded, with subsequent reduction in populations and potential extirpation (Nicholson and Egan, 2020; Soroye et al., 2020). The rate of climate change may induce potential mismatches in the timing of flowering and pollinator activity depending on the species (Bartomeus et al., 2011). For instance, Miller-Struttmann (2015) showed that long-tongued bumblebees may be at a disadvantage as warming temperatures are reducing their floral hosts, making generalist bumblebees more successful.

Overall, there is *medium confidence* that long-term mutualisms may be impacted directly by CO_2 increases in terms of nutrition, or by temperature and other climatic shifts that may alter floral emergence relative to pollinator life cycles. Additional research is needed to further our understanding of the biological basis for these effects, and their consequence for pollination services.

5.4.3.4 Observed and projected impacts on cultural ecosystem service

Cultural ecosystem services (CES) are those non-material benefits, such as aesthetic experiences, recreation, spiritual enrichment, social relations, cultural identity, knowledge and other values (Millennium Ecosystem Assessment, 2005), which support physical and mental health and human well-being (Chan et al., 2012; Triguero-Mas et al., 2015). CES in agricultural and wild landscapes include recreational activities, access to wild or cultivated products, and cultural foods, spiritual rituals, heritage and memory dimensions, and aesthetic experiences (Daugstad et al., 2006; Calvet-Mir et al., 2012; Ruoso et al., 2015). Relative to other ecosystem services, CES in agricultural landscapes has had less research (Merlín-Uribe et al., 2012; Milcu et al., 2013; Bernues et al., 2014; Plieninger et al., 2014; van Berkel and Verburg, 2014; Ruoso et al., 2015; Quintas-Soriano et al., 2016). Agricultural heritage is a key aspect of CES and plays an important role in maintaining agrobiodiversity (Hanaček and Rodríguez-Labajos, 2018).

Climate change is projected to have negative impacts on Cultural ecosystem services (*medium confidence*) (Table 5.4). There is limited evidence that climate change has been the main driver affecting CES of agroecosystems confounded by other drivers such as migration and changing farming patterns (Hanaček and Rodríguez-Labajos, 2018; Dhakal and Kattel, 2019). Recent studies observed declines in CES in Alpine pastures and floodplains in Europe in part due to climate change impacts (Probstl-Haider et al., 2016; Schirpke et al., 2019). Another study estimated that the scenic beauty enjoyed by those who visit the vineyards in central Chile will decline by 18-28% by 2050 due to a combination of reduced precipitation, increased temperatures, and natural fire cycles (Martinez-Harms et al., 2017). More research is needed, however, particularly on cultural heritage, spiritually significant places, and in low-income countries.

Table 5.4: Projected Impacts on CES from Climate Change.

Region	CES	Climate Change Scenario	Projected impacts from climate change	References
Central Chile, South America	Aesthetic experience of scenic beauty in vine-growing region.	RCP 2.6 and 8.5.	Increased temperature, reduced precipitation and increased fires will damage scenic beauty of vineyards. Participatory scenario analysis estimated reduction in aesthetic experience from scenic beauty by 18-28% by 2050 for RCP 2.6, with greater impacts under RCP 8.5.	Martinez-Harms et al. (2017)
Mountainous regions of Austria	Cultural and aesthetic experiences in alpine pastures and diverse agricultural landscapes	Temperature + 1.5 °C from 2008 to 2040 and 4 precipitation scenarios (High, similar, seasonal *s*hift and Low*)*.	Some decline in CES, with tradeoffs between diversity and cultural ecosystem services and provisioning services depending upon the scenario.	Kirchner et al. (2015)
Forest and agricultural landscapes in southern Saxony-Anhalt in Germany	Recreation, scenic landscape beauty and spiritual value of agricultural landscapes and forests.	Regional scenarios, do not specify RCPs.	Not anticipated to be significantly changed by climate change under most scenarios, except for intensification scenario, which would lead to a decline in the forest cultural services as they provide important historical and cultural ties.	Gorn et al. (2018)
Northeast Austria floodplains (grasslands and wetlands)	Tourism, recreation, cultural heritage.	Increased temperature by 2050 and 2100 and seasonal shifts in precipitation.	Increased agricultural intensification due to shifts in climate and decline in CES is predicted, based on farmer interviews.	Probstl-Haider et al. (2016)
Mount Kenya, Kenya	Tourism, recreation, spiritual and cultural values.	Not specified	Glacier disappearance may lead to reduced mountain trekking and other tourism and recreational activities.	Evaristus (2014)
Philippines	Nature-based tourism in agri-tourism	Not specified	Risk of typhoon, drought and strong wind, grass fire, heavy rains. Anticipated to increase vulnerability in terms of human health services and energy use in tourism.	Hidalgo (2015)

[START BOX 5.4 HERE]

Box 5.4: Soil Health

Soil health, defined as an integrative property that reflects the capacity of soil to respond to land management, continues to support provisioning ecosystem services (Kibblewhite et al., 2008). Climate change will have significant impacts on soil health indicators such as soil organic matter (SOM). For example, precipitation extremes can reduce soil biological functions, and increase surface flooding, waterlogging, soil erosion and susceptibility to salinization (Herbert et al., 2015; Chen and Mueller, 2018; Akter et al., 2019; Sánchez-Rodríguez et al., 2019).

The most significant threat to soil health is the loss of SOM (FAO and ITPS, 2015). SOM holds a great proportion of the nutrients, and regulates important soil physical, chemical, and biological processes, such as cation exchange capacity, pH-buffering, soil structure, water-holding capacity, and microbial activity (FAO and ITPS, 2015). Soils also hold the largest terrestrial organic carbon stock, 3-4 times greater than the atmosphere (Stoorvogel et al., 2017). At the global scale, climate and vegetation are the main drivers of soil carbon (SOC) storage (Wiesmeier et al., 2019). While organic matter input is the primary driver of SOC stocks (Fujisaki et al., 2018), temperature and soil moisture play a key role in SOC storage at the local scale (Carvalhais et al., 2014; Doetterl et al., 2015). Soil type, land-use and management practices also play important roles at the local scale.

Increase in soil temperature will negatively impact SOC, but primarily in higher latitudes (*medium confidence*) (Carey et al., 2016; Qi et al., 2016; Feng et al., 2017; Gregorich et al., 2017; Hicks Pries et al., 2017; Melillo et al., 2017; Hicks Pries et al., 2018). Experiments have shown that warming can accelerate litter mass loss and soil respiration (Lu et al., 2013) and reduces the soil recalcitrant C pool (Chen et al., 2020). SOC losses may speed up soil structural degradation, changes in soil stoichiometry and function (Hakkenberg et al., 2008; Tamene et al., 2019), with downstream effects on aquatic ecosystems. The rate and extent of SOC losses vary greatly depending on the scale of measurement (local to global), soil properties, climate, land-use, and management practices (Sanderman et al., 2017; Wiesmeier et al., 2019).

Adoption of practices that build SOC can improve crop resilience to climate change-related stresses such as agricultural drought. Iizumi and Wagai (2019) found that a relatively small increase in topsoil (0–30 cm) SOC could reduce drought damages to crops over 70% of the global harvested area. The effects of increasing SOC are more positive in drylands due to more efficient use of rainwater, which can increase drought tolerance (Iizumi and Wagai, 2019). Similarly, Sun et al. (2020) found that relative to local conventional tillage, conservation agriculture has a win-win outcome of enhanced C sequestration and increased crop yield in arid regions. However, the impact of no-till may be minimal if not supplemented with residue cover and cover crops. As such this is a highly debated area where some authors argue that no-till has limited effect and the evidence outside drylands is weak. Furthermore, the use of crop residues is constrained by its alternative uses (e.g., fuel, livestock feed, etc.) in much of the developing world. Practices that build up SOC may encourage soil microbial populations, which in turn can increase yield stability under drought conditions (Prudent et al., 2020).

Soil C sequestration is an important strategy to improve crop and livestock production sustainably that could be applied at large scales and at a low cost, if there was adequate institutional support and labour, using agroforestry, conservation agriculture, mixed cropping, and targeted application of fertiliser and compost (*high confidence*) (Paustian et al., 2016; Kongsager, 2018; Nath et al., 2018; Woolf et al., 2018; Corbeels et al., 2019; Kuyah et al., 2019; Corbeels et al., 2020; Muchane et al., 2020; Sun et al., 2020; Nath et al., 2021). For example, a widespread adoption of agroforestry, conservation agriculture, mixed cropping, and balanced application of fertiliser and compost by India's small landholders could increase annual C sequestration by 70–130 Tg CO_2e (Nath et al., 2018; Nath et al., 2021).

[END BOX 5.4 HERE]

5.4.4 Adaptation Options

Adaptation strategies in crop production range from field and farm-level technical options such as crop management and cultivar/crop options to livelihood diversification and income protection such as index-based insurance. This section assesses crop management options for different crop types. Feasibility of adaptation options in various systems are addressed in Section 5.14.

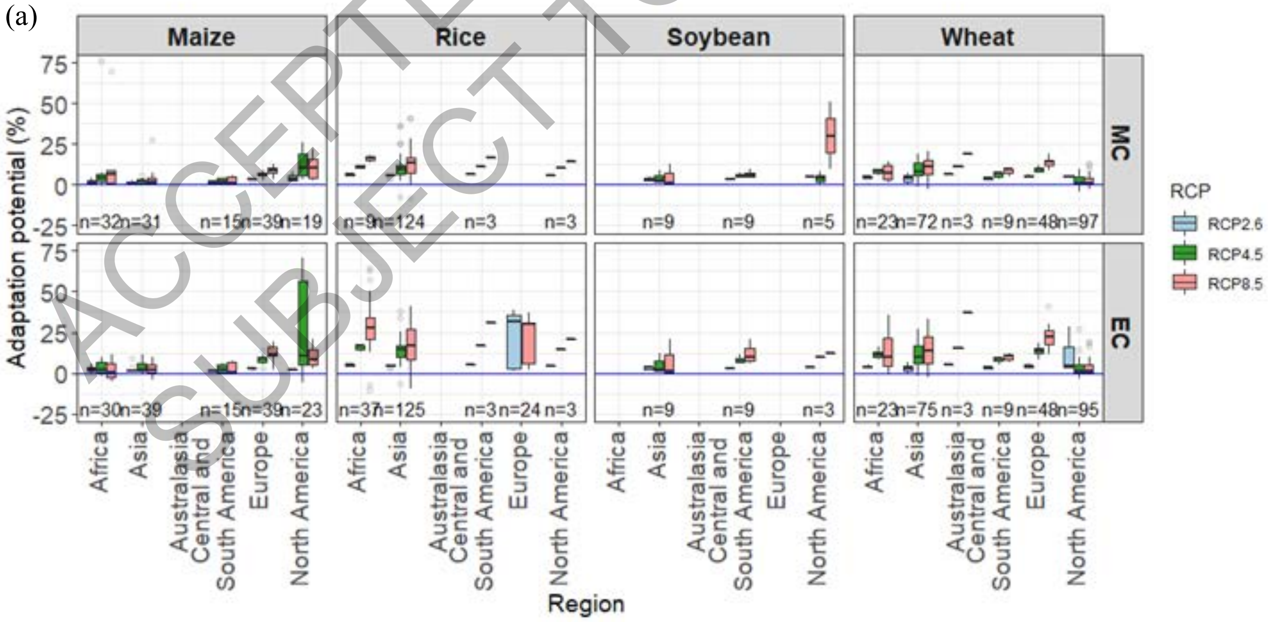
5.4.4.1 Adaptation options for major crops

Crop management practices are the most commonly studied adaptation measures (Shaffril et al., 2018; Hansen et al., 2019a; Muchuru and Nhamo, 2019), but quantitative assessments are mostly limited to existing agronomic options such as changes in planting schedules, cultivars, and irrigation (Beveridge et al., 2018a; Aggarwal et al., 2019). This section draws on the global dataset used in Sections 5.4.3.2 (Hasegawa et al., 2021b) to estimate adaptation potential, defined as the difference in simulated yields with and without adaptations. A caveat to the analysis is that the dataset includes management options if the literature treats them as adaptation. They include intensification measures such as fertilizer and water management, not allowing for physical and economic feasibility.

The overall adaptation potential of existing farm management practices to reduce yield losses averaged 8% in mid-century and 11% in end-century (Figure 5.9), which is insufficient to offset the negative impacts from climate change, particularly in currently warmer regions (Section 5.4.3.2). Emission scenarios, crop species, regions, or adaptation options do not show discernible differences. Combinations of two or more options do not necessarily have greater adaptation potential than a single option, though a fair comparison is difficult in the dataset from independent studies. One regional study in West Africa found that currently promising management would no longer be effective under future climate, suggesting the need to evaluate effectiveness under projected climate change.

A global-scale meta-analysis estimated a 3-7% yield loss per degree increase in temperature (Zhao et al., 2017). Two global-scale studies using multiple global gridded crop models found that growing-season adaptation through cultivar changes offsets global production losses up to 2°C of temperature increase (Minoli et al., 2019; Zabel et al., 2021). While these studies do not account for CO_2 fertilisation effects, another global-scale study with the CO_2 fertilisation effects (Iizumi et al., 2020) showed that residual damage (climate change impacts after adaptation) would start to increase almost exponentially from 2040 toward the end of the century under RCP 8.5. The cost required for adaptation and due to residual damage is projected to rise from US$63 billion at 1.5°C to US$80 billion at 2°C and to US$128 billion at 3°C (Iizumi et al., 2020). All these global studies project that risks and damages are greater in tropical and arid regions, where crops are exposed to heat and drought stresses more often than in temperate regions (Sun et al., 2019; Kummu et al., 2021; SM5.4). There are still large uncertainties in the crop model projections (Müller et al., 2021a), but these (Iizumi et al., 2020) multiple lines of evidence suggest that warming beyond +2 °C (projected to be reached by mid-century under high emission scenarios) will substantially increase the cost of adaptation and the residual damage to major crops (*high confidence*). The residual damage will prevail much sooner in currently warmer regions, where the effect of even a modest temperature increase is greater (Section 5.4.3.2).

(a)



(b)

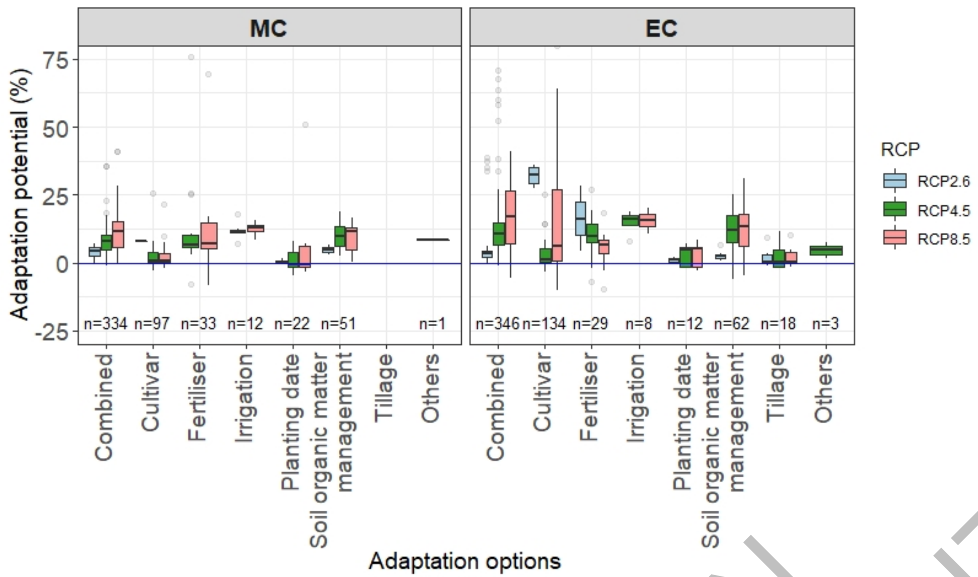


Figure 5.9: Adaptation potential, defined as the difference between yield impacts with and without adaptation in projected impacts (Hasegawa et al., 2021b). (a) projections under three RCP scenarios by regions and (b) by options at mid-century (MC, 2040-2069) and end-century (EC, 2070-2100). n is the number of simulations. See Figure 5.6 for legends.

Most crop modelling studies on adaptation are still limited to a handful of options for each crop type (Beveridge et al., 2018a). A range of other options are possible not just to reduce yield losses but to diversify risks to livelihoods, which are partially assessed in Sections 5.4.4.4 and 5.14.1. Current modelling approaches are not suited for the assessment of multiple dimensions of adaptation options. New studies are emerging that evaluate multiple options for productivity, sustainability, and greenhouse gas emission (Xin and Tao, 2019; Smith et al., 2020b), but local- and household-scale assessment, taking account of future climatic variability, needs to be enhanced (Beveridge et al., 2018a).

5.4.4.2 Adaptation options for other crops

Across this diverse group of cropping systems distinct adaptation options and adaptation limits have emerged (Figure 5. 10; Acevedo et al., 2020; Berrang-Ford et al., 2021b). Some crop types have already seen widescale implementation of climate adaptation (e.g., grapevines), while others show little evidence of preparation for climate change (e.g., leafy salad crops). Many adaptation responses are shared with the major crops, but prominent options such as plant breeding are under-utilized and there is a lack of evidence for assessing adaptation for many crops (Bisbis et al., 2018; Gunathilaka et al., 2018; Manners and van Etten, 2018). Figure 5.11 assesses several adaptation options based on the perceived importance of each in the literature. Fruit and vegetable crops tend to be more reliant on ecosystem services in the form of pollination, biocontrol, and other resources (water, nutrients, microbes, etc.), and ecosystem-based adaptation options are prominent. The range of crops means that there is great potential for crop switching, but cultural and economic barriers will make such options difficult to implement, with barriers to entry for production and marketing (Waha et al., 2013; Magrini et al., 2016; Kongsager, 2017; Rhiney et al., 2018). Perennial crops are exposed to a wide range of climate factors throughout the year and have significant barriers to implementing some of the common adaptation options, such as relocation or replacing tree species/cultivar, agronomic interventions on-farm are well used in high value tree crops and provide some climate resilience, but longer-term options will be needed (Glenn et al., 2013; Mosedale et al., 2016; Gunathilaka et al., 2018; Sugiura, 2019).

Many fruit and vegetable crops are water demanding, and adaptation responses relating to water management and access to irrigation water are crucial. Rainwater storage and deficit irrigation techniques are frequently mentioned as adaptation options and can minimise the burden on off-farm water supplies (Bisbis et al., 2018; Acevedo et al., 2020).

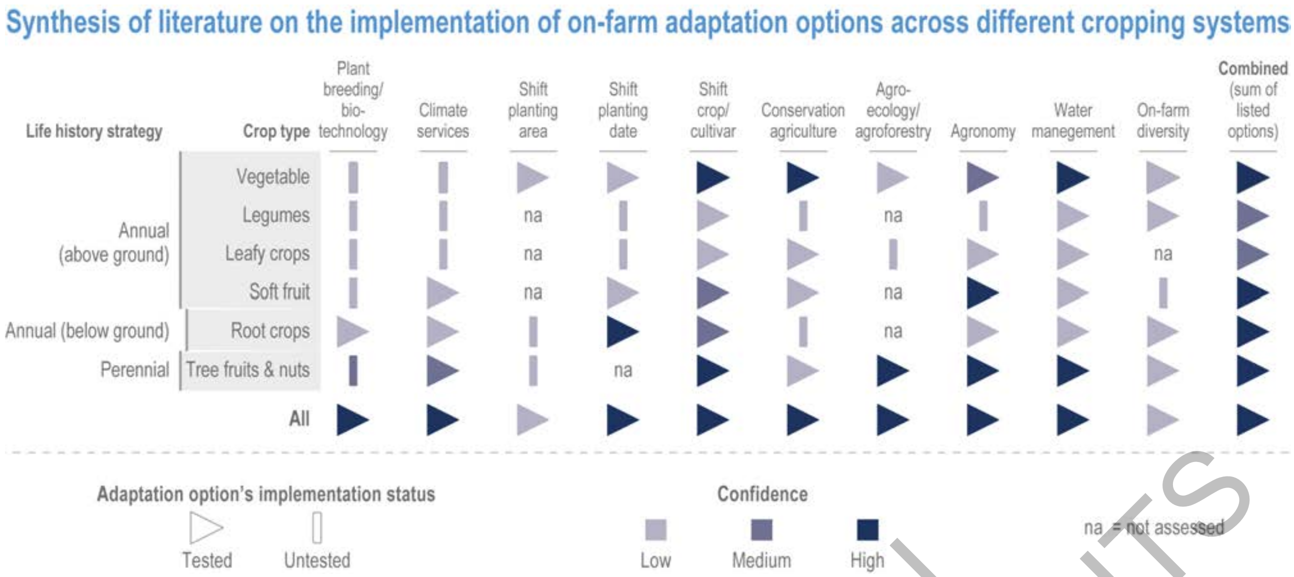

Figure 5.10: Synthesis of literature on the implementation of on-farm adaptation options across different cropping systems. Adaptation options that have been implemented by growers are considered 'tested', while those that have not are considered 'untested'. Untested options are those that appear in studies as suggestions by stakeholder or experts, but were not implemented within the study. The assessment draws on >200 articles published since AR5. The confidence is based on the evidence given in individual articles and on the number of articles. See SM5.2 for details.

5.4.4.3 Cultivar improvements

As stated in AR5, cultivar improvements are one effective countermeasure against climate change (Porter et al., 2014; Challinor et al., 2016; Atlin et al., 2017). Plant breeding biotechnology for climate change adaptation draws upon modern biotechnology and conventional breeding, with the latter often assisted by genomics and molecular markers. Plant breeding biotechnology will contribute to adaptation for large scale producers (*high confidence*). However, in addition to inconsistencies in meeting farmer expectations, a variety of socio-economic and political variables strongly influence, and limit, uptake of climate-resilient crops (Acevedo et al., 2020; Rhoné et al., 2020).

Genome sequencing significantly increases the rate and accuracy for identifying genes of agronomic traits that are relevant to climate change, including adaptation to stress from pests and disease, temperature, and water extremes (*high confidence*) (Brozynska et al., 2016; Scheben et al., 2016; Voss-Fels and Snowdon, 2016). Access to this information where it is needed and in practical timeframes, as well as the expertise to use it will limit the sharing of benefits by the most vulnerable groups and countries (*high agreement, limited evidence*) (Heinemann et al., 2018).

Genetic improvements for climate change adaptation using modern biotechnology have not reliably translated into the field (Hu and Xiong, 2014; Nuccio et al., 2018; Napier et al., 2019), but good progress has been made by conventional breeding. Desirable traits that adapt plants to environmental stress are inherited as a complex of genes each of which makes a small contribution to the trait (Negin and Moshelion, 2017). Adaptation by conventional breeding requires making rapid incremental changes in the best germplasm to keep pace with the environment (Millet et al., 2016; Atlin et al., 2017; Cobb et al., 2019). Further improvements would be difficult without in situ and ex situ conservation of plant genetic resources to maintain critical germplasm for breeding (Dempewolf et al., 2014; Castañeda-Álvarez et al., 2016).

Despite the advances in sequencing, phenotyping remains a significant bottleneck (Ghanem et al., 2015; Negin and Moshelion, 2017; Araus and Kefauver, 2018), the emergence of high-throughput phenotyping platforms may reduce this bottle neck in future. Emerging modern biotechnology such as gene/genome editing may in the future increase the ability to better translate genetic improvements into the field *(medium agreement, limited evidence)* (Puchta, 2017; Yamamoto et al., 2018; Friedrichs et al., 2019; Kawall, 2019; Zhang et al., 2019).

Other breeding approaches assisted by genomics have been making steady gains in introducing traits that adapt crops to climate change (*high confidence*). DNA sequence information is used to identify markers of desirable traits that can be enriched in breeding programs, as well as to quantify the genetic variability in species (Gepts, 2014; Brozynska et al., 2016; Voss-Fels and Snowdon, 2016). However, breeding for smallholder farmers and the stresses caused by climate change is unlikely to be addressed by the private sector and will require more public investment and adjusting to the local social-ecological system (Glover, 2014; Heinemann et al., 2014; Acevedo et al., 2020). Modern biotechnology has not demonstrated the scale neutrality needed to serve smallholder dominated agroecosystems, due to a combination of the kinds of traits and restrictions that come from the predominant intellectual property rights instruments used in their commercialization, as well as the focus on a small number of major crop species (*medium confidence)* (Fischer, 2016; Montenegro de Wit et al., 2020).

Globally, there is a notable lack of programs aimed specifically at breeding for climate resilience in fruits and vegetables, although there have been calls to begin this process (Kole et al., 2015). Breeding for climate resilience in vegetables has great potential given the range of crop species available. Tolerance to abiotic stress is reasonably advanced in pulses (Araújo et al., 2015; Varshney et al., 2018), but examples of translation to commercial cultivars are still limited (Varshney et al., 2018; Varshney et al., 2019). The infrastructure for germplasm collection, maintenance, testing, and breeding lags behind that of major crops (partly because of the large number of species involved) (Keatinge et al., 2016; Atlin et al., 2017).

Participatory plant breeding (PPB) facilitates interaction between Indigenous and local knowledge systems and scientific research and can be an effective adaptation strategy in generating varieties well adapted to the socio-ecological context and climate hazards (*high confidence*) (Table 5.5, Westengen and Brysting, 2014; Humphries et al., 2015; Anderson et al., 2016; Migliorini et al., 2016; Leitão et al., 2019; Ceccarelli and Grando, 2020; Singh et al., 2020).

Table 5.5: Participatory plant breeding as cultivar improvement adaptation method.

Region	Crop(s) used for breeding	Results
West Africa	Sorghum and pearl millet	• Released sorghum and millet varieties which were selected for climate variability (e.g., drought), low soil fertility, pest and disease resistance, gendered preferences for processing, and nutrition (Camacho-Henriquez et al., 2015; Weltzien et al., 2019). – • Farmers who adopted these varieties increased yield, income and food security, alongside increased technical knowledge of plant breeding, and increased breeders' understanding of local farmers' varietal requirements (Trouche et al., 2016). • Joint learning with scientists led to increased genetic gain both in terms of operational scale and focused breeding for diverse farmer priorities (Weltzien et al., 2019).
South America (Andes)	Potato	• PPB with Indigenous Quechua and Aymara farmers resulted in potato varieties with traits from wild relatives, with yield stability, higher yields under low input use and disease resistance under climate change impacts such as increased hail or frost events and upward expansion of pests and diseases (Camacho-Henriquez et al., 2015; Scurrah et al., 2019).
Asia (southwest China)	Maize	• PPB done primarily with women farmers, led to 1500 landraces safeguarded, 12 farmer-preferred varieties released and 30 landraces released, bred for improved yield (15-20% increases), drought resistance, taste, market potential and other priority traits (Song et al., 2019). • Studies suggest PPB improved farmer knowledge, income, and access to resilient seeds, and strengthened institutions

		such as women-led farmer cooperatives and a Farmer Seed Network of China (Song et al., 2019).

5.4.4.4 *Integrated approach to enhance agroecosystem resilience*

Diversifying agricultural systems is an adaptation strategy that can strengthen resilience to climate change, with socio-economic and environmental co-benefits, but tradeoffs and benefits vary by socio-ecological context (*high confidence*) (Table 5.6, M'Kaibi et al., 2015; Bellon et al., 2016; Jones, 2017b; Schulte et al., 2017; Jarecki et al., 2018; Jones et al., 2018; Luna-Gonzalez and Sorensen, 2018; Sibhatu and Qaim, 2018; Renard and Tilman, 2019; Rosa-Schleich et al., 2019; Bozzola and Smale, 2020; Mulwa and Visser, 2020). Crop diversification alongside livestock, fish and other species can be applied at various scales in a range of systems, from rainfed or irrigated to urban and home gardens in multiple spatial and temporal arrangements such as mixed planting, intercrops, crop rotation, diversified management of field margins, agroforestry (Section 5.10.1.3) and integrated crop livestock systems (Section 5.10.1.1, Isbell et al., 2017; Kremen and Merenlender, 2018; Dainese et al., 2019; Rosa-Schleich et al., 2019; Hussain et al., 2020; Renwick et al., 2020; Tamburini et al., 2020; Snapp et al., 2021; see Section 5.14 and Cross-Chapter Box NATURAL in Chapter 2).

Diversification improves regulating and supporting ecosystem services such as pest control, soil fertility and health, pollination, nutrient cycling, water regulation and buffering of temperature extremes (*high confidence*) (Barral et al., 2015; Prieto et al., 2015; Tiemann et al., 2015; Schulte et al., 2017; Beillouin et al., 2019a; Dainese et al., 2019; Kuyah et al., 2019; Tamburini et al., 2020), which can in turn mediate yield stability and reduced risk of crop loss according to socio-ecological contexts and time since adoption (*high confidence*) (Prieto et al., 2015; Roesch-McNally et al., 2018; Sida et al., 2018; Williams et al., 2018; Birthal and Hazrana, 2019; Degani et al., 2019; Amadu et al., 2020; Bowles et al., 2020; Li et al., 2020; Sanford et al., 2021).

Agroecosystem diversification often has variable impacts depending on crop combination, agro-ecological zone and soil types and rigorous assessments of adaptive gains with traditional and locally diversified systems and potential trade-offs still need to be conducted across socioecological contexts. The quantitative upstanding will assist in enhancing multiple benefits of diversification tailored for each condition (Table 5.6). Progress is also needed via breeding and/or agronomy to adapt underutilized as well as major food crops to diversified agroecosystems and optimize management of nutrients, pest and disease pressure and other socio-ecological constraints (Araújo et al., 2015; Foyer et al., 2016; Adams et al., 2018; Pang et al., 2018).

Managing for diversity and flexibility at multiple scales is central to developing adaptive capacity. Policies to support diversification include shifting subsidies towards diversified systems, public procurement for diverse foods for schools and other public institutions, investment in shorter value chains, lower insurance premiums and payments for ecosystem services that include diversification (Sorensen et al., 2015; Guerra et al., 2017; Nehring et al., 2017; Valencia et al., 2019). Integrated landscape approaches involving multiple stakeholders (Reed et al., 2016) including urban governments can support diversification at a regional scale through public and private sector investment in extension services, regional supply chains, agritourism and other incentives for diversified landscapes (Milder et al., 2014; Münke et al., 2015; Sorensen et al., 2015; Pérez-Marin et al., 2017; Caron et al., 2018; 5.14.1.5).

Table 5.6: Agroecosystem diversification practices, climate change adaptation mechanisms, tradeoffs, co-benefits and constraints to implementation.

Agroecosystem diversification practice and Mechanism for climate change adaptation	Benefits, tradeoffs and constraints to implementation with examples.
Crop diversification - Diversifying revenue streams and food supply (portfolio effect). - Can impact multiple plant and soil biological and physicochemical properties	• Crop diversification reduces cereal crop sensitivity to **precipitation variability**, yield losses and crop insurance payouts under **drought** (*high confidence*) (McDaniel et al., 2014; Williams et al., 2016; Iizumi and Wagai, 2019; Renwick et al., 2020; Huang et al., 2021; Kane et al., 2021)

associated with building soil organic matter, improving soil structure and water conservation	• For example, a study in Canada comparing diversified rotations to monoculture corn found significant positive yield impacts, yield stability and increased soil organic carbon under both RCP4.5 and RCP8.5 by 2100 (Jarecki et al., 2018). • Diverse agroecosystems with a range of native, neglected and introduced species, often maintained through Indigenous knowledge and farmer seed systems, offer adaptation opportunities in some regions (*medium evidence, high agreement*) (Bezner Kerr, 2014; Westengen and Brysting, 2014; Camacho-Henriquez et al., 2015; Ghosh-Jerath et al., 2015; Adhikari et al., 2017; Li and Siddique, 2018; Scurrah et al., 2019). • Diversified landscapes can also enhance cultural ecosystem services, by supporting cultural heritage crops, recreational and aesthetic experiences (*medium confidence*) (Novikova et al., 2017; Martínez-Paz et al., 2019; Alcon et al., 2020). • Diversified cropping systems often require new knowledge, equipment access to inputs and viable markets for new products (van Zonneveld et al., 2020). Barriers to diversification, or those which support agroecosystem simplification include environmental constraints such as elevation or soil type, along with institutional constraints such as low research investment, limited policy support, subsidies that encourage monocrops, poor market access, market instability and limited access to seeds (Kaushal and Muchomba, 2015; DeLonge et al., 2016; Burchfield and de la Poterie, 2018).
Legume diversification can be effective for both mitigation and adaptation, by reducing **use of nitrogen derived from fossil fuels**, and meat consumption, and providing ecosystem services through **nutrient cycling, increasing soil biological activity and erosion control** (Snapp et al., 2019).	• Can increase food security and nutrition by increasing cereal productivity and stability in intercropped systems, diversify diets, and increase income in crop sales (*high agreement, medium evidence*) (Snapp et al., 2019; Steward et al., 2019; Renwick et al., 2020), but legume production may be constrained by pest, disease, limited access to genetic material, market access and food preferences (Anders et al., 2020).
Organic amendments, no/low tillage or crop residue retention may increase diversity in soil biological organisms, which might be important in building resilience to multiple stresses such as **drought and pest pressure** (Furze et al., 2017; Blundell et al., 2020; de Vries et al., 2020; Stefan et al., 2021; Yang et al., 2021).	• Higher organic matter does not consistently improve soil hydraulic properties (Minasny and McBratney, 2018; Basche and DeLonge, 2019), • Can decrease **yield variability under dry conditions** and increase rainfed annual crop yield productivity (*high agreement*) (Pittelkow et al., 2014; Williams et al., 2016; Williams et al., 2018; Degani et al., 2019; Steward et al., 2019; Bowles et al., 2020; Marini et al., 2020; Sanford et al., 2021).
Livestock integration. Inclusion of legumes and other forage into crop rotation allows mixed crop and livestock operations to **mitigate farm-level risk and ecosystem buffering**	• Benefits to productivity and stability of annual crop yields in some contexts (see Section 5.10.3, *strong agreement, medium evidence*) (Stark et al., 2018; Peterson et al., 2020; de Albuquerque Nunes et al., 2021).
Traditional and locally adapted **mixed cropping and agroforestry practices** which include leguminous trees can improve soil fertility and microclimate (Sida et al., 2018; Amadu et al., 2020).	Benefits: Resilience to extreme events such as hurricanes can be promoted by supporting ecosystem functions to mitigate impacts and accelerate recovery (*high agreement, medium evidence*) (Altieri et al., 2015; Simelton et al., 2015; Sida et al., 2018; Perfecto et al., 2019).

	• Can increase food security, livelihoods, and productivity, but local context and resource availability must be considered to optimize species arrangement and benefits and can have considerable implementation barriers and costs (*high confidence*) (see Sections 5.10.3, 5.14 and Cross-Chapter Box NATURAL in Chapter 2). (Altieri et al., 2015; Simelton et al., 2015; Sida et al., 2018; Perfecto et al., 2019).

5.5 Livestock-based Systems

Livestock systems may be classified as industrial (monogastric, ruminant), grassland-based in which crop-based agriculture is absent or minimal (pastoralism, agro-pastoralism), mixed rainfed combining mostly rainfed cropping with livestock, and mixed irrigated systems with a significant proportion of irrigated cropping interspersed with livestock. Livestock systems are located widely across all regions of the world, and animal-sourced food provides humans with 39% of their protein and 18% of their calorie intake (FAO, 2019f). Some 400 million people depend on livestock for a substantial part of their livelihood (Robinson et al., 2011).

5.5.1 Observed Impacts

Climate change affects livestock productivity and production in many ways (Porter et al., 2014; Rojas-Downing et al., 2017). Evidence is accumulating that rising temperatures are increasing heat stress in domestic species and affecting productivity (*high confidence*) (Das et al., 2016b; Godde et al., 2021).

5.5.1.1 Pastoral systems

Many grassland-based livestock systems are vulnerable to climate change and increases in climate variability (*high confidence*) (Dasgupta et al., 2014; Sloat et al., 2018; Stanimirova et al., 2019). Decadal vegetation changes from warming and drying trends have been detected in North American grasslands, with implications for species composition, rangeland quality and economic viability of grazing livestock (Rondeau et al., 2018; Reeves et al., 2020). Feed quality in South Asian grasslands has been negatively affected, reducing food security (Rasul et al., 2019). Increased grassland degradation has been observed in parts of Inner Mongolia (Nandintsetseg et al., 2021). Changing seasonality, increasing frequency of drought and rising temperatures are affecting pastoral systems globally (*high confidence*). These and other drivers are reducing herd mobility, decreasing productivity, increasing incidence of vector borne diseases and parasites, and reducing access to water and feed (*high agreement, medium evidence*) (López-i-Gelats et al., 2016; Vidal-González and Nahhass, 2018; de Leeuw et al., 2020).

5.5.1.2 Livestock distribution and climate variability

There is *limited evidence* of observed distributional changes in livestock species because of climate changes. Asian buffalo and yak breeds in China over the past 50 years have shifted distribution due partly to increases in heat stress (Wu, 2015; Wu, 2016). Nepalese cattle numbers have declined, attributed to increases in the number of hot days (Koirala and Shrestha, 2017).

Climate variability has been identified as the primary cause of vegetation cover changes in Tibet since 2000 (Lehnert et al., 2016). Increasing inter-annual variability is a driver of farm extensification in Mediterranean dairy systems (Dono et al., 2016). In Australian rangelands (Godde et al., 2019) and dairy systems (Harrison et al., 2016; Harrison et al., 2017), increasing rainfall variability contributes more to stocking rate and profitability variability than changes in mean rainfall.

5.5.1.3 Diseases and disease vectors

Climate change is affecting the transmission of vector-borne diseases (Hutter et al., 2018; Semenza and Suk, 2018) and parasites (Rinaldi et al., 2015) in high latitudes (*high confidence*). Different processes link climate change and infectious diseases in domesticated livestock: some show a positive association between temperature and range expansion of arthropod vectors that spread the bluetongue virus. Others show a contraction, such as tsetse flies that transmit trypanosome parasites of several livestock species. Positive associations have been found between temperature and the spread of pathogens such as anthrax, and droughts and El Niño-Southern Oscillation (ENSO) weather patterns and Rift Valley fever outbreaks in East Africa (Bett et al., 2017). Observed range expansion of economically important tick disease vectors in North America (Sonenshine, 2018) and Africa (Nyangiwe et al., 2018) are presenting new public health threats to humans and livestock.

5.5.2 Assessing Vulnerabilities

5.5.2.1 Rising temperature and heat stress

Most domestic livestock have comfort zones in the range 10-30°C, depending on species and breed (Nardone et al., 2006). At higher temperatures, animals eat 3–5% less per additional degree of temperature, reducing their productivity and fertility. Heat stress suppresses the immune and endocrine system, enhancing susceptibility of the animal to disease (Das et al., 2016b). Recent stagnation in dairy production in West Africa and China may be associated with increased periods of high daily temperatures (*low confidence*) (Rahimi et al., 2020; Ranjitkar et al., 2020). Increases in the productive capacity of domestic animals can compromise thermal acclimation and plasticity creating further loss. Escalating demand for livestock products in LMICs may necessitate considerable adaptation in the face of new thermal environments (*medium confidence*) (Collier and Gebremedhin, 2015; Theusme et al., 2021). Heat effects on productivity have been summarised for pigs (da Fonseca de Oliveira et al., 2019), sheep and goats (Sejian et al., 2018), and cattle (Herbut et al., 2019). The direct effects of higher temperatures on the smaller ruminants (sheep and goats) are relatively muted, compared with large ruminants; goats are better able to cope with multiple stressors than sheep (Sejian et al., 2018). Under SSP5-8.5 to mid-century, land suitability for livestock production will decrease because of increased heat stress prevalence in mid and lower latitudes (*high confidence*) (Thornton et al., 2021).

5.5.2.2 Livestock water needs

Livestock production may account for 30 percent of all water (blue, green and grey) used in agriculture (Mekonnen and Hoekstra, 2010) and can negatively affect water quality. Cropland feed production accounts for 38% of crop water consumption (Weindl et al., 2017). High-input livestock systems may consume more water than grazing or mixed systems, though water used per kg beef produced, for example, depends on country, context, and system (Noya et al., 2019). In systems where feed production is rainfed, livestock and crop water productivity may be comparable (Haileslassie et al., 2009). Direct water consumption by livestock is <1-2% of global water consumption (Hejazi et al., 2014). Rising temperatures increase animal water needs, potentially affecting access of herders and livestock to drinking water sources (Flörke et al., 2018).

5.5.2.3 Rising temperatures and livestock disease

Climate change will have effects on future distribution, incidence, and severity of climate-sensitive infectious diseases of livestock (*high confidence*) (Bett et al., 2017). In an assessment of climate sensitivity of European human and domestic animal infectious pathogens, 63% were sensitive to rainfall and temperature, and zoonotic pathogens were more climate-sensitive than human- or animal-only pathogens (McIntyre et al., 2017). Over the last 75 years, >220 emerging zoonotic diseases, some associated with domesticated livestock, have been identified, several of which may be affected by climate change, particularly vector-borne diseases (Vaillancourt and Ogden, 2016; see Cross-Chapter Box ILLNESS in Chapter 2). Walsh et al. (2018) identified both temperature and rainfall as influential factors in predicting increasing anthrax outbreaks in northern latitudes. Growing infectious disease burdens in domesticated animals may have wide-ranging impacts on the vulnerability of rural livestock producers in the future, particularly related to human health and projected increases in zoonoses (*high confidence*) (Bett et al., 2017; Heffernan, 2018; Rushton et al., 2018; Meade et al., 2019).

5.5.2.4 Livestock and socio-economic vulnerability to climate change

There is *limited evidence* about the role of livestock in addressing socio-economic vulnerability. Although agriculture in parts of North America has become more sensitive to climate over the last 50 years, livestock have helped to moderate this effect, being less sensitive to increasing temperatures than some specialised crop systems (Ortiz-Bobea et al., 2018). Increasing frequency and severity of droughts will affect the future economic viability of grassland-based livestock production in the North American Great Plains (Briske et al., 2021). Purchasing more forage and selling more livestock have reduced household vulnerability in semi-arid parts of China over the last 35 years (Bai et al., 2019). A greater focus on sheep production away from cropping has increased the resilience of farming systems in Western Australia in low-rainfall years, although with mixed environmental effects (Ghahramani and Bowran, 2018). More insights are needed as to where and how livestock can affect the vulnerability of farmers and pastoralists.

5.5.2.5 Effects of climate on the health and vulnerability of livestock keepers

Vulnerability to the health impacts of climate change will be shaped by existing burdens of ill-health and is expected to be highest in poor and socio-economically marginalized populations (*high agreement, limited evidence*) (Labbé et al., 2016). As well as projected changes in infectious disease burdens, labour capacity in a warming climate is anticipated to decrease further, beyond the >5% drop estimated since 2000 (Watts et al., 2018). Loss of labour capacity may greatly increase the vulnerability of subsistence livestock keepers (*high agreement, limited evidence*).

5.5.2.6 Gender and other social inequalities

Vulnerability to climate change depends on demography and social roles (Mbow et al., 2019). Gender inequalities can act as a risk multiplier, with women being more vulnerable than men to climate change-induced food insecurity and related risks (*high confidence*) (Cross-Chapter Box GENDER in Chapter 18). Women and men often have differential and unequal control over different productive assets and the benefits they provide, such as income from livestock (Ngigi et al., 2017; Musinguzi et al., 2018). Indigenous livestock keepers can be more vulnerable to climate change, partly due to on-going processes of land fragmentation (Hobbs et al., 2008), historical land dispossession, discrimination, and colonialization, creating greater levels of poverty and marginalization (Stephen, 2018). Adaptation actions may also be affected by gender and other social inequalities (Balehey et al., 2018; Dressler et al., 2019). Men and women heads of household may access institutional support for adaptation in different ways (Assan et al., 2018). Further research is warranted to evaluate alternative gendered and equity-based approaches that can address differences in adaptive capacity within communities.

5.5.3 Projected Impacts

There is *limited evidence* on future impact of climate change on livestock production, particularly in LMICs (Rivera-Ferre et al., 2016).

5.5.3.1 Impacts on rangelands, feeds, and forages

Uncertainties persist regarding estimates of net primary productivity (NPP) in grazing lands (Fetzel et al., 2017; Chen et al., 2018b), so estimation of climate change impacts on grasslands is challenging. Mean global annual NPP is projected to decline 10 gC m^{-2} yr^{-1} in 2050 under RCP8.5, although herbaceous NPP is projected to increase slightly (Boone et al., 2018; see Figure 5.11). Similar estimates were made by (Havlik et al., 2014): large increases in projected NPP in higher northern latitudes (21% increase in the US and Canada) and large declines in western Africa (-46% in western Africa) and Australia (-17%). The cumulative effects of impacts on forage productivity globally are projected to result in 7-10% declines in livestock numbers by 2050 for warming of ~2°C, representing a loss of livestock assets ranging from USD 10 to 13 billion (Boone et al., 2018). Changes to African grassland productivity will have substantial, negative impacts on the livelihoods of >180 million people.

Increases in above-ground NPP, and woody cover at the expense of grassland, are projected in some of the tropical and subtropical drylands (Doherty et al., 2010; Ravi et al., 2010; Saki et al., 2018), in Mediterranean wood-pastures (Rolo and Moreno, 2019), and in the northern Great Plains of North America (Klemm et al., 2020). Godde et al. (2021) projected that woody encroachment would occur on 51% of global rangeland area by 2050 under RCP8.5. The future makeup of grasslands under climate change is uncertain, given the variation in responses of the component species; though this variation may provide a climate buffer (Jones, 2019) (*low confidence*). C4 grass species are regarded as less responsive to elevated carbon dioxide than C3 species, though this is not always the case (Reich et al., 2018).

There are other interactions between climate change and grazing effects on grasslands. Li (2018a) reported strong negative responses of NPP and species richness to 4°C warming, a 50% precipitation decrease, and high grazing intensity. Changes in grassland composition will inevitably change their suitability for different grazing animal species, with switches from herbaceous grazers such as cattle to goats and camels to take advantage of increases in shrubland (Kagunyu and Wanjohi, 2014). Rangeland feed quality may also be reduced via invasive species of lower quality than native species (Blumenthal et al., 2016).

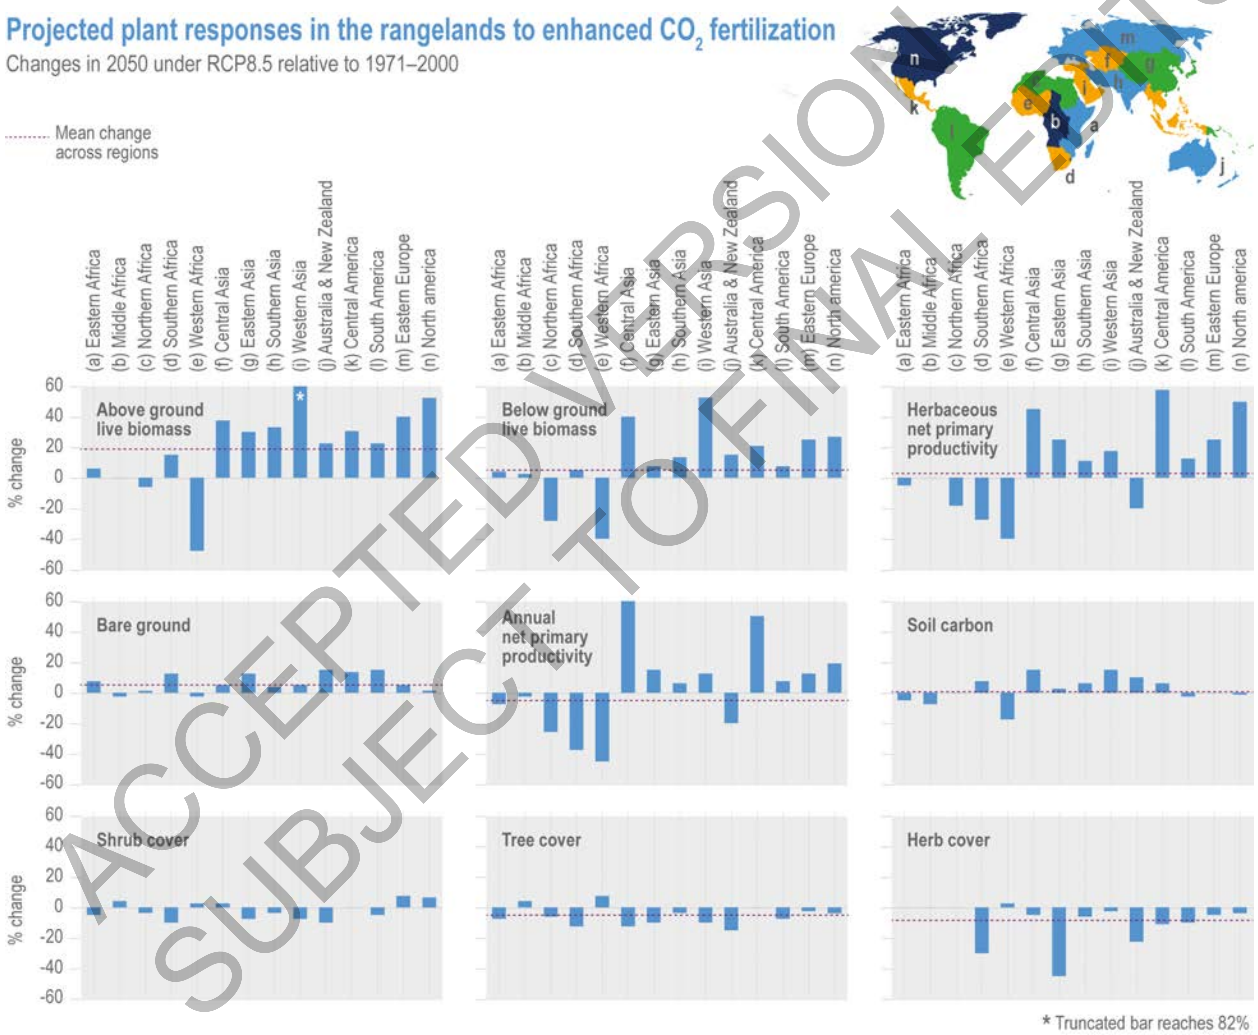

Figure 5.11: Regional percent changes in land cover and soil carbon from ensemble simulation results in 2050 under emissions scenario RCP8.5 compared with 1971-2000. Plant responses were enhanced by CO2 fertilization. The larger chart (lower left) shows mean changes for all rangelands, and all charts are scaled to -60 to +60 percent change. Shown are annual net primary productivity (ANPP), herbaceous net primary productivity (HNPP), bare ground, herbaceous (herb), shrub, and tree cover, soil organic carbon (soil carbon), aboveground live biomass (A. L. biomass), and belowground live biomass (B. L. biomass). Regions as defined by the United Nations Statistics Division. The bar for aboveground live biomass in Western Asia (*) is truncated and was 82%. (Boone et al., 2018).

Warming and water deficits impair the quality and digestibility of a C4 tropical forage grass, *Panicum maximum,* because of increases in leaf lignin (Habermann et al., 2019). A metanalysis Dellar (2018) of climate change impacts on European pasture yield and quality found an increase in above-ground dry weight under increased CO_2 concentrations for forbs, legumes, graminoids and shrubs with reductions in N concentrations in all plant functional groups. Temperature increases will increase yields in Alpine and northern areas (+82.6%) but reduce N concentrations for shrubs (−13.6%) and forbs (−18.5%).

Increased temperatures and CO_2 concentrations may increase herbaceous growth and favour legumes over grasses in mixed pastures (He et al., 2019). These effects may be modified by changes in rainfall patterns, plant competition, perennial growth habits, and plant–animal interactions. The cumulative effect of these factors is uncertain. Large, persistent declines in forage quality are projected, irrespective of warming, under elevated CO_2 conditions (600 ppm and +1.5°C day/3°C night temperature increases) in North American grasslands (Augustine et al., 2018). Rising CO_2 concentrations may result in losses of iron, zinc, and protein in plants by up to 8 percent by 2050 (Smith and Myers, 2018). Little information is available on possible impacts on carbon-based micronutrients, such as vitamins. About 57% of grasses globally are C3 plants and thus susceptible to CO_2 effects on their nutritional quality (Osborne et al., 2014). These impacts will result in greater nutritional stress in grazing animals as well as reduced meat and milk production (quality and quantity) (*high confidence, medium evidence*).

5.5.3.2 Impacts of increased temperature on livestock

Recent research confirms the seriousness of the heat stress issue (*medium evidence, high agreement*). Considerable increases are projected during this century in the number of "extreme stress" days per year for cattle, chicken, goat, pig and sheep populations with SSP5-8.5 but many fewer with SSP1-2.6 (Thornton et al., 2021: Figure 5.12; see Cross-Chapter Box MOVING PLATE in this Chapter). Resulting impacts on livestock production and productivity may be large, particularly for cattle throughout the tropics and subtropics and for goats in parts of Latin America and much of Africa and Asia. Pigs are projected to be particularly affected in the mid-latitudes of Europe, East Asia, and North America. (Lallo et al., 2018) estimated that global warming of 1.5°C and 2°C may exceed limits for normal thermo-regulation of livestock animals and result in persistent heat stress for animals in the Caribbean. Breed differences in heat stress resistance in dairy animals are now being quantified (Gantner et al., 2017), as are effects on sow reproductive performance in temperate climates (Wegner et al., 2016). Estimates of losses in milk production due to heat stress in parts of the USA, UK and West Africa to the end of the century range from 1-17% (Hristov et al., 2018; Fodor et al., 2018; Wreford and Topp, 2020; Rahimi et al., 2020). Much larger losses in dairy and beef production due to heat stress are projected for many parts of the tropics and subtropics: these could amount to USD 22 billion per year for dairy and USD 38 billion per for beef to end-century under SSP5-8.5, approximately 7% and 20% of the global value of production of these commodities in constant 2005 dollars.

In many LMICs, poultry contribute significantly to rural livelihoods including via modest improvements in nutritional outcomes of household children (de Bruyn et al., 2018). Rural poultry are generally assumed to be hardy and well adapted to stressful environments, but little information exists regarding their performance under warmer climates or interactions with other production challenges (Nyoni et al., 2019).

5.5.3.3 Impacts on livestock diseases

The impacts of climate change on livestock diseases remain highly uncertain (*medium evidence, high agreement*). Bett et al. (2017) showed positive associations between rising temperature and expansion of the geographical ranges of arthropod vectors such as *Culicoides imicola*, which transmits bluetongue virus. A 1-in-20-year bluetongue outbreak at present-day temperatures is projected to increase in frequency to 1-in-5- to 1-in-7 years by the 2050s, under RCP4.5 and RCP8.5, although animal movement restrictions can prevent devastating outbreaks (Jones et al., 2019).

The prevalence and occurrence of some livestock diseases are positively associated with extreme weather events (*high confidence*). There are high risks of future Rift Valley Fever (RVF) outbreaks under both RCP4.5 and RCP8.5 this century in East Africa and beyond (Taylor et al., 2016; Mweya et al., 2017).

Few studies explicitly consider the biotic and abiotic factors that interact additively, multiplicatively, or antagonistically to influence host-pathogen dynamics (Cable et al., 2017). Integrative concepts that aim to improve the health of people, animals, and the environment such as One Health may offer a framework for enhancing understanding of these complex interactions (Zinsstag et al., 2018). Much remains unknown concerning disease transmission dynamics under a warming climate (Heffernan, 2018), highlighting the need for effective monitoring of livestock disease (Brito et al., 2017; Hristov et al., 2018).

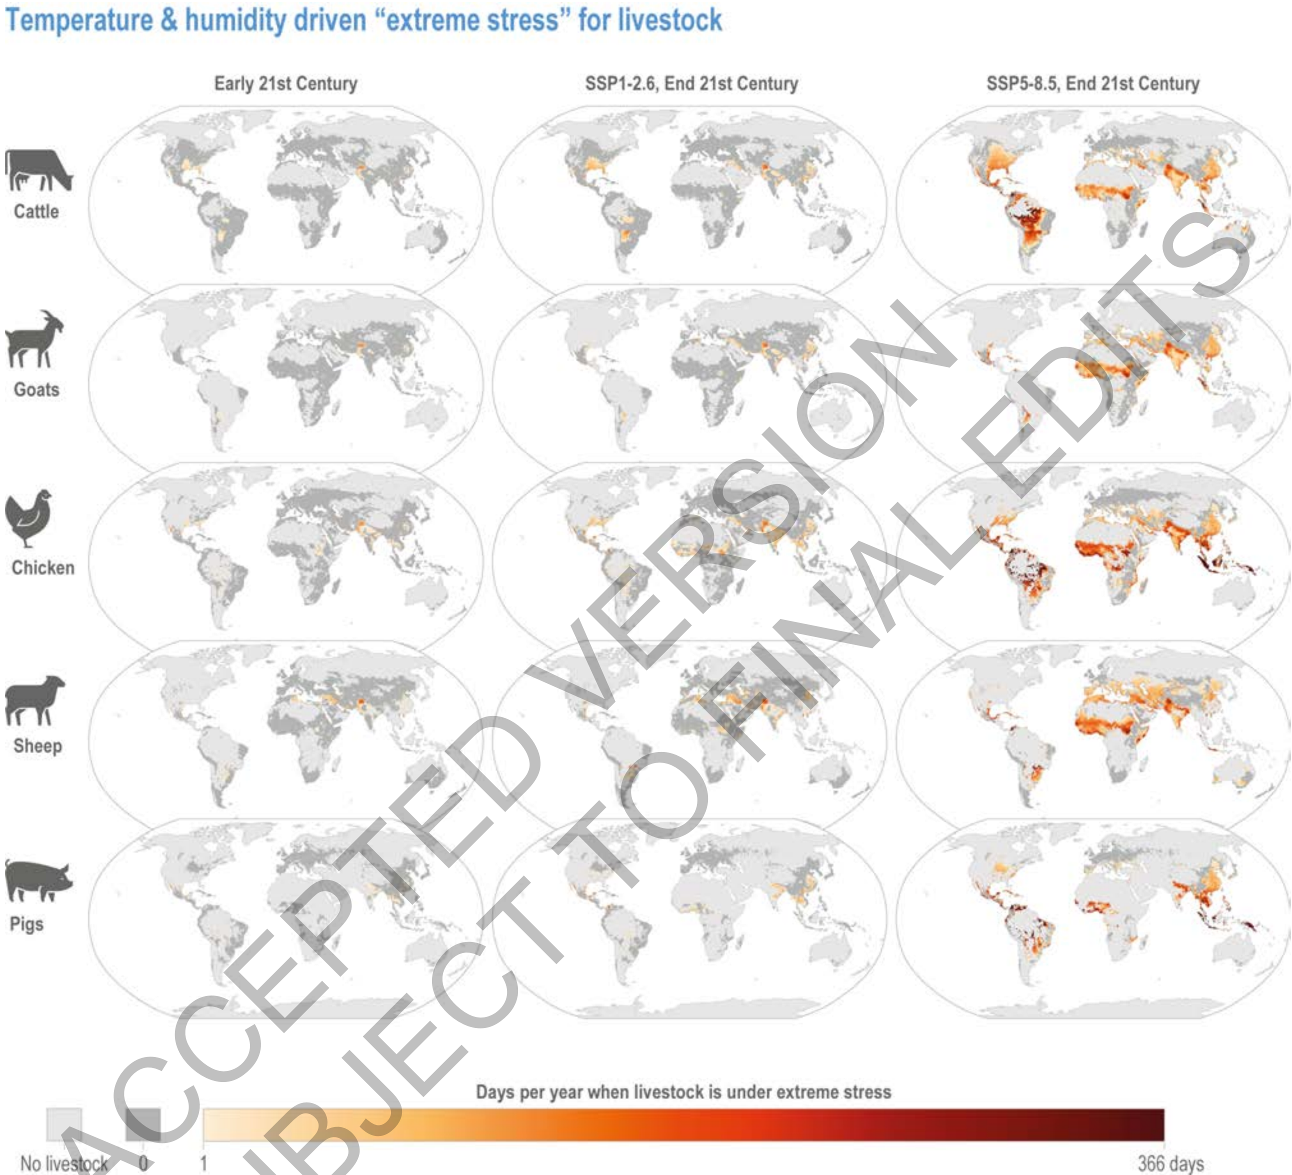

Figure 5.12: Change in the number of days per year above "extreme stress" values from 2000 to the 2090s for SSP5-8.5, estimated using the Temperature Humidity Index (THI). Mapped for species current global distribution (Gilbert et al., 2018) (grey areas, no change). (Thornton et al., 2021), Also see Annex 1: Global to Regional Atlas.

5.5.3.4 Impacts on livestock and water resources

Water resources for livestock may decrease in places because of increased runoff and reduced groundwater resources, as well as decreased groundwater availability in some environments (AR5). Increased temperatures will cause changes in river flow and the amount of water stored in basins, potentially leading to increased water stress in dry areas such as parts of the Volta River Basin (Mul et al., 2015). Toure (2017) estimated decreases in groundwater recharge rates of 49% and of stored groundwater by 24% to the 2030s in the Klela basin in Mali under both RCP4.5 and RCP8.5, with potentially serious consequences for water availability for livestock and irrigation.

Water intake by livestock is related to species, breed, animal size, age, diet, animal activity, temperature, and physiological status of animals (Henry et al., 2018). Direct water use by cattle may increase by 13% for a temperature increase of 2.7°C in a sub-tropical region (Harle et al., 2007). Changes in water availability may arise because of decreased supply or increased competition from other sectors. Availability changes may be accompanied by shifts in water quality, such as increased levels of microorganisms and algae, that can negatively affect livestock health (Naqvi et al., 2015). In arid lands, projected decreases in water availability will severely compromise reproductive performance and productivity in sheep (Naqvi et al., 2017). In higher-input livestock systems, water costs may increase substantially owing to increased competition for water (Rivera-Ferre et al., 2016).

5.5.3.5 Livestock and climate variability

Information on future climate variability changes on livestock system productivity does not exist yet. Increases in climate variability may increase food insecurity in the future, mediated through increased crop and livestock production variability (Thornton and Herrero, 2014) in LMICs. Rainfall variability increases in pastoral lands have been linked to declining cattle numbers (Megersa et al., 2014). Changes in future climate variability may have large negative impacts on livestock system outcomes (Sloat et al., 2018; Stanimirova et al., 2019); these effects can be larger than those associated with gradual climate change (*limited evidence, medium agreement*) (Godde et al., 2019). In grasslands, (Chang et al., 2017) (Europe) and Godde et al. (2020) (globally) projected increases in biomass inter-annual variability, the worst effects occurring in rangeland communities that are already vulnerable. Ways in which climate variability impacts have been addressed in the past, such as via herd mobility, may become increasingly unviable in the future (Hobbs et al., 2008).

5.5.3.6 Societal impacts within the production system

Livestock play important social (Kitalyi et al., 2005) and cultural (Gandini and Villa, 2003) roles in many societies. Climate change will negatively affect the provisioning of social benefits in many of the world's grasslands (*medium confidence*). Examples include moving to semi-private land ownership models, driven in part by climate change, that are changing social networks and limiting socio-ecological resilience in pastoral systems in East Africa (Kibet et al., 2016; Bruyere et al., 2018) and Asia (Cao et al., 2018a); altering traditional food, resource and medicine sharing mechanisms in West Africa (Boafo et al., 2016); and the limited ability of current livestock systems to satisfy societies' demand for cultural ecosystem services in Northwest Europe (Bengtsson et al., 2019). The societal impacts of climate change on livestock systems may interact with drivers of change and increase herders' vulnerability via processes of sedentarization and land fragmentation, both of which may result in decreased animal access to rangelands (Adhikari et al., 2015; Cross-Chapter Box MOVING PLATE this Chapter). Stronger linkages are needed between ecosystem service and food security research and policy to address these challenges (Gentle and Thwaites, 2016; Bengtsson et al., 2019).

5.5.4 Adaptation in Livestock-based Systems

Livestock adaptation options are increasingly being studied with methods such as agent-based household models (Hailegiorgis et al., 2018), household models that disaggregate climate scenarios as well as differentiating farms of varying types and farmer attributes (Descheemaeker et al., 2018), new meso-scale grassland models (Boone et al., 2018), and modelling approaches that capture decision making at the farm level for sample populations (Henderson et al., 2018).

Many grassland-based livestock systems have been highly resilient to past climate risk, providing a sound starting point for current and future climate change adaptation (Hobbs et al., 2008). These adaptations include more effective matching of stocking rates with pasture or other feed production; adjusting herd and watering point management to altered seasonal and spatial patterns of forage production; managing diet quality, which also helps reduce enteric fermentation in ruminants and thus greenhouse gas emissions (using diet supplements, legumes, choice of introduced pasture species and pasture fertility management); more effective use of silage, rotational grazing or other forms of pasture spelling; fire management to control woody thickening; using better-adapted livestock breeds and species; restoration of degraded pastureland; migratory pastoralist activities; and a wide range of biosecurity activities to monitor and manage the spread of pests, weeds, and diseases (Herrero et al., 2015; Godde et al., 2020). Combining adaptations can result in increases in benefits in terms of production and livelihoods over and above those attainable from single adaptations (*high confidence*) (Bonaudo et al., 2014; Thornton and Herrero, 2015; ul Haq et al., 2021).

The adaptations that livestock keepers have been undertaking in Asia (Hussain et al., 2016; Li et al., 2017) and Africa (Belay et al., 2017; Ouédraogo et al., 2017) are largely driven by their perceptions of climate change. Keeping two or more species of livestock simultaneously on the same farm can confer economic and sustainability benefits to European farmers (Martin et al., 2020). Some livestock producers are changing and diversifying management practices, improving access to water sources, increased uptake of off-farm activities, trading short-term profits for longer-term resilience benefits and migrating out of the area (Hussain et al., 2016; Berhe et al., 2017; Merrey et al., 2018; Thornton et al., 2018; Espeland et al., 2020). Others are adopting more climate-resilient livestock species such as camels (Watson et al., 2016a), using climate forecasts at differing time scales, and benefiting from innovative livestock insurance schemes, though challenges remain in their use at scale (Dayamba et al., 2018; Hansen et al., 2019a; Johnson et al., 2019).

In West Africa, cattle and small ruminant producers and traders are changing strategies in response to emerging market opportunities as well as to multiple challenges including climate change (Gautier et al., 2016; Ouédraogo et al., 2017). Niles (2017) found that reduced food insecurity in 12 countries was associated with livestock ownership, providing cash for food purchases. Livestock ownership or switching to smaller, local breeds does not automatically translate into positive nutrition outcomes for women and children, although it may if communities see such animals as suitable for husbandry by women (Chanamuto and Hall, 2015); the relationship is complex (Nyantakyi-Frimpong and Bezner-Kerr, 2015; Dumas et al., 2018).

Options for adapting domestic livestock systems to increased exposure to heat stress (Table 5.7) include breeding and crossbreeding strategies, species switching, low-cost shading alternatives and ventilation and building-design options (Chang-Fung-Martel et al., 2017; Godde et al., 2021). In utero exposure to heat stress may increase adaptive capacity in later life, though the underlying mechanisms are incompletely understood (Skibiel et al., 2018). For confined livestock systems in temperate regions, the economic consequences of adapting to heat stress are still being quantified.

New research is investigating the prospects for accelerating traditional and novel breeding processes for animal traits that may be effective in improving livestock adaptation as well as production (Stranden et al., 2019; Barbato et al., 2020). Even if the technical challenges of using new tools such as CRISPR-Cas9 for genome editing in livestock are overcome, the granting of societal approval to operate in this research space may be elusive (Herrero et al., 2020; Menchaca et al., 2020).

Table 5.7: Selected adaptations to heat stress in livestock systems.

Adaptation	Example	Reference
Breeding for heat stress tolerance	Sheep and cattle farming systems in southern Australia under SRES A2. Projected not to improve livestock productivity by 2070, even in drier locations.	Moore and Ghahramani (2014)
"Slick hair" breeding	In the Caribbean, introduction of a "slick hair" gene into Holstein cows by crossbreeding with Senepols to increase thermo-tolerance and productivity. An integrated approach to heat-stress adaptation will still be needed, including shading strategies, for example.	(Ortiz-Colón et al. (2018)
Crossbreeding	Crossbreeding with Indigenous sheep breeds as an adaptation option in Mongolia produced some benefits in productivity and improved adaptation to winter cold. Best combined with other improved management interventions. In general, effectiveness of crossbreeding as an adaptation strategy will be dependent on context.	Wilkes et al. (2017)

Species switching	Switching from large ruminants to more heat-resilient goats for dairy production in Mediterranean systems to adapt to increasing heat stress.	Silanikove and Koluman (2015)
	Switching from cattle to more heat- and drought-resilient camels in pastoral systems of southern Ethiopia as an adaptation to increasing drought.	Wako et al. (2017)
Shading, fanning, bathing	Low-capital relief strategies (shading with trees or different types of shed; bathing animals several times each day; installing electric fans in sheds) are effective at reducing heat stress impacts on household income in smallholder dairy systems in India.	York et al. (2017)
	Different tree arrangements in silvopastoral systems in Brazil were effective in reducing thermal loads by up to 22% for animals compared with full-sun pasture.	Pezzopane et al. (2019)
Ventilation & cooling systems	A wide range of different ventilation systems, cooling systems and building designs for confined and seasonally confined intensive livestock systems (pigs, poultry, beef, dairy) in temperate regions. Economic consequences and profitability of different options under different RCPs are still being assessed.	Vitt et al. (2017) Derner et al. (2018), Hempel and Menz (2019), Mikovits et al. (2019), Schauberger et al. (2019b)
In utero exposure to heat stress	Potential as an adaption option is uncertain, as there are different effects of *in utero* heat stress exposure and the mechanisms are not completely understood: • Cows may be better adapted to heat stress conditions at maturity via improved regulation of core body temperature. • Cow milk yield at first lactation was reduced • Nutrient partitioning and carcass composition were altered in pigs	Ahmed et al. (2017) Monteiro et al. (2016), Boddicker et al. (2014)

5.5.4.1 Contributions of Indigenous knowledge and local knowledge

Indigenous knowledge has a role to play in helping livestock keepers adapt (*medium confidence*), though the transferability of this knowledge is often unclear. Pastoralists' local knowledge of climate and ecological change can complement scientific research (Klein et al., 2014), and local knowledge can be mobilised to inform adaptation decision-making (Klenk et al., 2017). While Indigenous weather forecasting systems among pastoralists in Ethiopia (Balehegn et al., 2019; Iticha and Husen, 2019) and Uganda (Nkuba et al., 2020) are effective, synergies can be gained by combining traditional and modern knowledge to help pastoralists adapt. Sophisticated knowledge of feed resources among agro-pastoralists in West Africa is being used to increase system resilience (Naah and Braun, 2019). Understanding local knowledge for adaptation can present research challenges, for which new multi-disciplinary research methods may be needed (Reyes-Garcia et al., 2016; Roncoli et al., 2016). In particular, the complexities of knowledge, practice, power, local governance and politics need to be addressed (Hopping et al., 2016; Scoville-Simonds et al., 2020).

[START BOX 5.5 HERE]

Box 5.5: Alternative Sources of Protein for Food and Feed

Alternative protein sources for human food and livestock feed are receiving considerable attention. Laboratory or "clean meat" is one potential contributor to the human demand for protein in the future (SRCLL). Such technology may be highly disruptive to existing value chains but could lead to significant reduction in land use for pastures and crop-based animal feeds (Burton, 2019; Rosenzweig et al., 2020). The impacts on GHG emissions depend on the meat being substituted and the trade-off between industrial energy consumption and agricultural land requirements (Mattick et al., 2015; Alexander et al., 2017; Rubio et al., 2020b; Santo et al., 2020). Livestock feeds can make use of other protein sources: insects are generally rich in protein and can be a significant source of vitamins and minerals. Black soldier fly, yellow mealworm and the common housefly have been identified for potential use in feed products in the EU, for example (Henchion et al., 2017). Replacing land-based crops in livestock diets with some proportion of insect-derived protein may reduce the GHG emissions associated with livestock production, though these and other potential effects have not yet been quantified (Parodi et al., 2018; Section 5.13.2). Other sources are high-protein woody plants such as paper mulberry (Du et al., 2021) and algae, including seaweed. While microalgae and cyanobacteria are mainly sold as a dietary supplement for human consumption, they are also used as a feed additive for livestock and aquaculture, being nutritionally comparable to vegetable proteins. The potential for cultivated seaweed as a feed supplement may be even greater: some red and green seaweeds are rich in highly digestible protein. *Asparagopsis taxiformis*, for example, also decreases methane production in both cattle and sheep when used as a feed supplement (Machado et al., 2016; Li et al., 2018b). Novel protein sources may have considerable potential for sustainably delivering protein for food and feed alike, though their nutritional, environmental, technological, and socio-economic impacts at scale need to be researched and evaluated further.

[END BOX 5.5 HERE]

5.6 Forestry Systems

Forests play a vital role in the ecology of the planet, including climate regulation and provide a range of important ecosystem services within their local landscape. Moreover, they are essential to the well-being of millions of people around the world. Forests are sources of food contributing about 0.6% of global food consumption and provide important products, such as timber and non-timber forest products (NTFPs) (FAO, 2014). Indigenous Peoples and local communities are estimated to manage at least 17% of total carbon (or 293×10^9 Mg) stored in forest in sixty-four assessed countries (RRI, 2018a). While small in number, numerous local communities around the world are highly or entirely dependent on forests for their food supply (Karttunen et al., 2017). An estimated 9 percent of the world's rural population is lifted above the extreme poverty line because of income from forest resources (World Bank, 2016). Additionally, forest income plays a particularly important role in diversifying the income sources of poor households, reducing their vulnerability to loss from one source of income. This section covers an assessment of the impacts of climate change on forestry production systems and the adaptation options available. Non-timber forest products will be covered in the next section.

5.6.1 Observed Impacts

The IPCC AR5 stated that there is high confidence that numerous plants and animal species have already migrated, changed their abundance, and shifted their seasonal activities as a results of climate change (Settele et al., 2014). The report highlighted the widespread deaths of trees in many forested areas of the world. Forest dieback could significantly affect wood production among other impacts.

The Special Report on Climate Change and Land (SRCCL) (Barbosa et al., 2019) concluded that climate change will have positive and negative effects on forests, with varying regional and temporal patterns. For example, the SRCCL noted the increasing productivity in high latitude forests such as those in Siberia. In contrast, negative impacts are already being observed in other regions such as increasing tree mortality due to wildfires.

In the past years, tree mortality continued to increase in many parts of the world. Large pulses of tree mortality were consistently linked to warmer and drier than average conditions for forests throughout the temperate and boreal biomes (*high confidence*) (Sommerfeld et al., 2018; Seidl et al., 2020). Long-term monitoring of tropical forests indicates that climate change as begun to increase tree mortality and alter regeneration (Hubau et al., 2020; Sullivan et al., 2020). Climate related dieback has also been observed due to novel interactions between the life cycles of trees and pest species (Kurz et al., 2008; Lesk et al., 2017;

Sambaraju et al., 2019). A recent example of the impacts of climatic extremes is the European drought of 2018 (Buras et al., 2020), which led to a significant browning of the vegetation and resulted in widespread tree mortality (*high confidence*) (Brun et al., 2020; Schuldt et al., 2020). This brought markets for conifer timber close to a collapse in parts of Europe, posing considerable challenges for timber-based forestry and leading to cascading impacts on society (Hlásny et al., 2021). Overall, there is *robust evidence* and *medium agreement* that provisioning services of boreal and temperate forests are affected negatively by forest disturbances, while for cultural services only *limited evidence* with *medium agreement* exists (Thom and Seidl, 2016).

Increasingly, climate impacts on the recovery of forests after disturbance are observed: Using data from the past 20 years and 33 wildfires, it has been shown that post-fire regeneration of *Pinus ponderosa* and *Pseudotsuga menziesii* in the western United States has declined because of climate change and increased severity of fires (Davis et al., 2019). However, the observed patterns of post-disturbance recovery vary with region, with reduced tree regeneration reported for the Western US (Stevens-Rumann and Morgan, 2019; Turner et al., 2019) but robust recovery observed in Canada (White et al., 2017) and Central Europe (*medium confidence*) (Senf et al., 2019).

Also, the distribution and traits of trees are increasingly influenced by climate change, with impacts for local ecosystem service supply. In the United States, a study of 86 tree species/groups over the past three decades showed that more tree species have shifted westward (73%) than poleward (62%) in their abundance (Fei et al., 2017). This was due more to changes in moisture availability than to changes in temperature. As climate has warmed, trees are growing faster with longer growing seasons. However, a study of forests in Central Europe revealed that wood density has decreased since the 1870s (Pretzsch et al., 2018). This means that increasing tree growth might not directly translate to increased total biomass and carbon sequestration.

5.6.2 Projected Impacts

AR5 stated that other stressors such as human-driven land use change and pollution will continue to be the main causes of forest cover change in the next three decades (Settele et al., 2014). In the second half of this century, it was projected that climate change will be a strong stressor of change in forest ecosystems. Many forest species may not be able to move fast enough to adjust to new climate conditions. In some cases, a warmer climate could lead to extinction of species.

The SR15 concluded that limiting warming to 1.5°C will be more favourable to terrestrial ecosystems, including forests relative to a 2°C warming (Hoegh-Guldberg et al., 2018). In general, a 2°C warming could lead to two times more area of biome shifts compared to a 1.5°C warming. As a result, keeping a cooler average global temperature will lead to lower extinction risks. The special report supports the AR5 conclusion that a warmer planet will impact wide swaths of forests adversely. For example, higher temperatures will promote fire, drought, and insect disturbances. Consistent with AR5, SRCCL projected that tree mortality will increase with climate change (Barbosa et al., 2019). In addition, forests will be more exposed to extreme events such as extreme heat, droughts, and storms. The incidence of forest fires will likewise increase.

Additional evidence since the above reports were published supports their overall conclusions. For example, at the global scale, modelling the vulnerability of 387 forest ecoregions under future climate change (to 2080 using the average of five GCMs and RCP 4.5 and 8.5) across different biomes, biogeographical realms and conservation statuses showed that 8.8% of global forest ecoregions are highly vulnerable in a low-greenhouse-gas-concentration scenario, and 32.6% of the global forest ecoregions were highly vulnerable in the high-greenhouse-gas-concentration scenario (Wang et al., 2019a). Furthermore, a recent synthesis of the literature suggests that climate change will result in younger and shorter forests globally (McDowell et al., 2020). In Asia, a systematic review of climate change impacts on tropical forests revealed that future climate may lead to changes in species distribution, forest structure and composition as well as phenology (Deb et al., 2018).

Overall, studies indicate both negative and positive climate change impacts on forest production systems. Some forests in the US could benefit slightly from CO_2 fertilisation (using IGSM-CAM and MIROC3.2 till 2100) resulting in increased productivity especially for hardwoods (Beach et al., 2015). A study across

Europe showed that both productivity gains (mostly in Northern and Central Europe, up to +33%) and losses (predominately in Southern Europe, up to -37%) are possible until the end of the 21st century (Reyer et al., 2017). The study further indicated that disturbances would reduce gains and exacerbate losses of productivity throughout Europe under climate change (Reyer et al., 2017). For Central and Eastern Canada, decreasing biomass production is projected as a result of increasing disturbance from wildfire and drought (Brecka et al., 2020). Climate-induced disturbances could also reduce the temporal stability of ecosystem service supply (Albrich et al., 2018), increasing the volatility of timber markets (*medium confidence*). More broadly, climate change could lead to abrupt changes and the crossing of tipping points, resulting in profoundly altered future forest development trajectories (Turner et al., 2020). Some studies suggest that such threshold could already be crossed at relatively low warming levels of +2°C (Elkin et al., 2013; Albrich et al., 2020), with substantial implications for ecosystem service supply (*limited evidence, high agreement*).

Regional studies on the potential future effects of climate change on forest production systems indicate diverse impacts. In Germany, drier conditions in 2070 (RCP 8.5; GCMs INM-CM4, ECHAM6 and ACCESS1.0) are expected to benefit the mean annual increment at biological rotation age of Scots pine and oak, while beech might suffer losses of up to 3 $m^3ha^{-1}yr^{-1}$ depending on climate scenario and region (Albert et al., 2018). In India, 46% of the forest grid points were found to have high, very high, or extremely high vulnerability under future climate in the short term (2030s) under both RCP 4.5 and 8.5, increasing to 49 and 54%, respectively, in the long term (2080s) (Sharma et al., 2017). In addition, forests in the higher rainfall zones show lower vulnerability as compared to drier forests under future climate, which is in contrast to dry forests in Central and South America cited above. Warming and drying trends are projected to reduce timber production in the neotropics in some cases (Hiltner et al., 2021). Also in India, a study using CMIP (RCP4.5 and 8.5 with two time slices 2021–2050 and 2070–2099) shows how forests in five districts in Himachal Pradesh in Western Himalayan region are vulnerable to global warming (Upgupta et al., 2015). In the Guiana Shield, climate projections under RCP 2.5 and 8.5 led to decreasing the basal area, above-ground fresh biomass, quadratic diameter, tree growth and mortality rates of tropical forests (Aubry-Kientz et al., 2019). In Central Africa, projections under RCP 4.5 and 8.5 showed a general increase in growth, mortality and recruitment leading to a strong natural thinning effect, with different magnitudes across species (Claeys et al., 2019).

On a global and regional scale, there is *limited evidence* and *high agreement* (*medium confidence*) that climate change will increase global and regional supply of timber and other forest products. To date, there are eight studies assessing the total economic impacts of climate change on the forestry sector at the global level. Some of them have assumed only flow effects of climate change by using the projected changes in yields of forest types from integrated economic models (Perez-Garcia et al., 1997; Perez-Garcia et al., 2002; Buongiorno, 2015), while other studies have assumed both flow and stock effects by accounting for changes in forest yields, dieback effects and biomes migration (Sohngen et al., 2001; Lee and Lyon, 2004; Tian et al., 2016; Favero et al., 2018; Favero et al., 2021).

According to these studies, global timber supply will increase as the result of an increase in global forest growth under climate change scenarios (*medium confidence*). Some studies indicate that timber supply is projected to increase more in tropical and subtropical areas because of the assumed availability of short-rotation species which are likely to make adaptation easier for forest owners in these regions relative to others (Sohngen et al., 2001; Perez-Garcia et al., 2002; Tian et al., 2016) while others indicate that temperate areas will experience the largest increase in supply (Favero et al., 2018; Favero et al., 2021). The results are very sensitive to the climate change scenarios tested, the climate and vegetation models used and the climate drivers that are considered. For example, Tian et al.(2016) and Favero et al.(2018; 2021) used the same economic model (the global timber model) but different climate scenarios and vegetation models, obtaining different results.

The increasing supply induces lower global timber prices (*medium confidence*). Studies estimate that the prices are likely to decline between 1% to 38% in 2100 with respect to a no climate change scenario depending on the model and the climate change scenario assumed (climate change is represented as a change in greenhouse gas concentration, global average temperature or radiative forcing) (Favero et al., 2018; Favero et al., 2021). Clearly, further studies are needed considering a wider set of vegetation and climate models and incorporating the impacts of extreme events (such as droughts and wildfires).

There are a number of national and regional scale studies exploring the impact of climate change on yields and markets of wood products, with mixed results. In Finland, it is projected that timber yield in the north will increase in Scots pine and birch stands by 33–145% and 42–123%, compared to the current climate, depending on the GCM and thinning regime using a 90-year rotation (10 individual GCM projections under the RCP4.5 and RCP8.5 forcing scenarios) (ALRahahleh et al., 2018). However, in Norway spruce stands, yield could decline by up to 35%, under GFDL-CM3 RCP8.5 and increase by up to 39%, under CNRM-CM5 RCP8.5, compared to the current climate.

In Germany, timber harvest was projected to increase slightly (< 10%) in 2045 using the process-based forestry model (4C) driven by three management strategies (nature protection, biomass production and a baseline management) and an ensemble of regional climate scenarios (RCP2.6, RCP 4.5, RCP 8.5) (Gutsch et al., 2018). Similarly, average production of pulpwood in slash pine stands in the Southeastern United States are projected to increase by 7.5 m^3 ha^{-1} for all climatic scenarios using 3-PG forest growth model by 2100 (RCP4.5 and RCP8.5; CanESM2) (Susaeta and Lal, 2018).

5.6.3 Adaptation

AR5 notes that natural ecosystems have built-in adaptation ability (Settele et al., 2014). However, this capacity will not be enough to prevent loss of forest ecosystem services because of projected climate change in this century under RCP 6.0 and 8.5. Management actions could reduce the risks of impacts to forest ecosystems but only up to a certain point.

A systematic review of literature revealed that successful adaptation in forest management can be achieved if there are partnerships between key stakeholders such as researchers, forest managers, and local actors (Keenan, 2015). Such partnerships will lead to a shared understanding of climate-related challenges and more effective decisions. Forest managers in some countries of the world seem to have high awareness of climate change (van Gameren and Zaccai, 2015; Seidl et al., 2016; Sousa-Silva et al., 2016). However, they need more information on how they can adjust their practices in response to climate change. Institutional and policy context needs to be considered to facilitate adaptation by forest managers (Sousa-Silva et al., 2016; Andersson et al., 2017).

5.6.3.1 Adaptation measures in sustainable forest management

A wide range of measures exist to adapt sustainably managed forests of the boreal and temperate zone to climate change (Kolström et al., 2011; Gauthier et al., 2014; Keenan, 2015). Evidence emerging since the last assessment report further bolstered the notion that adapting the tree species composition to more warm-tolerant and less disturbance-prone species can significantly mitigate climate change impacts (*high confidence*) (Duveneck and Scheller, 2015; Seidl et al., 2018). Assisting the establishment of species in suitable habitats is one option to achieve climate-adapted tree species compositions (Benito-Garzón and Fernández-Manjarrés, 2015; Iverson et al., 2019). Furthermore, increasing the diversity of tree species within stands can have positive effects on tree growth and reduce disturbance impacts (*high confidence*) (Neuner et al., 2015; Jactel et al., 2018; Ammer, 2019). Some studies also suggest a positive effect of increased structural diversity, e.g., on forest resilience (*moderate confidence*) (Lafond et al., 2013; Koontz et al., 2020). Managing for continuous forest cover can also help to maintain the forest microclimate and buffer tree regeneration and the forest floor community against climate change (*high confidence*) (De Frenne et al., 2013; Zellweger et al., 2020). Reducing stocking levels e.g., through thinning has been found to effectively mitigate drought stress (Gebhardt et al., 2014; Elkin et al., 2015; Bottero et al., 2017), yet effects vary with species and ecological context (*robust evidence, medium agreement*) (Sohn et al., 2016; Castagneri et al., 2021). Also shortened rotation periods have been suggested in response to climate-induced increases in growth and disturbance (Jönsson et al., 2015; Schelhaas et al., 2015). However, recent evidence suggests that these measures diminish in efficiency under climate change and can have corollary effects on other important forest functions such as carbon storage and habitat quality (*medium confidence*) (Zimová et al., 2020). Also, measures targeting landscape structure and composition have proven effective for increasing the climate resilience of forest systems (*medium confidence*) (Aquilue et al., 2020; Honkaniemi et al., 2020). While an increasing number of adaptation measures exist for sustainably managed forests, many studies highlight that the lead times for adaptation in forestry are long and that some vulnerabilities might remain also after adaptation measures have been implemented. Furthermore, the costs and benefits of adaptation measures relative to other goals of sustainable forest management, such as the conservation of biological diversity, have to be considered (Felton et al., 2016; Zimová et al., 2020; see CCP7 5.3.1 Adaptation Response Options).

[START BOX5.6 HERE]

Box 5.6: Contributions of Indigenous and local knowledge: an example

Indigenous and local people have long histories of adaptation to climate hazards in forests (see Eriksen and Hankins, 2014; Neale et al., 2019; Bourke et al., 2020; Long et al., 2020; Williamson, 2021 for notable examples in Australia and North America). In this section we present a North American example of an indigenous adaptation practice developed by the Karuk Tribe in northern California. The Karuk Climate Adaptation Plan focuses on the use of cultural fire as climate adaptation, places a central importance on restoring human ecological caretaking responsibilities, and emphasizes the need for collaboration, public education, and policy advocacy to achieve these outcomes.

The Karuk Climate Adaptation Plan utilizes a combination of western science and Karuk traditional ecological knowledge. The plan centres on 22 focal species as **cultural indicators** as cues for human responsibilities and the particular techniques of fire application across seven habitat management zones (e.g., multiple forest types as well as riverine, riparian and montane systems). These adaptations range from specific prescriptions for the use of fire to lower river temperatures in acute scenarios (David et al., 2018), to protocols for treatment of grasslands and the use of high elevation meadows as fuel breaks. The plan also includes chapters on adaptations for tribal sovereignty, the mental and physical health effects of the changing climate and the protection of critical tribal infrastructure.

One aspect of Indigenous fire knowledge featured in the Karuk Climate Adaptation Plan is the culture-centric perspective on vegetation zones which are organized in relation to the elevation band in which smoke inversions occur (Figure Box 5.6.1). Within this system, burn timing follows a gradient that tracks the reproductive life cycles of season and elevational migrant species, the calving of elk as well as the nesting of birds. Within this system, elevational migrants are indicators of when to stop burning at one location and move upslope, following receding snows.

The plan also calls for the restoration of Indigenous fire science in emergency scenarios such as when rivers become too hot for salmon. With such fires localized, smoke inversions cool water temperatures through a variety of mechanisms including shading river systems and reducing evapo-transpiration thereby increasing stream flow (David et al., 2018).

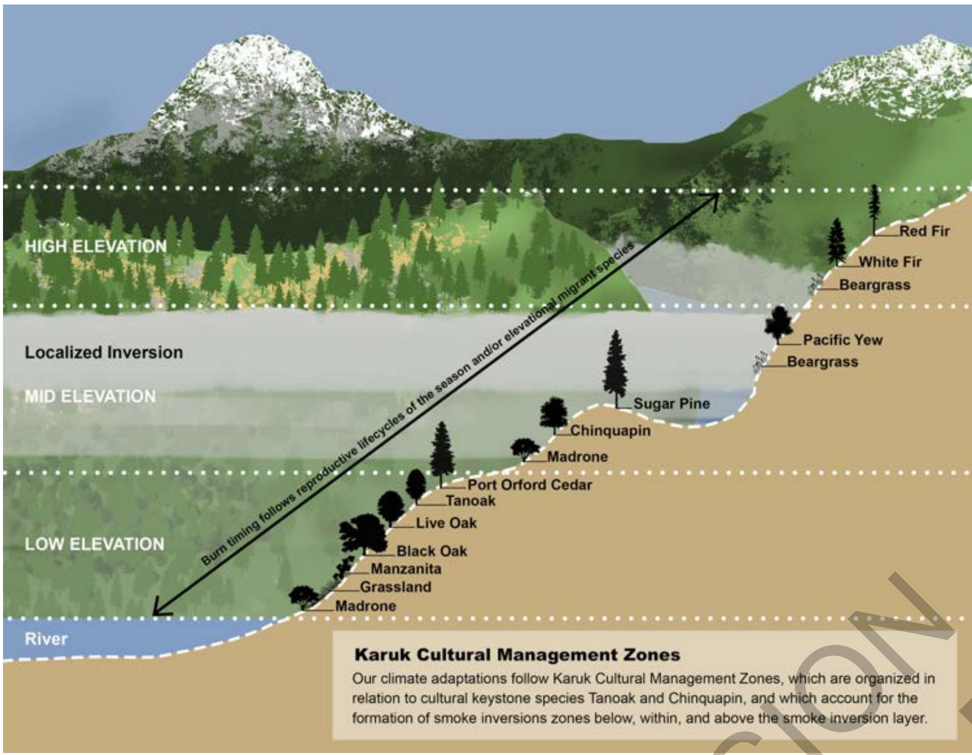

Figure Box 5.6.1: Seasonality and elevation dynamics of cultural indicators in Karuk Cultural Management Zones based in Karuk traditional ecological knowledge.

[END BOX 5.6 HERE]

5.6.3.2 Linking adaptation and mitigation through REDD+

Reducing Deforestation and Forest Degradation plus (REDD+) is a climate mitigation strategy which could also provide important climate change adaptation co-benefits, e.g., sustainable forest management could provide long term livelihoods to local communities and enhance resilience to climate risks (Turnhout et al., 2017), but with major challenges related to REDD+ implementation and forest use remain such that it has not been implemented successfully at scale (Table 5.8).

Table 5.8: Challenges and solutions for Reducing Deforestation and Forest Degradation (REDD+)

Challenges with REDD+ implementation	**Solutions for successful forest management**
Legal: lack of carbon rights in national legislations (Sunderlin et al., 2018; RRI, 2018b); unclear forestland tenure systems (Resosudarmo et al., 2014);.	There is *high confidence* that implementing social safeguards such as a Free Prior and Informed Consent (FPIC) is vital to adequately involving Indigenous Peoples and local communities in REDD+ (White, 2014; Raftopoulos and Short, 2019). Indigenous Peoples, consisting of at least 370 million people, manage or have tenure rights over a quarter of the world's land surface (around 38 million km^2) encompassing about 40% of the world's protected areas (Garnett et al., 2018; RRI, 2018a).
Food security and livelihoods: Negative impacts of REDD+ on food security, agroforestry and swidden agriculture (Fox et al., 2014; Holmes et al., 2017).	There is *high agreement* that REDD+ and other green adaptation and mitigation efforts need to cooperate with Indigenous Peoples and other local communities who depend on forest resources for their livelihoods and food security (Wallbott, 2014; Mccall, 2016; Brugnach et al., 2017; Vanclay, 2017; Garnett et al., 2018; Paneque-Galvez et al., 2018; Sunderlin et al., 2018; Schroeder and Gonzalez, 2019).

Political and socio-culural: land acquisition or 'green grabbing' (Asiyanbi, 2016; Corbera et al., 2017); (mis)communicating the concept of carbon (Kent and Hannay, 2020); and lack of influence of Indigenous and local communities' representation in global and national REDD+ negotiations (Wallbott, 2014; Dehm, 2016). In the absence of social and environmental safeguards, REDD+ could drive large-scale land acquisitions by states and corporations resulting in global land grabs (or green grabbing), negatively affecting the food security, livelihoods and tenure rights of Indigenous and local communities (*limited evidence, high agreement*) (Carter et al., 2017; Lund et al., 2017; Borras et al., 2020).	There is *low confidence* as to whether community forestry is compatible with REDD+ (Hajjar et al., 2021). This is mainly due to lack of carbon payments and the variety of approaches to REDD+. There is *high confidence* that restoring land access and rights via transfer of formal land titles to Indigenous and local communities improves biodiversity conservation and carbon sequestration.

5.7 Other Natural Products

Natural products such as medicinal plants, wild food (plants, animals, mushrooms) and resins (e.g., gum arabic and frankincense) have high commercial value and contribute an important source of livelihood in some regions. One in six persons globally live in or near forests and many depend on forest resources for some of their livelihood and needs, particularly in low- and middle-income countries (Vira et al., 2016; Newton et al., 2020). The FAO has estimated that in 2011 non-wood forest products, including medicinal plants, contributed over 88 billion USD to the global economy (FAO, 2014). Greater diversity in local knowledge and Indigenous knowledge of natural resources supports resilience in the face of hazards, especially in environments with high levels of uncertainty (Berkes et al., 2003; Blanco and Carriere, 2016).

5.7.1 Medicinal Plants

The World Health Organization lists traditional medicine as an essential component of culturally appropriate healthcare (WHO, 2013). Medicinal plants make up the primary source of medicine for 70 to 95% of people in low- and middle-income countries and are used widely in wealthier countries (Applequist et al., 2020). Continued use of medicinal plants ensures millions of rural people have access to effective treatments for day-to-day illness and infection and thus improves their health and resilience to climate change.

Indigenous Peoples largely depend on medicinal plants for their healthcare need in different parts of the world (de Boer and Cotingting, 2014; Silva et al., 2020). Medicinal and aromatic plants can support the economy and generate livelihood options for rural people through preparing and selling traditional medicine; collecting from wild; and trade for income generation (Fajinmi et al., 2017; Zahra et al., 2020). Income from medicinal plant collection increases livelihood diversification, which is widely accepted to improve resilience.

5.7.2 Resin and Gum

Resin and gum are economically important natural products: contributing 14-23% total household income in parts of Ethiopia and Sudan (Abtew et al., 2014; Fikir et al., 2016), Cambodia (Sakkhamduang et al.) and India (Tewari et al., 2017). They are an important source of raw material for many industries. For instance, in Africa, the genus *Boswellia* and *Commiphora,* which provide frankincense and myrrh resins, provide significant income generation and export value (Tilahun et al., 2015). Populations of many species that provide gums and resins are declining under pressure from unsustainable harvesting and deforestation and climate change may further threaten them.

In Sri Lanka, *Boswellia serrata* Roxb. is critically endangered or possibly extinct (Weerakoon and Wijesundara 2012). In India, *B. serrata* populations are 'vulnerable' (Chaubey et al., 2015; Brendler et al., 2018), and declining in the Western Ghats (Soumya et al., 2019). Invasion of *Lantana camara* and *Prosopis juliflora* has resulted in poor regeneration of *Commiphorawightii* in central India (Jain and Nadgauda, 2013). Other resin-producing species under threat include: *Daemonoropsdraco* (Dragon's blood resin) in Indonesia (Yetty et al., 2013; Widianingsih et al., 2019), *Pinus merkusii*(tusam) in Sumatra (Indonesia) (Hartiningtias et al., 2020), *Pinus pinaster* in Spain*, Pinus massoniana*in China*,* (Génova et al., 2014; Chen et al., 2015b), *Pistacia atlantica* in Iran (Yousefi et al., 2020).

5.7.3 Wild Foods

Wild foods can include both native and introduced species that are not cultivated or reared but may be under various degrees of management by humans and may include escapees of species that are cultivated in some contexts (Powell et al., 2015). Information on the use and importance of wild foods for nutrition is growing but remains limited (FAO, 2019e). The AR4 covered wild food briefly in the Polar Regions and noted the interrelated nature of climate change and Indigenous knowledge loss in reducing access to wild food (Anisimov et al., 2001). AR5 did not address wild foods and other natural products. There is large variation in the importance of wild foods (Powell et al., 2015; Rowland et al., 2017; Dop et al., 2020). A recent survey of 91 countries found that 15 reported regular use of wild foods by most of the population, and 26 reported regular use of wild foods by a subsection of the population (FAO, 2019e). While they contribute little to food energy intake, their contribution to nutrition can be significant because most wild and forest foods (vegetables, fruits, mushrooms, insects, and meat) are rich in proteins and micronutrients (Powell et al., 2015). The impacts of climate change on wild foods will vary in time, space, and among species.

5.7.4 Observed and Projected Impacts

5.7.4.1 Medicinal lants

Research is limited on the effects of climate change on the distribution, productivity, or availability of medicinal plants (Applequist et al., 2020), but some are facing threats due to climate change (Phanxay et al., 2015; Chirwa et al., 2017; Chitale et al., 2018). Climate change is projected to impact some medicinal plant species through changing temperature and precipitation, changes in pests and pathogens: unsustainable harvest of high value species will significantly exacerbate these impacts (*medium evidence; high agreement*) (Applequist et al., 2020). Table 5.9 highlights that climate change impacts on medicinal plant species will vary greatly by species. Medicinal plants that grow in arid environments are also highly susceptible to climate-induced change (Applequist et al., 2020). Arctic medicinal species may also be particularly at risk due to climate change (Cavaliere, 2009).

Changes in range distribution will interact with detailed local knowledge and Indigenous knowledge needed to harvest and use medicinal plants. Northward range shifts, for example, may mean certain plants still exist, but not where they have traditionally been important as medicine, and with protected areas, possibly moving suitable ranges outside of areas where plants species have sufficient protection (Kaky and Gilbert, 2017). Climate-induced phenological changes are already observed as a threat to some species (Gaira et al., 2014; Maikhuri et al., 2018). Other major climate-induced impacts on medicinal plants will be via the phytochemical content and pharmacological properties of medical plants (Gairola et al., 2010; Das et al., 2016a). Experimental trials have shown that drought stresses increase phytochemical content, either by decreasing biomass or increasing metabolites production (*high confidence*) (Selmar and Kleinwachter, 2013; Al-Gabbiesh et al., 2015).

Table 5.9: Observed and Predicted impacts of climate change on selected medicinal plant species.

Region	Species	Observed and Projected Impacts of Climate Change	Assessment of Evidence and level of agreement
Egypt, Sub-Saharan Africa, Spain, Central Himalaya, China, Nepal	General assessment of medicinal plants	Habitat suitability and/or range distribution will shift or may be lost (Munt et al., 2016; Yan et al., 2017; Brunette et al., 2018; Chitale et al., 2018; Zhao et al., 2018; Applequist et al., 2020) including in high elevation meadows which are home to some of the most threatened plant populations and contain a high number of and higher proportion of species used as medicine compared to lower elevation habitats (Salick et al., 2009; Brandt et al., 2013).	*medium confidence.*
Hindukush Himalaya	*Gynostemmapenta phyllum*	The elevated CO_2 and temperature can increase biomass, but the health-promoting	*medium confidence*

		properties such as total antioxidants, phenols, and flavonoids are expected to decrease (Chang et al., 2016).	
Arctic	Golden Root (*Rhodiola rosea)*	Population decline has been associated with drying of stream beds and alpine meadows, which are predicted to become more severe under climate change (Cavaliere, 2009; Brinkman et al., 2016)	*medium confidence*
North America	American ginseng (*Panax quinquefolius*)	Modelling of the combined impact of climate change (warming) and harvesting pressure indicates a non-linear increase in extinction risk (Souther and McGraw, 2014)	*medium confidence*
Asia	*Gentiana rigescens*	A model evaluating future climate impacts shows a westward range shift and major loss of highly suitable habitats. Modelling also shows a potential decline in quality (chemical concentration of iridoid glycoside, which is highest in highly suitable habitats) due to climate change (Shen et al., 2021)	*medium confidence*
Africa	*Alstoniaboonei*	Modelling indicates that the range for this species remains relatively stable with a possible modest expansion at the northern and southern margins of the range (Asase and Peterson, 2019).	*medium confidence*
Asia	*Homonoia riparia*	Modelling of future climate scenarios in Yanan province, China projects that habitat suitability improves (Yi et al., 2016). Modelling of future climate scenarios across the whole species range in China shows that both the suitable area and suitability of the habitat increase (Yi et al., 2018).	*medium confidence*
Asia	*Notopterygiuminc isum*	Modelling for future climate change shows areas of suitable habitat will significantly decrease, however, the area of marginally suitable habitat will remain relatively stable (Zhao et al., 2020).	*medium confidence*
Himalayas	Himalayan yew *Taxus wallichiana*	Modelling shows projected shrink in climatic niche of the species by 28% (RCP 4.5) and 31% (RCP 8.5) highlights the vulnerability to climate change impacts (Rathore et al., 2019).	*medium confidence*
Iran	*Daphne mucronata*	Modelling of future climate change projects disappearance of the species below 2000 m, significant change in distribution between 2000-3000m and no change above 3000 m (Abolmaali et al., 2018).	*medium confidence*
Central America	Pericón or Mexican Mint Marigold *Tagetes lucida*	Models predict range to contract somewhat and shift northward (Kurpis et al., 2019)	*medium confidence*
Africa	Rooibos tea *Aspalathus linearis*	Modelling of future climate scenarios shows substantial range contraction of both wild and cultivated tea with range shifts south-eastwards and upslope (Lotter and Maitre, 2014)	*medium confidence*
Himalayas	*Lilium polyphyllum*	Habitats of this species will shrink by 38–81% under future climate scenarios and shift towards the south-east region in western Himalaya, India (Dhyani et al., 2021).	*medium confidence*
Iran	*Fritillaria imperialis*	Modeling shows 18% and 16.5% of the habitats may be lost due to climate change by 2070 under RCP4.5 and RCP8.5, Further,	*medium confidence*

		it is observed that under the current climatic conditions, the suitable habitat may become unsuitable in the future resulting in local extinction (Naghipour Borj et al., 2019)	
Himalayas/ China	Snow lotus *(Saussurea spp.)*	Climate change is a significant threat to this species (Law and Salick, 2005). Laboratory and field trials show considerable plasticity and a wide thermal range for germination, which may help compensate for range reductions under climate change (Peng et al., 2019)	*medium confidence*
North Africa	Atlas cedar *Cedrusatlantica*	Modelling shows a significant and rapid contraction of distribution range, upward elevational range shift, increased fragmentation, and possible disappearance in many North African localities (Bouahmed et al., 2019)	*medium confidence*
Asia / South Korea	*Paeonia obovata*	Modelling of climate change scenarios shows significant loss of suitable habitat and possible disappearance of *P. obovata*in South Korea after 2080 (Jeon et al., 2020).	*medium confidence*
Iran	*Salvia hydrangea*	A projected loss of habitat in the south-east of the range will not be compensated by the northward or upward elevational range migration (Ardestani and Ghahfarrokhi, 2021)	*medium confidence*
Patagonian, Argentina	*Valerianacarnosa*	Modelling for future climate scenarios projects a 22% loss of the suitable habitat (Nagahama and Bonino, 2020)	*medium confidence*
Western Ghats, India	Kokum *Garcinia indica*	Predictions of Climate change impact on habitat suitability indicate drastic reduction in the suitability by over 10% under RCP 8.5 for the year 2050 and 2070 (Pramanik et al., 2018)	*medium confidence*
Himalaya	*Ophiocordyceps sinensis*	A decline of the species is largely due to over harvesting but ecological modelling indicates that climate warming is also contributing to this decline (Hopping et al., 2018)	*high confidence*
Pacific islands	noni (*Morindacitrifoli*), naupaka (*Scaevola spp*.), kukui (*Aleurites moluccana*), and milo (*Thespesia populnea*)	May be less susceptible to climate change as they are fast growing, have high reproduction rates, grow at sea-level (and are often salt-tolerant) and have significant room for range shifts (Cavaliere, 2009).	*Low confidence.*

5.7.4.2 Wild food

5.7.4.2.1 Wild Food in the Arctic, North America, and Europe

Changes to the availability, abundance, access, and storage of wild foods associated with changing climate are exacerbating high rates of food insecurity (*high confidence*) (Ford, 2009; Beaumier and Ford, 2010; Herman-Mercer et al., 2019). Wild foods are central to the food systems of communities throughout the Arctic and sub-Arctic (Kuhnlein et al., 1996; Ballew et al., 2006; Kuhnlein and Receveur, 2007; Johnson et al., 2009) and play an essential role in people's physical and emotional health (CCP 6.2.5; 2.8) (*high confidence*) (Loring and Gerlach, 2009; Cunsolo Willox et al., 2012). Wild foods consumed in the Arctic and Northern regions include animals and a wide variety of plant foods (Wein et al., 1996; Ballew et al., 2006; Kuhnlein and Receveur, 2007). Wild foods contribute most of important nutrients in the diets of Northern and Arctic people (Johnson et al., 2009; Wesche and Chan, 2010; Kenny et al., 2018). However, the use of traditional wild foods is declining across the region, lowering diet quality (Rosol et al., 2016). Indigenous communities in the Arctic perceive climate change related impacts on traditional wild foods, and availability and access to wild foods are forecast to continue to decline (Brinkman et al., 2016). Some communities hold positive views of the new opportunities a warmer climate will bring, seeing them as a favourable trade-off relative to the loss of some forms of subsistence hunting (Nuttall, 2009). Climate change is causing ecological changes that impact Arctic wild food availability and abundance in many different ways, including changes to breeding success, migration patterns, and food webs (Table 5.10, Markon et al., 2018).

Climate-change induced impacts of access to wild foods are also of concern in Arctic regions (*high confidence*). Coastal and inland communities of Alaska found that 60% of climate impacts on food security listed by hunters were related to access (Brinkman et al., 2016). Reduced duration, thickness and quality of sea ice are some of the most cited impacts of climate change on wild food consumption (Ford, 2009; Laidler et al., 2009; Downing and Cuerrier, 2011; Huntington et al., 2017; Nuttall, 2017; Fawcett et al., 2018; Ford et al., 2018; Markon et al., 2018). Lack of snowfall reduces and delays the ability to travel on the land using snowmobiles (Downing and Cuerrier, 2011), impacting safety of travel, time needed and costs of accessing wild foods (Cold et al., 2020).

Rising temperatures and humidity are also impacting wild food storage and increasing the risk of food-borne diseases (Cozzetto et al., 2013; Nuttall, 2017; Markon et al., 2018). Changes in air temperature and humidity can mean that whale and fish meat no longer dry properly, or meat may spoil before hunters can get it home (Downing and Cuerrier, 2011; Nuttall, 2017). Traditional permafrost ice cellars are no longer reliable (Downing and Cuerrier, 2011; Nyland et al., 2017; Herman-Mercer et al., 2019). Climate-related environmental change compounded with social, economic, cultural, and political change have had complex but overall negative impacts on wild foods (CCP 6.4, Lujan et al., 2018) .

Communities across other (non-Arctic) parts of North America and Europe also report declining availability of wild foods with climate change among the perceived drivers for decline (*medium confidence*) (Table 5.10, Serrasolses et al., 2016; Smith et al., 2019a). Even when climate change may not always be the primary driver of loss of these wild food resources, climate may interact with other stressors to exacerbate loss of wild foods (Lynn et al., 2013; Reo and Parker, 2013).

5.7.4.2.2 Wild food in the arid and semi-arid environments

Wild foods are also impacted by climate change in arid and semi-arid landscapes around the world (*medium evidence, high agreement*) (Table 5.10). A number of wild species are important traditional foods of Indigenous Peoples or local communities across arid regions of North America (Messer, 1972; Kuhnlein and Calloway, 1977; Santos-Fita et al., 2012; Vinyeta et al., 2016), South America (e.g. Argentina, Ladio and Lozada, 2004; Altrichter, 2006; Eyssartier et al., 2011), Australia (Scelza et al., 2014), the Mediterranean basin (Hadjichambis et al., 2008; Powell et al., 2014), India and the Himalayas (Pingle, 1975; Gupta and Sen, 1980; Delang, 2006; Bhatt et al., 2017).

Wild foods such as baobab, shea and nere from plants and animal make an important contribution to diets and nutrition in arid and semi-arid regions of African (Boedecker et al., 2014; Leßmeister et al., 2015; Bélanger and Pilling, 2019) and are being impacted by climate change (Moseley et al., 2015; Sango and Godwell, 2015; Hitchcock, 2016) (see Chapter 9). There has been little published research on the impacts on climate change on wild food in arid regions of Australia, although Aboriginal elders in one report suggested that climate related changes are impacting wild food (Memmott et al., 2013).

5.7.4.2.3 Wild Food in tropical humid environments

Wild foods are important to many communities that live in and adjacent to humid tropical forests, but climate change impacts are mixed (Table 5.10, Dounias et al., 2007; Colfer, 2008; Powell et al., 2015; Rowland et al., 2017; Reyes-García et al., 2019).. In some humid tropical forest regions, bushmeat is particularly important (Golden et al., 2011; Nasi et al., 2011; Fa et al., 2015; Powell et al., 2015; Rowland et al., 2017). In humid tropical regions the impact of climate change on wild food availability, access and consumption is currently unclear and research is limited. There are, however, important interrelationships between climate change and wild food use in humid forests. For example, the loss of large mammals to bushmeat consumption and global trade will likely slow the regeneration of tropical forests in which a large number of tree species are dependent on large mammals for seed dispersal (Brodie and Gibbs, 2009).

Conversely, others argue that bushmeat provides local communities with an important incentive to support local maintenance of forest cover and thus carbon sequestration (Bennett et al., 2007).

Table 5.10: Observed and Predicted impacts of climate change on selected wild food species.

Region	Species	Observed and Projected Impacts of Climate Change	Assessment of Evidence and level of agreement
Arctic region	Ringed Seals (*Pusahispida*)	Drastic declines in population size and major changes in population structure (Hammill, 2009; Reimer et al., 2019); habitat (dependent on snow cover or ice breathing holes for lairs) will decline by approximately 70%, and significantly reduce survival rates of pups (Freitas et al., 2008).	*high confidence*
Arctic region	Bearded seal (*Erignathus barbatus*)	Climate change affect the availability and stability of at least 11 ice-associated species including Bearded seal. Potential impacts due to climate change will reduce available habitat for birthing (Moore and Huntington, 2008; Fink, 2017).	*medium evidence, high agreement*
Arctic region	Walrus (*Odobenus rosmarus*)	Declines in the climate-vulnerable Pacific walrus populations, induced by overharvesting (Taylor et al., 2018); however, the species is considered highly vulnerable to loss of sea ice (Lydersen, 2018). Possible diet changes (related to climate-induced changes in food-web) raise concernsabout the health of the population (Clark et al., 2019).	*high confidence*
Arctic region	Narwhal (*Monodon monoceros*)	The impacts of climate change on other sea ice-associated marine mammals are somewhat less clear (Moor et al., 2017). Climate change may threaten narwhal given their vulnerability to ice entrapment (Laidre and Heide-Jorgensen, 2005) and the narrow range of prey in their diet (Heide-Jørgensen, 2018). In Greenland hunters report that narwhal now frequent fjords and other areas where manoeuvring a boat is difficult (Nuttall, 2017)	*low evidence, medium agreement*
Arctic region	Beluga (*Delphinapterus leucas*)	Belugas are thought to be less sensitive to climate change than some other sea mammals but can perish in large groups from ice entrapment. Climate impacts likely increased human activity (noise) (O'Corry-Crowe, 2009). Changes in migrating timing have been documented (Hsiang et al., 2017).	*low evidence, low agreement*
Arctic region	Bowhead (*Balaena mysticetus*)	The movements of some whale species are linked to sea surface temperatures (Moore and Huntington, 2008; Chambault et al., 2018). Some whale hunting communities are now reporting that whales pass by at a time of year when launching boats is impaired by rough weather and poor sea ice conditions (Noongwook et al., 2007; Huntington et al., 2017).	*medium confidence*
Artic region	Other sea ice associated marine mammals (harp seal, hooded seal)	The impacts of climate change on other sea ice associated marine mammals are somewhat less clear (Moor et al., 2017).	*low confidence*
Arctic and Northern regions	Reindeer and caribou (*Rangifer tarandus*)	Large herbivores are highly dependent on their food sources such as mosses, lichens and grasses which are sensitive to climate change (Istomin and Habeck, 2016). Combined impacts of climate change and other interrelated factors suggest significant declines in caribou and reindeer populations, although to varying extents from one population to another (Kenny et al., 2018; Mallory and Boyce, 2018).	*medium confidence*

		Warming has led to increased plant productivity and associated increases in body mass of some reindeer populations (Albon et al., 2017; Mallory and Boyce, 2018). Increasing primary production, warming will also change the plant composition, leading to increases in woody / shrubby vegetation which will have negative nutritional consequences for caribou and reindeer (Elmendorf et al., 2012; Mallory and Boyce, 2018). The loss of lichens, a key winter food source, due to increased wildfire or replacement by grasses and herbs that die back in the winter, may also be detrimental to caribou and reindeer, although there is not currently consensus on this among experts (Mallory and Boyce, 2018). Rain on snow and icing events during winter, which are predicted to become more frequent, have been documented to lead to large increases in arctic herbivore mortality because they create an ice barrier making access to food more difficult (Putkonen and Roe, 2003; Tyler, 2010; Stien et al., 2012; Hansen et al., 2013; Forbes et al., 2016). Rain on snow events may also impact reproductive success, although recent research suggests this relationship in not straight forward (Douhard et al., 2016). Increased summer insect harassment is also predicted to increase and further stress large herbivores both by the additional parasitic load and by decreasing the amount of time spent grazing as animals seek to outrun pests (Mallory and Boyce, 2018). Finally, many caribou and reindeer populations rely on sea and freshwater ice to facilitate their movement and migration: loss of ice may make some populations no longer viable (Mallory and Boyce, 2018).	
Arctic and Northern regions	Moose (*Alces alces*)	The distributional changes of Rangifer populations might be affected by the range expansions and the northward expansion of moose (Mallory and Boyce, 2018). This is due to increases in productivity on the tundra and more frequent wildfire activity resulted to improve habitat quality for moose in the northward.	*medium confidence*
North America	Geese (*Branta canadensis, Answer spp., Branta spp.*)	Phenological mismatch develops between the berries and migration timing may mean that Canadian geese no longer stop near some communities (Downing and Cuerrier, 2011).	*medium confidence*
Arctic and Northern regions	Berries (*Vaccinium spp., Rubus spp.* and others)	Berries are among the most important and widely consumed wild foods of plant origins in Arctic and northern regions (Vaara et al., 2013; Hupp et al., 2015; Boulanger-Lapointe et al., 2019). Berry production will be impacted by climate change, including snow cover, rainfall, soil moisture, air temperature, and availability of insect pollinators (Herman-Mercer et al., 2020) and possible risk from sea-level-rise associated soil salinization (Cozzetto et al., 2013). Increased growth of woody shrub vegetation, driven by increased temperatures, can also make moving across the land move difficult, impairing access to berry patches (Boulanger-Lapointe et al., 2019). Conversely, a recent modelling experiment suggested that the >2 °C warming experienced by Arctic communities over the past three	*high confidence*

		decades has had minimal impact on overall trail access (Ford et al., 2019). In Alaska, communities perceive berry abundance as declining and/ or becoming more variable (Kellogg et al., 2010; Hupp et al., 2015). In a Gwich'in community in Canada, Parlee and Berkes (2005) recorded that local women perceived climate change, especially extreme weather events as the greatest risk to traditional berry patches (cranberry, blueberry, and cloudberry). The expansion of trees and shrubs may cause shading and negatively impact the productivity of berry plants (Downing and Cuerrier, 2011; Lévesque et al., 2012). Berries are predicted to be increasingly susceptible to negative impacts of invasive species (which compete for pollinators) as climate change progresses (Spellman and Swenson, 2012) and infections (Turner and Clifton, 2009). Suitable area of Huckleberry (*Vaccinium membranaceum*) would shrink by 5–40% by the end of the 21st century (Prevéy et al., 2020). Phenological shifts are also important. Many communities report changes in phenology including failed ripening or "all of the berries are ripening at the same time" (Turner and Clifton, 2009; Herman-Mercer et al., 2020). Competition with growing populations of geese is viewed by many communities to be an important threat to berry harvesting. (Boulanger-Lapointe et al., 2019). In Labrador, Canada report that changes in permafrost, vegetation, water, and weather have had an impact on cloudberry (bakeapple) productivity, phenology, and patch fragmentation. Moreover, changes in summer settlement patterns (which are now farther from berry patches) are making it more difficult for people to respond to variations in growth and timing (Anderson et al., 2018). In Montana, USA, Crow Nation elders have noted that many of their important berry resources have been impacted by climate change, either because they bud earlier and are then vulnerable to cold snaps, or the timing of fruit production has changed (with many now ripening at the same time) (Doyle et al., 2013). Similarly, the Wabanaki Nations in Maine and Eastern Canada worry that climate change will impact berry resources already under pressure from dwindling territory and pollution (Lynn et al., 2013).	
North America (Washington State, USA)	Salmon (*Salmonidae*)	Indigenous communities in Washington State, USA report devastation of their salmon fishery due to loss of glacial run off and associated warming river and stream temperatures; potential damage to shellfish resources due to sea level rise and ocean acidification (Lynn et al., 2013). The Karuk people in California have also experienced losses in salmon (Lynn et al., 2013; Vinyeta et al., 2016).	*Medium confidence*
North America (California)	Acorns form oak trees (*Querus)*	In the arid south-west of the USA, wild foods are less widely consumed today, but their revitalization is important to identity and well-being of many Indigenous people. The Karuk people of the Klamath River in California have experienced an almost complete loss of two key traditional wild foods: salmon and acorns, foods which once made up 50 % of a traditional Karuk diet (Lynn et al., 2013; Vinyeta et al., 2016), as well as huckleberry (Vinyeta et al., 2016). Using regional climate models, Kueppers (2005) showed a	

		major reduction in the range of two species of oak in California that are used in traditional diets. Increasing frequency of severe fires in the western United States threaten a number of traditional wild food resources, especially acorns (Vinyeta et al., 2016).	
North America	Wild rice (*Zizania spp*.)	Significant reductions in wild rice area in Great lakes havebeen associated with mining, dams, and other activities but climate change may lead to further reductions (Cozzetto et al., 2013; Lynn et al., 2013)	*high confidence*
North America	Camas tuber (*Camassiaquamash*)	Historic changes in fire regimes, linked to changes in climate, are believed to have altered availability of the important Camas tuber (*Camassiaquamash*) (Lepofsky et al., 2005).	*medium confidence*
North America	Wapato tuber *(Sagittaria latifolia)*	The aquatic *Sagittaria latifolia* (the roots of which are consumed by Indigenous groups across North America) is vulnerable to both water salinity and temperature (Delesalle and Blum, 1994)	*medium confidence*
North America	Springbeauty *(Claytonia lanceolate)*	*Claytonia lanceolata* is particularly vulnerable to changes in snow melt and other climatic changes due to advancement in the flowering (Renner and Zohner, 2018).	*medium confidence*
North America	Seaweed (*Porphyraabbottiae;* among others)	In British Columbia, Canada, Gitga'at elders note that the ripening of an important edible seaweed (*Porphyraabbottiae*) rarely coincides with weather and needed to process in the traditional way (drying on rocks and then ripening and re-drying) (Turner and Clifton, 2009).	*low confidence*
Africa	Baobab (*Adansonia digitata*)	Baobab is thought to be vulnerable to climate change because it is long-lived, can take up to 23 years to start fruiting and leaf harvesting is often so intensive that it depresses fruit production. Modeling study using different records model shows the percentage of present distribution predicted to be suitable in the future ranged varied from 5% to 91% (Sanchez et al., 2011).	*low confidence*
Africa	Shea (*Vitellaria paradoxa*)	Shea (*Vitellaria paradoxa*), was expanded through human intervention and is linked to human migration; fruit traits such as fruit size and shape, pulp sweetness, and kernel fat content are determined both by temperature and rainfall, as well as human selection for preferred traits (Maranz and Wiesman, 2003). There is limited and conflicting evidence of the impacts of climatic conditions and future projected climate variations on *V. paradoxa* (Tom-Dery et al., 2018). Mixed evidence of the impact of climate and rainfall on fruit production and timing is reported (Tom-Dery et al., 2018). Fruit production was negatively correlated with mean annual temperature and positively correlated with annual rainfall (Bondé et al., 2019).	*Limited evidence, medium agreement*
North Africa (Morocco)	Argan (*Argania spinosa*)	Climate change projections suggest a 32% decrease in habitat suitable for *Argania spinosa* under some scenarios (Alba-Sánchez et al., 2015; Moukrim et al., 2019).	*medium confidence*
Asia (Nepal)	Fruit species and vegetables (e.g., *Asparagus racemosus, Urticadioica*).	In Nepal, Thapa (2015) report phenological changes in semi-domesticated fruit species, as well as decreased availability of a number of wild plants that can be consumed as vegetables.	*Limited evidence, medium agreement*
Worldwide, most important in Europe and Asia	Mushrooms	Wild mushrooms production (including truffles) is closely linked to climate factors including temperature and precipitation as well tree growth and carbohydrate production (Tahvanainen et al., 2016). Some species are sensitive to high temperatures (Büntgen et al., 2012; Le Tacon et al., 2014; Ágreda et al., 2015; Bradai et al., 2015; Taye et al., 2016; Alday et al., 2017; Karavani et al., 2018; Büntgen et al., 2019; Thomas and Buntgen, 2019). Models	*high confidence*

		for some varieties suggest "declines of 78–100% in European truffle production are likely for 2071–2100" (Thomas and Buntgen, 2019). For some species in norther Europe, the season is expanding (starting earlier and/or ending later), likely linked to warming (Büntgen et al., 2012; Le Tacon et al., 2014; Ágreda et al., 2015; Bradai et al., 2015; Taye et al., 2016; Alday et al., 2017; Karavani et al., 2018; Büntgen et al., 2019; Thomas and Buntgen, 2019). Matsutake mushroom (*Tricholoma matsutake*), highly prized in China, is sensitive to timing and amount of precipitation and temperature (Yang et al., 2012), and suitable habitat for this species is predicted to significantly decrease and highly suitable habitat would nearly disappear under various climate change scenarios (Guo et al., 2017).	
North America (California)	Acorns, nuts and berries and other fire-dependant wild foods	Low intensity traditional burning practices increased pyro-diversity (Vinyeta et al., 2016). Climate change will exacerbate the risks posed by exotic pathogens that attack oak species and further reduce access to acorns, as well as other foods founds in oak ecosystems (Voggesser et al., 2013).	*high confidence*
South America (Amazon region)	Aguaje, (*Mauritia felxuosa),* Brazilian nut (*Bertholletiaexcelsa*) fishing and hunting in general	Local communities perceived a lower yield of aguaje Hofmeijer et al. (2013) due to drought. Another study from the Colombian Amazon wild food use was reported to be vulnerable to extreme climate events which impact species migration patterns or restrict access to fishing and hunting rounds (Torres-Vitolas et al., 2019). In some humid regions the range of some wild food species may be extended by climate change, such as the Brazilian nut (*Bertholletiaexcelsa*) (Thomas et al., 2014).	
Small Islands (Papua New Guinea)	Sweet potato	Increases in the El Niño Southern Oscillation was associated with drought which increased sweet potato losses (Jacka, 2016) in highlands humid forest.	*Limited evidence, medium agreement*
Australasia (Australia)	General wild foods	Aboriginal communities in North Queensland, a humid tropical region of northern Australia reported some climate impacts on wild foods, however primarily for marine resources and those found in dry forest ecosystems (McIntyre-Tamwoy et al., 2013).	*Limited evidence, medium agreement*
Asia (Indonesia)	Sago (*Metroxylon sagu*)	People in a sago-dependent community in Papua Indonesia viewed climate variation as less important than other factors (logging, mining, infrastructure), but still expressed concerns about salinity of water supplies, floods, and reduced hunting success (Boissière et al., 2013).	*Limited evidence, medium agreement*

5.8 Ocean-based and Inland Fisheries Systems

The livelihoods of 10 to 12 percent of the world's population depend on fisheries and aquaculture (FAO, 2020c). Globally, fish provide more than 3.3 billion people with 20 % of their average per capita intake of animal proteins, reaching 50 % or more in countries such as Bangladesh, Cambodia, The Gambia, Ghana, Indonesia, Sierra Leone, Sri Lanka, and several Small Island Developing States (FAO, 2020c). Between 1961 and 2017, the average annual apparent global food fish consumption increased (3.1% per year; from 9.0 kg per person in 1961 to 20.5 kg in 2018), exceeding the rate of increase in consumption of meat from all terrestrial animals combined (2.1% annually, currently around 40 kg per person) (FAO, 2020d). Fish are a rich source of protein and specific vitamins and minerals (Khalili Tilami and Sampels, 2018), and are an essential food source in regions in need of nutritious, affordable food (Thilsted et al., 2016; FAO et al., 2018; Hicks et al., 2019; Cross-Chapter Box MOVING PLATE this Chapter).

Overall capture fishery production has remained relatively static since the 1990s, reaching 96.4 million tons in 2018, with over 87% of the production coming from marine environments and the rest from inland fisheries (FAO, 2020c). Finfish represent 85% of global marine seafood production, with small pelagic fishes (anchovies, sardines, and herrings) as the major contributor. Almost 60% of the total global marine catches come from China, Peru, Indonesia, the Russian Federation, the United States of America, India, Viet Nam, Japan, Norway, and Chile (FAO, 2020c). Inland fisheries are found on every continent other than Antarctica and provide 158 million people the equivalent of all dietary animal protein (McIntyre et al., 2016). Inland production accounted for 12 million tons in 2018, with nearly 70% of capture from low-income Asian and African countries (Harrod et al., 2018a).

The aquaculture and fisheries' share of GDP varies mostly from 0.01 to 10 percent (Cai et al., 2019), but the relative importance in countries' economies and welfare is greater in several low-income countries, especially in many African and Pacific Island states. Approximately 60 million people are directly employed along in fisheries value chains, from harvesting to distribution (Vannuccini et al., 2018), around 95% of those are in small-scale fisheries of low and middle-income countries, and almost half of them are women.

5.8.1 Observed Impacts

Ocean systems are already facing significant impacts of climate change. At the ocean surface, temperature has on average increased by 0.88 [0.68–1.01] °C from 1850–1900 to 2011–2020 (Fox-Kemper et al., 2021; Gulev et al., 2021). Marine heatwaves have increased in frequency over the 20th century, with an approximate doubling since the 1980s (*high confidence*), and their intensity and duration have also increased (*medium confidence*) (IPCC, 2021, Box 9.2). In the Northeast Pacific, for example, an intense and long-lasting marine heatwave during 2013 to 2015 bridged to the strong 2015-2016 El Niño (Tseng et al., 2017) resulted in over five years of warmer-than-normal temperatures affecting the migration, distribution and abundance of several marine species, including fisheries resources (Cornwall, 2019; Jiménez-Quiroz et al., 2019). The surface open ocean pH has declined globally over the last 40 years by 0.003–0.026 pH per decade (*virtually certain*), and a decline in the ocean interior pH has been observed in all ocean basins over the past 2–3 decades (*high confidence*) (Gulev et al., 2021). The ocean is losing dissolved oxygen (*very likely*) in the range of 0.5–3.3% between 1970 and 2010 for the 0–1000 m depth stratum (Bindoff et al., 2019; Canadell et al., 2021), salt content is being redistributed (*very likely*) (Liu et al., 2019a; Gulev et al., 2021), and vertical stratification is increasing (*virtually certain*) (HLPE, 2017a; Fox-Kemper et al., 2021; Ranasinghe et al., 2021). There is *high confidence* that all these new physical, chemical, and biological conditions affect marine organisms' physiology, distribution, and ecology, with an overall shift in biomass and species composition affecting ecosystem structure and function (Chapter 3). Under climate change, freshwater ecosystems are highly exposed to eutrophication, species invasion, and rising temperatures (Lynch et al., 2016; Hassan et al., 2020). Major threats to wetland fisheries include water stress, sedimentation, weed proliferation, sea-level rise, and loss of wetland connectivity (Naskar et al., 2018).

Changes in aquatic ecosystems directly affect humans by altering livelihood, cultural identity and sense of self, and seafood provision, quality, and safety. The state of marine fishery resources has continued to decline, with the proportion of fish stocks at biologically unsustainable levels of exploitation increasing from 10 percent in 1974 to 34.2 percent in 2017 (FAO, 2020d). There is *medium confidence* that fisheries production declines in different world regions can be partly attributed to climate change, along with overfishing and other socio-economic factors. It has been estimated that, from 1930 to 2010, the amount of fish that can be sustainably harvested from several marine fish populations has decreased by 4.1% globally due to ocean warming, with some regions (East Asian Marginal Seas, the North Sea, the Iberian Coast, and the Celtic-Biscay Shelf), experiencing losses of 15-35% (Free et al., 2019). There is regional variation such as redistribution of fishing grounds, due to climate-induced fish species migrations (Cross-Chapter Box MOVING PLATE this Chapter). In Tanzania, for example, most small-scale fishers (75 %) have reported shifting fishing grounds from nearshore to offshore areas during the last decade, due to perceived combined effects of overfishing and environmental impacts (Silas et al., 2020). Observed impacts in some inland aquatic systems indicate substantial productivity reductions (*medium confidence*). For example, sustained warming in Lake Tanganyika during the last ~150 years has affected the biological productivity by strengthening and shallowing stratification of the water column (Cohen et al., 2016). Still, over 60% of the published reports on directly observed impacts of climate change on freshwater biota are on salmonids in

North America and Europe, highlighting significant literature gaps for other fish species and regions (Myers et al., 2017a).

There is *low confidence* in climate change affecting the nutritious value of seafood. Contrasting evidence suggests that ocean warming and acidification could be altering the nutritional quality of commercial mollusks, primarily by reducing healthy fatty acids content (Tate et al., 2017; Ab Lah et al., 2018; Lemasson et al., 2019); but Coleman (2019) found no significant changes in a widely distributed coastal fish species.

In terms of food safety, there is *high confidence* that climate change increases the trends in seafood consumption related illnesses due to biological agents such as algae-produced toxins, Ciguatera, and *Vibrio* (Cross-Chapter Box ILLNESS in Chapter 2, Sections 5.11 and 5.12). Increased surface water warming changes the occurrence, intensity, species composition, and toxicity of marine and freshwater algae and bacteria, and expansion to areas where they had not been reported before (Botana, 2016; McCabe et al., 2016; Griffith et al., 2019). There is *limited evidence* suggesting that risks linked to the bioaccumulation of chemicals are also of concern, such as neurotoxic methilmercury (MeHg) and heavy metals, due to water quality and trophic changes induced by climate change (Shi et al., 2016; Schartup et al., 2019).

5.8.2 Assessing Vulnerabilities

In the absence of adaptive measures, climate-induced changes in the abundances and distributions of fish will impact the provision, nutrition, livelihood security of many people (*high confidence*) as well as regional and global trade patterns (*medium confidence*).

5.8.2.1 Food security: provision and nutrition

The importance of seafood in food security and nutrition is increasing, largely due to its contribution as high-quality food (*high confidence*) (Hicks et al., 2019), as seafood contains unique long-chain polyunsaturated fatty acids (LC-PUFAs) and highly bioavailable essential micronutrients—vitamins (A, B and D) and minerals (calcium, phosphorus, iodine, zinc, iron, and selenium). These compounds, often not readily available elsewhere in diets, have beneficial effects for adult health and child cognitive development (HLPE, 2014). Changes in marine and freshwater fish production can have significant consequences for human nutrition (Colombo et al., 2020). These changes are of particular concern in regions with few nutrition alternatives, such as low-income countries in Africa, Asia, Australasia, and Central and South America (*high confidence*) (Ding et al., 2017; Kibria et al., 2017).

Freshwater ecosystems that support most inland fisheries are under continuing threat from changes in land use, water availability and pollution and other pressures that will be exacerbated by climate change (*high confidence*) (Section 4.3.5). Declines in dissolved oxygen in freshwater are 2.75 to 9.3 times greater than observed in the world's oceans (Jane et al., 2021). These systems have a relatively low buffering capacity and are therefore more sensitive to climate-related shocks and variability (Harrod et al., 2018b). Freshwater faunae are projected to be highly vulnerable; in the tropics because organisms are closer to approaching their thermal physiological limits and in the northern hemisphere (30-50°N) because the rate of temperature change is faster (Comte and Olden, 2017). The worldwide spatial confluence of productive freshwater fisheries and low food security highlights the critical role of rivers and lakes in providing locally sourced, low-cost, nutritious food sources (McIntyre et al., 2016).

Deltas and other wetland fisheries are extremely vulnerable to climate change and home to a large and growing proportion of the world's population. In India, Ghana, and Bangladesh, where three of the most populated Deltaic systems are located, subsistence fisheries provide 12 to 60% of the animal protein in people´s diets (Lauria et al., 2018).

The concern over aquatic food products' safety due to climate change is increasing (*high confidence*). A strong positive relationship exists between specific bacterial growth rates and temperature, including pathogenic species of the genus *Vibrio, Listeria, Clostridium, Aeromonas, Salmonella, Escherichia,* and others, whose distributional area is expanding with changing climate conditions (Cross-Chapter Box ILLNESS in Chapter 2, Section 5.12.1).

5.8.2.2 Social vulnerabilities, including gender and marginalized groups and cultural services

There is *high confidence* that climate change is and will continue to be a threat to the livelihood of millions of fishers, with the most vulnerable being those with fewer opportunities and less income (Barange and Cochrane, 2018); Section 3.4.3. The social vulnerability can differ largely between locations, even between relatively close coastal or inland communities (Bennett et al., 2014; Maina et al., 2016; Ndhlovu et al., 2017; Martins et al., 2019) and among inhabitants within a location, depending on factors such as access to other economic activities, education, health, adults in the household, and political connections (*high confidence*) (Senapati and Gupta, 2017; Abu Samah et al., 2019; Lowe et al., 2019).

Indigenous coastal communities consume 1.5 million to 2.8 million metric tonnes of fish per year (about 2% of global yearly commercial marine catch), and reach a per capita consumption estimated to be 15 times greater than that of non-Indigenous country populations (Cisneros-Montemayor et al., 2016). There is *high confidence* that some Indigenous fishing communities are particularly vulnerable to climate change through a reduced capacity to conduct traditional harvests because of limited access to, or availability of, fish resources (Weatherdon et al., 2016), with consequences that include dietary shifts with significant nutritional and health implications (Marushka et al., 2019), displacement and loss of cultural identity (Sullivan and Rosenberg, 2018) and loss of social, economic, and cultural rights (Finkbeiner et al., 2018). Areas of high risk for Indigenous Peoples include the Arctic, coastal communities with a high dependency on marine and freshwater fisheries, and small island states and territories (Finkbeiner et al., 2018; Hanich et al., 2018, CCP6.2.5.1).

Women play a crucial role along the entire fisheries value chain, providing labour force in industrialized and small-scale fisheries all around the world (FAO, 2020d). For small-scale fisheries alone, women represent about 11% of the labour force, and their activity is generally in subsistence fisheries, highlighting their role in household food security (Harper et al., 2020). In general, gendered division of labour tend to cause lower salaries for women and different perception and experience of risk to climate change impacts (*high confidence*) (Lokuge and Hilhorst, 2017).

5.8.2.3 Management, economic and geopolitical vulnerabilities

Local, national, regional, and international fisheries are mostly underprepared for geographic shifts in marine animals driven by climate change over the coming decades (*high confidence*) (Pinsky et al., 2018; Oremus et al., 2020; Pinsky et al., 2020). With fisheries distribution changes, sometimes into areas dedicated to different historical uses or new ventures, the current management regimes will face constraining legal frameworks (Farady and Bigford, 2019; Pinsky et al., 2020), which will demand interventions in the form of policies, programs, and actions, at multiple scales.(Cross-Chapter Box MOVING PLATE this Chapter). Coordinated fisheries management can substantially expand capacity to respond to a changing climate (Pinsky et al., 2020), but a great deal of political will, capacity building, and collective action will be necessary (*high confidence*) (Teslic´ et al., 2017; Burden and Fujita, 2019; Section 5.8.4).

Today, approximately half the world's population (~4 billion out of 7.8 billion people) are assessed as being currently subject to severe water scarcity for at least one month per year (*medium confidence*) (Box 4.1), and freshwater inland fisheries are particularly vulnerable as they are given lower priority for water resources than other sectors (*high confidence*). In some cases, this situation results in the total loss of freshwater fisheries. Examples include diversion of water for agriculture, shifts from food provision to recreational fisheries, conserving biodiversity, and the requirement for high-quality water for drinking water supply (Section 5.13, Harrod et al., 2018a).

There is *high confidence* that climate change increases the risk of conflicts due to the redistribution of stocks and their abundance fluctuations, with subsequent impacts on resource sharing (Spijkers and Boonstra, 2017; Pinsky et al., 2018; Spijkers et al., 2018; Mendenhall et al., 2020; Pinsky et al., 2020). High vulnerability and lack of adaptive capacity to climate change impacts (including fisheries-dependent livelihoods, attachment to place, and pre-existing tensions) increase the risk of conflicts, including among fishery area users and authorities (Ndhlovu et al., 2017; Shaffril et al., 2017; Spijkers and Boonstra, 2017; Mendenhall et al., 2020). Similarly, shifts in the distribution of transboundary fish stocks under climate change alter the current sharing of resources between countries and create conflicts as well as new opportunities (Cross-Chapter Box MOVING PLATE this Chapter, Spijkers and Boonstra, 2017; Pinsky et al., 2018).

5.8.3 Projected Impacts

There is *medium confidence* that climate change will reduce global fisheries' productivity (Section 3.4.4.2.3), with more significant reductions in tropical and sub-tropical regions and gains in the poleward areas (Bindoff et al., 2019; Oremus et al., 2020). Through an ensemble of marine ecosystem models and earth system models, mean global animal biomass in the ocean has been estimated to decrease by 5% under the Representative Concentration Pathway (RCP)2.6 emissions scenario and 17% under RCP8.5 by 2100, with an average decline of 5% for every 1°C of warming (Lotze et al., 2019), affecting food provision, revenue distribution, and potentially hindering the rebuilding of depleted fish stocks (Britten et al., 2017). The projected declining rates result in a 5.3-7% estimated global decrease in marine fish catch potential by 2050 (Cheung et al., 2019), particularly accentuated in tropical marine ecosystems and affecting many low-income countries (Barange and Cochrane, 2018; Bindoff et al., 2019; Cross-Chapter Box MOVING PLATE this Chapter). Projections indicate that by 2060 the number of exclusive economic zones (EEZ) with new transboundary stocks will increase to 46 under strong mitigation RCP2.6, and up to 60 EEZs under the RCP8.5 greenhouse gas emissions scenario (Pinsky et al., 2018). Similarly, by combining six intercompared marine ecosystem models, (Bryndum-Buchholz et al., 2019) projected that under the RCP8.5 scenario a total marine animal biomass decline of 15%–30% would occur in the North and South Atlantic and Pacific, and the Indian Ocean by 2100. In contrast, polar ocean basins would experience a 20%–80% increase. In the eastern Bering Sea, simulations based on RCP8.5 predict declines of pollock (>70%) and cod (>35%) stocks by the end of the century (Holsman et al., 2020). Temperate tunas (albacore, Atlantic bluefin, and southern bluefin) and the tropical bigeye tuna are expected to decline in the tropics and shift poleward by the end of the century under RCP8.5, while skipjack and yellowfin tunas are projected to increase abundance in tropical areas of the eastern Pacific but decrease in the equatorial western Pacific (*medium confidence*) (Erauskin-Extramiana et al., 2019). In the western and central Pacific, redistribution of tropical tuna due to climate change is projected to affect license revenues from purse seine fishing and shift more fishing into high seas areas (Bell et al., 2018a; Table 15.5). For the east Atlantic, observational evidence indicates that not only will tuna distribution change with temperature anomalies, but also fishing effort distribution (Rubio et al., 2020a). There is *medium confidence* that climate change will create new fishing opportunities when exploited fish stocks shift their distribution into new fishing regions in enclosed seas, such as the Mediterranean and the Black Sea (Hidalgo et al., 2018; Pinsky et al., 2018). However, in general, where land barriers constrain the latitudinal shifts, the expected impacts of climate change are population declines and reduced productivity (*high confidence*) (Oxenford and Monnereau, 2018). Besides direct impacts on the abundance of fisheries-targeted species, climate-change-induced proliferation of invasive species could also affect fishery's productivity (*low confidence*) (Mellin et al., 2016; Goldsmith et al., 2019).

Shifting marine fisheries will affect national economies (*high confidence*) (Bindoff et al., 2019). It has been suggested that without government subsides, fishing is already non-profitable in 54% of the international waters (Sala et al., 2018). Projections are that Fishing Maximum revenue potential from landed catches will decrease further by 10.4% (±4.2%) by 2050 relative to 2000 under RCP8.5, close to 35% greater than the decrease projected for the global maximum catch potential (7.7% ±4.4%); (Lam et al., 2016). The global revenue potential loss for that period ranges from USD 6-15 billion (depending on the model), but impacts may be amplified at the regional scale for fisheries-dependent and low-income countries. The maximum revenue potential percentage decrease in the EEZ under RCP8.5 is estimated to be over 2.3 times larger than that of the high seas (Lam et al., 2016). Ocean acidification is also expected to drive large global economic impacts (*medium confidence*) (Cooley et al., 2015; Fernandes et al., 2017; Macko et al., 2017; Hansel et al., 2020), and there is *high confidence* that the integrated economic consequences of all interacting climate change-related factors would result in even larger losses. Changes in the frequency and intensity of extreme events will also alter marine ecosystems and productivity. Marine heatwaves can lead to severe and persistent impacts, from mass mortality of benthic communities to decline in fisheries catch (IPCC, 2021, Box 9.2). These events have *very likely* doubled in frequency between 1982 and 2016 and have also become more intense and longer (Smale et al., 2019; Laufkotter et al., 2020); for all future scenarios Earth System Models project even more frequent, intense, and longer-lasting marine heatwaves (Eyring et al., 2021; IPCC, 2021, Box9.2).

In addition to temperature and water availability stress, climate change will bring new water quality challenges in freshwater systems, including increased dissolved organic carbon and toxic metal loads (*high confidence*) (Chen et al., 2016). Harrod et al. (2018a) found that the two major inland fishery producers (China and India) will face significant stress in the future, a large group of countries that produce around 60 percent of total yield is projected to face medium stress, and a small group of 17 countries has the least severe repercussions (*medium confidence*). Climate warming may enhance northward colonization of water bodies of commercial freshwater species in the Arctic, where there are few ecological competitors (*medium confidence*) (Campana et al., 2020), but at the same time may also accentuate the age-truncation effect of harvesting, elevating the population's vulnerability to environmental perturbations (Smalås et al., 2019). Detailed information on many of the most important inland fisheries is limited.

In terms of food safety, major concerns linked to climate change include the continued trend of increasing Harmful Algal Blooms (HABs), and the quantity of pollutants reaching aquatic systems (Box 3.3; section 5.11).

5.8.4 Adaptation

Adaptation options in land and aquatic-based culturing food production systems include both governance actions and changes in the factors of production (Section 5.4.4, 5.5.4, Reverter et al., 2020). In contrast, adaptation options in fisheries are primarily concentrated in the socio-economic dimension, especially governance and management (Brander et al., 2018; Holsman et al., 2019), and given the scale of the problem, there are relatively few intentional, well-documented examples of implemented tactical responses (Bell et al., 2020).

The proportion of fisheries operating at levels that are considered biologically unsustainable by the FAO has increased from 10% in 1974 to 34.2% in 2017 (FAO, 2020d). There is *high confidence* that reducing stresses on marine ecosystems reduces vulnerability to climate change and augments resilience (Barange, 2019; Woodworth-Jefcoats et al., 2019; Ogier et al., 2020). Specifically, overfishing is the most critical non-climatic driver affecting the sustainability of fisheries, and therefore improving management could help rebuild fish stocks, reduce ecosystem impacts, and increase the adaptive capacity of fishing (*high confidence*); (Barange, 2019; Das et al., 2020). Pursuing sustainable fisheries practices under a low emissions scenario would decrease risk by 63%; in contrast, under the most extreme RCP 8.5, both profit and harvest decline relative to today even under the most optimistic assumptions about global fisheries management reforms (Gaines et al., 2018; Sumaila et al., 2019; Free et al., 2020).

One adaptation strategy in the fishing sector is developing the capacity to recognize and respond to new opportunities that might arise from climate change by establishing a policy and planning setting that augments the fishers' flexibility to change target species of fisheries or even engage in different productive activities. A key element would be the design and implementation of management schemes that consider flexible permits, sharing quotas, rethinking boundaries, and reference points in response to system changes (Brander et al., 2018; Cross-Chapter Box MOVING PLATE this Chapter). Large-scale distribution and productivity changes of commercial fish species will demand the ability to implement cooperative fishing strategies (Cisneros-Montemayor et al., 2020; Østhagen et al., 2020), and adjust multi-lateral treaties and other legal instruments used for managing shared transboundary ecosystems (Butler et al., 2019; Cross-Chapter Box MOVING PLATE this Chapter).

There is *high confidence* that making climate change and adaptive capacity a mainstream consideration in global, regional, environmental, and fisheries governance structures can improve the response capacity to ocean change (Gaines et al., 2018; Bindoff et al., 2019; Holsman et al., 2020; Ojea et al., 2020). For example, spatial management that includes strategies such as Territorial Use Rights for Fishing (TURFs), Locally Managed Marine Areas (LMMAs) and customary tenure is an approach that has climate change adaptation potential in small-scale fisheries but will require adjustments in governing and managing institutions that allow them to be more dynamic and flexible (Le Cornu et al., 2018). In regions where some of these measures have already been tested, institutional, legal, financial, and logistical barriers to successful adaptation have been encountered, such as market failures stemming from uncertainty around new or emerging species, or policy barriers derived from the fact that the creation of scientific information needed to change regulations is likely slower than the pace of changes in stocks (Peck and Pinnegar, 2018).

Adaptation capacity is limited by the financial capacity of some countries (Bindoff et al., 2019). For example, in West African fisheries, adaptation costs associated with replacing the loss of coastal ecosystems and productivity is estimated to require 5–10% of countries' Gross Domestic Product (Zougmoré et al., 2016). For Pacific Islands and Coastal Territories, fisheries adaptation will require significant investment from local governments and the private sector (Rosegrant et al., 2016), and reducing dependence on or finding alternatives to vulnerable marine resources (Johnson et al., 2020; Mabe and Asase, 2020).

Adaptive capacity is strongly associated with social capital (i.e., the networks, shared norms, values, and understandings that facilitate co-operation within or among groups) (*high confidence*) (Stoeckl et al., 2017; D'agata et al., 2020) and depends on to what extent are stakeholders aware of climate change and their perception of risk (Ankrah, 2018; Martins and Gasalla, 2018; Chen, 2020). Improving information flows allows for a more efficient co-management implementation (*medium confidence*) (Vasconcelos et al., 2020). Utilization of local and Indigenous knowledge has the potential to facilitate adaptation (Bindoff et al., 2019), not only because it represents actual experiences and autonomous adaptations, but also because it facilitates reaching shared understanding among stakeholders and adoption of solutions. Challenges to hybridizing local ecological knowledge and scientific knowledge include differences in stakeholder or governance perceptions about the validity of each knowledge set and issues of expertise and trust (Harrison et al., 2018). Engaging Indigenous Peoples and local communities as partners across climate research ensures this knowledge is utilized, enhancing the usefulness of assessments (Bindoff et al., 2019) and facilitating the co-construction and implementation of sustainable solutions (*medium confidence*); (Braga et al., 2020; Bulengela et al., 2020). Building climate resilience in the fishing sector also involves recognizing gender and other social inequities (Call and Sellers, 2019), and ensure that all stakeholders are equally involved in the adaptation plans, including their design and the capacity-building training programs.

There is *high confidence* that for the freshwater fisheries systems, the most immediate adaptation option is the effective linkage of fisheries management to the adaptation plans of other sectors, especially water management (hydropower, irrigation, and the commitment to maintaining environmental flows) (Harrod et al., 2018a; Kao et al., 2020). In some regions, organizations are already addressing this issue, for example The Office of Water (OW) in the USA is aimed at ensuring that drinking water is safe while ecosystem is conserved to provide healthy habitat for fish, plants and wildlife; however, success strongly depends on the possibility of integrating the jurisdictional framework of different agencies (Poesch et al., 2016), the implementation of effective monitoring programs (Paukert et al., 2016), and finding ways to incentivize the early restoration of degraded systems (Ranjan, 2020).

Cross-Chapter Box: MOVING PLATE: Sourcing food when species distributions change

Authors: H. Gurney-Smith (Canada/United Kingdom), W. Cheung (Canada), S. Lluch Cota (Mexico), E. Ojea (Spain),C. Parmesan (France/United Kingdom/USA), J. Pinnegar (United Kingdom) P. Thornton (Kenya/United Kingdom), M-F. Racault (United Kingdom/France), G. Pecl (Australia), E.A. Nyboer (Canada), K. Holsman (USA), K. Miller (USA), J. Birkmann (Germany), G. Nelson (USA) and C. Möllmann (Germany)

This Cross-Chapter Box the 'moving plate' addresses climate-induced shifts and domesticated production suitability of food species consumed by people. Marine, freshwater, and terrestrial systems are already experiencing species shifts in response to climate change (*very high confidence*) (see also Sections 2.4.2.1.and 3.4.3., Figure Cross-Chapter Box MOVING PLATE.1), with subsequent impacts on food provisioning services, pests, and diseases (*high confidence*) (see Box 5.8 and Cross-Chapter Box ILLNESS in Chapter 2). This Box highlights food insecurity and malnutrition of vulnerable peoples under climate change for both wild and domesticated aquatic and terrestrial species, discusses challenges for adaptation, and the roles that management (transboundary and ecosystem-based) can play to enable food security, reduce conflicts, and prevent resource over-extraction.

Range contractions, shifts or extirpations are projected for terrestrial and aquatic species under warming with greater warming leading to larger shifts and losses, where mitigation would therefore benefit climate refugia and reduce projected biodiversity declines (Smith et al., 2018; Warren et al., 2018). Marine species are moving poleward faster than terrestrial and freshwater species, despite faster warming on land (Pecl et al., 2017; Lenoir et al., 2019; Woolway and Maberly, 2020), leading to new or exacerbated socio-economic conflicts within and between countries (see Figure Cross-Chapter Box MOVING PLATE.1, see Sections 13.5.2.2., 15.3.4.4., FAQ 15.3., Mendenhall et al., 2020). There is large variation in the magnitude and pattern of species shifts, even among similar species within a region, leading to changes in communities in a given region (Brown et al., 2016; Pecl et al., 2017). The number of extreme heat stress days are projected to increase for domesticated species like cattle (see Figure Cross-Chapter Box MOVING PLATE.1), leading to shifts in suitable habitat for raising livestock in the open with associated impacts in animal productivity and the costs of adapting in Africa, Asia, Central and South America (Thornton et al., 2021).

Nutritional dependency, cultural importance, livelihood, or economic reliance on shifting species will increase impacts of climate change, especially for small scale fishers (marine and freshwater), farmers, women, and communities highly dependent on local sources of food and nutrition (*high confidence*) (see Figures Cross-Chapter Box MOVING PLATE.1 and 3, Sections 3.5.3., 8.2.1.2. and 15.3.4.4, McIntyre et al., 2016; Blasiak et al., 2017; Kifani et al., 2018; Bindoff et al., 2019; Atindana et al., 2020; Hasselberg et al., 2020; Farmery et al., 2021). Micronutrient concentrations from marine fisheries vary with species, providing higher concentrations of calcium, iron and zinc in tropical regions and higher concentrations of omega-3 fatty acids in polar regions (Hicks et al., 2019). While consumption of smaller species rich in micronutrients may provide significant benefits against deficiencies in Asia and Africa, local dietary changes in fish consumption may be linked to food preferences, fish availability due to international trade or illegal fishing and competing usage of fish (see Figure Cross-Chapter Box MOVING PLATE.3, Hicks et al., 2019; Sumaila et al., 2020; Vianna et al., 2020). Industrial fleets are likely to switch target species (Belhabib et al., 2016) and inhibit small-scale fishers via illegal, unreported, or unregulated fishing in Exclusive Economic Zones (Belhabib et al., 2019; Belhabib et al., 2020). Extreme events can exacerbate issues, as fisheries are frequently increasingly exploited as a coping mechanism under times of crisis, increasing illegal fishing activities and conflict amongst maritime users (Pomeroy et al., 2016; Mazaris and Germond, 2018). Spatial conflicts between artisanal and commercial foreign fishing fleets are already occurring in Ghana (Penney et al., 2017), and from climate-induced tropical tuna shifts in the Western and Central Pacific Ocean Islands (see Section 15.3.4.4., (Bell et al., 2018a)). Properly managed small-scale fisheries can reduce poverty and improve localized food security and nutrition in low-incom countries but will likely require restriction in the number of fishers, boat size or fishing days (Purcell and Pomeroy, 2015; Hicks et al., 2019).

Shifting species have negative implications for the equitable distribution of food provisioning services, increasing the complexity of resolving sovereignty claims and climate justice (*high confidence*) (Allison and Bassett, 2015; Ayers et al., 2018; Baudron et al.; Ojea et al., 2020; Palacios-Abrantes et al., 2020). Higher latitude countries generally have higher GHG emissions and will benefit from poleward migrating resources from tropical poorer and lower-emitting GHG countries (Free et al., 2020). In this context, climate justice supporting fishing arrangements could offset socio-economic impacts from exiting species (Mills, 2018; Lam et al., 2020) and have negative implications particularly for small-scale operators (Farmery et al., 2021), However, considerations of climate justice have not been used by Regional Fisheries Management Organizations (RFMOs) allocation shares to date (Engler, 2020). Species shifting from one historical jurisdiction to another may result in an incentivized depletion of the resource by the country the stock is shifting away from; reforming management to allocate resource sharing of quotas and permits, or stock-unrelated side payments in bilateral or multilateral cooperative agreements may compensate or prevent loss (Diekert and Nieminen, 2017; Free et al., 2020; Ojea et al., 2020; Østhagen et al., 2020; Cross-Chapter Paper Polar 6.2.).

Strong governance, ecosystem-based and transboundary management are considered fundamental to ameliorate the impacts of climate change (*high confidence*) but may be limited in effectiveness by the magnitude of change projected under low or no mitigation scenarios (see Sections 2.6.2., 14.4.2.2. and 15.3.4.4., Harrod et al., 2018c; Pinsky et al., 2018; Holsman et al., 2020; Ojea et al., 2020). Flexible and rapid policy reform and management adaptation will help to meet sustainability targets (Nguyen et al., 2016; Pentz and Klenk, 2020), and may only be available for countries with the scientific, technical, and institutional capacity to implement these (*high confidence*) (Peck and Pinnegar, 2018; Figures Cross-Chapter

Box MOVING PLATE.2 and 3). Other adaptation options include 'follow the food' thereby migrating further (Belhabib et al., 2016), provision of alternative livelihoods (Thiault et al., 2019; Cross-Chapter Box MIGRATE in Chapter 7, Free et al., 2020), increasing ecosystem resilience by rebuilding coastal mangroves (Tanner et al., 2014; and Box 1.3) and riparian areas of freshwater ecosystems (Mantyka-Pringle et al., 2016) and autonomous adaptations, such as harvesting gear modifications to access new target species (Harrod et al., 2018c; Kifani et al., 2018), practice change, and early-warning systems (see Section 11.3.2.3; Pecl et al., 2019; Melbourne-Thomas et al., 2021). Adaptive capacity will change with country, region, scale (commercial, recreational, Indigenous) of fishery, jurisdiction and resource dependence (see Figure Cross-Chapter Box MOVING PLATE.2 for adaptation options for marine, freshwater, and terrestrial systems). Whilst shifting fishing fleets or herding may be an adaptation option to follow resources, limits to feasibility include institutional, legal, financial, and logistical barriers such as costs of sourcing food and operational economic viability (Belhabib et al., 2016); this could potentially lead to maladaptation through increased greenhouse gas emissions from fuel usage and cultural displacement from traditional fishing and herding lands. Overall, decreases in greenhouse gas emissions under future scenarios would reduce increases in global temperatures and limit species shifts, thereby lowering the likelihood of conflicts and food insecurity (*high confidence*).

Coastal regions of the Gulf of Guinea: Ghanian fisheries

Marine fisheries in Ghana are dominated by artisanal fishers with overfished stocks, high nutritional fish dependency, high illegal fishing, low governance capacity (-0.21 2018, (World Bank, 2019)) and low climate awareness in regional fisheries management (Figure Cross-Chapter Box MOVING PLATE.3, see Chapter 9; Nunoo et al., 2014; Belhabib et al., 2015; Belhabib et al., 2016; Kifani et al., 2018; Belhabib et al., 2019). Artisanal fishing plays a pivotal role in reducing poverty and food insecurity, and the impacts of climate change will risk developing poverty traps (see Section 8.4.5.6., (Kifani et al., 2018)). Climate change induced species redistribution is a large risk to Ghanian fisheries, with projections of over 20 commercial fish species exiting the region with no new species entering under RCP4.5 by 2100 (Oremus et al., 2020), and has already seen increases in warmer-water species with declining stocks. Adaptation options being applied are extending fishing ranges increasing fishing effort (and cost) to access declining fish (with government fuel incentives) (Kifani et al., 2018; Muringai et al., 2021), developing aquaculture for alternative livelihoods, implementation of fleet monitoring to reduce illegal fishing and developing a robust Fisheries Information and Management System that accounts for environmental and climate drivers (Johnson et al., 2014; FAO, 2016; Kassi et al., 2018). However, fisheries remain insufficiently regulated, there is a lack of a skilled workforce, and there is low access to credit; collectively these factors limit options for artisanal fishers to find alternative sustainable employment (FAO, 2016).

Shifting distributions of freshwater fishery resources: knowledge gaps

Freshwater fisheries provide the primary source of animal protein and essential micronutrients for an estimated 200 million people globally and are especially important in tropical developing nations (see Section 9.8, Lynch et al., 2017; Funge-Smith and Bennett, 2019.). There is evidence that freshwater fishes have undergone climate-induced distribution shifts (Comte and Grenouillet, 2015; see Section 9.8.5.1.), and further shifts are projected as water temperatures rise and hydrological regimes change, with the largest effects predicted for equatorial, subtropical, and semi-arid regions (Barbarossa et al., 2021). Currently, the effects of distribution shifts on local fishery catch potential, food security, and/or nutrition have not been quantified for any major inland fishery, representing a key knowledge gap for anticipating future adaptation needs for freshwater fishing societies. However, studies on fishers' perceptions of climate-induced changes in fishery catch rates have revealed that using local knowledge to adjust management practices (see Chapter 12 Central and South America this volume; Oviedo et al., 2016) and shifting gears, fishing grounds and target species (see Section 9.8.5.3.; Musinguzi et al., 2016) can be effective adaptation options.

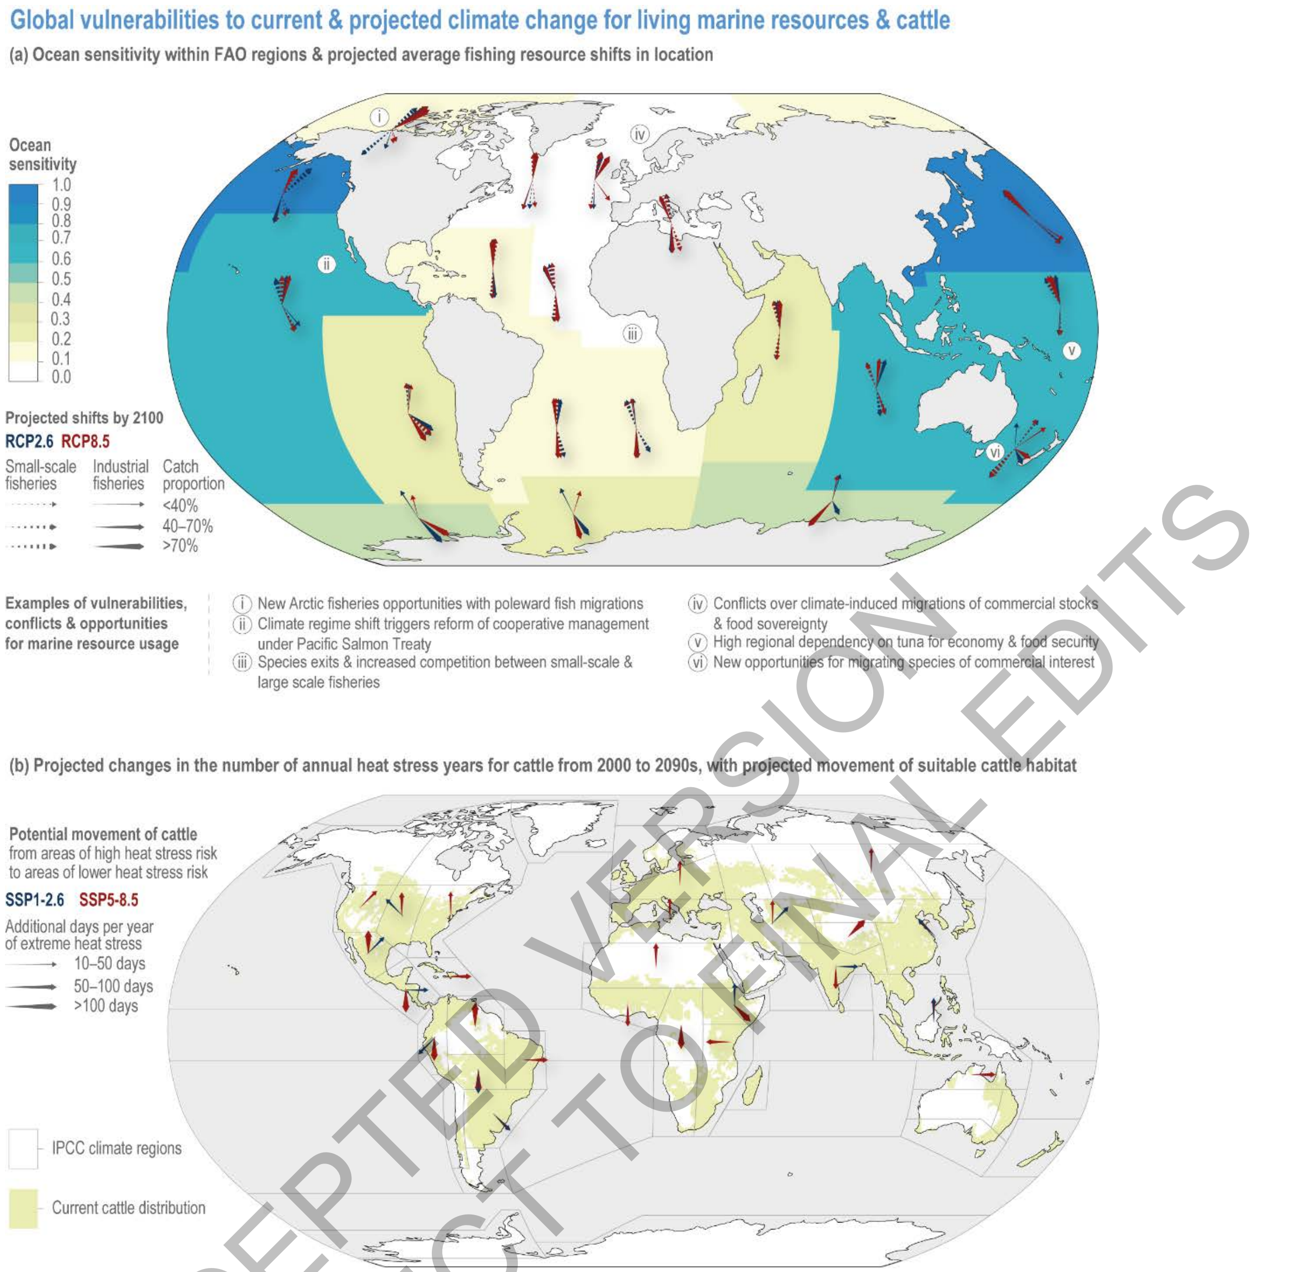

Figure Cross-Chapter Box MOVING PLATE.1: Global vulnerabilities to current and projected climate change for living marine resources and cattle. **a** - Ocean areas are delineated into FAO (Food and Agricultural Organization of the United Nations) regions. Ocean sensitivity is calculated from aggregated sensitivities from Blasiak et al. (2017) S1 country data based on number of fishers, fisheries exports, proportions of economically active population working as fishers, total fisheries landings and nutritional dependence, which was subsequently reanalyzed for each FAO region depicted here. Arrows denote projected average commercial (light blue) and artisanal (orange arrows) fishing resource shifts in location under RCP2.6 and under RCP8.5 (dark blue and red arrows respectively) scenarios by 2100. Text boxes highlight examples of vulnerabilities (Bell et al., 2018a), conflicts (Miller et al., 2013; Blasiak et al., 2017; Østhagen et al., 2020), or opportunities for marine resource usage (Robinson et al., 2015; Stuart-Smith et al., 2018; Meredith et al., 2019). **b** – Projected changes in the number of extreme heat stress days per year for cattle (*Bos taurus*, temperate sub-regions, grey background; *Bos indicus*, tropical sub-regions, orange background) from 2000 to the 2090s, shown as arrows rooted in the most affected area in each IPCC sub-region pointing to the nearest area of reduced or no extreme heat stress.. Arrows are shown only for sub-regions where > 1 million additional animals affected. Areas in green are those with >5000 animals per 0.5 degree grid cell (Thornton et al., 2021).

Terrestrial species shifts

There is *robust evidence* of shifts that terrestrial species have shifted poleward in high latitudes, with general declines of sea-ice dependent as well as some extreme-polar-adapted species (*high confidence*) (Arctic and Siberian Tundra, see Section 2.4.2.2., Cross-Chapter Paper 6), with often deleterious effects on the food security and traditional knowledge systems of Indigenous societies (Horstkotte et al., 2017; Pecl et al., 2017; Mallory and Boyce, 2018; Forbes et al., 2020). Recent decades have seen declines in Arctic reindeer and caribou (see Section 2.5.1., Cross-Chapter Paper 6) and adaptation responses include utilization of Indigenous knowledge with scientific sampling to maintain traditional management practices (Pecl et al., 2017; Barber et al.; Forbes et al., 2020). Preserving herder livelihoods will necessitate novel solutions (supplementary feeding, seasonal movements), where governance, ecological and socio-economic trade-offs will be balanced at the local level (Horstkotte et al., 2017; Pecl et al., 2017; Mallory and Boyce, 2018; Forbes et al., 2020). Wild meat consumption plays a critical, though not well understood, role in the diets and food security of several hundred million people (*medium evidence*), for example in lower latitudes such as central Africa and the Amazon basin (Bharucha and Pretty, 2010; Godfray et al., 2010; Nasi et al., 2011; Friant et al., 2020). Although illegal in many countries, wild meat hunting occurs either in places where there is no or limited domesticated livestock production, or in places where shock events such as droughts and floods that threaten food supply, forcing increased reliance on wild foods including bush meat (Mosberg and Eriksen, 2015; Bodmer et al., 2018). Appropriate management of wild meat for reliant peoples under projected climate change will necessitate incorporating social justice elements into conservation and public health strategies (see Cross-Chapter Box ILLNESS in Chapter 2, Cross-Chapter Box COVID in Chapter 7, Friant et al., 2020; Ingram, 2020; Pelling et al., 2021).

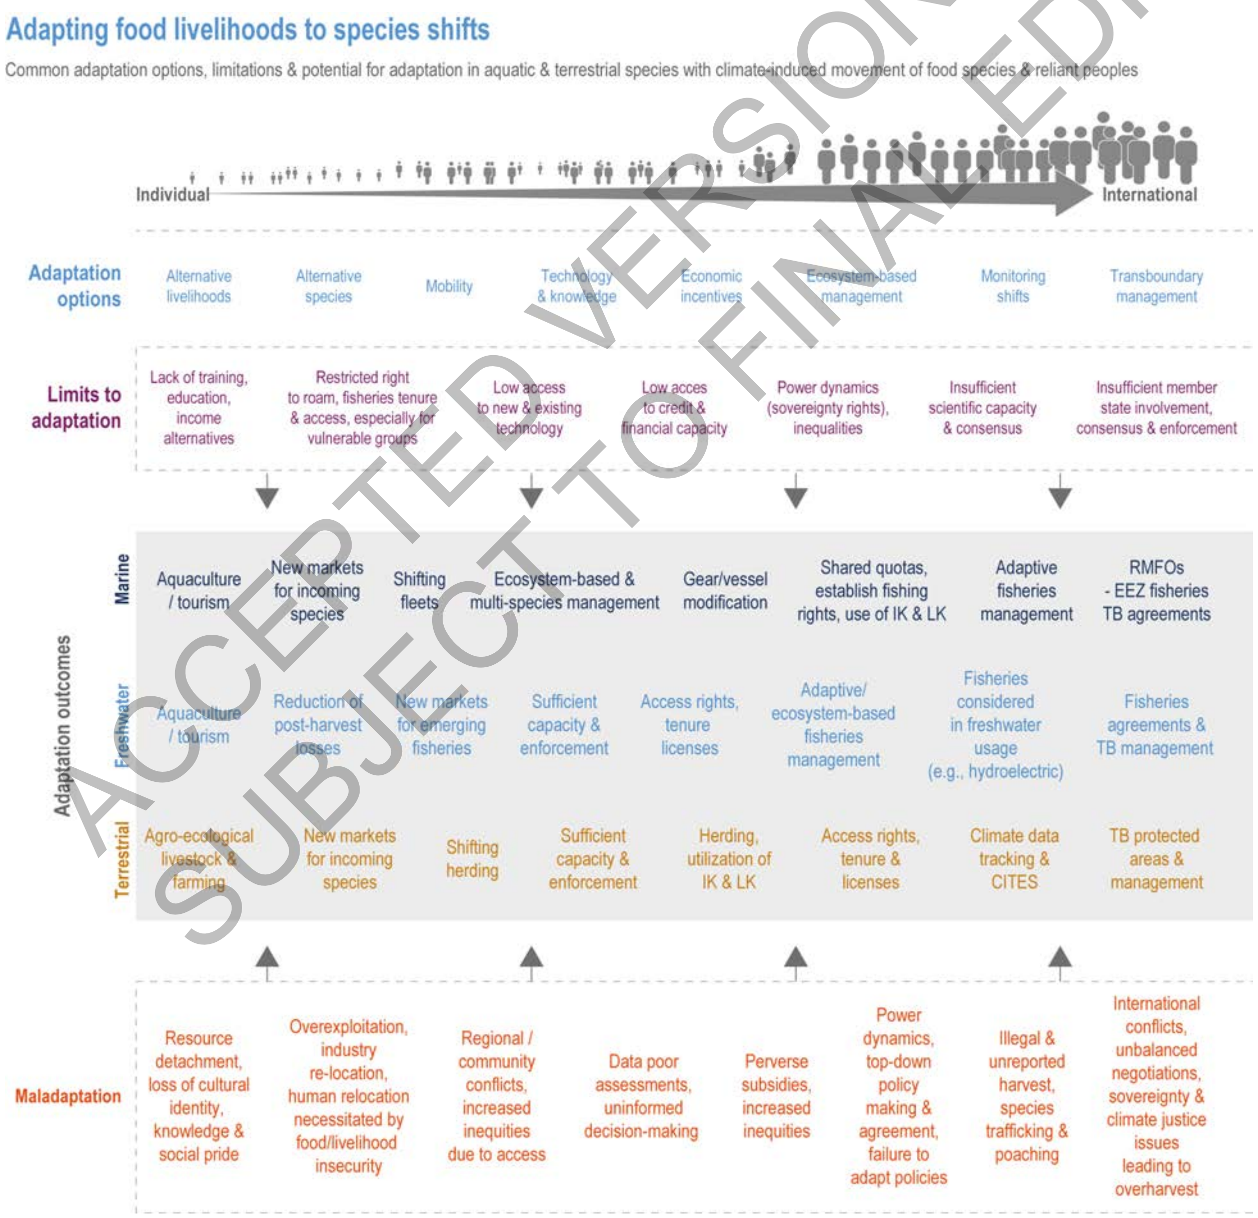

Figure Cross-Chapter Box MOVING PLATE.2: Common adaptation options, limitations, and potential for adaptation and maladaptation in aquatic and terrestrial species with climate-induced movement of food species and reliant peoples.

In terrestrial, marine, and freshwater systems human populations already impacted by poverty and hunger experience greater risk under climate change. Future food security will depend on access to other sustainable sources either via transnational agreements or resource / livelihood diversification. Sudden shocks across food production systems (Cottrell et al., 2019) can lead to increases in fisheries harvest and wild meat consumptions and following food species may result in community relocations or disruption and loss of access to historical places of attachment (*high confidence*) (Pecl et al., 2017; Lenoir et al., 2019; Meredith et al., 2019; Melbourne-Thomas et al., 2021; see Cross-Chapter Box MIGRATE in Chapter 7). Ecosystem based management approaches exist for terrestrial, marine and freshwater systems, but have proved successful only with early engagement of local small-scale, subsistence fishers / harvesters, utilizing Indigenous knowledge and local knowledge and needs, in addition to those of larger-scale operators (*high confidence*) (Huntington et al., 2015; McGrath and Costello, 2015; Huq and Stubbings, 2016; Huq et al., 2017; Raymond-Yakoubian et al., 2017; Nalau et al., 2018; Raymond-Yakoubian and Daniel, 2018; Pecl et al., 2019; Planque et al., 2019). Currently there is large regional differences in climate literacy in RFMOs (Sumby et al., 2021) which, when combined with low governance and GDP per capita, will limit adaptation capacity and increase vulnerabilities, particularly for tropical and sub-tropical regions already at increased risk due to poleward species migrations (see Figure Cross-Chapter Box MOVING PLATE.3). Trade will be an alternative to compensate for the moving plate but has specific risks that can amplify inequities and maladaptation (Asche et al., 2015; Vianna et al., 2020).

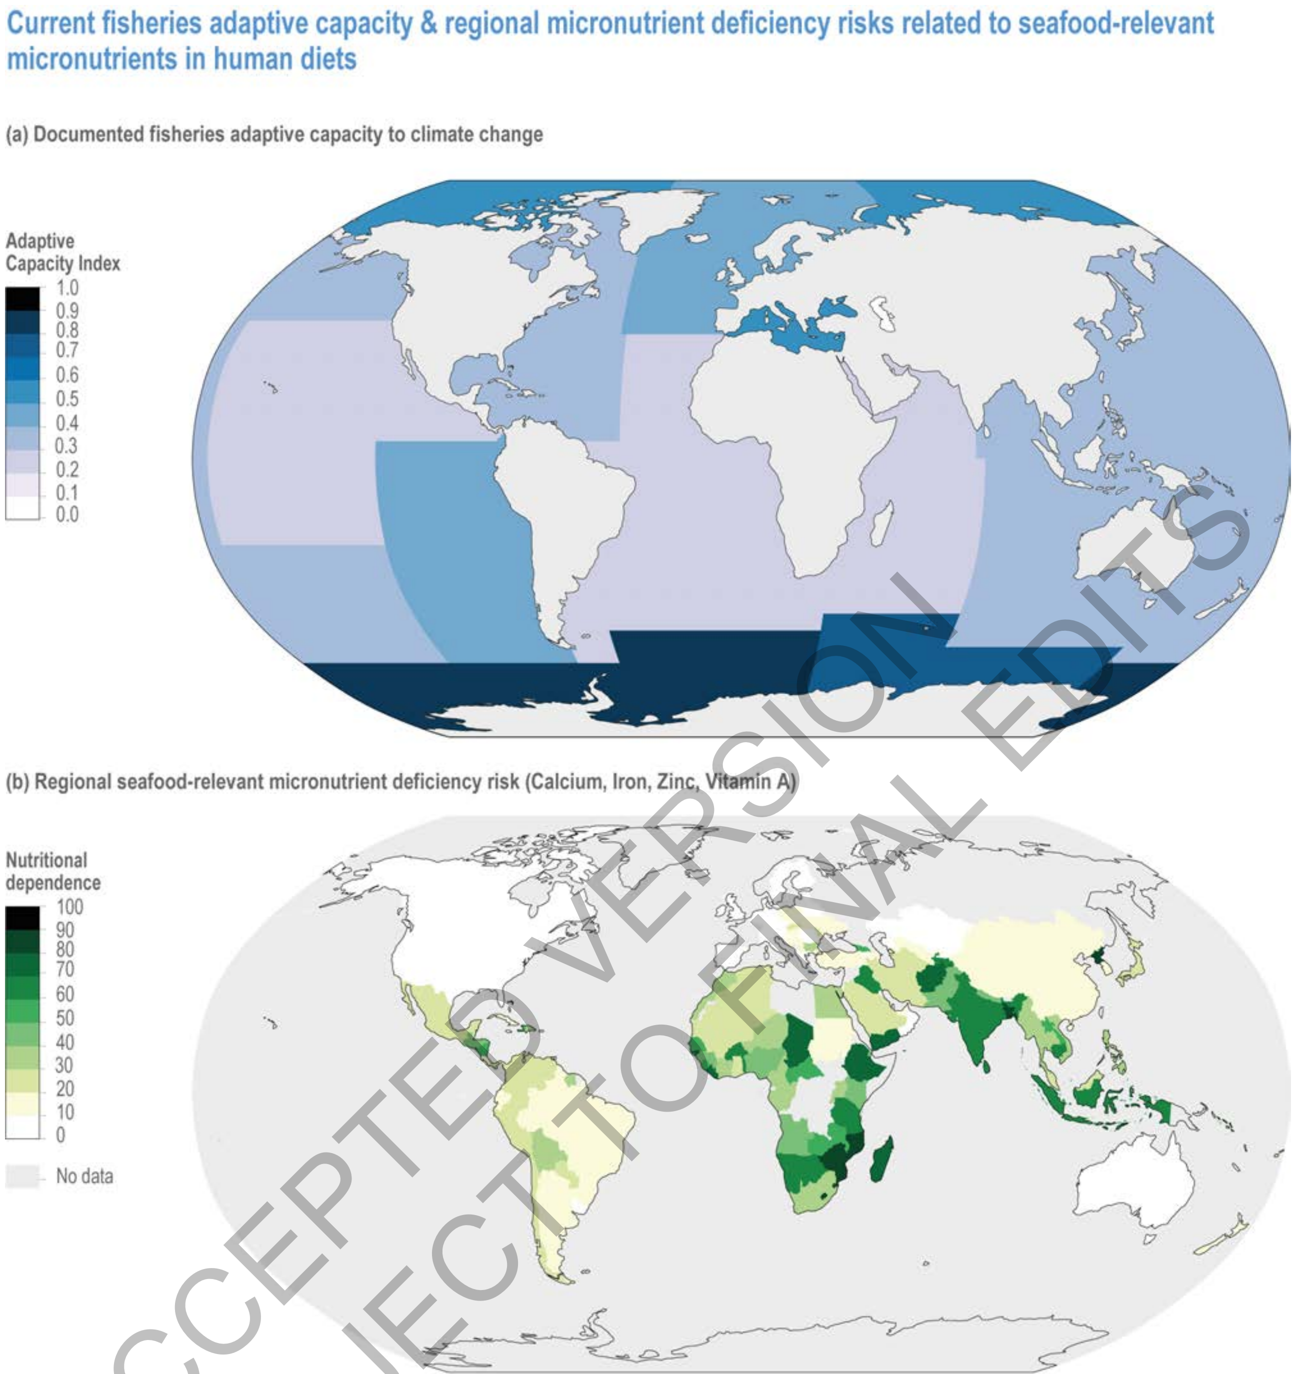

Figure Cross-Chapter Box MOVING PLATE.3: Global documented fisheries adaptive capacity to climate change and regional seafood micronutrient deficiency risk. Ocean areas are delineated into FAO (Food and Agricultural Organization of the United Nations) regions. Fisheries management adaptive capacity is a function of: averaged GDP World Development Indicators for 2018 (World Bank, 2020); climate awareness assessments of 30 of the FAO recognized most recent Regional Fisheries Management Organizations with direct fisheries linkages (see Supplementary Material SM5.5); governance effectiveness index based on six aggregate indicators (voice and accountability, political stability and absence of violence / terrorism, government effectiveness, regulatory quality, rule of law, control of corruption) from 2018 World Governance Indicator (World Bank, 2019) data, and; heterogeneity of countries within each FAO zone (highly heterogeneous regions are less likely to establish sustainable and efficient fisheries management for the entire FAO zone). Land area represents the percentage regional averaged seafood micronutrient deficiency risk of calcium, iron, zinc, and vitamin A from 2011 data (Beal et al., 2017).

[END CROSS-CHAPTER BOX MOVING PLATE HERE]

5.9 Ocean-based and Inland Aquaculture Systems
