Global aquaculture provides more fish for human consumption than wild capture fisheries, with projected provisioning of 60% by 2030 (FAO, 2018c). Aquaculture can contribute to SDGs by reducing poverty and food insecurity, filling increasing aquatic food demand shortages from declining capture fisheries production, (*medium confidence*) (Figure 5.13a and c, World Bank, 2013; Béné et al., 2016; Hambrey, 2017; Beveridge et al., 2018b; Kalikoski et al., 2018; Belton et al., 2020), improving social inequities for poor rural communities (Béné et al., 2016; FAO, 2018c; Vannuccini et al., 2018; Pongthanapanic et al., 2019). Global aquaculture production reached 82 million tonnes (Mt) of food fish, crustaceans, molluscs, and other aquatic animals from inland (51 Mt) and marine (31 Mt) systems, and 32 Mt of aquatic plants in 2018 (FAO, 2020d). China, India, Indonesia, Vietnam, Bangladesh, Egypt, Norway and Chile are major production regions (FAO, 2020d). The range of species, farming methods and environments makes aquaculture the most diverse, long-standing farming practice in the world with an estimated global sectoral value of USD 250 billion in 2018 (Figure 5.13b and 5.14d, Bell et al., 2019; Harland, 2019; FAO, 2020d; Houston et al., 2020; Metian et al., 2020), but is dominated by 20 finfish, 9 mollusc and 6 crustacean species (FAO, 2020). Inland aquaculture in freshwater and coastal ponds accounts for 85-90% of farmed production (Beveridge et al., 2018b; Naylor et al., 2021). Globally 20.5 million people are engaged in aquaculture (FAO, 2020d), where marine finfish farming is primarily conducted by high-income countries and inland production is dominated by small-scale producers in lower-middle-income countries (Vannuccini et al., 2018).

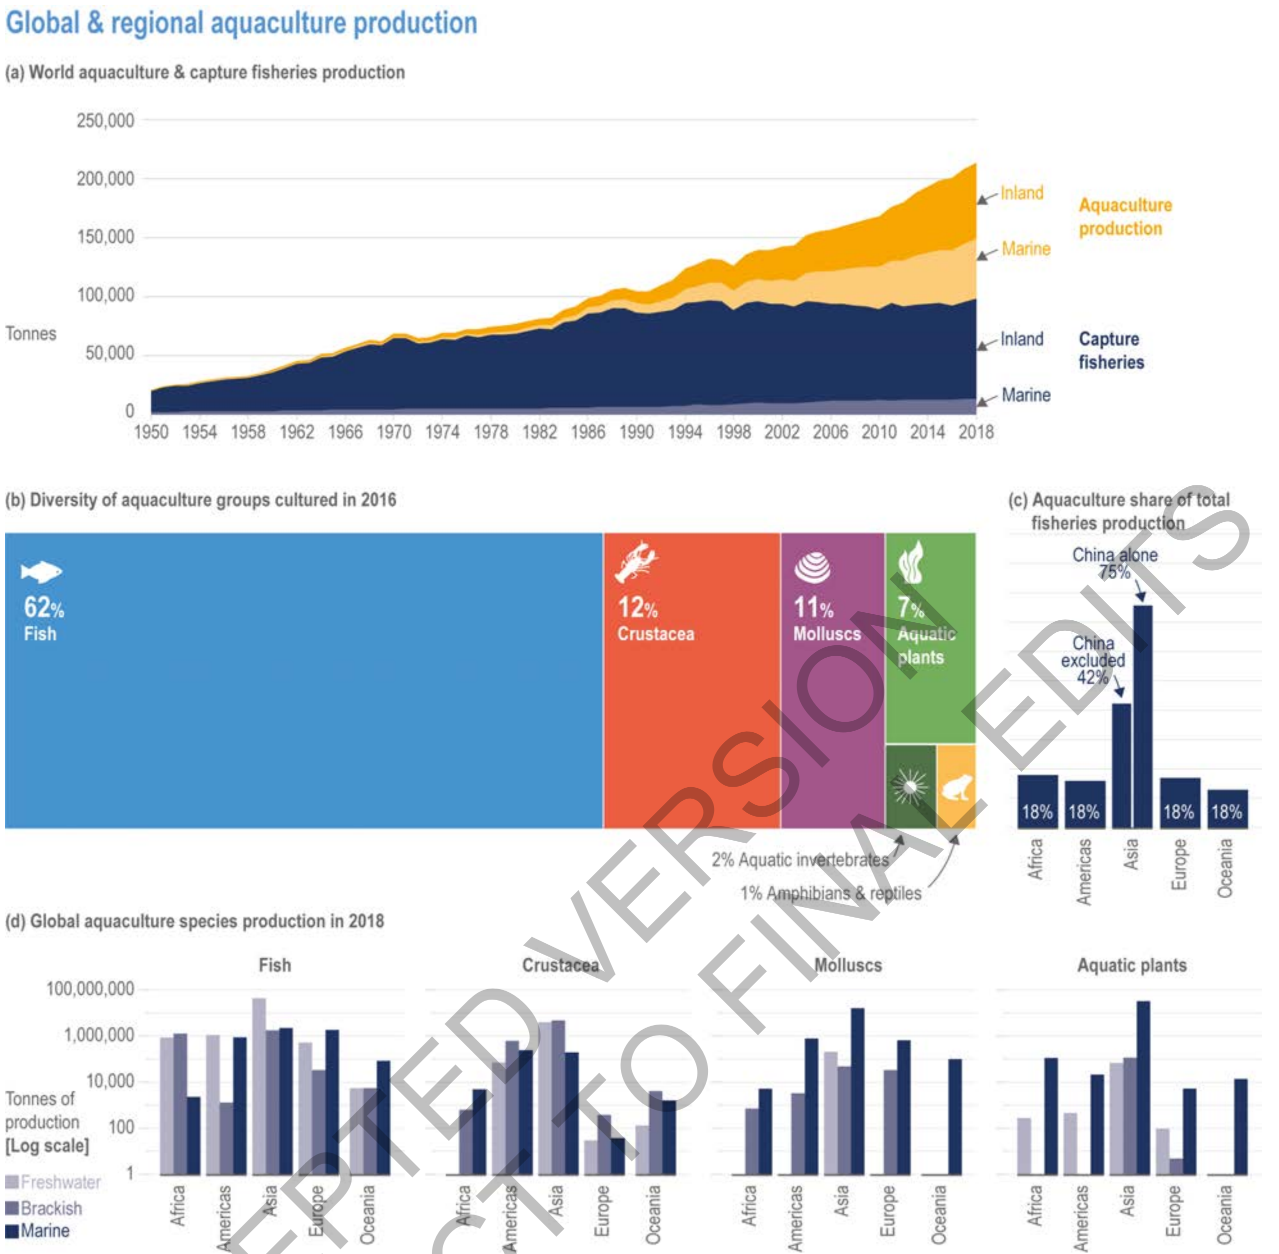

Figure 5.13: Global and regional aquaculture production a) world wild capture fisheries and aquaculture inland (freshwater and brackish) and marine production from 1950-2018, b) diversity of aquaculture groups cultured in 2016, and c) regional aquaculture share of total fisheries production, and d) global aquaculture species production in 2018 by region and type (freshwater, brackish, or marine) on a logged scale (FAO, 2018c; FAO, 2020c; FAO, 2020d).

5.9.1 Observed Impacts

Marine aquaculture food production is being impacted directly and indirectly by climate change (*high confidence*) (Bindoff et al., 2019). Ocean pH and oxygen levels are declining, whereas global warming, sea level rise and extreme events are increasing (Cross-Chapter Box SLR in Chapter 3, Canadell et al., 2021; Eyring et al., 2021; Fox-Kemper et al., 2021; Lee et al., 2021;). Marine heatwaves have been increasing in both incidence and longevity over the past century (Frolicher and Laufkotter, 2018; Oliver et al., 2018; Bricknell et al., 2021) with productivity consequences for marine aquaculture (mariculture), carbon sequestration and local species extinctions (*high confidence*) (Weatherdon et al., 2016; Smale et al., 2019). Temperature increases related to El Niño climatic oscillations have caused mass fish mortalities either through warming waters (e.g. Pacific threadfin in Hawaii (McCoy et al., 2017)), or associated harmful algal blooms (e.g. 12% loss of Atlantic salmon as well as other fish and shellfish in Chile in 2016 with estimated $800 million in losses (*high confidence*) (Clement et al., 2016; Apablaza et al., 2017; Leon-Munoz et al., 2018; Trainer et al., 2020)). Increases in sea lice parasite infestations on salmon are related to higher salinity and warmer waters (*medium confidence*) (Groner et al., 2016; Soto et al., 2019). Ocean acidification is having negative impacts on the sustainability of mariculture production (*high confidence*) (Bindoff et al., 2019) with observed impacts on shellfish causing significant production and economic losses for regions, estimated at losses of nearly USD $110 million by 2015 in the Pacific Northwest (Barton et al., 2015; Ekstrom et al., 2015; Waldbusser et al., 2015; Zhang et al., 2017b; Doney et al., 2020). Ocean oxygen levels are declining due to climate change (Hoegh-Guldberg et al., 2018; IPCC, 2021) and decreased oxygen (hypoxia) has negative impacts on fish physiology (Cadiz et al., 2018; Hvas and Oppedal, 2019; Martos-Sitcha et al., 2019; Perera et al., 2021), fish growth, behaviour and sensitivity to concurrent stressors (*high confidence*) (Stehfest et al., 2017; Abdel-Tawwab et al., 2019).

Observed impacts on inland systems have generally been site and region specific (*high confidence*) (Hoegh-Guldberg et al., 2018; Sainz et al., 2019; Lebel et al., 2020). Salinity intrusions into freshwater aquaculture systems have changed oxygen and water quality of inland ponds, resulting in mortalities in areas such as India and Bangladesh (*medium confidence*) (Dubey et al., 2017; Dabbadie et al., 2018). Rapid changes in temperature, precipitation, droughts, floods and erosion have created significant production losses for aquatic farmers in Cambodia, Laos, Myanmar, Thailand, Viet Nam and Ghana (*medium confidence*) (Asiedu et al., 2017; Pongthanapanic et al., 2019; Lebel et al., 2020). Algal blooming and inland lake browning related to warming was found to negatively affect fish biomass (van Dorst et al., 2018). Observed indirect effects of climate change on aquaculture include extreme weather events that damage coastal aquaculture infrastructure or enable flooding, both leading to animal escapees (e.g. fish, shrimp), damaged livelihoods and interactions with wild species (*high agreement, medium evidence*) (Beveridge et al., 2018b; Dabbadie et al., 2018; Kais and Islam, 2018; Pongthanapanic et al., 2019; Ju et al., 2020).

5.9.2 Assessing Vulnerabilities

Aquaculture vulnerability assessments have shown that countries from both high and low latitudes are highly vulnerable to climate change, where vulnerability is driven by particular exposures, economic reliance, type of production sector (freshwater, brackish, marine) and adaptive capacity (*high confidence*) (Handisyde et al., 2017; Soto et al., 2018). Regional aquaculture vulnerabilities and risk mitigation potentials for the major FAO reporting regions are shown in Figure 5.14. Best practice guidelines for assessments exist (Brugère et al., 2019; FAO, 2020d), but in practice most only cover some climatic drivers (*medium agreement, limited evidence*) (Soto et al., 2018). Holistic vulnerability assessments include ecosystem services (Custódio et al., 2020; Gentry et al., 2020) and farming practices which can exacerbate production pressures (stocking densities, eutrophication, fish stress) (Soto et al., 2018; Sainz et al., 2019). Common vulnerabilities to inland and marine aquaculture include increasing incidence and toxicity of harmful algal blooms related to warming waters, causing fish kills and product consumption risks, negatively impacting the productivity and stability of production sectors and reliant communities (*high confidence*) (Soto et al., 2018; Aoki et al., 2019) (Bannister et al., 2019).

There is *high confidence* that inland aquaculture in Southeast Asia is highly vulnerable to climate change, due to fluctuations in water resources either through climatic variability in precipitation, flooding or salinity inundation or through competition (Handisyde et al., 2017; Nguyen et al., 2018; Soto et al., 2018; Islam et al., 2019; Nguyen et al., 2019b; Prakoso et al., 2020). Studies in Bangladesh and Indonesia highlighted regional and species-specific vulnerabilities (Prakoso et al., 2020) and roles of governance in vulnerability reduction (Islam et al., 2019).

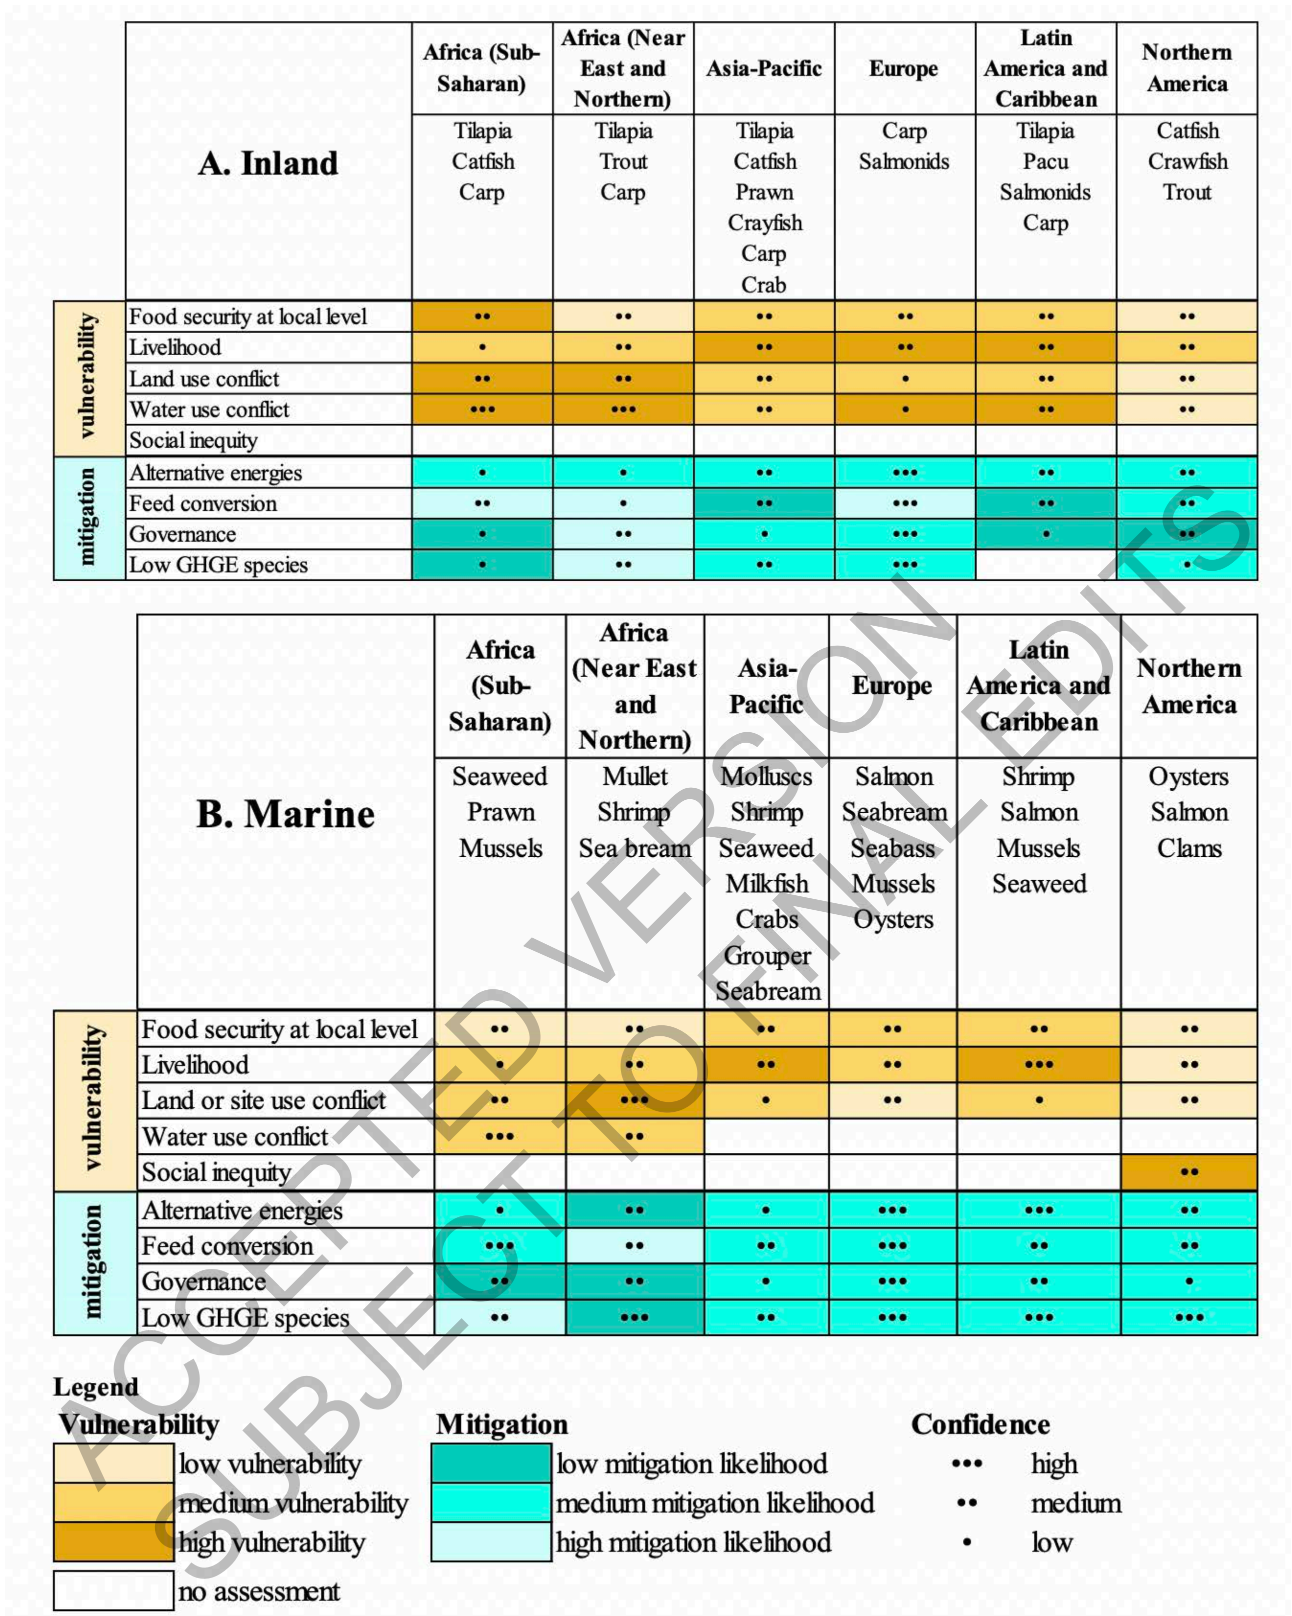

Figure 5.14: Assessment of a) inland freshwater and brackish aquaculture (salinities of <10ppm and / or no connection to the marine environment) b) marine aquaculture vulnerabilities and mitigation potential per major FAO production zones. See SM5.6 (Tables SM5.4, 5.5, 5.8,5.9) for assessment methodologies.

In the marine sector, vulnerability models (Brugère and De Young, 2015; Handisyde et al., 2017) have been adapted and applied to semi-quantitative spatial risk assessments for Chilean Atlantic salmon, where analysis of exposure threat coupled with mortality and temperature farm data could enhance salmon production (Soto et al., 2019). Vulnerability assessments in Korea (RCP8.5 temperature increase of 4-5°C by 2100) (Kim et al., 2019a) and the U.S. (ocean acidification, Barton et al., 2015; Ekstrom et al., 2015) found major exposure-related vulnerabilities for seaweeds and shellfish, with reduced vulnerabilities under higher production control and adaptive capacity. Global bivalve vulnerability assessments (RCP8.5 by 2100) show high vulnerabilities for major producing countries related to cyclones (China, Japan, South Korea, Thailand, Viet Nam, and North Korea), regional risk of high sensitivity and low adaptive capacity (Chile, Peru, Spain, Italy), with few major producers (France, the Netherland and U.S.) anticipated to remain moderately vulnerable by 2100 (Stewart-Sinclair et al., 2020).

Climate uncertainty and data limitations hinder vulnerability assessments (*high confidence*), so broader vulnerabilities and qualitative assessments can be used (Brugère and De Young, 2015; Soto et al., 2018; Brugère et al., 2019; Cochrane et al., 2019). Filling data gaps with monitoring (*high confidence*), increasing governmental support to assist particularly vulnerable small- and medium-scale farmers with increased costs associated with risk management and uncertainty (*medium confidence*) and the early inclusion of community stakeholders (*high agreement, medium evidence*) can reduce vulnerabilities (Handisyde et al., 2017; Dabbadie et al., 2018; Soto et al., 2018; Bindoff et al., 2019; Cochrane et al., 2019).

5.9.2.1 Gender and other social vulnerability and roles in aquaculture

There are regional differences in women's roles, responsibilities and involvement in adaptation strategies in the aquaculture sector. Women comprise 14% of the 2018 global aquaculture workforce of 20.5 million (FAO, 2020c), representing up to 42% of the salmon workforce in Chile (Chávez et al., 2019), predominantly in processing roles (Gopal et al., 2020). In the majority of lower-middle-income countries seaweed culture is dominated by women in family-owned businesses as in Zanzibar and the Philippines (Brugere et al., 2020; Ramirez et al., 2020), where women are not always paid directly but contribute to family incomes (*high confidence*) (Msuya and Hurtado, 2017; Brugere et al., 2020; Ramirez et al., 2020). In India women collect stocking juveniles and assist in pond construction, in Bangladesh women do the same tasks as men and in Ghana women undertake post-harvest fishing activities (Lauria et al., 2018). Women employed in aquaculture cooperatives gained adaptive capacity, which reduced gender inequities (*medium confidence*) (Farquhar et al., 2018; Gonzal et al., 2019), but lack of financial access for women can create gender inequality at larger commercial scales (Gurung et al., 2016; Call and Sellers, 2019).Women in aquaculture experience competing roles between employment, childcare and home duties (*high confidence*) (Morgan et al., 2015; Lauria et al., 2018; Chávez et al., 2019; see Cross-Chapter Box GENDER in Chapter 18), and differ from men in terms of perceptions of environmental risk, climate change, adaptation behaviour, with limited contributions to decision-making (*medium confidence*) (Barange and Cochrane, 2018). Therefore, effective climate aquaculture adaptation options need to address gender inequality e.g. suitable technology designs that fit with social norms and access to credit to facilitate independent uptake (*medium evidence, high agreement*) (Morgan et al., 2015; Oppenheimer et al., 2019). Generalized best practices for gender-sensitive approaches to adaptation are relevant for aquaculture (UNFCCC, 2013).

5.9.3 Projected Impacts

Projected impacts on regional inland and marine aquaculture production are summarized in Figure 5.15.

5.9.3.1 Inland freshwater and brackish aquaculture

Predicted sea level and temperature rise will result in coastal inundation into brackish and inland aquaculture systems (*high confidence*) (Mehvar et al., 2019; Nhung et al., 2019; Oppenheimer et al., 2019; IPCC AR6), with negative impacts on aquaculture production in Viet Nam, East Africa and Jamaica (*medium confidence*) (Lebel et al., 2018; Nguyen et al., 2018; Bornemann et al., 2019). Precipitation and temperature changes will cause drought and flooding, negatively affecting near-shore fishpond productivity (*limited evidence*) (Canevari-Luzardo et al., 2019), but provide competitive advantages to non-native shrimp in Australia (*limited evidence*) (Cerato et al., 2019). Warming and acidification will increase harmful algal bloom toxicity in freshwater systems, but responses may be strain-specific (Griffith and Gobler, 2020; Hennon and Dyhrman, 2020). As for molluscs in marine systems, projected climate change in freshwater and brackish systems may limit the availability of wild-sourced juveniles from fisheries (Beveridge et al., 2018). Projected impact studies for the inland and small-scale aquatic sectors are very limited (Halpern et al., 2019; Galappaththi et al., 2020b), therefore this is a noted knowledge gap.

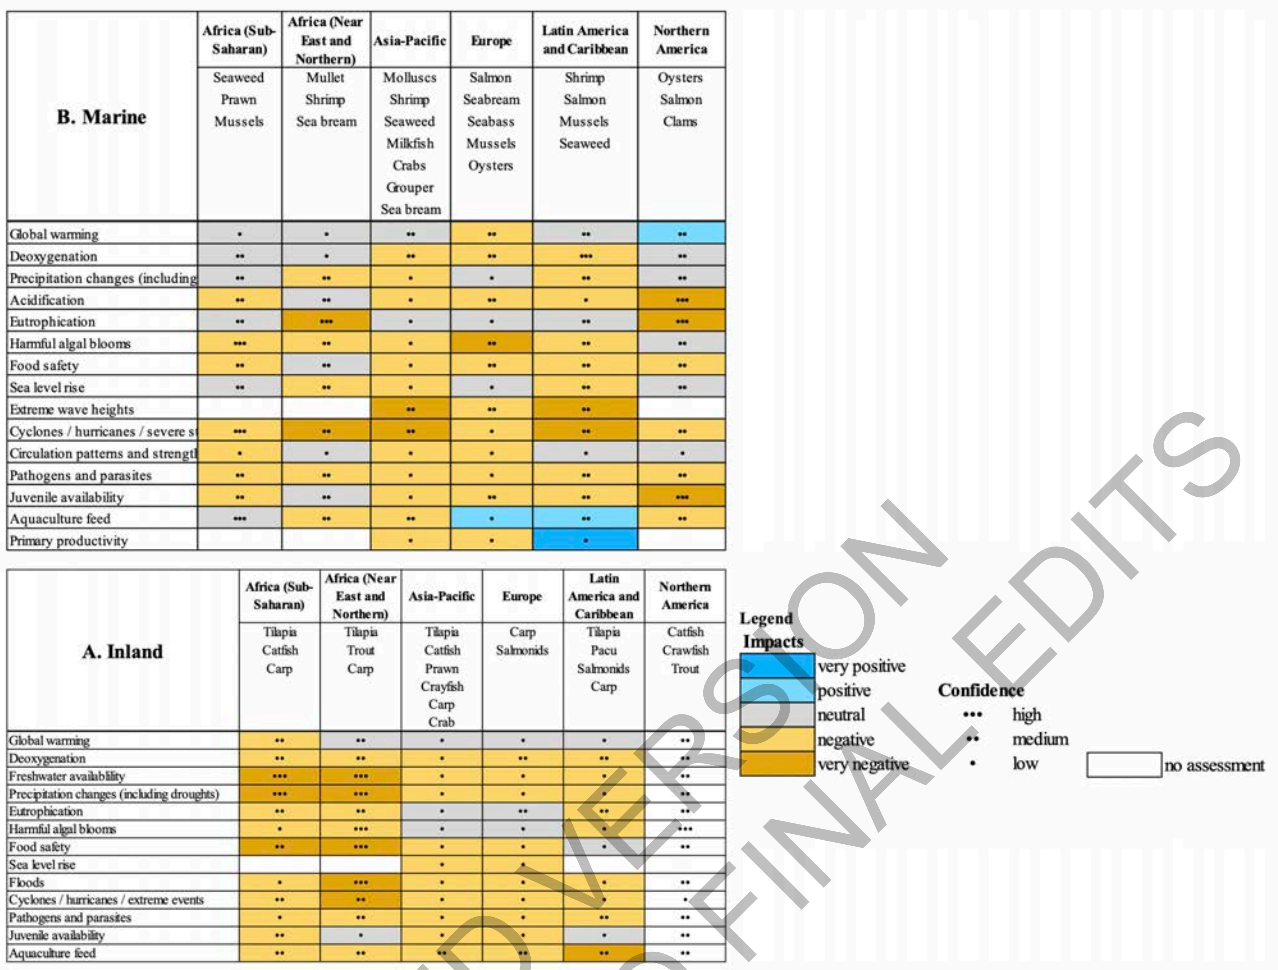

Figure 5.15: Assessment of projected impacts of climate change on a) inland freshwater and brackish aquaculture (salinities of <10ppm and / or no connection to the marine environment) b) marine aquaculture per major FAO production zones. See SM5.6 (Tables SM5.6, 5.10) for assessment methodologies.

5.9.3.2 Marine aquaculture

5.9.3.2.1 Finfish culture

Global projections of ocean warming, primary productivity and ocean acidification predict suitable habitat expansions and short-term growth benefits for finfish aquaculture for some regions (*medium confidence*) (see Figure 5.15) until thermal tolerances or productivity constraints are exceeded by 2090 (Beveridge et al., 2018b; Dabbadie et al., 2018; Froehlich et al., 2018a; Catalán et al., 2019; Thiault et al., 2019; Falconer et al., 2020a). Sensitivities for marine finfish may be high even under +1.5-2.0°C (*medium confidence*) (Gattuso et al., 2018), resulting in finfish farms moving northward to maintain productivity (e.g., Arctic (Troell et al., 2017). Downscaled projections of regionally specific tolerances (Klinger et al., 2017) may be particularly useful for management and planning; a 0.5°C rise is predicted for Chilean salmon aquaculture (Soto et al., 2019) and potential projected negative impacts on productivity in Norway by 2029 (*limited evidence*) (Falconer et al., 2020a). Marine heatwaves are predicted to increase in occurrence, intensity, and persistence under RCP4.5 or RCP8.5 by 2100 (Oliver et al., 2019; Bricknell et al., 2021) with risk partly mitigated by husbandry (*medium confidence*) (McCoy et al., 2017). Generally, negative impacts are predicted for marine species with residual risk increasing with level of exposure (Sara et al., 2018; Smale et al., 2019), where warming will affect oxygen solubility and reduce salmon culture capacity (*limited evidence*) (Aksnes et al., 2019, Chapter 3) and combine with increasing incidence of harmful algal blooms (*high confidence*) resulting in negative impacts for food security and nutrition and health (Oppenheimer et al., 2019; Colombo et al., 2020; Glibert, 2020; Raven et al., 2020). Climate change is predicted to affect the incidence, magnitude and virulence of finfish disease, e.g., *Vibriosis* (Barber et al., 2016; Mohamad et al., 2019a; Mohamad et al., 2019b), but specific host-pathogen-climate relationships are not yet established (*high confidence*) (Slenning, 2010; Marcogliese, 2016; Montanchez et al., 2019; Bandin and Souto, 2020; Behringer et al., 2020; Filipe et al., 2020; Montanchez and Kaberdin, 2020). Projected climate change will also increase competition for feed ingredients between aquatic and terrestrial animal production systems (see Section 5.13.2.).

5.9.3.2.2 Shellfish culture

Globally, there is overall *high confidence* that suitable shellfish aquaculture habitat will decline by 2100 under projected warming, ocean acidification and primary productivity changes, with significant negative impacts for some regions and species before 2100 (Table 5.9, Froehlich et al., 2018a; Ghezzo et al., 2018). Shellfish growth will increase with warming waters until tolerances are reached, e.g., through extreme El Niño events (*high confidence*) (Beveridge et al., 2018b; Dabbadie et al., 2018; Liu et al., 2018b; Liu et al., 2020). Rising temperatures and ocean acidification will result in losses of primary productivity and farmed species from tropical and subtropical regions, and gains in higher latitudes (*high confidence*) (Froehlich et al., 2018a; Aveytua-Alcazar et al., 2020; Chapman et al., 2020; Des et al., 2020; Oyinlola et al., 2020), but net marine production gains could be achieved under strong mitigation (Thiault et al., 2019). Shellfish *Vibrio* infections will increase with warming waters and extreme events, increasing shellfish mortalities (*medium confidence*) (Green et al., 2019; Montanchez et al., 2019) with ocean acidification impairing immune responses (*limited evidence*) (Cao et al., 2018b). Bivalve larvae are known to be highly vulnerable to ocean acidification (*high confidence*) (see Section 3.3, Bindoff et al., 2019), with projected regional and species-specific levels of impact (*high confidence*) (Ekstrom et al., 2015; Zhang et al., 2017b; Mangi et al., 2018) (Greenhill et al., 2020). Ocean acidification is also projected to weaken shells, affecting productivity and processing (*high confidence*) (Martinez et al., 2018; Cummings et al., 2019) and dependent livelihoods (Doney et al., 2020).

5.9.3.2.3 Aquatic plant culture

There is *medium confidence* that cultivated seaweeds are predicted to suffer habitat loss resulting in population declines and northward shifts (Table 5.11).

Table 5.11: Projected impacts of climate on specific inland, brackish, and marine culture systems and species.

Exposure	Scenario	Region	Production system	Species	Impact	Reference
Temperature increase	RCP4.5 and RCP8.5 by 2050	Northern Thailand	Inland	Nile tilapia	Reduced productivity	Lebel et al. (2018)
Precipitation change (drought, hurricane, heavy rainfall)	-	Jamaica	Inland	Tilapia	Reduced productivity, infrastructure damage	Canevari-Luzardo et al. (2019)
Temperature increase	4°C increase, B2, A1B by 2100	Australia	Inland	Freshwater shrimp	Increased production in non-native zones	Cerato et al. (2019)
Temperature increase, ocean acidification, primary productivity declines	CMIP5 RCP 8.5 in 20-year increments to 2090	Global	Marine	Finfish species	Increased suitable habitat expansion for regions (Russia, Norway, U.S. Alaska, Denmark, Canada). By 2100 reduction in productivity for major producers (Norway, China)	Froehlich et al. (2018a), Thiault et al. (2019)
Temperature increase	2-5°C increase under RCP8.5	Europe	Marine	Atlantic salmon	Increased growth	Catalán et al. (2019)

Temperature increase	RCP4.5 to 2029	Norway	Marine	Atlantic salmon	Growth threshold reached by 2029	Falconer et al. (2020a)
Temperature increase	Downscaled CM2.6 by 2050	Global	Marine	Atlantic salmon, cobia and sea bream	Increased or decreased growth rates depending on region	Klinger et al. (2017)
Temperature increase, ocean acidification, primary productivity declines	CMIP5 RCP 8.5 in 20-year increments to 2090	Global	Marine	Shellfish	Overall declines in suitable habitat globally, up to 50-100% reductions regions in China, Thailand, and Canada	Froehlich et al. (2018a)
Temperature increase	CMIP5 RCP8.5 by 2050, 2100	Italy	Marine	Clams	Negative impacts for juvenile timing, spatial distribution, and quality	Ghezzo et al. (2018)
Temperature increase	CMIP5 RCP2.6 and RCP8.5 by 2035, 2070	France	Marine	Oysters	Increase incidence of oyster mortality; increase by 2035 to annual occurrence by 2070	Thomas et al. (2018)
Temperature increase	RCP2.6 and RCP8.5 by 2050	Global	Marine	Shellfish	Species reduction (10-40%) in tropical and subtropical regions with increase (40%) in higher latitudes	Oyinlola et al. (2020)
Temperature increase, ocean acidification	Ecopath with RCP 8.5 by 2100 (2.8°C warming and pH 7.89)	U.S.	Marine	Shellfish	Reduction primary productivity and subsequent bivalve carrying capacity	Chapman et al. (2020)
Temperature increase, stratification change	RCP8.5 by 2088-2099	Spain	Marine	Mussels	Decline in mussel optimal culture conditions of 60% in upper and 30% in deeper waters by 2099	Des et al. (2020)
Temperature increase, ocean acidification	RCP2.6 and 8.5 by 2070-2090	Global	Marine	Shellfish	Under RCP8.5 a decline in shellfish production due to primary productivity reduction in tropical regions and gains in high latitudes. Under RCP2.6 marine production will have net gain	Thiault et al. (2019)
Temperature increase	4°C increase	Global	Marine	*Vibrio* spp. (mortality causative agent)	Increased virulence	Montanchez et al. (2019)
Temperature increase (marine heat wave)	5°C increase	Global	Marine	Oysters	Increased oyster mortality	Green et al. (2019)
Ocean acidification	~2000ppm CO_2	Global	Marine	Oysters	Impaired immune function	Cao et al. (2018b)
Ocean acidification	RCP8.5 in 20-year	U.S.	Marine	Shellfish	Regional projected vulnerabilities – Southern Alaska and	Ekstrom et al. (2015)

	increments to after 2099				Pacific Northwest at more immediate risk	
Ocean acidification	A1B and RCP8.5 by 2100	U.K.	Marine	Shellfish	Regional projected vulnerabilities - Wales and England at more immediate risk	Mangi et al. (2018)
Ocean acidification	RCP2.6 and RCP8.5 by 2300	East China	Marine	Shellfish	Carbonate saturation projected to decrease by 13% and 72% under RCP2.6 and RCP8.5 respectively, projecting decreased shellfish productivity	RCP2.6 and RCP8.5 by 2300 (Zhang et al., 2017b)
Increased temperature	RCP2.6 and RCP8.5 by 2100	North Sea	Marine	Seaweed	Northward population shift by 110-163km and 450-635km under RCP2.6 and RCP8.5 respectively	Westmeijer et al. (2019),
Increased temperature	RCP4.5 and RCP8.5 by 2090	Japan	Marine	Kelp	Habitat decline to 30-51% and 0-25% under RCP4.5 and RCP8.5 respectively	Sudo et al. (2020).

5.9.3.2.4 Societal impacts within the production system

Marine aquaculture provides distinct ecosystem services through provisioning (augmenting wild fishery catches), regulating (coastal protection, carbon sequestration, nutrient removal, improved water clarity), habitat and supporting (artificial habitat) and cultural (livelihoods and tourism) services (Gentry et al., 2020), which vary with species, location, and husbandry (Alleway et al., 2019). Projected thermal increases of 1.5°C will reduce ecosystem services, further reduced under 2°C warming, with associated increases in acidification, hypoxia, dead zones, flooding, and water restrictions (*medium confidence*) (Hoegh-Guldberg et al., 2018). Sudden production loses from extreme climate events can exacerbate food security challenges across production sectors, including aquaculture, increasing global hunger (*high confidence*) (Cottrell et al., 2019; Food Security Information Network, 2020). While aquaculture provides positive influences such as food security and livelihoods, there are negative concerns over environmental impacts (including high nutrient loads from sites) and socio-economic conflicts (Alleway et al., 2019; Soto et al., 2019) and adoption of ecosystem approaches are dependent on particular user groups and regions (Gentry et al., 2017; Brugère et al., 2019; Gentry et al., 2020). In coastal Bangladesh projected saline inundation to wetland ecosystem services will result in ecosystem services losses of raw materials and food provisioning, ranging from USD 0-20.0 million under RCP2.6 to RCP8.5 scenarios (Mehvar et al., 2019). Mangrove deforestation for shrimp farming in Asia negatively impacts ecosystem services and reduces climate resilience (*medium confidence*) (Mehvar et al., 2019; Nguyen and Parnell, 2019; Reid et al., 2019; Custódio et al., 2020), while mangrove reforestation efforts may have some effectiveness in recreating important nursery grounds for aquatic species (*low confidence)* (Gentry et al., 2017; Chiayarak et al., 2019; Hai et al., 2020). Families are highly vulnerable to climate change where nutritional needs are being met by self-production, e.g., Mozambique, Namibia (Villasante et al., 2015), Zambia (Kaminski et al., 2018) and Bangladesh (*high confidence*) (Pant et al., 2014). Climate change will therefore affect multiple ecosystem services where ultimately decisions on balance or trade-offs will vary with regional perceptions of service value (*high confidence*).

5.9.4 Aquaculture Adaptation

5.9.4.1 Adaptation planning

Aquaculture is often viewed as an adaptation option for fisheries declines, thereby alleviating food security from losses of other climate change impacts (Sowman and Raemaekers, 2018; Johnson et al., 2020) e.g., Pacific Islands freshwater aquaculture, Bangladesh crop-aquaculture systems, or Viet Nam rice-fish cultivations (Soto et al., 2018). Many adaptations are specific to regions, countries, or sector, implemented on a regional to national scale (FAO, 2018c; Galappaththi et al., 2020b). Adaptation likelihood (potential), effectiveness and risk of maladaptation was assessed per major FAO production region for inland, brackish, and marine aquaculture (Figure 5.16) production systems. Potential adaptation measures to reduce production loss can be built upon existing adaptation planning and guidelines, to reduce the risk of maladaptation including feedback loops (e. g. FAO, 2015; Bueno and Soto, 2017; Dabbadie et al., 2018; FAO, 2018c; Poulain et al., 2018; Brugère et al., 2019; Pham et al., 2021; Soto et al., 2021). Large climate change adaptation strategies for the aquaculture sector exist e.g. U.S. (Link et al., 2015), Australia (Hobday et al., 2017) and South Africa (Department of Environmental Affairs, 2016). Lower income countries often lack financial, technical, or institutional capacity for adaptation planning (Galappaththi et al., 2020b), but examples include Bangladesh and Myanmar (FAO, 2018c), with programs offering adaptation funding (Dabbadie et al., 2018). Early participation of stakeholders in adaptive planning has promoted action and ownership of results (*high confidence*) e.g. India and U.S. (Link et al., 2015; FAO, 2018c; Soto et al., 2018) Early outreach, education, and knowledge gap assessments raises awareness, where utilization of local knowledge and Indigenous knowledge and scientific involvement support informed adaptive planning and uptake for all stakeholders (*high confidence*) (Cooley et al., 2016; FAO, 2018c; Rybråten et al., 2018; Soto et al., 2018; McDonald et al., 2019; Galappaththi et al., 2020b), as perceptions of climate risk and capacity will vary (Tiller and Richards, 2018). Supporting the active involvement of women helps address gender inequity and perceived risk, particularly for smallholder farmers (*high confidence*) (Morgan et al., 2015; Barange and Cochrane, 2018; FAO, 2018c; Avila-Forcada et al., 2020). However, regional, and national political influences, financial and technical capacity, governance planning and policy development will ultimately support or hinder adaptation for aquaculture (*high confidence*) (Cooley et al., 2016; FAO, 2018c; Galappaththi et al., 2020b; Greenhill et al., 2020).

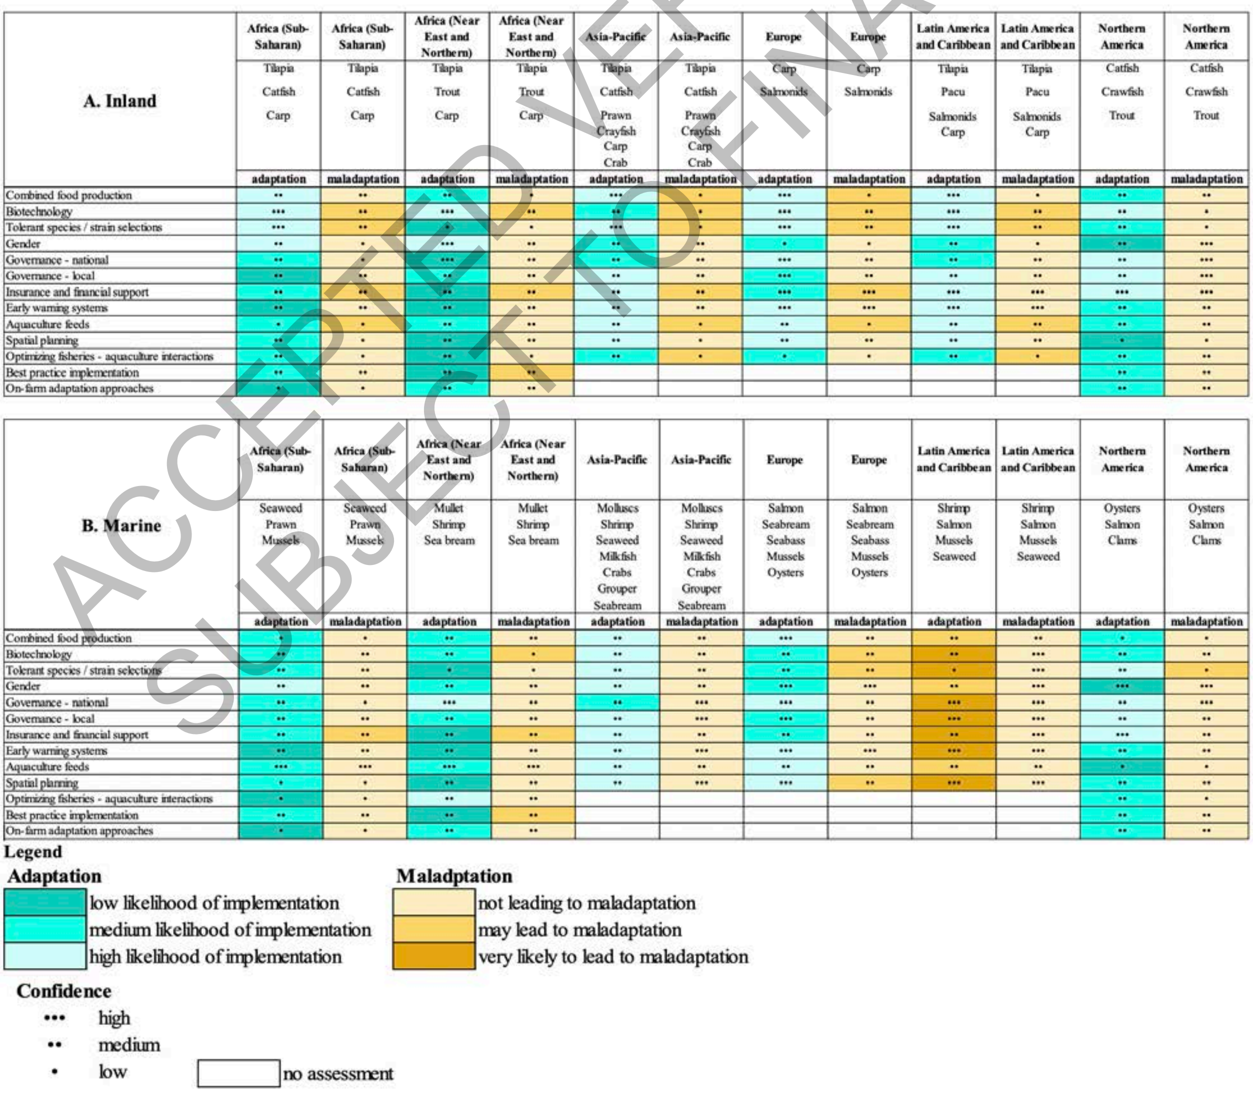

Figure 5.16: Assessment of the likelihood and effectiveness of a range of adaptation options for potential implementation in the near-term (next decade) for a) inland freshwater and brackish aquaculture (salinities of <10ppm and / or no connection to the marine environment) and b) marine aquaculture systems per major FAO production zone. See SM5.6 (Tables SM5.7, 5.11) for assessment methodologies.

5.9.4.2 Species selections and selective breeding

Adaptation options at the operational level include species selections, e.g., cultivation of brackish species (shrimp, crabs) during dry seasons, and rice-finfish in wetter seasons in Thailand (Chiayarak et al., 2019), use of salt-tolerant plants in Viet Nam (Nhung et al., 2019; Paik et al., 2020), converting inundated rice paddies into aquaculture, rotating shrimp, and rice culture (*high confidence*) (Chiayarak et al., 2019). Species diversification through co-culture, integrated aquaculture-agriculture (e.g. rice-fish) or integrated multi-trophic culture (e.g. shrimp-tilapia-seaweed or finfish-bivalve-seaweed) may maintain farm long-term performance and viability by: creating new aquaculture opportunities; promoting societal and environmental stability; reducing GHG emissions through reduced feed usage and waste, and; carbon sequestration (*medium confidence*) (see Section 5.10, Li et al., 2019; Galappaththi et al., 2020b; Prakoso et al., 2020; Tran et al., 2020) (Ahmed et al., 2017; Bunting et al., 2017; Gasco et al., 2018; Soto et al., 2018; Ahmed et al., 2019; Dubois et al., 2019; FAO, 2019c; Freed et al., 2020). In practice, most aquaculture operations concentrate on single-species systems (Metian et al., 2020) and barriers such as land availability, freshwater resources and lack of credit access may limit the uptake and success of integrated adaptation approaches to climate change (Ahmed et al., 2019; Tran et al., 2020; Kais and Islam, 2021).

Selective breeding can promote climate resilience (*medium confidence*) (Klinger et al., 2017; Fitzer et al., 2019) and operations have already intentionally, or unintentionally, selected for production traits for changing conditions (de Melo et al., 2016; Tan and Zheng, 2020). Exposure of broodstock to future climate conditions may or may not confer advantages to offspring (*moderate evidence, low agreement*) (Parker et al., 2015; Griffith and Gobler, 2017; Thomsen et al., 2017; Durland et al., 2019). Traditional pedigree developments require extensive phenotypic data, but genomic selections can rapidly select for robust climate-associated traits (Sae-Lim et al., 2017; Gutierrez et al., 2018; Zenger et al., 2018; Houston et al., 2020; Tan and Zheng, 2020). Genomic resources are available for salmon, rainbow trout, coho, carp, tilapia, seabass, bream, turbot, flounder, catfish, yellow drum, scallops, oysters and shrimp, but have been developed for disease and growth selections rather than climate resistance (Guo et al., 2018; Houston et al., 2020) (Dégremont et al., 2015a; Dégremont et al., 2015b; Abdelrahman et al., 2017; Gjedrem and Rye, 2018; Gutierrez et al., 2018; Liu et al., 2018a; FAO, 2019d), although bivalve selections for ocean acidification and warming resiliency are underway (Tan and Zheng, 2020). Targeted genome editing could modify phenotypes of major aquaculture species (Li et al., 2014a; Elaswad et al., 2018; Yu et al., 2019; Houston et al., 2020), but uptake is dependent upon national regulatory and public approvals. Local adaptations within species with higher climate resiliencies may assist in selections (Thomsen et al., 2017; Falkenberg et al., 2019; Scanes et al., 2020; Toomey et al., 2020), but highlights the need to consider specific farming environments for selective processes (Houston et al., 2020). Projections of climate on aquaculture production traits are not well understood (Lhorente et al., 2019), therefore genetic diversity needs to be maintained to ensure population fitness (*high confidence*) (Bitter et al., 2019; Lhorente et al., 2019; Visch et al., 2019; Houston et al., 2020; Mantri et al., 2020).

5.9.4.3 Farm site selection, infrastructure, and husbandry

Land-based aquaculture systems including hatcheries may reduce exposure to climatic extremes (due to better control of the culture environment), limit water usage, reduce juvenile reliance and buffer climate effects using optimal diets (*high confidence*) (Barton et al., 2015; Reid et al., 2019; Cominassi et al., 2020). However, land-based aquaculture requires large capital and operational costs, use of land increasing conflicts between land and water use, increased energy demands increasing GHG if fossil fuels are primary energy source, require necessary expertise and will not reduce outgrowing exposures (*high confidence*) (see Section 5.13, Beveridge et al., 2018b; Soto et al., 2018; Tillotson et al., 2019; Costello et al., 2020; Prakoso et al., 2020).

Geographical selection of marine farm sites may prevent climate productivity declines (*medium confidence*) (Froehlich et al., 2018a; Sainz et al., 2019; Oyinlola et al., 2020), particularly for temperature–related mortality hotspots (Garrabou et al., 2019), harmful algal bloom occurrences (Dabbadie et al., 2018) or extreme events (Liu et al., 2020; Wu et al., 2020). However, while downscaled climate forecasts facilitate localized adaptation planning (Falconer et al., 2020a), such projections are rare (Whitney et al., 2020). GIS can be used for climate adaptive planning along with routine site assessments (Falconer et al., 2020b; Galappaththi et al., 2020b; Jayanthi et al., 2020). Building coastal protection, stronger cages and mooring systems, deeper ponds and using sheltered bays can reduce escapees and mortalities related to flooding, increased storms and extreme events (*medium confidence*) (Dabbadie et al., 2018; Bricknell et al., 2021; Kais and Islam, 2021). Inshore aquaculture in low-lying areas prone to sea-level salinity intrusion (e.g. Mekong delta and Viet Nam) have already implemented adaptation measures, such as conversion of land to mixed plant-animal systems (Nguyen et al., 2019a), converting freshwater ponds to brackish or saline aquaculture (Galappaththi et al., 2020b), building of dams and dykes (Renaud et al., 2015) and intensification of shrimp or fish pond culture to reduce water and land usage (Nguyen et al., 2019b; Johnson et al., 2020). Other adaptation options for limited water supply are government equitable water allocations and water storage (*high confidence*) (Bunting et al., 2017; Galappaththi et al., 2020b).

Feed formulations and improved feed conversion can reduce climate-associated stress for freshwater species, significantly reducing waste and increase sustainability (*medium confidence*) (Chen and Villoria, 2019) (FAO, 2018c; Gasco et al., 2018). Projected decreases in fish meal and global targets of limiting warming to under 2°C may increase the ratio of plant-based diets, but reduce fish nutritional content (see Sections 5.10 and 5.13, Hasan and Soto, 2017; Johnson et al., 2020) (). Companies provide insurance in major production areas, but aquaculture is considered high risk with large levels of small claims (Secretan et al., 2007). Insurance covers natural disasters and disease, helping to reduce and cope with climate-induced risk, enabling faster livelihood recoveries and preventing poverty (*high agreement, limited evidence*) (Xinhua et al., 2017; Kalikoski et al., 2018; Soto et al., 2018). For example, small-scale shrimp farmers were willing to pay higher premiums to manage risk, after participation in government pilot insurance schemes, ensuring greater pay-outs if a mortality event occurred (Nyguyen and Pongthanapanic, 2016; Pongthanapanic et al., 2019). Technological innovations are more widely implemented in larger operations, with internet access promoting adoption at the farm site (Joffre et al., 2017; Salazar et al., 2018). Improved farm management is a key opportunity (*high confidence*) to reduce climate risks on aquaculture, where Best Management Practices can increase resiliency (Soto et al., 2018), lower additional risk from non-climatic stressors (Gattuso et al., 2018; Smith and Bernard, 2020), and decision-tree frameworks can provide adaptation choices when events occur (Nguyen et al., 2016).

5.9.4.4 Early warning and monitoring systems

Globally monitoring is increasing to fill scientific uncertainties (Goldsmith et al., 2019), but is not often at spatial scales which facilitate farm or regional adaptation management (Whitney et al., 2020) or data complexities prevent direct uptake by operators, resource managers and policymakers (*medium confidence*) (Soto et al., 2018; Gallo et al., 2019). Specialized industry portals (Pacific shellfish) and government-established monitoring programs (Chilean salmon) and other observational networks (e.g., GOA-ON) can provide real-time monitoring, early-warning event alerts and facilitate aquaculture decision-making (*medium confidence*) (Cross et al., 2019; Farcy et al., 2019; Soto et al., 2019; Bresnahan et al., 2020; Peck et al., 2020) (Tilbrook et al., 2019). Seasonal forecasting, downscaled models and early-warning systems provide valuable regional or farm site risk information (Hobday et al., 2018; Galappaththi et al., 2020b; Whitney et al., 2020), but monitoring will need to be useful for farmers, involve farmers, accurate, timely, cost-effective, reviewed and maintained in order to ensure uptake (*high confidence*) (Soto et al., 2018). Early warning systems for harmful algal blooms enable rapid decision-making and risk mitigation (*medium confidence*), e.g., ocean colour monitoring in South Africa (Smith and Bernard, 2020), where early harvesting and additional husbandry were used to minimize production and economic losses (Pitcher et al., 2019). New tools, strategies and observations are needed to predict harmful algal bloom occurrences and range shifts with changing climate (*high confidence*) (Schaefer et al., 2019; Tester et al., 2020), as there is uncertainty on drivers of incidence and toxicity (Wells et al., 2020).

5.9.5 Contributions of Indigenous, Traditional, and Local Knowledge

Indigenous mariculture practices, e.g., intertidal clam gardens, have been occurring for thousands of years, providing knowledge of traditional practices still applicable to mariculture (Deur et al., 2015; Jackley et al., 2016; Poulain et al., 2018; Bell et al., 2019; Toniello et al., 2019). Indigenous groups differ in opinions on aquaculture acceptability, implications for coastal management and territorial rights (*high confidence*) (Young et al., 2019). Such perceptions may determine culturally appropriate types and benefits of aquaculture (employment, food diversification, income, building autonomy and skillsets), e.g., Australia (Petheram et al., 2013) and Canada (Young and Liston, 2010). Marginalized people, like small-scale aquaculture farmers in lower-income and lower-middle-income countries, are often overlooked and are not represented at a governance level (Barange et al., 2014; Kalikoski et al., 2018). Therefore policy, economic, knowledge and other support needs to ensure representation with traditional and other stakeholder ecological knowledge at national, regional, and local levels to facilitate climate change adaptation and safeguard human rights for poor and vulnerable groups (*high confidence*) (Kalikoski et al., 2018; Poulain et al., 2018).

5.10 Mixed Systems

The food and livelihoods of many rural people depend on combinations of crops, livestock, forestry, and fisheries, and still information on these mixed systems is scarce. Rural households in low and middle-income countries earn almost 70% of their income through mixed production systems (Angelsen et al., 2014). These systems produce about half of the world's cereals, most of the fruits, vegetables, pulses, roots, and tubers, and most of the staple crops and livestock products consumed by poor people in lower-income countries (Herrero et al., 2017). They can help in adapting to climatic risks and reducing GHG emissions by improving nutrient flows and improving the recycling of nutrients within the production system and by increasing food production and diet quality per unit of land and diversifying income sources (Smith et al., 2019c). Indigenous groups often practice mixed production, integrating crops, animals, fisheries, forestry, and agroforestry through traditional ecological knowledge.

Some evidence exists of the buffering capacity that integrated systems can provide in the face of climate change (Gil et al., 2017). This buffering, often affecting the farming system as a whole rather than the individual agricultural enterprises involved, applies to some aquaculture-agriculture systems as well as to crop-livestock systems (Bunting et al., 2017; Stewart-Koster et al., 2017). In some situations, there may be tradeoffs and constraints at the household level that affect this resilience-conferring ability: for instance, mixed systems often need relatively high levels of management skill, and extra labour may be required (van Keulen and Schiere, 2004; Thornton and Herrero, 2015). The diversification of food production systems offers promise for enhanced resilience at the global level (Kremen and Merenlender, 2018; Dainese et al., 2019; section 5.4.4.4), though policies need to provide adequate incentives for resource efficiency, equity, and environmental protection (Havet et al., 2014; Thornton and Herrero, 2014; Troell et al., 2014).

5.10.1 Observed Impacts

5.10.1.1 Mixed crop-livestock systems

Overall, there is *high confidence* that farm strategies that integrate mixed crop-livestock systems can improve farm productivity and have positive sustainability outcomes (Havet et al., 2014; Thornton and Herrero, 2014; Herrero et al., 2015; Thornton and Herrero, 2015; HLPE, 2019). The scale of the improvement varies between regions and systems and is moderated by overall demand in specific food products and the policy context. Integrated crop-livestock systems present opportunities for the control of weeds, pests, and diseases. They can also provide a range of environmental benefits, such as increased soil carbon and soil water retention, increased biodiversity, and reduced need for inorganic fertilizers (Havet et al., 2014; Thornton and Herrero, 2014; Herrero et al., 2015; Thornton and Herrero, 2015; HLPE, 2019).

Research indicates that mixed crop-livestock systems are often more resilient to climate change *(medium confidence*). In the southern Afar region of Ethiopia, crop-livestock households were more resilient than livestock-only households to climate-induced shock (Mekuyie et al., 2018). However, the benefits of managing crop-livestock interactions in response to climate change depend on local context. For example, in higher-rainfall zones in Australia, Nie et al. (2016) found some yield reductions and difficulty in maintaining groundcover. The systematic review of Gil et al. (2017) concluded that the integration of crop and livestock enterprises as an adaptation measure can enhance resilience (FAQ 5.1).

Reconfiguring mixed farming systems is occurring. In semiarid eastern Senegal, Brottem and Brooks (2018) found increasing reliance on livestock production mostly because of changing climate conditions. Many poorer households are having to rely on migration to compensate for shortfalls in crop production arising from a changing climate. Some farmers have successfully shifted to crop-livestock systems in Australia, where they have allocated land and forage resources in response to climate and price trends (Bell et al., 2014).

Mixed livestock-crop systems may increase burdens on women, require managing competing uses of crop residues, and have higher requirements of capital and management skills. These factors can be challenging in many lower-income countries (Rufino et al., 2013; Thornton and Herrero, 2015; Jost et al., 2016; Thornton, 2018). The policy actions needed for the successful operation of mixed crop-livestock systems may be similar across widely different situations: good access to credit inputs and capacity-building needed to facilitate uptake (Hassen et al., 2017; Marcos-Martinez et al., 2017), and good levels of market infrastructure (Ouédraogo et al., 2017; Iiyama et al., 2018).

5.10.1.2 Mixed crop-aquatic systems

Households may have a mix of aquatic and land-based food production, contributing to food security and nutrition and income generation (Freed et al., 2020; see also discussion of aquaponics and hydroponics in Section 5.10.4.3. and combined rice-aquatic species production in Section 5.9.4). Failures in agricultural outputs due to climate-associated factors may result in diversification to fisheries as a way of alleviating food production shortfalls; for example, fisheries landings may dramatically increase after agricultural failures following hurricanes, which can subsequently create overfishing collapses (Cottrell et al., 2019). Where climatic impact drivers affect multiple sectors, adaptation may become more difficult because of the interacting challenges (Cottrell et al., 2019). One study of 12 countries with high food insecurity levels found that fish-reliant households utilized as much land as those not reliant on fish (Fisher et al., 2017). To meet food security requirements, most of these households needed to both farm and fish, illustrating the interdependence of aquatic-terrestrial food systems.

5.10.1.3 Agroforestry systems

Agroforestry is frequently mentioned as a strategy to adapt to and mitigate climate change and address food security ((de Coninck et al., 2018; Smith et al., 2019c). There is strong evidence of net positive biophysical and socioeconomic effects of agroforestry systems under both smallholder and large-scale mechanized production systems (Quandt et al., 2017; Hoegh-Guldberg et al., 2018; Sida et al., 2018; Wood and Baudron, 2018; Table 5.10; Cross-Chapter Box NATURAL in Chapter 2; Quandt et al., 2019). Many of these effects also reduce climate risk. At the same time, agroforestry systems are subject to impacts from climate change, potentially reducing the benefits they provide. Still, there is limited evidence of observed climate impacts on agroforestry systems, and modeling climate impacts is more complex for agroforestry than for single cropping systems (Luedeling et al., 2014).

5.10.2 Assessing Vulnerabilities

5.10.2.1 Assessing vulnerability in mixed systems

Important information gaps exist concerning the costs and benefits of many adaptation options in mixed systems, where the interactions between farming enterprises may be complex. Among communal crop-livestock farmers in Eastern Cape province of South Africa, Bahta (2016) reported high levels of vulnerability to drought and highlighted the need for more coordination between monitoring agencies in terms of reliable early warning information that can be communicated appropriately, between farmers' organizations and the private sector to facilitate adaptation options that can overcome feed shortages such as fodder purchases in times of drought, and between government departments at the national and provincial level that address the concerns and needs of affected communities. Nyamushamba (2017) reviewed the use of indigenous beef cattle breeds in smallholder mixed production systems in southern Africa. Some of these breeds exhibit adaptive traits such as drought and heat tolerance and resistance to tick-borne diseases. However, their adaptation potential in crossbreeding programs is essentially unknown, as most African cattle populations are still largely uncharacterized.

5.10.2.2 Social vulnerabilities

As in other production systems, Indigenous groups, gender, race, and other social categories can result in heightened vulnerability to climate change in mixed production systems due to historical and current marginalization and discrimination (*high confidence*) (Parraguez-Vergara et al., 2016; Baptiste and Devonish, 2019; Moulton and Machado, 2019; Popke and Rhiney, 2019; Fagundes et al., 2020). A study of the Mapuche Indigenous group in Chile found that marginalization and discrimination worsened their vulnerability and observed impacts of climate change because they had less access to services, lower incomes and were not as high a priority as other groups (Parraguez-Vergara et al., 2016). Among fisherfolk on Lake Wamala, Uganda, Musinguzi (2018) found evidence of considerable diversification to crop and livestock production as a means of increasing households' food security and income, but women had greater workloads and had less control over new income sources than men. Ngigi (2017) evaluated adaptation actions within households in rural Kenya and found that women tended to adopt adaptation strategies related to crops, men to livestock and agroforestry activities. Chingala (2017) found substantial gender- and age-related differences in control of access to animal feed, animal health, and water resources in beef producers in mixed crop-livestock systems in Malawi. In a review of agriculture-aquaculture systems in coastal Bangladesh, Hossain et al. (2018) showed that existing policies and adaptation mechanisms are not adequately addressing gender power imbalances, and women continue to be marginalized, leading to increasing feminization of food insecurity. Such studies highlight the need to consider gender and other social inequities when examining adaptation in mixed production systems, particularly in situations in which men and women have different levels of control over productive assets (Cross-Chapter Box GENDER in Chapter 18).

5.10.3 Projected Impacts

The impacts of climate change on risk in mixed farming systems are projected to be dependent on market, ecosystem, and policy context (*medium evidence, low agreement*). In mixed crop-livestock farms in a semiarid region of Zimbabwe, Descheemaeker (2018) found that feeding forages and grain could alleviate dry-season feed gaps to the 2050s, but their effectiveness depended on the household's livestock stocking density. In comparing different commercial production systems, Tibesigwa (2017) found that under South African conditions, climate change to the 2050s will reduce productivity across the agricultural sector, with the largest impacts occurring in specialized commercial crop farms owing to their relative lack of diversity. Mixed farming systems were the least vulnerable in terms of relative effects on farm output; this applied to commercial and subsistence sectors (Tibesigwa et al., 2017). Other studies suggest increased risk in mixed systems in semiarid conditions. In northern Burkina Faso, Rigolot (2017) examined different crop fertilization and animal supplementation levels under RCP8.5 to the 2050s. They found that although aggregate profits could be increased via moderate levels of inputs, the use of external inputs may increase risk because of marginal costs exceeding marginal benefits in lower rainfall years. In the Western Australian wheat belt, Thamo (2017) assessed climate-change-induced shifts in farm profitability to the 2050s. For most options, the adverse effects on profitability were greater than the advantageous effects, profit margins being much more sensitive to climate change than production levels. However, in the same system Ghahramani (2018) evaluated adaptation options to 2030 and found that a shift to a greater reliance on livestock could be profitable, even in years with low rainfall.

Risk management in integrated production systems may constitute a barrier to uptake of adaptation options (Rigolot et al., 2017). Watson (2018) highlighted the current lack of financial risk management tools that could be used in smallholder coastal communities. Alongside other risk management tools such as weather-based index insurance, risk pooling may find wide application in different farming systems as an effective adaptation measure (*medium agreement, limited evidence*) (Hansen et al., 2019a).

Climate change impacts on productivity of agroforestry systems are similar to individual perennial crops, although there is limited research on tree crops (see section 5.4.1.2). Impacts include increased temperature or water stress, an increase in pathogens affecting crops, changes to pollinator abundance, and changes in the nutrient content of one or more of the agroforestry components. Many tree products such as fruits and nuts are grown in agroforestry settings. The quality and nutrition of these products and other specialty crops are often negatively affected by rising temperatures, ambient CO_2 concentrations, and tropospheric ozone

(Ahmed and Stepp, 2016). There is also evidence that the fungus coffee rust will be positively affected by climate change (Avelino et al., 2015; Bebber et al., 2016), with adverse effects on coffee agroforestry systems.

While shade trees can ameliorate increasing stand temperatures that will significantly impact arabica coffee (Ovalle-Rivera et al., 2015; Schroth et al., 2015), the opposite can also be true. Comparing shade and full-sun coffee systems in Ghana, Abdulai (2018) concluded that the leguminous tree species providing shade and additional nitrogen led to soil water competition with the coffee trees during severe drought, resulting in enhanced coffee mortality. On the other hand, experimentally induced drought in a soybean-intercropping agroforestry system in eastern Canada led to crop losses in the monocropping system only, whereas N-fixation declined in both systems (Nasielski et al., 2015). Thus, balancing the synergies and tradeoffs of multiple component systems is necessary based on local context. While species diversification can enhance resilience to climate shocks, lack of water can constrain the implementation of agroforestry practices in arid locations (Apuri et al., 2018).

For people reliant on both agriculture and fisheries for food production, regional differences in productivity effects of climate change are expected; populations in LMICs that are already vulnerable will be most affected by simultaneous reductions in fisheries and agricultural productivity (Blanchard et al., 2017). Twelve out of 17 high-income countries in Europe showed projected increases in agricultural production where adaptive capacity is higher, and agricultural and food fisheries' dependence were lower. Some LMIC countries (Nigeria, Cameroon, Ghana, and Gabon) showed relative reductions in both fisheries and agricultural production, where food insecurity, human population growth, and fisheries overexploitation rates are high (Blanchard et al., 2017). Model projections under the RCP6.0 scenario show decrease in marine and terrestrial production to 2050 in 87 out of the 119 coastal countries studied, even though there is a wide variance in adaptive capacity and relative and combined dependencies on fisheries and agriculture (Blanchard et al., 2017). A projected 2050 move towards greater consumption of cultured seafood and less meat showed that aquaculture requires less feed crops and land, but was regionally dependent upon differing patterns of production, trade, and feed composition (Froehlich et al., 2018b).

[START BOX 5.7 HERE]

Box 5.7: Perspectives of crop and livestock farmers on observed changes in climate in the Sahel

The Sahel region of West Africa has experienced some of the most severe multi-decadal rainfall variations in the world: excessive rainfall in the 1950s–1960s followed by two decades of deficient rainfall, leading to a large negative trend until the mid-to-late 1980s with a decrease in annual rainfall of between 20 and 30%. Recently, there has been a partial recovery of annual rainfall amounts, more significant over the central than the western Sahel. This recovery is characterized by new rainfall features including false starts and early cessation of rainy seasons, increased frequency of rainy days, increased precipitation intensity, and more frequent and longer dry spells (Salack et al., 2015; Sanogo et al., 2015; Salack et al., 2016; Biasutti, 2019). The Sahel is experiencing a new era of rainfall extremes (Bichet and Diedhiou, 2018; Panthou et al., 2018), suggesting an intensification of the hydrological cycle (Doblas-Reyes et al., 2021).

The ways in which crop and livestock farmers in the Sahel have responded to climatic variability have been studied widely (Sissoko, 2011; Gonzalez et al., 2012; Jalloh et al., 2013; Gautier et al., 2016; Sultan and Gaetani, 2016; Zougmoré et al., 2016; Segnon, 2019). Local communities have developed an extensive Indigenous ecological knowledge system, enabling them to make use of ecosystem services to support their livelihoods and to survive environmental change (Nyong et al., 2007; Mertz et al., 2009; Lahmar et al., 2012; Segnon et al., 2015). These knowledge systems have been crucial in people's resilience to and recovery from major environmental change, such as the severe drought period experienced in the region in the 1970s and 1980s (Nyong et al., 2007; Lahmar et al., 2012; Segnon et al., 2015; Gautier et al., 2016; Zouré et al., 2019). As climate change became evident and a primary concern on the global agenda, interest in local people's knowledge and understanding of climate change has also increased (Mertz et al., 2009; Tambo and Abdoulaye, 2013; Traore et al., 2015; Kosmowski et al., 2016; Sanogo et al., 2017; Segnon, 2019).

There is no simple understanding of crop and livestock farmers' response in the Sahel to rainfall variability. Nielsen and Reenberg (2010) developed human-environment timelines for the period 1950-2008 for a small village in northern Burkina Faso, relating livelihood diversification and crop-livestock management changes that map closely to local rainfall variability, such as fields abandoned in dry years and intense animal manure use in wet years. Although they found a significant correlation between crop-livestock management practice changes and major climatic events, the climate is only one of many interacting factors that influence local adaptation strategies (Mortimore, 2010; Nielsen and Reenberg, 2010; Sendzimir et al., 2011). Robust attribution of observed changes to specific change drivers remains a challenge.

Crop and livestock farmers' knowledge and perceptions of increases in temperature and temperature-related stressors (heat waves, number of extreme hot or cold days) are consistent with the observed meteorological data (Mertz et al., 2009; Mertz, 2012; Tambo and Abdoulaye, 2013; Traore et al., 2015; Sanogo et al., 2017; Segnon, 2019). Their perceptions of changes in rainfall amounts have not always been consistent with the observational record (Mertz, 2012; Segnon, 2019). Nevertheless, their perception of increases in dry spell occurrence during the rainy season and changes in rainfall pattern (onset, cessation, rainfall intensity, and distribution) were consistent with the recent observations (Barbier et al., 2009; Ouédraogo et al., 2010; Tambo and Abdoulaye, 2013; Salack et al., 2015; Traore et al., 2015; Kosmowski et al., 2016; Salack et al., 2016; Segnon, 2019). Rainfall patterns within the season, rather than the total amounts of rainfall, matter more for crop and livestock farmers in the Sahel (Segnon, 2019).

Crop and livestock farmers in the Sahel have a sophisticated understanding of the local climate. There is considerable potential to harness this knowledge, coupled with an enabling institutional environment, in developing policies and adaptation plans (Rasmussen et al., 2018); the Sahel is a region where meteorological stations and observed data are scarce (Buytaert et al., 2012; Nkiaka et al., 2017). A deeper understanding of the resilience of local ecological knowledge systems, in light of the hydro-climatic intensification currently experienced in the region and future changes, may well provide further insights into their long-term effectiveness.

[END BOX 5.7 HERE]

5.10.4 Adaptation Strategies

5.10.4.1 Increasing integration and diversity within mixed systems

There is *medium confidence* in the effectiveness of changing the nature of the integration between crops and livestock as an adaptation: moving from crops to livestock, moving from livestock to crops, and moving from one species of livestock to others, for example (Roy et al., 2018). Such transitions that increase integration between farm enterprises may contribute to risk reduction and increased food security. In areas with adequate rainfall and relatively limited rainfall variability under climate change, where agricultural diversity is the greatest, transitions towards more diverse and integrated systems may bring substantial adaptation benefits (Waha et al., 2018).

Barriers to increasing integration and diversification include policies which support cereals and crop specialization, lack of markets, limited post-harvest processing, limited technical or biophysical research on implementation and poor market infrastructure (Keatinge et al., 2015; Bodin et al., 2016; Garibaldi et al., 2016; Bassett and Koné, 2017; Kongsager, 2017; Rhiney et al., 2018; Roesch-McNally et al., 2018; Clay and King, 2019; Ickowitz et al., 2019). Proactive policy and market development are needed to reduce these barriers (Clay and King, 2019; Ickowitz et al., 2019; See 5.14.3.8 for Insurance).

5.10.4.2 Agroforestry as an adaptation–mitigation strategy for mixed systems

Agroforestry, the purposeful integration of trees or shrubs with crop or livestock systems, increases resilience against climate risks through a range of biophysical and economic effects (*high confidence*). Traditional agroforestry has been practiced for millennia and provides prime examples of sustainable agroecological production systems meeting the production, income, and socio-cultural needs of farming communities within their ecological niches, but market forces have often led to their demise (McNeely and

Schroth, 2006; Plieninger and Schaar, 2008; García-Martínez et al., 2016; Krčmářová and Jeleček, 2016; Coq-Huelva et al., 2017; Paudel et al., 2017; Doddabasawa et al., 2018; Maezumi et al., 2018; Lincoln, 2020). The wide range of options to associate different trees with crops, livestock and aquaculture allow agroforestry to be practiced in most regions, including those with precipitation regimes ranging from semiarid to humid. While most agroforestry systems occur in smallholder settings, there are examples of successful industrial-scale mechanized agroforestry systems (Feliciano et al., 2018; Lovell et al., 2018). Agroforestry delivers medium to large benefits to all five land challenges described in the SRCCL - climate change mitigation, adaptation, desertification, land degradation, and food security - and is considered to have broad adaptation and moderate mitigation potential compared with other land challenges (Smith et al., 2019c). Agroforestry is also able to deliver multiple biophysical and socioeconomic benefits (Table 5.12).

Table 5.12: Some of the biophysical and socioeconomic benefits of agroforestry.

Contribution	Pathway	References
Increased food security and household income	Diversification of production, avoiding tradeoffs between crop and tree products	Nath et al. (2016), Coulibaly et al. (2017), Montagnini and Metzel (2017), Waldron et al. (2017), Blaser et al. (2018), Sida et al. (2018), Quandt et al. (2019), Amadou et al. (2020)
Increased productivity per unit of land	Introduction of multiple species leading to higher land equivalency ratios	van Noordwijk et al. (2018), Reppin et al. (2019)
Improved biophysical site properties	Via limiting soil erosion, facilitating water infiltration, increasing nutrient use efficiency, improving soil physical properties, improving crop nutritional quality, modifying the site micro-climate, and helping to buffer against extreme events	Nguyen et al. (2013); Carsan et al. (2014), Rosenstock et al. (2014), Quandt et al. (2017), Hoegh-Guldberg et al. (2018), Sida et al. (2018), Wood and Baudron (2018), de Leeuw et al. (2020), Muchane et al. (2020), Nyberg et al. (2020)
Enhanced biodiversity and supporting ecosystem services	Via integrating different perennial and annual species in different spatial or temporal associations, thereby providing greater habitat diversity for other species, including pollinators and predators	McNeely and Schroth (2006), Imbach et al. (2017), Isbell et al. (2017), Sonwa et al. (2017b), Tran and Brown (2019)
Enhanced cultural ecosystem services	Enhanced recreational, cultural and spiritual uses	Nyberg et al. (2020)
Carbon dioxide removal	Via enhanced above-ground carbon sequestration compared with most cropping or livestock systems, ranging from 2.6 -10 Mg C ha^{-1} yr^{-1} depending on regional and climatic conditions (> 0.7 Gt CO_2e yr^{-1} globally between 2000 and 2010)	Ramachandran Nair et al. (2009), Zomer et al. (2016), Rochedo et al. (2018), Wolz et al. (2018), Crous-Duran et al. (2019), Platis et al. (2019)
Enhanced gender balance	Via providing women with more diversified income sources	Kiptot et al. (2014), Ngigi et al. (2017), Benjamin et al. (2018)
Strengthened urban & peri-urban agricultural systems	Via provision of regulating and provisioning ecosystem services such as shade, water infiltration, new food and livelihood opportunities	Borelli et al. (2017) See Section 5.12

The adoption and maintenance of agroforestry practices require appropriate incentives or the removal of barriers (*high confidence*). Agroforestry adoption has been limited to date in both higher-income and lower-income countries. Several constraints need to be carefully addressed for successful scaling up of agroforestry systems, including costs of establishment, limited short-term benefits, lack of reliable financial support to incentivize longer-term returns on investments, land tenure, knowledge of and experience with trees and the management of multiple component systems, and inadequate market access, (Coulibaly et al., 2017; Iiyama et al., 2017; Jacobi et al., 2017; Kongsager, 2017; Hernández-Morcillo et al., 2018; Iiyama et al., 2018; Lincoln, 2019). Kongsager (2017) Roupsard et al. (2020) also highlight the need for vertical integration of measures from local to national scales to successfully address local barriers to adoption. Although there are few studies evaluating the long-term performance of agroforestry systems (Coe et al., 2014; Meijer et al., 2015; Brockington et al., 2016; Kongsager, 2017; Toth et al., 2017), the available results suggest that successful adoption of agroforestry practices depends strongly on the local enabling environment, including appropriate markets, technologies, and delivery systems (*medium evidence, high agreement*).

5.10.4.3 Links between crops and aquaponics-hydroponics as adaptation

Hydroponic systems produce plants in a soilless environment requiring mineral fertilizers to meet plant nutritional needs, whereas aquaponics combines an aquaculture production system with hydroponics, where fish waste provides nitrogen, phosphorous, and potassium for plant growth and nitrifying and mineralizing bacteria act as filters (Goddek et al., 2015; Pérez-Urrestarazu et al., 2019; Ghamkhar et al., 2020). The relative environmental impact of hydroponic systems is lower compared with conventional systems owing to the significant reductions in land use and fertilizer usage (*high confidence*) (Goddek et al., 2015; Datta et al., 2018; Pantanella, 2018; Suhl et al., 2018; El-Essawy et al., 2019; Jaeger et al., 2019; Monsees et al., 2019; Mupambwa et al., 2019; Pérez-Urrestarazu et al., 2019; Ghamkhar et al., 2020). While studies indicate that aquaponics and hydroponics have higher yields and a lower environmental footprint than conventional agriculture (*medium confidence*), aquaculture and heated greenhouse production (Pantanella, 2018; Romeo et al., 2018), aquaponic production may need to be coupled, decoupled, or have double-recirculation systems to meet the different requirements of farmed fish and crop species (Pantanella, 2018; Suhl et al., 2018; Mupambwa et al., 2019). Aquaponics and hydroponics are a promising adaptation option for urban agriculture, benefits including a protected growing environment from climate extremes, reduced GHG emissions related to food transportation, reduced food waste, rainwater harvesting and use of food waste (*medium agreement, limited evidence*) (Goddek et al., 2015; Al-Kodmany, 2018; Clinton et al., 2018; Weidner and Yang, 2020). Such systems show promise for reducing food production environmental footprints and increasing food security, particularly in arid or water-stressed environments (Doyle et al., 2018; Mupambwa et al., 2019). Barriers to aquaponics and hydroponics adoption include market acceptance of cultured fish species and desirability of plant crops, lack of expertise, legal constraints or high investment costs and financial feasibility (Bosma et al., 2017; Al-Kodmany, 2018; Datta et al., 2018; Pantanella, 2018; El-Essawy et al., 2019; Martin and Molin, 2019; Pérez-Urrestarazu et al., 2019; Specht et al., 2019). There is *high confidence* (*high agreement, medium evidence*) that a major barrier to hydroponic and aquaponics adoption is the requirement for skilled operators (Goddek et al., 2015; Bosma et al., 2017; Datta et al., 2018; McHunu et al., 2018; Pantanella, 2018), which could be mitigated by decoupling systems and disciplines (Pantanella, 2018). As yet, these systems are not widely implemented and information on their climate change impacts is limited.

5.10.4.4 Transitions in and between mixed systems as adaptation strategy

Transitions in and between the different elements of integrated agricultural systems can be an effective adaptation option *(medium confidence*). Havlik et al. (2014) projected that by 2030 market-driven autonomous transitions toward more efficient production systems would increase ruminant meat and milk productivity by up to 20% and decrease emissions by 736 $MtCO_2e \cdot y^{-1}$, most of this arising through avoided emissions from the conversion of 162 Mha of natural land. Weindl et al. (2015) assessed the implications of several climate projections on land use change to 2045 and found that shifts in livestock production towards mixed crop-livestock systems would represent a resource- and cost-efficient adaptation option, reducing global agricultural adaptation costs and abating deforestation by about 76 million ha globally. Both studies suggest that public policy support for transitioning livestock production systems to increase their efficiency could be an important lever for reducing adaptation costs and contributing to emissions reductions. This policy support could include modified regulatory and certification frameworks that incentivise livestock producers to adapt and mitigate (Weindl et al., 2015).

Recent reviews have summarised literature on production system transitions, driven at least partly by a changing climate or changing climate variability, that sometimes involves substantial shifts in enterprises and land configurations. These reviews found several cases of transitions affecting pastoral and mixed systems, with a range of responses including intensification, diversification, sedentarisation, as well as the abandonment of agriculture (see section 5.14.3.1, Vermeulen et al., 2018; Thornton et al., 2019). The consequences of these system transitions have been mixed; in some cases, the household level outcomes have been beneficial, while in others not. Policy environments, defined in terms of multi-level governance structures and institutions, are critical enablers of change. The vulnerability of many crop-livestock keepers to climate change is particularly affected by property and grazing rights (*high confidence*). Identifying the winners and losers from changes in land ownership and the use of communal lands in the coming decades is a key challenge for the research agenda, particularly as climate change impacts in the marginal lands intensify (Reid et al., 2014).

[START BOX 5.8 HERE]

Box 5.8: Climate Adaptation and Maladaptation in Cocoa and Coffee Production

Coffee and cocoa are important crops in low latitude regions where agriculture is projected to be heavily impacted by climate change. Both crops are at risk from climate change impacts by 2050 (Baca et al., 2014; Ovalle-Rivera et al., 2015; Chemura et al., 2016; Schroth et al., 2016; Bacon et al., 2017; Schreyer et al., 2018; de Sousa et al., 2019; Lahive et al., 2019; Pham et al., 2019; Cilas and Bastide, 2020). Chocolate and coffee are notable among foods in that their carbon footprint ranges from negative to high, as these industries include both low-input agroforestry systems that have many co-benefits, and high-input monoculture systems where crops are grown without shade, in some cases on sites that have been deforested (Poore and Nemecek, 2019). While the coffee industry in many countries has already transitioned from agroforestry to a full-sun production (Jha et al., 2014), the cocoa industry is at a turning point with many growers deciding whether to move to the potentially more productive ‘full-sun system', despite a general view that the agroforestry system is more resilient to climate change impacts (Rajab et al., 2016; Schroth et al., 2016; Farrell et al., 2018; Niether et al., 2020).

Shade-grown cocoa and coffee agroforestry systems provide an array of ecosystem services, including regulating pests and diseases, maintaining soil fertility, maintaining biodiversity and carbon sequestration (*high confidence*) (Jha et al., 2014; Rajab et al., 2016; Cerda et al., 2017; Pham et al., 2019). For example, a comparison of Indonesian cocoa stands found that total carbon stocks above and below ground were five times higher in multi-shade agroforestry stands compared to monoculture stands (57 compared to 11 Mg C ha^{-1}) and total net primary production was twice as high (18 compared to 9 Mg C ha^{-1} yr^{-1}). The extra carbon sequestration was achieved without any notable difference in cocoa yield (Rajab et al., 2016). At higher levels of shade there can be negative impacts on the yield of the understory crop, but careful management of shade trees allows for both crops to thrive (Andreotti et al., 2018; Blaser et al., 2018; Niether et al., 2020).

Cocoa grown under shade in some situations may be more resilient to climate change (Schwendenmann et al., 2010; Schroth et al., 2016). Schwendenmann et al. (2010) implemented drought experimentally in the field and found shade trees increased drought resilience. Shade trees insulate the understory crop from the warming and drying sun (Schroth et al., 2016). On the other hand, full-sun cocoa systems may be more climate resilient in some cases (Abdulai et al., 2018), as interactions between understory trees and shade trees are complex; in addition to shade effects, evapotranspiration and root interactions must be considered (Niether et al., 2017; Wartenberg et al., 2020). Moving to a full-sun system may also involve additional inputs in irrigation, fertiliser, and labour. Neither (2020) reviewed the literature comparing the two cocoa production systems and concluded that the agroforestry system was superior in terms of climate adaptation.

The choice of cropping-system will have wide-reaching consequences for climate vulnerability and climate justice. Coffee and cocoa are often a main source of income for small-scale producers who are among the most vulnerable to climate hazards (Bacon et al., 2014; Schroth et al., 2016). Most of their produce is exported by large corporations and sold to relatively better-off consumers. In the context of climate justice, underlying structural inequalities (socioeconomic, ethnicity, gender, caste), marginality, and poverty help to shape the vulnerabilities of small-scale farmers to climate hazards (Beckford and Rhiney, 2016; Schreyer et al., 2018). Climate change may compound their vulnerability, if for example the loss of pollination services leads to a reduction in productivity (Avelino et al., 2015). Adaptation needs to consider the inequalities associated with the commodity chain, and the adaptative capacity of producers as they seek to move into the more advanced processing stages of the commodity chain to realize higher returns from their exports (Ovalle-Rivera et al., 2015). Blue Mountain Coffee is a 'specialty' coffee associated with a Protected Area forest ecosystem that attracts a high price premium owing to its distinct flavour and aroma. The livelihoods of coffee farmers in this region are characterized by multiple socioeconomic, environmental, and institutional stressors related to climate change, pests, plant diseases and production costs. Some coping strategies employed by these coffee farmers have increased their susceptibility to future climate impacts (Guido et al., 2019). Davis (2017) showed that these coffee farmers' food security challenges could be alleviated by improved marketing of fruit tree products under shade coffee farming systems. Adaptation measures in such systems need to consider co-benefits and negative trade-offs, especially in vulnerable communities, to avoid widening further the inequalities, rural livelihood loss, migration, and marginalisation, and ensure progress towards the SDGs (*high confidence*).

[END BOX 5.8 HERE]

5.11 The Supply Chain from Postharvest to Food

The food system is more than just the production of food. It includes domestic and international transportation, storage, processing, market infrastructure and institutions that make up value chains, as well as the food environment in which consumers make food purchasing decisions (HLPE, 2017a). Climate change impacts along the value chain alter availability, access, and stability of food security. Nutrition-dense foods tend to be more perishable and are thus more vulnerable to limitations of food storage and transportation infrastructure (Ickowitz et al., 2019). Climate-change-related damage to food in storage (e.g., electricity failures and loss of cold storage) and transportation infrastructure (e.g., extreme weather events damaging roads and other infrastructure) could significantly decrease availability and increase the cost of highly perishable, nutritious foods such as fruits, vegetables, fish, meat, and dairy.

This discussion of the post–harvest food system (i.e., after production or catch) focuses on three key elements – food safety, storage, and domestic and international transactions – that could see significant climate change impacts, either directly or indirectly. Higher temperatures and humidity can increase post–harvest loss from pests and diseases, increase occurrence of food borne diseases and contamination, and raise the cost of refrigeration and other forms of preservation. Extreme weather events can cause disruptions to food transport networks and storage infrastructure. Changes in regional weather can cause production centres to shift locations, potentially requiring changes in storage and processing locations. Prices to producers and consumers will change although directions and magnitudes are determined by local conditions and policies.

Food *loss* is the harvest not used by industry or for food. Food *waste* is the subset of food loss that is potentially recoverable for food use. As a product moves in the postharvest chain to end users, post-harvest food loss from climate change can occur from improper handling to damage from microorganisms, insects, rodents, or birds. Post-harvest losses in quality can be the result of stresses and damage to a plant or animal before harvest, including from climate change (Hodges et al., 2011; Medina et al., 2015a). Food *waste* caused by climate change may occur at both retail units and homes because fresh ingredients and freshly prepared foods are vulnerable to quality reduction and spoilage from exposure to higher temperatures and humidity. Food waste also contributes to climate change by utilizing resources that emit GHGs (Galford et al., 2020).

5.11.1 Current and Future Climate Change Impacts on Food Safety

Emerging food safety risks from climate change include those posed by toxigenic fungi, plant and marine based bacterial pathogens, harmful algal blooms (HABs), increased use of chemicals (plant protection products, veterinary drugs) potentially leaving residues in food (European Food Safety Authority Panel on Plant Protection Products and their Residues et al., 2017; Deeb et al., 2018; Mbow et al., 2019; FAO et al., 2020).

Mycotoxins, produced by toxigenic fungi found on many crops, contaminate food and feed and cause a wide range of adverse impacts to human and animal health. Climate change can affect the growth and geographical expansion of these fungi (*high confidence)* (Wild et al., 2015; Battilani, 2016; FAO and WHO, 2016; Watson et al., 2016b; Alshannaq and Yu, 2017; Chen et al., 2018a; Avery et al., 2019; Milicevic et al., 2019; Van der Fels-Klerx et al., 2019; FAO, 2020a; FAO et al., 2020).

Aspergillus flavus is a fungus that infects a range of crops and can reduce grain quality. Several strains also produce aflatoxin, a particularly problematic mycotoxin. Increasing CO_2 and drought stress has little effect on growth of *Aspergillus* but significantly increases the production of aflatoxin (Medina et al., 2015b). In Europe one estimate is that the risk of aflatoxin contamination will increase in maize in a + 2°C temperature scenario in Europe with nearly 40% of Europe exceeding the current legal limits (Battilani and Toscano, 2016). In Malawi, maize aflatoxin levels above EU legal thresholds are possible for most of the country by mid-21st century (Warnatzsch and Reay, 2020). The occurrence of toxin-producing fungi will increase and expand from tropical and subtropical areas into new regions and where appropriate capacity for surveillance and risk management is lacking *(medium confidence)* (Miller, 2016). The increase in toxigenic fungi in crops, and consequent contamination of staple foods with mycotoxins, will increase the risks of human and animal exposure *(high confidence)* (Botana and Sainz, 2015; Rose and Wu, 2015; Battilani, 2016; Avery et al., 2019; Bosch et al., 2019; Milicevic et al., 2019; Moretti et al., 2019; Van der Fels-Klerx et al., 2019; FAO, 2020a).

In aquatic systems, mycotoxins produced by *Vibrio* during HABs also cause food safety problems (*high confidence*) (Botana, 2016; Estevez et al., 2019; section 5.8). Increased poleward expansion of Vibrios in coastal mid- to high-latitude areas has been observed (Baker-Austin et al., 2017). Vibrio-related mortalities from finfish consumption are expected to rise with climate change (water temperature, salinity, oxygen and pH) (*medium confidence*) (Mohamad et al., 2019a; Mohamad et al., 2019b). For shellfish species oxygen deficits (Mohamad et al., 2019b), sea-level rise (Deeb et al., 2018) and temperature (Green et al., 2019) will be most important for food safety.

Food safety is also anticipated to worsen from increased contaminant bioaccumulation under climate-induced warming (*high confidence*) (Sections 3.5.8, 3.5.9, 5.8, 5.9, Bindoff et al., 2019;), with changes in pathogen, parasite, fungi and virus abundance and virulence (Bondad-Reantaso et al., 2018). Coastal communities who depend on fisheries for livelihoods and nutrition are especially vulnerable (Hilmi et al., 2014; Golden et al., 2016; Bindoff et al., 2019).

Occurrence of bacterial pathogens such as Salmonella and Campylobacter will increase with rising temperatures (*high confidence*). Foodborne pathogen risks will increase through multiple mechanisms, though in general the impacts of climate change on different pathogens are uncertain (Akil et al., 2014; Hellberg and Chu, 2016; Lake and Barker, 2018). Even species within a genus can be affected differently. For example, higher CO_2 levels depress the growth rate of *F. graminearum*, an economically important pathogen on barley but have little effect on *F. verticillioides*, which is the most reported fungal species infecting maize.

Increases in rainfall intensity will have some effect on the transport of heavy metals by enhancing run-off from soil and increasing the leaching of heavy metals into water systems with magnitudes dependent on local conditions (*high confidence*) (Joris et al., 2014; Wijngaard et al., 2017). Methyl mercury (MeHg) is highly neurotoxic and nephrotoxic and bioaccumulates and biomagnifies through the food web via dietary uptake (fish, seafood, mammals) (Fort et al., 2016). Ocean warming facilitates methylation of mercury, and the subsequent uptake of methyl mercury in fish and mammals has been found to increase by 3–5% for each 1°C rise in water temperature (Booth and Zeller, 2005; FAO, 2020a). A changing climate will release mercury from snow and ice, raising the amount of mercury in aquatic ecosystems although its importance relative to industrial sources is unknown (Morrissey et al., 2005).

Increased frequency of inland floods has been associated with contamination of food with toxic and fat-soluble persistent organic pollutants (POPS), polychlorinated biphenyls (PCBs) and dioxins (Lake et al., 2014; Tirado, 2015; Alava et al., 2017). Exposure to POPs can lead to serious health effects including certain cancers, birth defects, and impairments to the immune, reproductive, and neurological systems.

Climate change–contaminant interactions may alter the bioaccumulation and biomagnification of POPs and PCBs as well as (MeHg) (Alava et al., 2017). Of particular concern is the pollution risk influenced by climate change in Arctic ecosystems and because of the bioamplification of POPs and MeHg in seafoods resulting in long-term contamination of traditional foods in Indigenous communities (Tirado, 2015; Alava et al., 2017).

The high risk associated with emerging zoonoses (animal diseases that can infect humans) and alterations in the distribution, survival and transmission of vectors and associated pathogens and parasites, could lead to an increased use of veterinary drugs and more rapid development of microbial resistance (European Food Safety Authority et al., 2020; FAO, 2020a) and higher veterinary drug residues in food of animal origin, potentially posing health issues for humans (Beyene et al., 2015; FAO et al., 2018; European Food Safety Authority et al., 2020). These outcomes will depend, at least in part, on the extent of changes in current regulatory systems for veterinary drugs. Preharvest stress on animals can increase the contamination of meat products with zoonoses. Climate change may also increase rodent populations and rodent-born zoonoses (Naicker, 2011). Extreme weather events that cause flooding, such as hurricanes or extreme rain events, increase the chance of inundating areas that contain waste from animal farms where antibiotics are used for production, increasing the spread of antibiotic-resistant bacteria into the surrounding environment (FAO, 2020a).

5.11.2 Current and Future Climate Change Impacts on Food Loss in Storage, Distribution and Processing

The potential for climate-change-based food losses exists in all parts of the food system – post-harvest storage, distribution, and processing – with the potential for impacts in one part of the system to be passed on to other elements (Davis et al., 2021). Storing a product destined for food use makes it available in times other than immediately after harvest, especially important for products with a pronounced seasonal availability or are not available from other regions with different seasons. Storage of fresh products (meat, fish, fruits, and vegetables) even with the best cold storage technology results in some quality loss relatively quickly. Higher temperatures increase the cost of maintaining quality. One estimate is that an increase in outdoor temperature from 17°C to 25°C increases cold storage power consumption by about 11% (James and James, 2010). Post–harvest storage of roots and cereals is subject to physical and quality losses from damage by mice, rats, and birds and by microorganisms such as the toxigenic fungi discussed above, all of which are expected to increase in warmer and more humid conditions.

The higher temperatures and humidity will generally raise storage costs and lower the quantity and quality of stored product, reducing producer incomes and raising consumer prices (*high agreement, medium evidence*) (Mbow et al., 2019). For example, in the US state of Michigan, climate change will shorten the period of reliably cold local storage of potato by 11-17 days and 14–20 days further south by mid-century and by 15–29 days and 31–35 days, respectively by late century. These changes would increase future demand for ventilation and/or refrigeration immediately after harvest and again in spring and early summer (Winkler et al., 2018).

Insects are a main source of food loss. Climate change can alter insect damage in at least two ways – increases in reproductive rate from temperature increases and changes in pheromone effectiveness (*high confidence*). Increasing temperature up to about 40°C raises the rates of insect food digestion and reproduction (Deutsch et al., 2018), but temperatures above that level are fatal for many insects (Neven, 2000). Most insects rely on pheromones to facilitate reproduction. Higher temperatures, but also increases in atmospheric CO_2 and O_3 levels, can affect this process. Insect species that rely on long-range chemical signals (such as ladybirds, aphids, bark beetles and fruit flies) will be most impacted, because these signals suffer from longer exposure to processes that reduce pheromone effectiveness (Medina et al., 2015b; Moses et al., 2015; Boullis et al., 2016; Verheecke-Vaessen et al., 2019).

There are several potential pathways for climate change impacts on processing that would negatively affect quality and appearance, but with limited research to date. For example, some studies have indicated that recent increases in temperature have decreased the appearance and milling quality of rice in the US and East Asia, owing to increased occurrence of chalky grains (Lyman et al., 2013; Morita et al., 2016; Masutomi et al., 2019; Ishigooka et al., 2021). Impacts on quality of perennial crops and annual fruits and vegetables are discussed above (Section 5.4.3 and Box 5.2).

5.11.3 Current and Projected Impacts on Transportation and Distribution: Domestic and International Trade

Regional differences in resource availability are a key underlying driver of domestic and international trade. Climate change can change resource availability, both in quantity and quality terms, altering trade flows, prices, and incomes of producers. Climate change can also affect food access and its stability can be affected through climate change driven disruption of infrastructure (FAO et al., 2018; Mbow et al., 2019). Extreme events are expected to become more common as climate change progresses. Recent examples illustrate the potential for trade disruptions. In March 2019, Cyclone Idai affected 1.7 million people in Mozambique and 920,000 in neighbouring Malawi, according to UN officials. The World Food Program reported that satellite imagery of flooding in central Mozambique showed an 'inland ocean' the size of Luxembourg with potentially large impacts on distribution of existing supplies, and uncertain effects on future food production and availability. The extreme rainfall events in the US state of Iowa in spring 2019 destroyed large numbers of well-built grain silos. In addition, major road and bridge damage required rebuilding.

Trade plays a sizeable role in global food supplies. More than 1 billion people relied on international food trade in the early 21st century (Fader et al., 2013; Pradhan, 2014). Domestic and international trade flows can be dramatically affected by climate change impacts *(medium evidence, high confidence)* (Nelson et al., 2014; Pradhan, 2014; Wiebe et al., 2015). Since the impacts of climate change will not be uniform, profitable locations for exports production will change. In addition, the effects of increasing local weather variability caused by climate change means increasing variability of food availability for domestic use and international trade. Finally, extreme events driven by climate change can disrupt transportation along the food value chain. Countries more at risk of natural hazards that disrupt transportation and distribution, and with less extensive routes, are more vulnerable to climate change impacts. A global multi-hazard risk assessment (Koks et al., 2019) suggests surface and river flooding, which are projected to increase in a warmer climate, are the main hazards for road and railway infrastructure, increasingly disrupting international and domestic transportation of agricultural commodities.

Climate change impacts will increase most global prices relative to early 21st levels with varying effects on the cost of food imports *(high confidence)* (Nelson et al., 2014; Wiebe et al., 2015; Fujimori et al., 2018; Lee et al., 2018). For example, analysis using results from one study (using CMIP5 data for RCP8.5 and SSP2) found that net food importing countries in the early 21st century would see expenditures on food imports decrease by USD 36 billion in mid-century in real terms with climate change over a no climate change scenario. (Table 5.13).

Table 5.13: Net exports of agricultural products, by net exporting and net importing countries, 2010 and 2050 (billion constant parity US dollars), based on analysis in Beach et al. (2019)

	2010	2050
Net importers in 2010		
No climate change	-301	-838
Climate change	-301	-802

Global economic models with a focus on agriculture provide a perspective on the range of potential changes in market outcomes because of climate change. In one study comparing several SSPs to a future with no climate change to one with impacts from RCP8.5, 2050 yields with climate changes impacts are 17% smaller on average than those without climate change. Adaptation by farmers reduce that to an 11% decline. The change in 2050 prices of all crops and regions after climate change impacts and farm level adaptation is a mean 20% increase (Nelson et al., 2014). Substantial differences arise from both the heterogeneous impacts of climate change over crops and geography and the diversity of modelling approaches in the GCM and crop models. A later study with more socio-economic scenarios and fewer models got roughly similar results (Wiebe et al., 2015) as did a modelling study focused on food security in South Asian countries (Cai et al., 2016).

Most climate scenario modelling to date does not incorporate increasing variability nor the use of storage, a critical tool to manage variability. Two recent studies are exceptions. In one, climate change generally reduces mean yields and increases their variability in the Midwestern U.S. and causes modest increases in price volatility (Thompson et al., 2018). A second study (Chen and Villoria, 2019) focuses on maize net importers across Africa, Asia, and Latin America during 2000–2015. A 1% increase in the ratio of imports to total consumption reduces domestic price variability by 0.29%. A 1% increase in stocks at the beginning of the season is correlated with a 0.22% reduction in the coefficient of variation.

5.11.4 Adaptation in the Post-harvest Supply Chain

The SRCCL (Mbow et al., 2019) findings on adaptation support targeting food value chains and intervention types to the needs of specific locations. Furthermore, adaptation choices will need to be dynamic as climate change impacts are expected to worsen over time.

As discussed above and in section 6.2.5, climate change is expected to cause increasingly severe effects on infrastructure needed for food security: roads and harbours for transport, water storage facilities for irrigation and storage facilities able to withstand climate-related damage. Three categories of adaptation could be considered – adoption of technologies already in use elsewhere, including indigenous and local knowledge, or available or near ready that become profitable as impacts become more severe, development of new technologies, and taking advantage of changing comparative advantage across regions. Specific examples of post-harvest technical adaptation options that are already available but could be more widely adopted include solar driers, cold storage facilities and transport and use of ultrasonic humidification of selected fruits and vegetables, a technology that has been shown in Europe to reduce losses in each post–harvest stage by 20% or more (Fabbri et al., 2018). Hermetic storage containers using community-based farmer research networks to scale out (Singano et al., 2020; Wenndt et al., 2021) also show promise. Another innovation is to introduce Aspergillus fungi that do not produce aflatoxins in biocontrol formulations, such as being undertaken in the Aflasafe project in Kenya (Bandyopadhyay et al., 2016).

International trade changes are a potentially important adaptation mechanism for both the short-term effects of climate variability and long-term changes in comparative advantage with globally substantial benefits but that are distributed unevenly (Mosnier et al., 2014; Baldos and Hertel, 2015; Fuss et al., 2015; Costinot et al., 2016; Hertel and Baldos, 2016; Gouel and Laborde, 2021). One estimate is that with a reduction in tariffs as well as institutional and infra-structural barriers, the negative impacts of climate change globally would be reduced by 64%, with hunger-affected import-dependent regions seeing the greatest benefit. However, in hunger-affected export-oriented regions, partial trade integration might lead to increased exports at the expense of domestic food availability (Janssens et al., 2020). It is possible for policy changes that result in increased trade flows to also increase the potential for maladaptation, for example by encouraging conversion of environmentally sensitive areas to agriculture (Fuchs et al., 2020; 5.13.3).

As discussed in section 5.4, climate change is expected to increase variability in yields. As long as the variability is not correlated across regions, trade flows within a year can partially compensate, with in-period exports from countries less affected to those that are. Alterations in trade flow patterns to accommodate these impacts will reduce the negative effects so long as this variability is not correlated across regions (UK, 2015; Janetos et al., 2017).

In terms of food safety impacts, (Lake and Barker, 2018) highlight a range of approaches to enhance preparedness for more serious foodborne disease effects from climate change: adoption of novel surveillance methods to speed up detection and improve intervention in foodborne outbreaks; genotype–based approaches to surveillance of food pathogens to enhance spatiotemporal resolution in tracing and tracking of illness; improving integration of plant, animal and human surveillance systems under the rubric of One Health, increased commitment to cross–border and global information initiatives; improved clarity regarding the governance of complex societal issues such as the conflict between food safety and food waste and strong user–centric (social) communications strategies to engage diverse stakeholder groups.

The range of potential adaptation approaches from production to transportation to reduce food loss and waste is captured in Figure 5.17 (Galford et al., 2020).

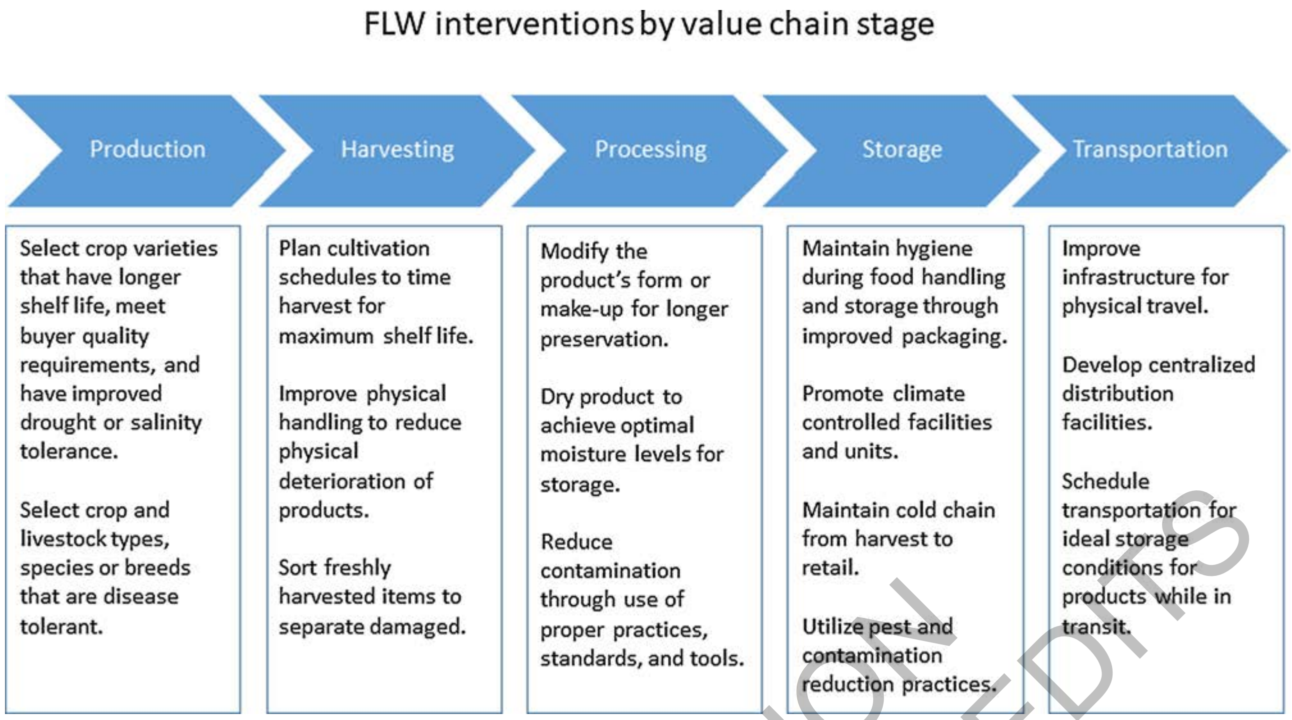

Figure 5.17: Examples of food loss and waste (FLW) interventions at five stages in the food value change (Galford et al., 2020).

The importance of reducing food loss and waste due to climate change is widely recognized, but literature on cost-effective reductions is sparse, particularly in low-income countries (Parfitt et al., 2010). A list of farm and post-harvest methods to reduce food loss (Sheahan and Barrett, 2017) includes potential farm interventions such as varietal choice, education in harvest and post-harvest handling, hermetic storage technologies (see above), chemical sprays and integrated pest management techniques in storage. The evidence on their effectiveness, especially in the face of increased climate change impacts, is limited.

5.12 Food Security, Consumption and Nutrition

5.12.1 Introduction

Food security and nutrition are key desired outcomes of food systems. Climate change is already contributing to reduced food security and nutrition and will continue to do so (*high confidence*) (Sections 5.4, 5.5, 5.8, 5.9, 5.10). Climate change impacts affect all four dimensions of food security: availability, access, utilization, and stability (Table 5.14) through both direct and indirect pathways.

Global food security improved dramatically in the 20th century even as global population increased from 2 to 6 billion. While some may assume that global food security is primarily provided by large-scale producers, research since AR5 has shown the sizeable role of small and mid-sized food producers in Asia, Africa and Latin America contributing to global food security and nutrition, while being highly vulnerable to climate change impacts on food security (Samberg et al., 2016; Herrero et al., 2017; FAO et al., 2018; Ricciardi et al., 2018).

In 2019 more than 750 million people in the world, almost 1 in 10 people, suffered from severe food insecurity, a figure which has risen since 2014 in every region except North America and Europe (FAO et al., 2020). Overnutrition, a result of high-calorie unbalanced diets, is also rising, with over 2 billion adults overweight or obese (FAO et al., 2018; Swinburn et al., 2019; FAO et al., 2020; Venkatesh Mannar et al., 2020; WHO, 2021). Many low and middle-income countries now have both high under- and overnutrition rates (FAO et al., 2018).

There are multiple drivers of food security including changing dietary patterns, urbanization and population growth (HLPE, 2017b; FAO et al., 2018; Swinburn et al., 2019). Vulnerability to climate change impacts on food insecurity and malnutrition is worsened by other underlying causes, including poverty, multiple forms of inequality (e.g., gender, racial, income), low access to water and sanitation, macroeconomic shocks, and conflict (Smith and Haddad, 2015; Clay et al., 2018; FAO et al., 2018; Cook et al., 2019). Climate change frequently acts to compound these drivers of food insecurity (Table 5.14).

The covid-19 pandemic has increased vulnerability to food insecurity and malnutrition of particular groups and sectors in the food system, including low-income households, farmworkers, food service workers, informal food market sellers, and low-income countries dependent on food imports (Cross-Chapter Box COVID in Chapter 7). Climate change will compound pandemic vulnerabilities in the food system (*high agreement, low evidence*) (HLPE, 2020; UNDRR (United Nations Office for Disaster Risk Reduction - Regional Office for Asia and Pacific), 2020; WFP-FSIN, 2020). The pandemic may also increase coordination among sectors and a willingness to address food system weaknesses made visible by the impacts of COVID-19 (Blay-Palmer et al., 2020; Cohen, 2020; Ramos et al., 2020).

Ecosystem services, the provisioning, supporting, and regulating mechanisms we all depend on for food security and nutrition, are also undermined by climate change impacts (Section 5.4.3). Even in the absence of climate change, our current food system threatens to exceed planetary, regional, or local boundaries of long-term sustainable development (Campbell et al., 2017). Climate change will make efforts to reduce this threat more difficult to achieve (*medium confidence)* though many solutions to enhancing food security are also potential climate change adaptation responses (Sections 5.4, 5.6, 5.8, 5.10, 5.14).

5.12.2 Mechanisms for Climate Change Impacts on Food Security

Climate change is increasing the number of people experiencing food insecurity through greater incidence and severity of climatic impact drivers (CIDs), (Seneviratne et al., 2021) such as extreme heat, drought, and floods. Increasing CO_2 concentrations have positive effects on food and forage crops by enhancing photosynthesis and alleviating drought stresses (5.4.3.1, 5.5.3.1), but have negative effects on nutrient concentrations in food crops. Ocean acidification is also caused by increasing CO_2, causing negative impacts on aquatic systems. Tropospheric ozone concentrations already hinder crop production (Section 5.4.1.4). Several CIDs increase the number of people experiencing food insecurity (*high confidence*) (SROCC 2019, FAO et al., 2018; Mbow et al., 2019; Baker and Anttila-Hughes, 2020; Table 5.12).

Vulnerability to climate impacts on food security and nutrition vary by region and group. Countries that experience CIDs such as extreme heat, severe drought or floods and have a large proportion of the population dependent on rainfed agriculture or livestock for their livelihoods and food supply have experienced rising food insecurity due to climate change impacts (FAO et al., 2018; Cooper et al., 2019; Mbow et al., 2019). Children in Sub-Saharan Africa are particularly at risk of undernutrition and mortality from increasing temperatures (Belesova et al., 2019; Baker and Anttila-Hughes, 2020). An additional estimated 5.9 million children became underweight due to rising temperatures in 51 countries affected by El Niño Southern Oscillation intensity in 2015-2016 (Anttila-Hughes et al., 2021). Low-income urban households and marginalized groups such as landless and ethnic minorities are at risk of increased food insecurity due in part to climate change extreme events such as extended drought, floods or cyclones that interrupt supply chains and impact livelihoods (Rodriguez-Llanes et al., 2016; FAO et al., 2018; Algur et al., 2021). A systematic review in India found that women often experience greater workloads and stress during drought events (Algur et al., 2021).

In the subsequent sections, the four dimensions of food security will be discussed in relation to observed and projected impacts and vulnerabilities (Table 5.14).

Table 5.14: Impacts from climate change drivers on the four dimensions of food security. Adapted from Table 5.1 in SRCCL

Climatic impact drivers and mechanism for food security impacts	**Examples of regions and groups most affected**	**References**
Food security dimension: Availability		

Increased heat and drought reduce crop and animal productivity and soil fertility and increase land degradation for some regions and crops.	Countries in which a large proportion relies on agriculture for livelihoods. Food production systems that rely on rainfed agriculture and pastoral rangeland. Urban populations and the poor.	FAO et al. (2018), Dury et al. (2019), Mbow et al. (2019), Section 5.4 and 5.5).
Extreme heat affects crop productivity. Combined with high humidity reduces agricultural labour capacity and animal productivity.	Countries and sectors that rely extensively on outdoor manual agricultural labor and experience high temperatures and humidity	Zander et al. (2015), Kjellstrom et al. (2016), Ioannou et al. (2017), Mitchell et al. (2017), FAO et al. (2018), Flouris et al. (2018), Kjellstrom et al. (2018), Levi et al. (2018).
Increasing temperatures and precipitation changes increase and shift crop and livestock pests and diseases	East African pastoral groups who experienced increased livestock morbidity and mortality from Rift Valley Fever in El Niño years.	Bebber (2015), FAO et al. (2018), Mbow et al. (2019), Sections 5.4.1.3 and 5.5.1.3
Increasing temperatures and drought stress has led to higher post-harvest losses due to mycotoxins.	Tropical and sub-tropic regions with limited food safety surveillance	Miller (2016), FAO et al. (2018), Section 5.11
Rising ocean temperatures, marine heatwaves and ocean acidity has reduced availability of fish in coastal communities.	Coastal people and coastal areas of tropical countries with high dependence on fisheries e.g., West African coastal communities	Hilmi et al. (2014), Golden et al. (2016), Bindoff et al. (2019), Section 5.8 and 5.9
Increased number and intensity of extreme events such as cyclones lead to reduced food production and distribution from crop damage, increased pest incidence and transportation disruption.	Delta regions where there are high populations and are often important food production regions. E.g., Cyclone Nargis in Myanmar estimated to reduce crop production by 19%, production declined for subsequent 3 years.	Omori et al. (2020)
Increased atmospheric CO_2 concentrations increase total plant biomass and plant sugar content, which can increase crops as well as pests and weeds. High CO^2 also reduces transpiration during drought which can increase plant drought resistance.	All regions are anticipated to have increased atmospheric CO^2 concentrations, but due to impacts of other CIDs (e.g., drought, heat stress, pests), the impacts on crop growth, forage, and subsequent food availability are mixed.	Iizumi et al. (2018); Canadell et al. (2021), Ranasinghe et al. (2021), Cross-Chapter Box MOVING PLATE this Chapter)
Food security dimension: Access		
Increased **drought** and **flood events** and increased pests and disease from **rising temperatures** lead to loss of agricultural income due to reduced yields, and higher costs of production inputs such as water. Reduced ability to purchase food leads to lower dietary diversity and consumption levels.	Low-income smallholder farmers and pastoralists in Ethiopia, Mali, Niger, Malawi, Zambia, and Tanzania.	Saronga et al. (2016), Giannini et al. (2017), FAO et al. (2018) Mbow et al. (2019) Omori et al. (2020)
Increase in number and intensity of **extreme weather events (e.g droughts, floods**) lead to increased food prices, which often leads to lower dietary diversity as well as lower consumption levels.	Low-income consumers. Women and girls.	FAO et al. (2018), Mbow et al. (2019), Ilboudo Nébié et al. (2021)
Extreme events (e.g. floods) disrupt food storage and transport networks, reducing access and availability of food supplies.	Countries dependent on food imports e.g Small Island Developing States. Poor households living in flash flood and saline zones in Bangladesh who rely on monocropped rice. Women and children may experience greater impacts from extreme events.	Toufique and Belton (2014), FAO et al. (2018), Hickey and Unwin (2020), Algur et al. (2021)
Food security dimension: Utilization (food quality and safety)		
Increased temperatures reduce food safety caused by microorganisms, including increased mycotoxins in food and feed.	Countries with limited food safety surveillance systems.	FAO et al. (2018), Mbow et al. (2019), Section 5.11

Climate change **extreme events** make fruits and vegetables relatively unaffordable compared to less nutrient dense foods.	Urban low-income households and rural households who purchase the majority of their food. Children in regions such as West Africa, with lower access to diverse food types as a result of climate impact drivers e.g. drought.	An et al. (2018), Algur et al. (2021), Baker and Anttila-Hughes (2020), Niles et al. (2021)
Rising air temperatures, **ocean warming, and high CO_2 conditions** increase risk of food poisoning and pollutant contamination of food through increased prevalence of pathogens (e.g., mycotoxins), harmful algal bloom, and increased contaminant bioaccumulation and threaten human health.	Low-income tropical countries where current ability to reduce and monitor mycotoxin contamination is limited. Coastal Indigenous Peoples and other poor populations in coastal areas of tropical countries with high dependence on fisheries e.g., west African coastal communities	Golden et al. (2016), Bindoff et al. (2019), Sections 5.7, 5.8, 5.9, 5.11
Increased atmospheric CO_2 concentrations reduce nutritional quality of grains, some fruits, and vegetables.	Low-income households who have limited access to range of diverse foods.	Mbow et al. (2019), Section 5.4
Rising ocean temperatures, marine heatwaves and ocean acidity reduce fish populations, which reduce consumption of fish high in iron, zinc, omega-3 fatty acids and vitamins in areas where fish populations decline.	Coastal areas of tropical countries; coastal Indigenous Peoples and other groups who rely on fisheries.	Golden et al. (2016); Bindoff et al., 2019; Section 5.7, 5.8, 5.9
Food security dimension: Stability		
Increased frequency and severity of extreme events (e.g., **droughts** and **heatwaves)** lead to greater instability of supply through production losses and disruption to food transport.	Landlocked countries; low-income countries reliant on imports; lo- income households in areas prone to floods.	Toufique and Belton (2014), FAO et al. (2018), Algur et al. (2021), Section 5.11
Increased drought and **flood events** and increased pests and disease from **rising temperatures** lead to unstable incomes from agriculture and fisheries.	Small-scale producers (crops and livestock) and fishers	Ruiz Meza, (2015), FAO et al. (2018), Sections 5.8, 5.9
Climate change **extreme events** increase food prices due to climate shocks.	Low-income countries reliant on imports; Urban low-income households and rural households who purchase the majority of their food.	Bene et al. (2015), Peri (2017), Mbow et al. (2019), Section 5.11
Increased drought and **flood events** and increased pests and disease from **rising temperatures** cause widespread crop failure. **Rising ocean temperatures, marine heatwaves, and ocean acidity** lead to dramatic decline in fisheries contributing to migration and conflict.	Coastal communities in West Africa, SE Asia, and other tropical countries highly dependent on fisheries.	Golden et al. (2016), Bindoff et al. (2019) Mbow et al. (2019)
Reduced frost days and snow days will increase stability of food security in some temperate regions since there will be less loss of food crops to frost damage and a longer growing season. However, they also raise pest and disease risks due to increased range and overwintering.	Australia, most Asian regions, Europe, Central and South America, North America The benefits of yield gains at high latitudes may be tempered by greater risks of pests and pathogen damages.	Jones and Barbetti (2012), IPPC Secretariat (2021), Ranasinghe et al. (2021)

5.12.3 Observed Impacts

5.12.3.1 Impacts on food availability

All food production systems (crops, livestock, marine, fish, mixed, aquaculture) have been undermined by climate change and are expected to experience larger impacts in the future as described in earlier sections (see Sections 5.4.1, 5.5, 5.8, 5.9, 5.10). In addition, sudden production losses from extreme climate events can reduce food security (FAO et al., 2018; Cottrell et al., 2019; FAO et al., 2020; Anttila-Hughes et al., 2021). For example, a 2007 drought-induced crop failure in southern Africa led to severe food insecurity in

Lesotho because of the land-locked country's dependence on imports from South Africa that aggravated food availability and access under conditions of declining food production and land degradation (Verschuur et al., 2021). Pest and disease outbreaks in both crops and livestock due to climate change (Sections 5.4.1, 5.5.1) have also impacted food availability and access (see Box 5.8 Desert Locust case study). Loss in labour productivity from climate change-related heat stress is a growing problem.

[START BOX 5.9 HERE]

Box 5.9: Desert Locust Case Study: Climate as Compounding Effect on Food Security

At the end of 2019, desert locust swarms infested Eastern Africa and caused widespread damage to crops and pastures, threatening food security and livelihoods (Kimathi et al., 2020; Salih et al., 2020). The FAO estimates that over 200,000 ha of crop and pastureland were damaged, rendering 2 million people in the region acutely food insecure (IGAD, 2020). The desert locust infestation was facilitated by two tropical cyclones that created desert lakes in a usually dry region of Saudi Arabia. Moist soils, warm temperatures and ample vegetation provided a suitable environment for desert locust breeding and migration to Yemen and Somalia, where the pest remained uncontrolled due to conflict and spread to neighbouring countries. A series of political and socioeconomic weaknesses such as armed conflict, limited financial resources, and lack of early actions compounded the impact of the current invasion and made it the most damaging in 70 years (Meynard et al., 2020; Salih et al., 2020).

Although desert locusts have been here for centuries, this recent outbreak can be linked to a unique feature of the positive Indian Ocean Dipole event (IOD), in part caused by long-term trends in sea surface temperatures (Wang et al., 2020a). The warming of the western Indian Ocean has increased frequency and intensity of severe weather, including tropical cyclones (Roxy et al., 2014; Murakami H, 2017; Roxy et al., 2017). Under a 1.5° C warmer climate, extreme positive IODs are anticipated to occur twice as often, which could also increase the occurrence of pest outbreaks (Cai et al., 2018).

Climate change increases the need for robust adaptation measures, such as transnational early warning systems, biological control mechanisms, crop diversification, and further technological innovations in areas of sound and light stimulants, remote sensing, and modeling for tracking and forecasting of movement (Maeno and Ould Babah Ebbe, 2018; Peng et al., 2020). The desert locust outbreak and the role of the Indian Ocean warming show that the impacts of climate change extend can increase unpredictable events. Extreme weather events act as a compounding effect, exacerbated further by weak governance systems, political instability, limited financial resources, and poor early warning systems (Meynard et al., 2020).

[END BOX 5.9 HERE]

Climate change affects agricultural labour productivity through increased intensity and frequency of heat stress events, with those performing physical labour in high humidity and ambient temperatures most vulnerable to heat stress (*high confidence*) (Hsiang et al.; FAO et al., 2018; Kjellström et al., 2019; Antonelli et al., 2020; Shayegh et al., 2020). Labour capacity, supply, and productivity loss in moderate outdoor work due to heat stress is estimated between 2% and 14% depending on the location and indicator (Ioannou et al., 2017; Kjellstrom et al., 2018), with an overall estimate of 5.3% loss in productivity for outdoor work between 2000 and 2015 (*medium confidence*) (Watts et al., 2018) but as high as 14% in low-income tropical countries (Antonelli et al., 2020; Shayegh et al., 2020). Highly vulnerable occupation groups affected by heat stress include farmers, farmworkers and livestock keepers working outdoors in low-income tropical countries (*high confidence*) (Zander et al., 2015; Kjellstrom et al., 2016; Flouris et al., 2018; Kjellstrom et al., 2018; Levi et al., 2018). Farmworkers and small-scale food producers in high- and middle-income countries involved in outdoor labour are also affected by heat stress (Zander et al., 2015; Gosling et al., 2018; Szewczyk et al., 2018; Watts et al., 2021). There is also evidence that heat stress is affecting labour supply through variation in nutrition intake (Antonelli et al., 2020).

5.12.3.2 Impacts on food access (physical, economic, and socio-cultural) and vulnerabilities

Increased extreme events (e.g., droughts, floods, and tropical storms, (Seneviratne et al., 2021) due to climate change are key drivers of recent rises in food insecurity rates and severe food crises in some regions (*high confidence*) (Section 5.4.1, Yeni and Alpas, 2017; FAO et al., 2018; Cooper et al., 2019; Baker and Anttila-Hughes, 2020; Bogdanova et al., 2021; Ilboudo Nébié et al., 2021). Extreme weather events reduce physical and economic access to food, increase food prices, and compound underlying conditions of food insecurity and malnutrition such as low access to diverse healthy foods, and safe water (FAO et al., 2018; Niles et al., 2021). Increased incidence of severe drought conditions since 2005 are contributing to food insecurity in affected regions, including Africa, Asia, and the Pacific (Chapter 7, Phalkey et al., 2015; FAO et al., 2018; Cooper et al., 2019; Ilboudo Nébié et al., 2021; Verschuur et al., 2021;). In Arctic western Siberia, high temperatures, melting ice and forest and tundra fires have degraded reindeer pastures; Indigenous Peoples have reduced traditional diets and increased purchased food with increases in hypertension and related health impacts (Bogdanova et al., 2021).

There is growing evidence that anthropogenic climate warming has already intensified climate extreme events induced by large-scale sea surface temperature oscillations such as ENSO (Herring et al., 2018; Seneviratne et al., 2021). For example, the 2015-2016 El Niño, the strongest for the past 145 years, induced severe droughts in southeast Asia, eastern and southern Africa, some intensified by anthropogenic warming (Funk et al., 2018). As a result, 20.5 million people faced acute food insecurity in 2016 (FSIN, 2017) and an estimated additional 5.9 million children became underweight (Anttila-Hughes et al., 2021).

Weather extreme events increased food prices and food price volatility (Peri, 2017), thereby worsening food insecurity (Shiferaw et al., 2014; Bene et al., 2015; Miyan, 2015; FAO et al., 2018; Ilboudo Nébié et al., 2021). Rising food prices can affect conflict, political instability, and migration (Bush and Martiniello, 2017) but the relationship between climate change, political instability and conflict is often mediated by other underlying factors such as poor governance (Chapter 7.2.7, Mach et al., 2019; Selby, 2019).

Low-income urban and rural households who are net food buyers are particularly affected by food price increases, with reduction of consumption of diverse food groups (*high confidence*) (Green et al., 2013; Villasante et al., 2015; FAO et al., 2018). Depending on the context, particular groups, including women, ethnic and religious minorities will be more vulnerable to worsening food insecurity from climate change impacts (Clay et al., 2018; Jantarasami et al., 2018; Nature climate change Editorials, 2019; Algur et al., 2021 and see Cross-Chapter Box GENDER in Chapter 18). Indigenous Peoples are often more vulnerable to climate change, due to conditions of poverty, limited resources, discrimination, and marginalization (*high confidence*) (Smith and Rhiney, 2016; Vinyeta et al., 2016; Jantarasami et al., 2018). Indigenous Peoples may experience loss of culturally significant foods and declining traditional ecological knowledge (Dounias and Ichikawa, 2017; Ross and Mason, 2020; 5.7).

5.12.3.3 Impacts on food utilization and vulnerabilities

Food utilization refers to the way the body most effectively uses food, and includes food preparation, food quality, and intra-household distribution. Food utilization is affected by climate change in several ways: food safety, dietary diversity, and food quality (Aberman and Tirado, 2014).

Climate change hazards have increased food safety risks (*high confidence*) including animal diseases (5.5), harmful algal blooms and marine toxins (Section 5.8, 5.9) and mycotoxins (Section 5.11). Other foodborne and waterborne infectious diseases such as cholera are further covered in Chapter 7.

Weather variability and extreme events (Seneviratne et al., 2021) have reduced availability and access to diverse foods to sell and to purchase in rural markets, thereby reducing access to affordable, diverse foods for both rural small-scale producers and net consumers, particularly for landlocked and low-income countries (*high confidence*) (Pant et al., 2014; Villasante et al., 2015; Alston and Akhter, 2016; FAO et al., 2018; Park et al., 2019; Niles et al., 2021) and otherwise marginalised communities (Algur et al., 2021). One study of 87 countries and 150 extreme events estimated that low-income food deficit and landlocked countries had reduced nutrient supply ranging from -1.6 to -7.6% of average supply, a significant portion of a healthy child's average dietary intake (Park et al., 2019).

Rural children in low-income countries are at particular risk of undernutrition from climate change impacts, due to a combination of factors: potential reduction in food quantity and quality from heat impacts; greater exposure from outdoor play and agricultural activities, and increased likelihood of heat exhaustion, vector borne and diarrheal diseases (Oppenheimer and Anttila-Hughes, 2016). A study of child growth data in 30 countries in Africa between 1993-2012 found that increased temperature was significantly related to children's wasting (Baker and Anttila-Hughes, 2020). Another study examined 30 years of climate data and child dietary diversity outcomes in 19 countries, and found that higher-than-average annual temperatures correlated with declines in child diet diversity at levels equal to or greater than other factors which often are the focus of policy, such as market access or education (Niles et al., 2021).

5.12.3.4 Impacts on food stability

Climate change has already changed the start and duration of the growing season and increased variability of rainfall in some places with impacts on food intake and nutritional status and income for low-income and small-scale producers (*medium evidence, high agreement*, (FAO et al., 2018; Cooper et al., 2019). Evidence to date suggests that climate change has negative impacts on the stability of food supply over the medium to long term, thereby affecting food stability (Myers et al., 2017b). Increasing number and intensity of adverse weather events, driven by climate change (Seneviratne et al., 2021), are important factors decreasing food stability, through reduced availability, increased local price volatility, reduced livelihoods for food producers and disruption to food transport (Toufique and Belton, 2014; Verma et al., 2014; Ruiz Meza, 2015; Clay et al., 2018; FAO et al., 2018; Mbow et al., 2019).

5.12.4 Projected Impacts on Food Security

5.12.4.1 Food availability and access

Climate change will have negative effects on food security and nutrition in 2050 (*high agreement, medium evidence*) (Amjath-Babu et al., 2016; Springmann et al., 2016; Lloyd et al., 2018; Richardson et al., 2018; see Chapter 7; Hasegawa et al., 2021a). How many people are affected will depend considerably on non-climatic drivers of food security (van Dijk et al., 2021), but modelling studies agreed that climate change would increase the risk of food insecurity. For example, one study comparing an RCP8.5 scenario with one that has zero climate impacts estimates 65 million additional people (10% increase) will experience food insecurity due to climate change impacts in 2050 (modelling results in Nelson et al. (2018)). Another study accounting for climate extreme events estimates that by 2050, the number of people at risk of hunger will increase by 20% and 11 % under high and low emission scenarios, respectively, owing to a once-per-100-year extreme climate event (Hasegawa et al., 2021a). Sub-Saharan Africa and South Asia in this study were projected to be at the greatest risk, with triple the amount of South Asia's current food reserves needed to offset such an extreme event. Models suggest that food security and malnutrition impacts will be much more severe from 2050 onwards relative to pre-2050, but the scale and extent of the impacts will strongly depend on the greenhouse gas emission scenario (FAO, 2018a; Richardson et al., 2018). Due to climatic impact drivers and non-climate drivers of food insecurity, Sub Saharan Africa is projected to be the hardest hit, followed by south Asia and Central and South America, but contingent on adaptation level (Richardson et al., 2018; Hasegawa et al., 2021a).

Without adaptive measures, heat stress impacts on agricultural labour will increase with climate change (*high confidence*) (Im et al., 2017; Levy and Roelofs, 2019; Hertel and de Lima, 2020). Climate-change-related heat stress will reduce outdoor physical work capacity on a global scale. Depending on greenhouse gas concentrations, some regions will experience losses of 200 to 250 outdoor workdays per year at century's end. Using results from one study reporting experimental procedures to assess loss of work capacity (Foster et al., 2021) regions hardest hit in an SSP5-8.5 scenario include much of South Asia, tropical Sub-Saharan Africa and parts of Central and South America (Figure 5.18) de Lima et al. (2021) projected that negative impacts of warming on crop yields and labour capacity would affect crop production and cost for workers and labour-saving mechanisation, raising food price by 5 % at +3° from the baseline period (1986-2005) globally, with significant implications for vulnerable regions (sub-Saharan Africa and Southeast Asia). Large uncertainties, however, exist around population diversity and adaptive capacity (Vanos et al., 2019). Agricultural labour productivity impacts of heat attributed to climate change are expected to be worse in low- and middle-income countries (Kjellstrom et al., 2016). Adaptation options needed to protect agricultural worker productivity outdoors and reduce occupational heat illnesses and deaths include cooled working environments, improved surveillance systems and education about the need to monitor (*high confidence)* (Xiang et al., 2016; Quiller et al., 2017; Flouris et al., 2018; Day et al., 2019; Vanos et al., 2019). Currently available options, however, are more difficult to achieve in lower-income economies (Kjellstrom et al., 2016; Im et al., 2017).

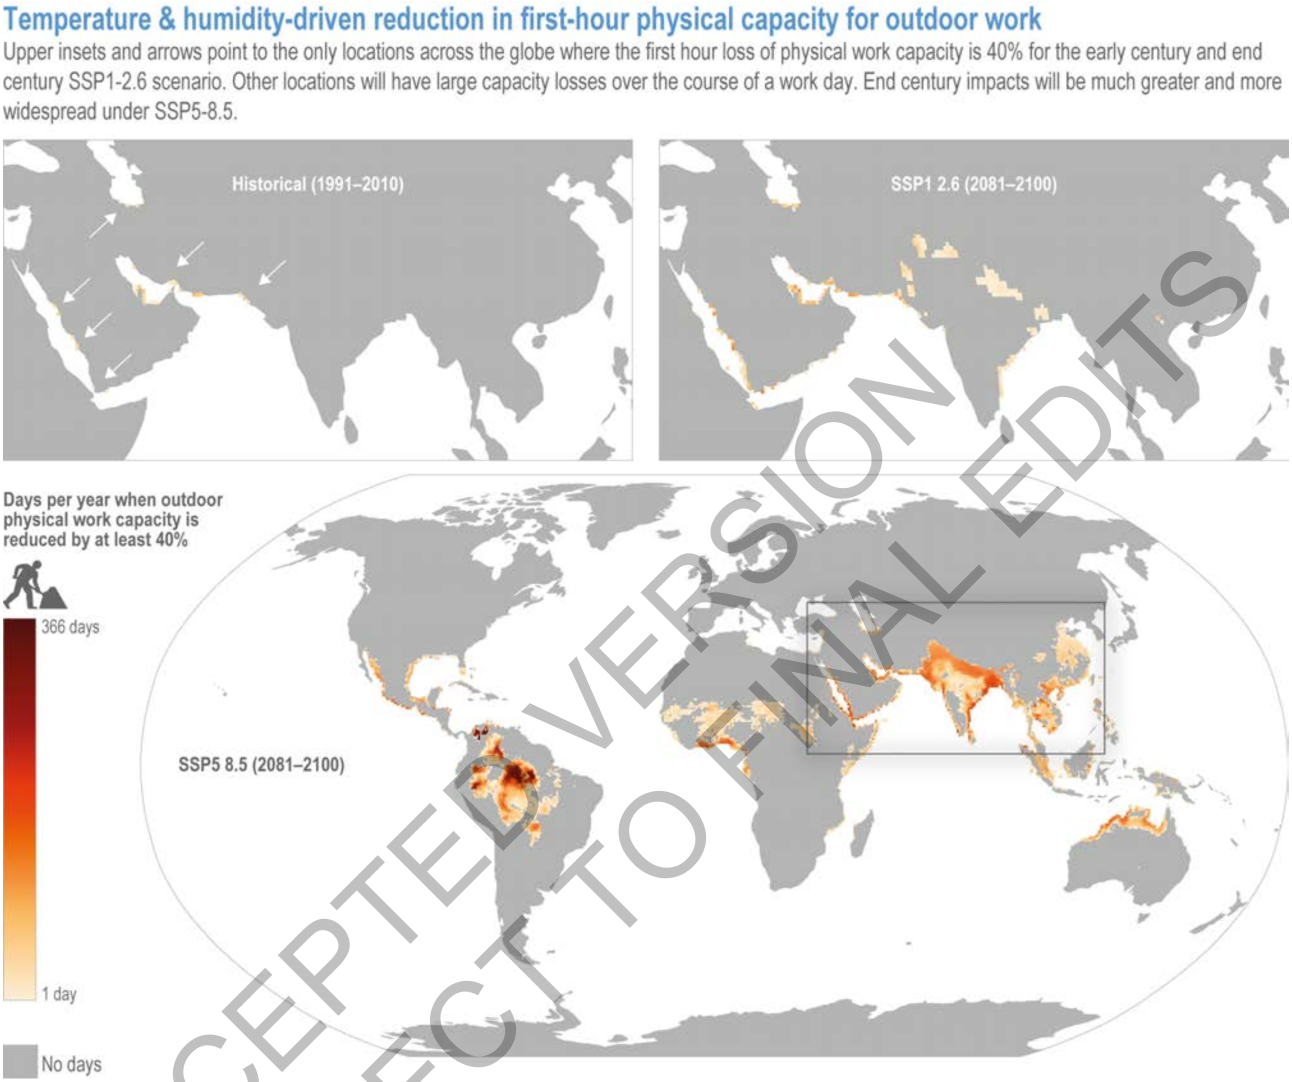

Figure 5.18: The number of days per year where physical work capacity (PWC) is less than 50% based on average daily air temperature and relative humidity (Foster et al., 2021). PWC is defined as the maximum physical work output that can be reasonably expected from an individual performing moderate to heavy work in a 'cool' reference environment of 15oC. Values plotted are from the early (A) and end of century (B) for SSP 585 using ensemble means from the ISIMIP CMIP6 data set. See SM5.4 for detail.

Under higher emission scenarios, food availability will be further reduced after 2050, due to the potential for widespread crop failure, and decline in livestock and fisheries stocks (Mbow et al., 2014; Kelley et al., 2017; Challinor et al., 2018; Hendrix, 2018; Bindoff et al., 2019). At +3° from the preindustrial era, all food production sectors will experience greater, and pronounced, losses due to climate change compared to +1.5° or +2° (see Sections 5.2, 5.4.3, 5.8.3 and 5.9.3).

Food insecurity from food price spikes due to reduced agricultural production associated with climate impact drivers such as drought can lead to both domestic and international conflict, including political instability (Abbott et al., 2017; Bush and Martiniello, 2017; WEF, 2017; D'Odorico et al., 2018; de Amorim et al., 2018;Chapter 7.2.7). While climate change impacts, including drought impacts on food security are important risk factors for conflict, other key drivers are often more influential, including low socioeconomic development, limited state capacity, weak governance, intergroup inequities, and recent histories of conflict (*medium confidence*) (Mach et al., 2019; Selby, 2019; Chapter 7.2.7). The interaction between extreme weather events, conflict and human migration may increase vulnerability of particular communities of low-income countries (WEF, 2017; D'Odorico et al., 2018; de Amorim et al., 2018; Chapter 7). Further research is needed to better understand how increased drought-risk under future climate change might affect food prices and water availability (Abbott et al., 2017).

5.12.4.2 Projected impacts on food safety and quality

Increasing levels of CO_2 directly contribute to reduced food quality by reducing levels of protein, iron, zinc and some vitamins, varying by crop species and cultivars (*high confidence*) (Section 5.4.3, Myers et al., 2014; Smith and Haddad, 2015; Bisbis et al., 2018; Scheelbeek et al., 2018; Weyant et al., 2018; Zhu et al., 2018a). Higher levels of CO_2 are predicted to lead to 5-10% reductions in a wide range of minerals and nutrients (Loladze, 2014). Climate warming will also reduce food quality of seafood, by changing the long-chain polyunsaturated fatty acid content in phytoplankton (Section 5.8; Hixson and Arts, 2016).

[START BOX 5.10 HERE]

Box 5.10: Food Safety Interactions with Food Security and Malnutrition

Climate change significantly increases the future food safety risks (*high confidence*) (Sections 5.8.2, 5.8.3, 5.11.1, Box 5.9). Increasing temperatures and drought stress are expected to lead to greater aflatoxin contamination of food crops. Aflatoxins, a major foodborne hazard, contaminate staple crops and are associated with various health risks including stunting in children and cancer (Koshiol et al., 2017). In LICs, children with high exposure to aflatoxins were found to be more likely to suffer from micronutrient (zinc and vitamin A) deficiencies (Watson et al., 2016b). Climate change is expected to cause decreases in micro- and macronutrient content of foods, leading to an increased burden of infectious diseases, diarrhea and anaemia, with an estimated 10 % increase in disability-adjusted life years (DALYs) by 2050 associated with undernutrition and micronutrient deficiencies (Aberman and Tirado, 2014; Smith and Myers, 2018; Weyant et al., 2018; Zhu et al., 2018a; Ebi and Loladze, 2019; FAO, 2020a; Sulser et al., 2021b).

Children in low-income countries will be at greater risk of undernutrition from these multiple climate change impacts, including lower food availability, lower food quality, food safety and risk of diarrheal disease (*high confidence*) (Aberman and Tirado, 2014). One study of 30 countries in Africa estimated that by 2100, increased temperatures under RCP8.5 could increase children's wasting in western Africa by 37% and 25% in southern Africa (Baker and Anttila-Hughes, 2020).

The combination of climate change and the presence of arsenic in paddy rice fields is expected to increase the toxic heavy metal content of rice and reduce production by 2100, threatening food security and food safety mainly in low-income countries where rice is the main staple (Neumann et al., 2017; Muehe et al., 2019; Farhat et al., 2021).

[END BOX 5.10 HERE]

5.12.4.3 Reaching SDG2

Current projections indicate that it is *highly likely* that the UN SDG 2 ('Zero Hunger') by 2030 will not be achieved, with climate impacts one of several drivers on food security and nutrition preventing this goal including in Africa, Small Island States and South Asia (*high confidence)* (FAO et al., 2018; Otekunrin et al., 2019; Singh et al., 2019; Atukunda et al., 2021; Kumar et al., 2021; Vogliano et al., 2021). Integrated policy strategies that consider synergies and tradeoffs between different food system components would strengthen the likelihood of meeting SDG2 goals (Dyngeland et al., 2020; Lipper et al., 2020; Vogliano et al., 2021) (Grosso et al., 2020). Adaptation options which address climate risks for food security and nutrition are discussed below.

5.12.5 Adaptation Options for Food Security and Nutrition

Since AR5 there has been increased research on adaptation options that address climate risks for food security and nutrition. In this section cultivar improvements, urban and peri-urban agriculture, changing dietary patterns, integrated multisectoral approaches and rights-based approaches are assessed for their potential as an adaptation option that addresses food security and nutrition. Feasibility and effectiveness assessment of several options is in section 5.14.

5.12.5.1 Potential, barriers, and challenges for genetically modified crops to address food security and nutrition

While biotechnology can be used as an adaptation strategy (Section 5.4.4.3), there is low confidence that genetically modified (GM) crops can increase food security and nutrition in smallholder farming systems relative to alternative agronomic strategies (National Academies of Sciences Engineering and Medicine, 2016; Qaim, 2016). Some underline their potential in building resilience to changing climatic conditions, in the form of enhanced drought/heat tolerance, pest/disease protection and/or reduced land usage, thus serving to bolster food security and nutrition (Sainger et al., 2015; Muzhinji and Ntuli, 2021). Others suggest that the empirical evidence supporting GM crops as a climate-resilience strategy remains thin (Leonelli, 2018). Technical and social barriers and potential solutions are summarized in Table 5.15.

Table 5.15: Barriers, challenges and potential solutions for GM crops

Barriers and challenges	Examples and potential solutions to barriers
Major challenges as a food security and nutrition adaptation include the introgression of GM traits into host varieties (Dowd-Uribe, 2014), and confusion around proper growing practices that can accelerate resistance (Iversen et al., 2014; Fischer et al., 2015). The combination of the kinds of traits and restrictions that come from the predominant intellectual property rights instruments used in their commercialization, and concentration of plant and animal breeding industry (Bonny, 2017) mean that benefits from released GM crops tend to be captured disproportionately by farmers with more land, wealth and education (Afidchao et al., 2014; Ali and Rahut, 2018; Azadi et al., 2018) but also increase debt levels for growers (Dowd-Uribe, 2014; Leguizamón, 2014). Underlying gender inequities also play a critical role in shaping food security and nutrition outcomes associated with the introduction of GM crops in part due to unequal control over income and agricultural decision-making; in some cases women reported decreased workload and enhanced decision-making power (Gouse et al., 2016), while in others the introduction of GM crops could increase workload and devalue womens' role as seed savers.(Carro-Ripalda and Astier, 2014; Addison and Schnurr, 2016). Major hurdles for genetically modified crops include translating promising research results into real-world farming systems and consumer trust in the food product. Experimental programs have been dogged by issues including complications with the introgression of genetically modified traits into high-performing varieties (Dowd-Uribe and Schnurr, 2016; Stone and Glover, 2017), strict management regimes that clash with the realities of smallholder agricultural systems (Iversen et al., 2014; Whitfield et al., 2015), and a lack of attention to farmer decision-making (Schnurr, 2019).	One case study is the Water Efficient Maize for Africa program (WEMA), a Public Private Partnership that transplants a cold shock protein B, known as Droughtgard, into maize in order to mitigate yield losses from drought. Proponents suggest that this GM venture, which will be distributed free to smallholder farmers, represents the best strategy for ensuring stable yields in the face of climatic change across Africa (Kyetere et al., 2019). Critics argue that WEMA maize is not a good fit with the smallholder farming systems it is designed to benefit, with particular concerns around how farmers will access the extra inputs, credit, and labour that WEMA maize requires in order to be successful (Schnurr, 2019). Emergent genome edited crops are considered a more precise, accessible and accelerated means of targeting stressors that matter to poor farmers, but evidence is limited (Kole et al., 2015; Haque et al., 2018; Zaidi et al., 2019). A more iterative and flexible adaptation approach beyond just genomic improvement to tackle the multiplicity of factors limiting smallholder production is anticipated to increase the likelihood that these promising technologies can enhance food security and nutrition (*medium confidence*) (Giller et al., 2017; Stone, 2017; Montenegro de Wit, 2019). To address food security and nutrition, future breeding needs to move from just enhancing agronomic traits of a single crop to improving multiple traits of multiple crops suited to local conditions that will increase climate resilience of farming systems. To make breeding technologies scale-neutral, the policy structure is needed to support and protect smallholders *(medium confidence)*.

5.12.5.2 Urban and peri-urban agriculture, vertical and horizontal

Urban areas have more than half of the global population and consume about 70 % of the total food supply (FAO, 2019b). The urban population is projected to grow further to about 70 % of the global population by 2050 (UN, 2018). Direct evidence supporting climate resilience of UPA is limited and contextual, but there is *medium confidence* of multifunctional benefits from UPA, depending on regions and types of UPA (Artmann and Sartison, 2018; Kareem et al., 2020). UPA takes different forms of production, and can be broadly classified into four categories, depending on operating characteristics and capital inputs (Table 5.16) (Goldstein et al., 2016). Controlled environments can protect crops, livestock, and fish from extreme weather events or pest and disease outbreak (Mohareb et al., 2017). Innovative indoor farming such as vertical farming can be highly productive with minimal water and nutrient supply but can be capital intensive with high energy demand (O'Sullivan et al., 2019) and those with aquaponics can be water demanding (Love et al., 2015). Currently, commodities are often limited to crops with short growing seasons such as leafy vegetables. Vertically grown crops are more expensive than field-grown produce, and thus not accessible for low-income urban dwellers (Al-Kodmany, 2018). Community and institutional unconditioned (outdoor) farms and gardens are better positioned to provide increased access to healthy food to those who need it (Eigenbrod and Gruda, 2015; Goodman and Minner, 2019).

Many UPA farmers are migrant workers or other socially marginalized racial and ethnic groups and often limited by access to land (Lawanson et al., 2014; Horst et al., 2017). There is *high agreement* that proactive policies for urban design accounting for food-energy-nexus and social inclusion including addressing questions of governance and rights to green urban spaces are necessary to enhance food provisioning and to gain multiple functions of UPA (Lwasa et al., 2014; Horst et al., 2017; Mohareb et al., 2017; Siegner et al., 2018; O'Sullivan et al., 2019; Titz and Chiotha, 2019; Halvey et al., 2020).

Table 5.16: Urban agriculture classifications based on operating characteristics and capital inputs (Goldstein et al., 2016; O'Sullivan et al., 2019), and a summary of literature search on positive and negative aspects.

Summary of adaptation option and evidence for improved food security and nutrition		
Urban agriculture has two components – vertical (e.g., grown on or in buildings) and horizontal (grown on land within urban boundaries, in backyards and marginal spaces). The horizontal component of urban and peri-urban agriculture (UPA) has gained attention because of multiple functions that could improve food systems and ecosystem services under climate change (Revi et al., 2014; Artmann and Sartison, 2018; FAO, 2019b; Mbow et al., 2019; Chapter 6). UPA cannot fully feed urban dwellers within its boundaries but can make an important contribution to local food security and nutrition (*medium confidence*) (Martellozzo et al., 2014; Badami and Ramankutty, 2015; Algert et al., 2016; Mohareb et al., 2017; Clinton et al., 2018; Kriewald et al., 2019). UPA is also expected to play important roles in ecosystem functions in addition to alleviating food shocks caused by natural disasters and reducing food mileage.		
***Categories* and Description**	**Synergies**	**Tradeoffs**
Ground-based Unconditioned Traditional, peri-urban field farms, market gardens, community farms, community gardens, home gardens. *Building-integrated Unconditioned* Rooftop gardens, balcony agriculture, and green wall, but production quantity is small.	- Multi-species cropping can increase access to diverse healthy foods and reduce food costs for low-income households (Algert et al., 2016; Horst et al., 2017). -Green cover helps to attenuate heat island effects, reduce run-off and flood risks (Lwasa et al., 2015; Di Leo et al., 2016; Gondhalekar and Ramsauer, 2017; Artmann and Sartison, 2018; Small et al., 2019). -Green garden spaces can reduce vulnerability to heat stress and food insecurity for low-income neighborhoods and address racial inequities in access to green spaces if UA governance addresses equity concerns (Horst et al., 2017; Titz and Chiotha, 2019; Halvey et al., 2020; Hoffman et al., 2020)	- Can increase the value of land and thereby push out lower income households via gentrification (Horst et al., 2017). -unconditioned UPA is under strong pressure from other lucrative land-use demands and can be difficult to maintain without addressing urban social inequities, (Martellozzo et al., 2014; Horst et al., 2017; White and Bunn, 2017). -Yields are lower than conventional, rural production and water demand is high (Goldstein et al., 2016; Bisaga et al., 2019). - Air, soil and water quality in urban areas, can disturb crop production and reduce food safety (Eigenbrod and Gruda, 2015; Titz and Chiotha, 2019), and create health

	-Multi-species cropping helps to conserve biodiversity (Lovell, 2010; Goldstein et al., 2016). -Skill building and job opportunities (Lovell, 2010; Mok et al., 2014; Horst et al., 2017), sometimes in regions and for groups that have been socially and economically disadvantaged (Horst et al., 2017). - cultural ecosystem service benefits through cultivation of specific crops, cultural learning, sharing culinary and garden knowledge and strengthening social networks for socially marginalized ethnic, racial groups (Horst et al., 2017; Nadeau et al., 2019). -UPA provides social and health co-benefits such as increased social interaction, physical and mental health benefits (Horst et al., 2017; White and Bunn, 2017). -can divert organic waste produced in cities as compost, to reduce water contamination and input costs (Menyuka et al., 2020)	risks from contamination (Mok et al., 2014) which causes mixed or even negative public perceptions against the produce (Specht et al., 2019; Menyuka et al., 2020). Trace metal contamination in soils and plants is an increased risk in outdoor UPA (Eigenbrod and Gruda, 2015; Titz and Chiotha, 2019). -May provide limited job and income opportunities in low income urban areas (Daftary-Steel et al., 2015; Biewener, 2016) - outdoor fields are exposed to rising temperatures and urban heat islands (Chapman et al., 2017). Low water availability may be another limit for UPA as a form of adaptation (Kareem et al., 2020; Tankari, 2020). In coastal cities, sea level rise and flooding from climate change impacts may make significant portions of cities unuseable for UPA (Algert et al., 2016; Kareem et al., 2020).
Ground-based Conditioned Horticultural farms using glasshouses or polyhouses. Often exist on the city fringes. Aquaponics that grow fish in aquaculture systems and reuse nutrient-rich wastewater. One of the few options that provide proteins in urban farms. *Building integrated Conditioned* Rooftop glasshouses, fully indoor, artificially lit plant factories. Recent advancements include production using vertical stacks to produce more food per land area. Indoor aquaculture is also included.	-Controlled environments can protect crops, livestock, and fish from extreme weather events or pest and disease outbreak (Mohareb et al., 2017). -Some building integrated conditioned farms can utilise wastewater and waste heat from buildings or other urban source (De Zeeuw et al., 2011; Thomaier et al., 2015; Mohareb et al., 2017). - Innovative indoor farming such as vertical farming (VF) is highly productive with minimal water and nutrient supply, but highly energy-demanding (O'Sullivan et al., 2019). - Some initiatives combine with social justice goals and use abandoned buildings in low income neighbourhoods to grow diverse food types for addressing food security of low income groups (Thomaier et al., 2015; Horst et al., 2017).	-Power outages and/or system failure can easily destroy the production system (Small et al., 2019). -Initial costs and energy requirements, particularly are substantially higher than unconditioned farms (Goodman and Minner, 2019; O'Sullivan et al., 2019). -Greenhouse gas emissions may be higher than conventional rural agriculture (Santo et al., 2016) and full mitigation potential only realized with low energy systems (WGIII, 12.4) -Commodities are often limited to short-cycled crops such as leafy vegetables and herbs and the produce is more expensive, which are difficult for the urban poor to access (O'Sullivan et al., 2019).

5.12.6 Changing Dietary Patterns

Dietary change in regions with excess consumption of calories and animal-sourced foods to a higher share of plant-based foods with greater dietary diversity and reduced consumption of animal-sourced foods and unhealthy foods (as defined by scientific panels such as EAT-Lancet), has both mitigation and adaptation benefits along with reduced mortality from diet related non-communicable diseases, health, biodiversity and other environmental co-benefits (*high confidence*) (Springmann et al., 2016; Springmann et al., 2018; Branca et al., 2019; Henry et al., 2019; Searchinger et al., 2019; Swinburn et al., 2019; Willett et al., 2019; Rosenzweig et al., 2020; Chapter 7.4.2.1.3 and WGIII Chapter 12). Reducing food waste, especially of environment- and climate- costly foods would further extend these benefits (Rosenzweig et al., 2020 and see section 5.11).

Dietary behaviour is complex: shaped by the broader food system (HLPE, 2017a), the food environment (Herforth and Ahmed, 2015; Turner et al., 2018) and socio-cultural factors (Fischler, 1988). Since most food-related decisions are made at a subconscious level (Marteau et al., 2012), achieving dietary change for personal health reasons has proven difficult: it seems unlikely that dietary change for climate will be achieved without careful attention to the factors that shape dietary choice and behaviour. Food environments, defined as "the physical, economic, political and socio-cultural context in which consumers engage with the food system to make their decisions about acquiring, preparing and consuming food" (HLPE, 2017a): 28), include food availability, accessibility, price/ affordability, food characteristics, desirability, convenience, and marketing.

There are a range of options to change dietary patterns, but more research is needed in this area, adjusted to the regional, socio-economic, and cultural context. Studies of policy instruments to change diets include changes in subsidies, taxes, marketing regulation and efforts to change the retail physical environment. Subsidies directed at staple foods and animal sourced foods could be shifted towards diversified production of plant-based foods in order to change the relative price of foods and thus dietary choice (Franck et al., 2013; Harris et al., 2021). Taxes on animal-sourced foods that are climate-costly and unhealthy, as defined by scientific panels such as the EAT-Lancet report, could similarly impact relative price (Mbow et al., 2019; Willett et al., 2019). Regulation of marketing could change desirability of climate-unfriendly and unhealthy foods (Willett et al., 2019). Many of the same strategies used to increase sales by conventional food marketing efforts hold potential to change the desirability and people's preferences for plant foods which are strongly shaped by social-cultural norms. Studies have shown that changes to the number, placing, or prevalence vegetarian options on a menu (Bacon and Krpan, 2018; Kurz, 2018; Garnett et al., 2019; Gravert and Kurz, 2019), the relative price of vegetarian options (Garnett et al., 2021)and the "access" (order and distance) to vegetarian options in the retail physical environment (Garnett et al., 2020) can all increase consumption of plant-based foods and decrease meat consumption (Bianchi et al., 2018). Studies on food environment 'nudging' methods found that making the vegetarian meal option the default during conference registration or on a meal plan significantly reduced meat consumption (Campbell-Arvai et al., 2012; Hansen et al., 2019b). Studies simply educating people about the negative health and environmental/ climate outcomes of meat consumption have been found to have very little impact (Byerly et al., 2018). More research is needed to understand the potential for motivational crowding in shaping pro-climate dietary choice, as has been demonstrated in development (Agrawal et al., 2015) and conservation interventions (Rode et al., 2015).

5.12.7 Integrated Multisectoral Food Security and Nutrition Adaptation Options

Integrated multisectoral strategies that incorporate social protection are effective adaptation responses (*high confidence*) (Gros et al., 2019; Ulrichs et al., 2019; Medina Hidalgo et al., 2020; Daron et al., 2021; Ilboudo Nébié et al., 2021; Verschuur et al., 2021; 7.4.2, Cross-Chapter Box-GENDER in Chapter 18). Social protection programmes, such as cash transfers, weather index insurance and asset-building activities such as well construction, can support short-term responses to acute food insecurity in response to extreme events, but can also build adaptive capacity longer-term (Table 5.16, Costella et al., 2017; Ulrichs et al., 2019). An assessment of an adaptive social protection programme in the Sahel found that tailored seasonal forecasting can improve responsiveness to climate-related extreme events, but investment in capacity building and dialogue between forecasters, community groups and humanitarian organizations is needed (Daron et al., 2021). Forecast-based financing, which automatically disperses funds when threshold forecasts are reached for an extreme event (Coughlan de Perez et al., 2016), used in Bangladesh prior to a 2017 flood event allowed low-income, flood-prone communities to access better quality food in the short term without accruing debt (Gros et al., 2019).

Differentiated responses based on food security level and climate risk can be effective. A study of drought impacts on food security in Senegal between 1997-2016 recommended different adaptation strategies based on whether the region was a higher risk of acute short-term food insecurity and/or faced higher risk of drought (Table 5.16; Ilboudo Nébié et al., 2021).Given identified linkages between higher temperatures and extreme events with declines in child dietary diversity, safeguarding diverse diets is one important adaptation priority (Niles et al., 2021). Humanitarian responses are appropriate for short-term acute hunger, while in the medium term, home-grown school feeding programmes with diverse foods can support child nutrition and learning, and with local procurement can also increase income and food security of smallholder farmers (Ilboudo Nébié et al., 2021). Farmer associations can manage regional staple food storehouses, in which farmers store their harvest and receive credit, and can sell their harvest later in the season and pay back the credit with interest, strengthening local supplies and farmer income (Ilboudo Nébié et al., 2021).

A study in Lesotho examined the extent to which climate change increased the likelihood of an acute drought in 2007, and a related food crisis (Verschuur et al., 2021). Given land degradation, reliance on rainfed agriculture and food imports from neighbouring South Africa, the study recommended crop diversification, increased use of drought tolerant crop varieties and expanded trade partners in the medium to long term, to both strengthen regional food production, reduce risk of crop failure, and the likelihood of climate-induced drought from trade partners reducing food imports (Verschuur et al., 2021). A longitudinal study of smallholder coffee farmers in Nicaragua found that crop diversification, alongside crop management and varietal improvement, would help farmers strengthen food security long term in the face of climate hazards such as drought and coffee leaf rust (Bacon et al., 2021). Another medium to long-term adaptation response is to address systemic gender, land tenure and other social inequalities as part of an inclusive approach (Bezner Kerr et al., 2019; Khatri-Chhetri et al., 2020; Bacon et al., 2021). This long-term strategy could be part of a human-rights-based approach (HRBA, 5.12.8)

Table 5.17: Examples of adaptation responses to drought and floods by food security level and time frame. Adapted from Ilboudo Nébié et al. (2021) Table 4, with information from (Bahadur et al., 2015; Costella et al., 2017; Gros et al., 2019; Ulrichs et al., 2019; Medina Hidalgo et al., 2020; Bacon et al., 2021; Verschuur et al., 2021).

	Food insecurity level and time frame of adaptation			
Adaptation response to drought or floods	**Acute, short-term**	**Moderate, medium term**	**Chronic, long-term**	**Resilience type**
Forecast-based financing (provides unconditional cash in advance of extreme event)	X			*Anticipatory*: people and systems are better prepared for climate shock by reduced exposure or vulnerability.
Early warning systems / climate services and education for disaster preparation	X	X	X	
Social protection programmes with regular provisions which allow for asset building e.g., savings, build informal networks, purchase of livestock	X	X		
Humanitarian food aid and malnutrition treatment	X	X		*Absorptive capacity*: people or systems cope with climate-related shocks or systems while and immediately after they occur.
Home grown nutrition-sensitive school feeding programmes		X	X	
Social protection programmes with short-term targeted response e.g., short-term cash transfers, food assistance for asset building e.g., wells	X			
Weather index insurance program	X	X	X	
Regional grain banks run by farmer associations		X	X	*Adaptive capacity*: can adjust to long-term climate risks and disasters reduce vulnerability to future shocks.
Savings, credit and local food procurement support for smallholder farmers		X	X	
Agroecosystem diversification, other agroecological practices to strengthen ecosystem services in long-term (see Box 5.10)		X	X	

Rainwater evacuation infrastructure combined with flood management and waste collection and urban gardening		X	X

5.12.8 Incorporating Human Rights-based Approaches into Food Systems

A human rights-based approach (HRBA), endorsed by the United Nations, is one strategy for addressing core inequities that are key drivers for food insecurity and malnutrition of particular groups such as low-income consumers, children, women, small-scale producers and different regions of the world (FAO, 2013; Claeys and Delgado Pugley, 2017; Caron et al., 2018; Le Mouël et al., 2018; Springmann et al., 2018; Tramel, 2018; HLPE, 2019; Willett et al., 2019). Climate change impacts, mitigation and adaptation approaches can also worsen inequities (Eastin, 2018; Borras et al., 2020). HRBA includes core principles of participation, accountability, non-discrimination, transparency, human rights, empowerment, and rule of law, which can be integrated into policymaking and implementation as part of transforming the food system (FAO, 2013; Caron et al., 2018; Toussaint and Martínez Blanco, 2020). The right to wellbeing can serve as the overarching umbrella of HRBA to addressing climate change within food systems and includes a right to health, right to food, cultural rights, the rights of the child and the right to healthy environment (Swinburn et al., 2019). A HRBA has a specific focus on those groups who are vulnerable due to poverty, discrimination and historical inequities and involves meaningful participation of vulnerable groups in governance, design and implementation of adaptation and mitigation strategies, including gender-responsiveness and integration of Indigenous Peoples' knowledge (UNHRC 2017; Caron et al., 2018; Mills, 2018). There can be conflicts and trade-offs, such as between addressing land rights or traditional fishing grounds, the right to food, and addressing climate justice concerns (Mills, 2018; Borras et al., 2020; section 5.13). Adaptation strategies that incorporate HRBA include legislation, programmes that address gender inequities in agriculture, agroecology, recognition of rights to land, fishing areas and other natural resources, protection of culturally significant seeds, and community-based adaptation that explicitly involves marginalized groups in governance (Mills, 2018; Tramel, 2018; Huyer et al., 2019; Borras et al., 2020; section 5.14).

5.13 Climate Change Triggered Competition, Trade-offs and Nexus Interactions in Land and Ocean

This section presents information about the impacts generated by competition and trade-offs in food systems and discusses opportunities and challenges associated with the use of the Nexus framework.

5.13.1 Impacts of Global Land Deals on Land Use, Vulnerable Groups, and Adaptation to Climate Change

Land deals, also known as large-scale land acquisitions (LSLAs), describe recent changes in access to land globally (Borras et al., 2011). Since 2000, at least 160 million hectares have been under negotiation (Land Matrix, 2021). Land deals surged after the 2007-2008 food price crisis and farmland investment boom (Fairbairn, 2014), with a diverse range of drivers (Arezki et al., 2015; Zoomers and Otsuki, 2017; Conigliani et al., 2018) including land-based climate change interventions (Dunlap and Fairhead, 2014; Davis et al., 2015a; Hunsberger et al., 2017; Franco and Borras, 2019). Examples are the expansion of biofuel crops (e.g. Yengoh and Armah, 2016; Aha and Ayitey, 2017), Afforestation and Reforestation (A/R) projects (Olwig et al., 2016; Richards and Lyons, 2016; Scheidel and Work, 2018), REDD+ (Bayrak and Marafa, 2016; Ingalls et al., 2018), conservation areas (Lunstrum, 2016; Schleicher et al., 2019), renewable energy installations (e.g. Sovacool, 2021), or natural disaster management (e.g. Uson, 2017).

Land deals raise important social justice questions (Franco et al., 2017; Hunsberger et al., 2017; Borras and Franco, 2018b; Borras et al., 2020; Sekine, 2021) (*high confidence*). Specific impacts of land deals vary according to their purpose, location, actors, land use history, and procedural aspects. However, multi-case analyses identify severe adverse impacts (Table 5.18). LSLAs are a significant driver of tropical forest loss

(Davis et al., 2020) increasing emissions through deforestation (Liao et al., 2021) and industrialization of agriculture (Rosa et al., 2021). LSLAs entail large water appropriations (Breu et al., 2016; Chiarelli et al., 2016; Adams et al., 2019) affecting local populations' access to water and food security (Dell'Angelo et al., 2018; Veldwisch et al., 2018). By increasing exported crops, and limiting local populations' access to land, LSLAs produce food security risks (Marselis et al., 2017; Müller et al., 2021b). Negative livelihoods impacts arise through enclosure of assets, elite capture (Oberlack et al., 2016), crowding out of small farmers (Nolte and Ostermeier, 2017) and reducing local populations' access to commons (Dell'Angelo et al., 2016; Giger et al., 2019). Indigenous People are affected facing high levels of violence in land acquisition conflicts (Dell'Angelo et al., 2021). The social burdens of land deals tend to be gendered (e.g. Fonjong et al., 2016; Nyantakyi-Frimpong and Bezner Kerr, 2017; Atuoye et al., 2021).

Local populations can experience declining access to livelihood resources and deteriorating food security, increasing gendered vulnerabilities (Yengoh et al., 2015; Faye and Ribot, 2017; Atuoye et al., 2021). Vulnerable groups displaced by land deals may face higher exposure to climate change (Dell'Angelo et al., 2017). LSLAs affecting common-pool resources governed by Indigenous institutions jeopardize the resilience and adaptive capacity of local socio-ecological systems (Dell'Angelo et al., 2016; D'Odorico et al., 2017; Hak et al., 2018; Haller, 2019; Haller et al., 2020). Growing land tenure insecurity may force farmers to engage in unsustainable farming and forestry practices (Aha and Ayitey, 2017; Gabay and Alam, 2017) and hinder agroecological innovations to manage climate risks (Nyantakyi-Frimpong, 2020b). Social justice concerns and vulnerability of local populations can be addressed by promoting land redistribution and recognition, particularly for customary lands of Indigenous and ethnic minorities; and land restitution to those who were forcibly displaced (Franco et al., 2015; Borras and Franco, 2018a).

Table 5.18: Adverse social and ecological risks and impacts of agricultural land deals on land use and vulnerable groups.

Land use dimensions	**Impacts and implications**	**References (2014- present)**
Forestry	Direct and indirect land use change provoked by LSLAs accelerate deforestation of tropical forests globally.	*Multi-case analyses* Davis et al. (2020) *Case study examples* Davis et al. (2015b) Scheidel and Work (2018), Magliocca et al. (2020)
Energy use and access	Expected land use changes provoked by agricultural LSLAs have high fossil-energy footprints. LSLAs may adversely affect local population' access to energy resources.	*Multi-case analyses* Rosa et al. (2021)
Carbon emissions	LSLAs have high carbon footprints resulting from deforestation and industrialization of agriculture.	*Multi-case analyses* Liao et al. (2021) Rosa et al. (2021) *Case study examples* Johansson et al. (2020) Liao et al. (2020)
Water use and access	LSLAs frequently involve water appropriations, which may affect access to water, traditional agriculture, and the human right to food of local populations.	*Multi-case analyses* Breu et al. (2016) Chiarelli et al. (2016) Dell'Angelo et al. (2018) *Case study examples* Adams et al. (2019) Tejada and Rist (2018)
Food security and nutrition	LSLAs pose food security risks by re-orienting crop production to nutrient-poor crops predominantly destined for export,	*Multi-case analyses* Cristina Rulli and D'Odorico (2014) Mechiche-Alami et al. (2021) Marselis et al. (2017)

	and/or excluding local populations from agricultural land.	Müller et al. (2021b) *Conceptual studies* Häberli and Smith (2014) *Case study examples* Shete and Rutten (2015) Mabe et al. (2019) Bruna (2019) Hules and Singh (2017) Moreda (2018) Atuoye et al. (2021)
Livelihoods	LSLAs frequently provoke adverse livelihood impacts and increased livelihood vulnerability of local populations.	*Multi-case analyses* Davis et al. (2014) Oberlack et al. (2016) Nolte and Ostermeier, 2017) Vandergeten et al. (2016) Schoneveld (2017) *Conceptual studies* Zoomers and Otsuki (2017) *Case study examples* Richards and Lyons (2016) Shete and Rutten (2015) Yengoh and Armah (2016) Mabe et al. (2019) Gyapong (2020)
Indigenous People and commons	LSLAs have adverse impacts on Indigenous peoples and lands, including land encroachment, dispossession, and displacement. Land deals frequently target common land and may increase the vulnerability of customary, traditional, and Indigenous systems common property, while reducing their adaptive capacity.	*Multi-case analyses* Dell'Angelo et al. (2016) Giger et al. (2019) Dell'Angelo et al. (2021) *Conceptual studies* Haller et al. (2020) *Case study examples* Olwig et al. (2016) Moreda (2017) Montefrio (2017) Scheidel and Work (2018) Konforti (2018) Pietilainen and Otero (2019) Mingorría (2018) Bukari and Kuusaana (2018) Haller (2019) Hak et al. (2018) Gabay and Alam (2017) Imbong (2021)
Gender	Impacts and implications of land deals are frequently suffered in different ways among genders.	*Case study examples* Tsikata and Yaro (2014) Yengoh et al. (2015) Fonjong et al. (2016) Nyantakyi-Frimpong and Bezner Kerr (2017) Elmhirst et al. (2017) Bottazzi et al. (2018) Ndi (2019) Osabuohien et al. (2019) Porsani et al. (2019) Atuoye et al. (2021)
Impacts on other climate	LSLAs may undermine mitigation and adaptation initiatives and other land uses	*Multi-case analyses* Carter et al. (2017)

change mitigation and adaptation initiatives	relevant for climate change mitigation and adaptation	*Case study examples* Borras et al. (2020) Gabay and Alam (2017) Nyantakyi-Frimpong (2020b) Scheidel and Work (2018) Rodríguez-de-Francisco et al. (2021)
Other environmental impacts	LSLAs expected to provoke lasting global environmental change (Lazarus, 2014); LSLAs are a potential driver of slope instability (Chiarelli et al., 2021); LSLAs affect natural habitats such as tiger landscapes (Debonne et al., 2019); LSLAs jeopardize biodiversity (Balehegn, 2015).	

5.13.2 Trade-offs Generated by Agricultural Intensification and Expansion

Agricultural intensification seeks to increase agricultural productivity per input unit, reducing the pressure on land use, generating positive impacts in greenhouse gas emissions (Mbow et al., 2019), but valuing the final effect requires common metrics in terms of carbon capture or emission reductions (Searchinger et al., 2018). It has been suggested to address multiple Sustainable Development Goals (SDG2, SDG13, SDG15), but only occasionally leads to simultaneous positive ecosystem service and well-being outcomes (Rasmussen et al., 2018). When the process relies only on increasing input use there is a risk of generating adverse outcomes that may override positive effects, such as CO_2 emissions, (McGill et al., 2018); NOx emissions (Hickman et al., 2017), soil salinization and groundwater depletion (Doody et al., 2015; Daliakopoulos et al., 2016; Fragaszy and Closas, 2016; Foster et al., 2018; Flörke et al., 2019). Agricultural intensification could meet short-term food security and livelihood goals, but reduces biological and landscape diversity, and ecosystem services (*high confidence*) (Campbell et al., 2017; Balmford et al., 2018; Springmann et al., 2018; Ickowitz et al., 2019; Mbow et al., 2019). Agricultural intensification can also affect livelihoods of small-scale producers, compromising food security. It can increase low-waged casual farm work, increasing gender and income inequality (Bigler et al., 2017; Clay and King, 2019; Table 5.18).

Table 5.19: Case studies of trade-offs and negative outcomes associated with Agricultural Intensification on biodiversity and ecosystem services.

Ecosystem service	**Trade-offs / Negative Outcomes**	**References**
Provisioning: Water quality	Negative impacts on ephemeral wetlands	Dalu et al. (2017)
Provisioning: Water availability	Contribution to water scarcity	Satgé et al. (2019)
Supporting: Soil	Increasing erosion risk	Govers et al. (2017)
Regulating: Climate	Reduced soil organic carbon sequestration	Olsen et al. (2019)
Regulating: Pest control	Reduced level of biological control of pests: Reduced number of insectivorous birds	Emmerson et al. (2016)
Cultural: Recreational	Reduction on river wildlife	DeBano et al. (2016)
Biodiversity	Reduced global biodiversity	Newbold et al. (2015), Egli et al. (2018), Beckmann et al. (2019)
Biodiversity	Reduction of taxonomic diversity	Jeliazkov et al., (2016), Kehoe et al. (2017), Banerjee et al. (2019)
Biodiversity	Negative impacts on mean population stability	Olivier et al. (2020)

Land available for provisioning ecosystem services is declining in many places because of agricultural expansion, bioenergy crops and reforestation for mitigation (Kongsager, 2018), with adverse climate impacts

(Froese and Schilling, 2019). Cropland expansion can deteriorate biodiversity (Delzeit et al., 2017), water quality (Ayala et al., 2016) and carbon storage (Goldstein et al., 2012) and increase water demands (Yokohata et al., 2020).

A systems-based perspective on land use is needed to address climate change impacts on nutrition security, and ecosystem services (Springmann et al., 2018; IPCC, 2019b; Willett et al., 2019). Land sparing sets aside some land for conservation purposes and intensifies production on farmland (Balmford et al., 2018; Benton et al., 2018; IPCC, 2019b) with potential to offset greenhouse gas emissions (Lamb et al., 2016). Alternatively 'land sharing' approach, through principles such as minimizing fossil-fuel based inputs, maximizing synergies, addressing both climate change mitigation and adaptation and biodiversity (Kremen and Miles, 2012; Kremen, 2015; Kremen and Merenlender, 2018; HLPE, 2019; section 5.14, Box on Agroecology). Community-managed initiatives can address biodiversity and ecosystem conservation, livelihoods, food provisioning and other ecosystem services (Kremen and Merenlender, 2018; HLPE, 2019).

The concept of sustainable intensification has emerged, looking for enhancements in environmental outcomes, while maintaining or increasing agricultural systems performance. There is a potential to find synergies between agricultural production and landscape systems if systems are design to operate within planetary boundaries (Rockström et al., 2017; Liao and Brown, 2018; Pretty, 2018; Pretty et al., 2018).

5.13.3 Competition Between Food Systems in Land and Ocean

Livestock and aquaculture feeds utilize crops such as soyabean and maize, with food conversion efficiencies similar in chicken and Atlantic salmon, and higher in pigs and cattle (Troell et al., 2014; Fry et al., 2018b; Fry et al., 2018a). Use of wild fish meal and oil has been decreasing, partly due to concerns regarding vulnerable small pelagic fish stocks (Bindoff et al., 2019). The instability of wild fish stocks has increased terrestrial crop feed components (Troell et al., 2014; Blanchard et al., 2017; FAO, 2017; Cottrell et al., 2018). The use of wild fish in fish feeds that may have been directly consumed may put low-income households at risk of food insecurity (Troell et al., 2014). An increasing demand for aquaculture products intensifies competition for feed supplies (*medium confidence*) (Troell et al., 2014; Blanchard et al., 2017). Increases in demands for animal protein and shifts to pescatarian diets will increase the existing competition for land resources, particularly in low and medium income countries, with negative impacts on food security (Makkar, 2018), but may be mitigated by dietary changes, novel feeds and food waste usage for aquatic systems (Berners-Lee et al., 2018; Hua et al., 2019; Cottrell et al., 2020).

Competition over use of major aquaculture feed crops (Fry et al., 2016) with terrestrial livestock (Troell et al., 2014), and fish use by terrestrial livestock, will also place pressure on fish and crop resources (*medium confidence*) (Cottrell et al., 2018). Increases in feed prices will affect fish and meat prices (Troell et al., 2014), and changes in agriculture will be needed to satisfy aquaculture demands (Blanchard et al., 2017). Aquaculture and livestock dietary components may also compromise crops and forage fish that provide essential nutrients for low-income households increasing nutritional insecurity, in regions of sub-Saharan Africa, Asia and Latin America (Troell et al., 2014). Waste fish products can supplement fish meal and oil to reduce competition for feed, as well as reducing use of fish that could go to human consumption (*medium confidence*) (Little et al., 2016; Shepherd et al., 2017; Dave and Routray, 2018; Naylor et al., 2021). Use of algae, bacteria, yeast and insect diets could replace fishmeal for aquaculture (Cohen et al., 2018; Hua et al., 2019; Cottrell et al., 2020), not affecting nutritional profiles (Campanaro et al., 2019) and fish could be reared on waste by-products of other food production systems (Bava et al., 2019). Complete fish oil substitutions with microalgae may be possible without compromising omega-3 contents, but energy usage in diet production should be considered Cottrell et al. (2020). Substitutions of plant-based and alternative feeds may decrease food conversion efficiencies (Cottrell et al., 2020), affect omega-3 content of farmed seafood (Fry et al., 2016; Shepherd et al., 2017), be problematic for the fish themselves (Little et al., 2016; Naylor et al., 2021) and lead to reduced productivity (Shepherd et al., 2017).

Competition will be heightened by other climate impacts, such as changes in water availability. Water usage is relatively high in animal production (Abraham et al., 2014; Sultana et al., 2014; de Miguel et al., 2015; Palhares and Pezzopane, 2015; Weindl et al., 2017). In some areas, increased demand for plant-based animal feeds will be affected by sea level rise and competing usage of available freshwater with other users, and ecosystem needs (Karttunen et al., 2017).

5.13.3.1 Agricultural and river run-off

Flooding on agricultural land will enhance nutrient run-off, creating eutrophication and increasing hamr phytoplankton blooms, affecting fisheries and aquaculture, human health and ecosystem biodiversity. Changes in precipitation, monsoons, run-off and flood potential combine with deforestation and poor sewage treatment, resulting in larger volumes of nutrients and freshwater reaching coastal ecosystems (Jin et al., 2018; Nasonova et al., 2018; Tamm et al., 2018). Rising surface temperatures, ocean acidification and eutrophication will increase pathogenic *Vibrio* bacterial loads in marine organisms with potential transfer to humans (Hernroth and Baden, 2018). Shallow and microtidal estuaries will be more vulnerable to changing river runoffs and saltwater intrusions, eutrophication, and hypoxia (*high confidence*) (IPCC, 2019c).

5.13.4 Maladaptation Responses and sustainable solutions

Maladaptation can result in three types of outcomes (Juhola et al., 2016) 1) *Rebounding vulnerability*: short term adaptations that decrease adaptive capacity and hinder future choices; 2) *Shifting vulnerability*: larger-scale adaptation actions that produce spill-over effects in other locations; 3) *Eroding sustainable development*: adaptation strategies which increase emissions, deteriorate environmental conditions and/or social and economic values (Tables 5.20 and 5.21).

Existing climate policies do not adequately consider tradeoffs, adaptive limits, cumulative costs and potential risks of maladaptation (*robust evidence and medium agreement*) (Dovie, 2017; Holsman et al., 2019; IPCC, 2019b; Work et al., 2019; Thomas, 2020: Table 5.19). Government policies are seldom coordinated across scales and often focused on regional short-term risks (*medium evidence, medium agreement*) (Dovie, 2017; Holsman et al., 2019; Rahman and Hickey, 2019; Butler et al., 2020). Past development trajectories and dominant political economic structures may narrow adaptation pathways, be restrictive and increase the vulnerability of particular groups (Paprocki, 2018; Quan et al., 2019; Rahman and Hickey, 2019; Work et al., 2019).

Case Studies of Maladaptation

Large-scale irrigation project in Navarre, Spain

Many small-scale producers could not afford the irrigation investment and had to sell or rent their land to those who joined the irrigation project. Many large-scale farmers using irrigation switched to corn and forage and dropped crops with high labour costs. Water costs are now paid to a private company, and small-scale farmers lost access to communal water rights. The project increased inequity, land concentration and lowered crop diversity, with small scale producers more vulnerable to climate change. Large-scale intensive farmers are more exposed to crop price volatility than to climate vulnerability but have greater access to subsidies and water rights (Albizua et al., 2019).

Constraining adaptation: previous agricultural development pathways in India

Government policies in colonial and postcolonial India, invested in infrastructure, export production and synthetic input use (Gupta, 1998; Davis, 2001), setting the stage for current development trajectories, closing out other adaptive options. Although such policies increased national food production, they failed to address high levels of malnutrition, worsening regional inequalities, degraded natural resources, and an agrarian debt crisis (Singh, 2000; Gupta et al., 2016; Gajjar et al., 2019). Agricultural livelihoods are increasingly considered unviable, with lower adaptive capacity of farmers, high debt levels (Gupta et al., 2016), Indigenous and local knowledge loss and denigration (Kumar, 2016) alongside lower crop diversification (Srivastava et al., 2016). Government institutions aimed at infrastructure often lack adaptive capacity needed to address rural livelihoods (Singh et al., 2017; Gajjar et al., 2019).

Table 5.20: Summary of the emerging literature on potential risks of maladaptation.

Description of adaptation strategy	Potential Negative impacts	Maladaptation Typology (1= Rebounding vulnerability, 2= shifting or 3=eroding SDGs)	Regions and countries affected	Groups affected	References
Agricultural intensification to increase productivity, in places with heavy rainfall events or rising pest/disease incidence	Increases GHG emissions, water pollution, possible insect resistance and costs to farmers, possibly increased inequities. May constrain adaptation policy options for development pathways due to lock-ins and trade-offs which entrench inequities.	1,2,3	United States, Africa, Asia (India, China), Europe	Farmers, pastoralists / nearby communities who rely on water; small-scale farmers who cannot afford inputs; Policymakers.	Gajjar et al. (2019), Guodaar et al. (2019), Houser and Stuart (2019), Neset et al. (2019b), Quan et al. (2019), Young and Ismail (2019)
Livelihood diversification into charcoal production	Increases GHG emissions and deforestation rates	1,3	Africa (Northern Ghana), South America (Peru)	Small-scale food producers; Indigenous communities	Antwi-Agyei et al. (2018), Zavaleta et al. (2018), Young and Ismail (2019)
Irrigation projects or programs either large-scale and/or that rely on groundwater	Reduces long term potential for hydropower and groundwater availability, can increase salinization and cost of water. Can increase cost of farming and debt levels of farmers, squeezing out small-scale producers. Can reduce water availability for aquaculture.	1,2 and 3	Northern China; India; Mediterranean areas; Europe; United States	Food producers who rely on irrigation; consumers who rely on hydropower or groundwater; Small-scale diversified producers who cannot afford irrigation; Aquaculture.	Doody et al. (2015), Herbert et al. (2015), Barik et al. (2016), Daliakopoulos et al. (2016) Fragaszy and Closas (2016) Dalin et al. (2017), Foster et al. (2018) Hanaček and Rodríguez-Labajos (2018), Albizua et al. (2019), Flörke et al. (2019) Gajjar et al. (2019), Xu et al. (2019)
Investment in improved cultivars or shift to different crops	May displace local varieties, reduces diversity if too much policy/extension emphasis falls on a few varieties; may increase risk of crop loss from pests, disease, drought if reliant on a few varieties; may increase fertilizer use; may lead to loss of Indigenous or local knowledge	1, 3	South America (Bolivia); Pacific Islands; Asia	Small scale food producers; Indigenous communities	Mcleod et al. (2018), Meldrum et al. (2018), Neset et al. (2019b) Rahman and Hickey (2019)
Migration	Can increase the workload of people left behind (often women), worsen rural livelihoods and food insecurity; can lead to worsened living conditions, food security and	1,3	Asia, Africa, Central and South America	Small-scale low-income food producers or rural workers; women	Bettini et al. (2017), Paprocki (2018), Chen et al. (2019), Jacobson et al.

	poverty in precarious urban conditions, may increase vulnerability to flooding in urban locations. May affect mental health by disrupting eisting social ties				(2019), Michael et al. (2019), Young and Ismail (2019), Singh and Basu (2020), Torres and Casey (2017)
Coastal sea walls, embankments, canals, riverbed draining and dikes to reduce flood risk	Can degrade coastal mangroves, deplete open freshwater fisheries, sedimentation of rivers, reduce fish diversity and increase flooding risk for particular vulnerable groups; may divert funds from other more sustainable measures.	1,2,3	Asia, South Pacific Islands, west Africa	Coastal communities dependent on mangroves and fisheries; low-income rural households with seasonal dependence on inland fisheries	Dovie (2017), Owusu-Daaku (2018), Freduah et al. (2019), IPCC (2019c), Rahman and Hickey (2019), Nunn et al. (2020) Seddon et al. (2020), Thomas (2020)
River regulation for hydropower	May have negative impacts on inland fisheries.	2,3	Global	Small-scale inland fisheries and low-income rural households with seasonal dependence on inland fisheries	FAO (2018c)
Government policies to manage coastal fisheries which promote overcapitalization of fisheries, including index insurance	Government confiscation of fishing nets to prevent rapid decline of fish population can worsen livelihoods for small scale fishers; Subsidies of pre-mixed fuel to allow fishers to stay out longer due to shifting fish populations may increase total number of fishers and total fish catch. Insurance payments may benefit larger-scale fishing fleets and push out small-scale fishers.	1,3	West Africa	Coastal small-scale fishery communities	FAO (2018b), Freduah et al. (2019), Holsman et al. (2019), Sainsbury et al. (2019)
Consultative stakeholder systems in fisheries or flood management	May encourage inertia in the system due to a few powerful stakeholders participating in the consultative process.	2	North America; Asia	Coastal fisheries	Holsman et al. (2019), Rahman and Hickey (2019)
Climate services	May reinforce existing inequalities if climate services are attuned to powerful stakeholders in industry, services are privatized, there are limited ways to get input from vulnerable groups and planning budgets that use climate services are constrained.	1,2,3	North America	Coastal fisheries, Farming	Furman et al. (2014), Webber (2017), Nost (2019)
Nature-based solutions mitigation and adaptation	Can displace local communities' access to land for food production and other ecosystem services, have negative impacts	2,3	Africa, Asia, and South America	Indigenous communities; small-scale producers and	Lunstrum et al. (2016), Work et al. (2019),

strategies such as reforestation or afforestation	on Indigenous rights, reduce biodiversity and may not reduce GHG as much as conserving natural forests and wetlands or agroecological systems such as agroforestry or other means to increase soil C.		e.g., Indonesia, Amazon, west-central Africa	forest dependent communities	Seddon et al. (2020), Cross-Working Group Box BIOECONOMY this Chapter)
Social safety nets provide funds which increases consumption of processed, purchased food and erodes Indigenous knowledge	Decline in Indigenous knowledge of and collective approaches to seasonal adaptation strategies in hunting, fishing, and food production; shift in dietary patterns to more processed and non-local foods; reduction in farming. Reduced capacity to respond to hazards through dispersed settlement e.g. hunting, fishing, wild food collection. Increased population density increases deforestation and vulnerability.	1,3	South America (Amazonian region of Peru); Africa (South Africa)	Indigenous communities	Lemos et al. (2016), Zavaleta et al. (2018)
Community-based adaptation strategies	Local gender and other social inequities can lead to 'elite capture' that reinforces inequality; power dynamics between the funding agency and local participants can make local community involvement tokenistic. There may be inadequate attention to socio-cultural preferences and structural factors which foster maladaptation such as inappropriate crops or animals used.	1,3	Pacific Islands; Africa; Asia	Small scale food producers; Indigenous communities, other vulnerable groups such as women and low caste groups	McNamara and Buggy (2017) Jamero et al. (2018), Singh (2018) Bezner Kerr et al. (2019) Piggott-McKellar et al. (2020), Westoby et al. (2020)
Digital agriculture for increased precision and efficient use of fertilizers, pesticides, water	Could lead to net job losses, particularly for those with lower levels of education; increased surveillance and employer scrutiny of lower-skilled workers in fields, greenhouses and processing plants and warehouses; separate workers from employees and companies who collect data. Overall increased racial, income inequities and unequal working conditions.	2,3	North America, South America, Europe, Asia, parts of Africa.	Farmworkers; small-scale food producers who cannot afford digital technologies; rural communities.	(Furman et al. (2014), Rotz et al. (2019)
Increased credit access for livelihood diversification	High interest rates, tight return policies could increase debt loads for low-income households, which could rebound vulnerability. Household may invest in livelihood strategies which are vulnerable to climate change impacts, or which increase GHG.	1,3	Asia (Bangladesh)	Low-income landless people or small-scale producers	Rahman et al. (2018)
Aquaculture	Large-scale coastal aquaculture can increase soil salinization and reduce land available for other food production and can increase migration	2,3	Asia (Bangladesh)	Small-scale mixed systems including rice production and other rural livelihoods	Paprocki (2018), Paprocki and Huq (2018)

Adaptation options that consider adverse effects for different groups reduce the risk increasing vulnerability, negatively affecting socio-economic factors to deal with climate impacts, or impeding efforts to implement sustainable development goals (*high confidence*) (Juhola et al., 2016; Antwi-Agyei et al., 2018; Paprocki and Huq, 2018; Holsman et al., 2019; IPCC, 2019b; Stringer et al., 2020). Adaptation methods considering historical roots of current vulnerabilities can identify viable solutions, which are difficult to undertake because of path dependencies (*high confidence*) (Ribot, 2014; Albizua et al., 2019; Gajjar et al., 2019; Paprocki, 2019; Thomas, 2020). Planning techniques that model outcomes for different groups from different adaptation options could be put in place to diminish maladaptation risks (Rodríguez et al., 2019).

Inclusive planning initiatives such as community-based anticipatory adaptation combined with 'two-way learning' that considers future scenarios and different adaptation pathways, can prevent maladaptation (*high confidence*) (Dovie, 2017; Bezner Kerr et al., 2019; Neset et al., 2019a; Rahman and Hickey, 2019; Work et al., 2019; Butler et al., 2020; Nunn et al., 2020; Piggott-McKellar et al., 2020; Westoby et al., 2020; Table 5.20). Promising policy management tools combine temporal scales, mitigation-adaptation interactions, consider political dynamics, socio-economic impacts and trade-offs for vulnerable groups, long-term support for policy leaders, efforts to establish livelihood 'niches' and ongoing participatory evaluation (Dovie, 2017; Holsman et al., 2019; Rahman and Hickey, 2019; Work et al., 2019; Butler et al., 2020). A focus on the most disadvantaged groups can help small-scale producers at higher risk to prevent maladaptation (FAO, 2018c). Governance mechanisms have emerged that consider food security, socio-cultural factors, land and water rights, using participatory, inclusive 'two-way learning' methods that involve vulnerable people alongside government (IPCC, 2018; Holsman et al., 2019; IPCC, 2019b; Rahman and Hickey, 2019; Butler et al., 2020).

Table 5.21: Strategies to avoid maladaptation (adapted from (Magnan, 2014; Lim-Camacho et al., 2015; Sovacool et al., 2015; FAO, 2018b; Paprocki and Huq, 2018; Sainsbury et al., 2019).

Type of maladaptation	Strategies
Environmental	1. Prevent negative effects on ecosystem services in situ (e.g., habitat degradation, pollution) that increases exposure to climate hazards. 2. Avoid increasing pressure on other socio-ecological systems. 3. Ensure ecosystems' protective role as natural buffer zones is sustained against current and future climate-related hazards, such as storms, floods, and sea level rise. 4. Provide some duplication and ensure flexibility of adaptation strategies to reduce risk because of uncertainties about climate change impacts and ecosystem response (e.g., agrobiodiversity to reduce pest outbreaks).
Socio-cultural	1. Consider local social characteristics and cultural values that could affect risks and environmental dynamics. 2. Support local skills and knowledge related to climate-related hazards. 3. Support capacity-building for new skills needed by local communities.
Political-Economic	1. Consider the political dynamics and power imbalances and create inclusive processes to involve the most vulnerable and disadvantaged groups in decisions. 2. Work to reduce socio-economic inequalities, poverty, and food insecurity. 3. Support livelihood diversification. 4. Focus on the impacts of adaptation on the poorest, structurally disadvantaged, and vulnerable groups, and take power imbalances into account. 5. Work across the full supply chain to consider linkages and possible ripple effects.

5.13.5 Climate Change and Climate Response Impacts on Indigenous People

Indigenous people and ethnic minorities, many of them having special cultural associations to local foods, are particularly vulnerable to climate change due to changes in the availability of wild foods, crop failure and food production loses or via increased food prices (Norton-Smith et al., 2016; Otto et al., 2017).

Changes in sea level rise or coastal erosion can reduce ecosystem services to a point where either subsidies are used to enable human populations to remain in their place of attachment, or ultimately to displace coastal residents thereby removing connections to places of intrinsic value. For example, the United Houma Nation in Louisiana is experiencing coastal land loss, sea level rise and strong Gulf hurricanes, which leads to the relocation of some tribes causing loss of Houma identity (Sullivan and Rosenberg, 2018). Another example is the relocation of Alaska Native communities due to climate change (Hamilton et al., 2016)

Expansion of agriculture can bring distress to Indigenous communities because of environmental deterioration and the stress associated with relocation or displacement (Otto et al., 2017). Afforestation and reforestation (A/R) programs can also bring inequalities to Indigenous communities (Godden and Tehan, 2016) and even violent displacement with tragic results (Celentano et al., 2017). A/R programs can negatively affect a range of substantial and procedural Indigenous Peoples' rights entrenched in international human rights law (Table 5.22) and their potential for climate change adaptation (*high confidence*).

A significant proportion of land targeted for A/R projects is inhabited and used by Indigenous Peoples and local communities (Cagalanan, 2016). Indigenous Peoples have rights to and/ or manage at least 37.9 million km^2 of land and influence land management across at least 28.1% of the land area (Garnett et al., 2018). At least a quarter of the global land area is traditionally owned, managed, used or occupied by Indigenous Peoples overlapping 35 to 40 per cent of the area that is formally protected (Garnett et al., 2018; Brondizio et al., 2019). In many cases, A/R is implemented in areas where tenure rights are insecure and Indigenous Peoples' rights are in risk of being disregarded (Naughton-Treves and Wendland, 2014; Kohler and Brondizio, 2017; Garnett et al., 2018) (*medium evidence, high agreement*). Many projects are also found in areas where complex socio-political contexts challenge management (Jurjonas and Seekamp, 2019). It is anticipated that A/R projects will create huge pressures on existing land uses and generate further land use conflicts (Aggarwal, 2014; Robinson et al., 2014; Paul et al., 2016; Brancalion and Chazdon, 2017; Pye et al., 2017; Bond et al., 2019). In addition, many afforestation projects are conducted in regions that are not bio-climatically suitable, leading to the degradation of ecosystems that are key to local livelihoods (Veldman et al., 2015; Robinson et al., 2016b).

Table 5.22: Indigenous rights recognized in international human rights law negatively affected by A/R projects.

Negative impacts of monoculture plantations (and other A/R projects)	Indigenous Peoples' rights affected	Degree of certainty	References
Local community not informed, not adequately consulted, not provided means for meaningful participation in project design, implementation, and monitoring (with specific attention to women and poor households); disruption or non-recognition of local or traditional institutions; elite capture; no access to third-party grievance mechanisms.	Right to self-determination; consultation and free, prior and informed consent (FPIC); participation	*Medium evidence, high agreement*	Aggarwal (2014), Maraseni et al. (2014), Ravikumar et al. (2015), Bayrak and Marafa (2016), Loaiza et al. (2016), Vijge et al. (2016), Pye et al. (2017), Ryngaert (2017), Wolde et al. (2016), Brancalion and Chazdon (2017), Seddon et al. (2020)
Evictions and displacement; dispossession; livelihood precarity; and criminalization of forest-dwelling people	Right not to be forcibly removed	*Medium evidence, high agreement*	Mingorría (2014), Richards and Lyons (2016), Witasari (2016), Corbera et al. (2017), Pye et al. (2017), Sarmiento Barletti et al. (2020), Brancalion and Chazdon (2017)
Loss, transfer or acquisition of land. A/R projects involve changes in land use for medium to long term and often lack consideration for local dynamics including land tenure and competition with agriculture or conservation.	Rights to land and territory	*Limited evidence, high agreement*	Aggarwal (2014), Robinson et al. (2014), Bayrak and Marafa (2016), Pye et al. (2017), Bond et al. (2019)
A/R projects exacerbate conflicts, accentuate uneven power relations,	Rights to land and territory	*Limited evidence,*	Aggarwal (2014)

increase existing inequalities within communities, exclude the poor and deepen structural injustices including racism and stigmatization.		*low agreement*	
Forest expansion intensifies already acute land shortages for growing food and forces villagers to take their animals for grazing to new areas as a result of forests being fenced off.	Rights to land and territory (with implications for food security)	*Limited evidence, high agreement*	Lyons et al. (2014), Wolde et al. (2016), Brancalion and Chazdon (2017), Mousseau and Teare (2019)
Decreased stream flows and water yields; exacerbated water scarcity.	Right to water	*Robust evidence, high agreement*	Veldman et al. (2015), Aitken and Bemmels (2016), Brancalion and Chazdon (2017), Pye et al. (2017), Bond et al. (2019), Seddon et al. (2020)
Pollution of lakes with agrochemicals; heavy chemical use including the spread of pesticides, herbicides and fertilizers by aircraft and other means causing runoff into rivers	Right to a healthy environment	*Medium evidence, high agreement*	Richards and Lyons (2016), Johansson and Isgren (20179, Pye et al. (2017)
Encroachment on other ecosystems with devastating impacts on biodiversity; pressures on ecologically sensitive ecosystems such as wetlands; reduction in seed-dispersing animals; planted tree species becoming invasive, introducing pests and diseases	Right to a healthy environment, right to food	*Medium evidence, high agreement*	Richards and Lyons (2016), Holmes et al. (2017), Seddon et al. (2020), Ennos et al. (2019)
Loss of habitat, degradation of savannas, native grasslands (grassy biomes) or mangroves wrongly characterized as degraded land suitable for afforestation	Right to a healthy environment, right to food	*Robust evidence, high agreement*	Veldman et al: (2015), Cormier-Salem and Panfili (2016), Brancalion and Chazdon (2017), Bond et al. (2019), Seddon et al. (2020)
Direct negative health impacts; loss of traditional medicine	Right to health	*Limited evidence, medium agreement*	Dotchamou et al. (2016), Johansson and Isgren (2017)
A/R projects affect burial sites as for many communities, the forest is also the resting place for deceased ancestors	Right to cultural identity and to main and control their traditional knowledge	*Limited evidence, high agreement*	Lyons et al. (2014), Gabriel and Mangahas (2017), Mousseau and Teare (2019)
Loss of traditional or Indigenous ecological knowledge and forest management practices	Right to cultural identity and traditional knowledge	*Limited evidence, medium agreement*	Bayrak and Marafa (2016)
Increased labor burden. Benefit sharing by direct cash transfer or in-kind modalities tends to not compensate lost income opportunities. Some projects bring employment opportunities, but these are short term and limited and rarely viable if the opportunity cost of land and labour is considered. Poor farmers may drop out in order to regain access to their land for uses that provide cash returns in the shorter term.	Right to an adequate standard of living; right to decent work; right to benefit-sharing	*Medium evidence, medium agreement*	Boyd et al. (2007), Aggarwal (2014), Cagalanan (2016), Witasari (2016), Corbera et al. (2017), Pye et al. (2017)

Until 2010, most A/F projects had technical, carbon-related goals and did not consider issues of livelihoods, community involvement or broader ecosystem impacts (Wolde et al., 2016). New strategies such as Nature-based Solutions (Seddon et al., 2020) and Forest and Landscape Restoration (Brancalion and Chazdon, 2017) integrate a larger set of social and environmental objectives. Indigenous Peoples enjoy a range of co-benefits of A/F initiatives such as improved habitat, fire management or protection from climatic shocks such as drought (Robinson et al., 2016b; Seddon et al., 2020) provided they are able to manage carbon funds collectively, meet the monitoring and reporting requirements, and protect forests from illicit uses and natural disasters (Wolde et al., 2016).

Policies and safeguards attached to specific A/R initiatives determine their impact (*high confidence*) (Talor, 2015; West, 2016; Brancalion and Chazdon, 2017). In countries where there is a great level of devolution of rights to Indigenous Peoples there is a risk that the A/R agenda will lead to recentralization (*limited evidence, medium agreement*) (Bayrak and Marafa, 2016). Some A/R initiatives specify the need to respect the rights of Indigenous Peoples and local communities and protect biodiversity (*medium evidence, high agreement*) (Seddon et al., 2020).

Local communities' ability to participate in project design, implementation and monitoring is directly linked to the autonomy and independence of local institutions (Pye et al., 2017), their ability to formulate by-laws (Wolde et al., 2016) and handle funds in a transparent way (*medium evidence, high agreement*) (Witasari, 2016). It is further dependent on cohesion in the community (Cagalanan, 2016), the existence of clear rules delineating community membership and the presence of elders and community members with relevant local knowledge (Robinson et al., 2016b) as well as gender and out-migration dynamics affecting participation structures (*robust evidence, medium agreement*) (Cormier-Salem and Panfili, 2016; Witasari, 2016; Wolde et al., 2016; Jurjonas and Seekamp, 2019).

5.13.6 Increased Presence of Financial Actors in the Agrifood System

Financial actors, markets, institutions, and incentives have gained importance in agricultural commodities and farmland markets in the past two decades (Clapp and Isakson, 2018; Fairbairn, 2020).New types of investment vehicles such as commodity index funds that track prices of commodities and farmland have emerged and the use of older vehicles such as forward and futures markets has increased (Schmidt and Pearson, 2016; Clapp and Isakson, 2018). These trends are connected to climate change as financial investments are influenced by the likelihood that climate change will increase commodity and farmland price variability (*medium confidence*) (Cotula, 2012; Isakson, 2014; Tadesse et al.).

Financial investors pool their investments through intermediaries, alongside other dynamic forces in the global economy, making unambiguous assessments of their effect difficult (Clapp, 2014; Clapp, 2017). However, assessment of the broader trends at the interface of financial investment, food system dynamics, and climate change shows potential connections.

Climate-induced variability in food production has the potential to introduce a new level of uncertainty into food and farmland markets, encouraging financial investment into products to capitalize on price volatility and to hedge risks. The new financial instruments enable investors to speculate more easily on the direction of food and land prices, especially when they are volatile (Ouma, 2014; Baines, 2017).

5.13.7 Climate Change Interactions with other Drivers – Food-Water-Health-Energy-Security Nexus

Linkages between food security and nutrition with water and energy as well as other important socio-environmental issues are increasingly being described within a nexus framework (see also Chapters 3, 4, 6, and 7) with food systems frequently located at the centre of nexus concepts (Caron et al., 2018).

Climate change will affect the food-energy-water (FEW) nexus, commonly in the form of risk multiplier (*high confidence*) (e.g. Conway et al., 2015; Barik et al., 2016; Keairns et al., 2016; Abbott et al., 2017; Ebhuoma and Simatele, 2017; Caron et al., 2018; D'Odorico et al., 2018; de Amorim et al., 2018; Mpandeli et al., 2018; Nhamo et al., 2018; Soto Golcher and Visseren-Hamakers, 2018; Yang et al., 2018; Amjath-Babu et al., 2019; Froese and Schilling, 2019; Mercure et al., 2019; Momblanch et al., 2019; Pastor et al., 2019; Xu et al., 2019). Xu et al. (2019) assessed the need for an increase in irrigation water to sustain maize production in Northeast China. As droughts will become more frequent, this could lead to groundwater depletion and other environmental knock-on effects. Barik et al. (2016) described how the growing demand for food in India has led to more irrigation with a reduction in groundwater levels in some regions.

Increasing demands for food, energy and water can lead to domestic and international conflict, including political instability and migration, often in the context of drought (*high confidence)* (Abbott et al., 2017; Bush and Martiniello, 2017; WEF, 2017; D'Odorico et al., 2018; de Amorim et al., 2018). de Amorim et al. (2018) conclude that the WEF nexus is susceptible to many global risks, including extreme weather events and human migrations and predominantly endanger vulnerable communities of less developed countries. There is emerging evidence that food and water insecurity enhance social conflicts, including protests and violent riots, at least partially, by accelerating existing grievances (Heslin, 2021; Koren et al., 2021). Closer coordination at global, regional, and national levels could be recommended to manage these risks.

Meeting growing demands for food, water, and energy under a changing climate require technical solutions and behavioural change as well as greater coordination across multilateral institutions and governance. Supply-side solutions focus on enhancing production, reducing food waste and loss or lowering water demand through both technological approaches (e.g., breeding, improved irrigation) and agroecological approaches, such as agroforestry, underutilized and more adapted crops, and transition toward a circular economy (Alexander et al., 2015; Obersteiner et al., 2016; D'Odorico et al., 2018; Nhamo et al., 2018; Soto Golcher and Visseren-Hamakers, 2018). Demand-side solutions focus primarily on changes in consumer behaviour toward healthier diets with lower carbon footprints, particularly reduction of meat consumption (Alexander et al., 2015; Obersteiner et al., 2016). Improving the coordination of multilateral organizations could result in improved cross-boundary management of natural resources, particularly related to water (Conway et al., 2015; Nhamo et al., 2018; Soto Golcher and Visseren-Hamakers, 2018).

As relationships between individual subsystems are systemic, integrated solutions would result in better outcomes across the FEW nexus (*strong agreement*). Obersteiner et al. (2016) concluded that single-sector policies can create strong trade-offs with other policy targets and SDGs, whereas strategies that reduce pressure on food production systems diminish trade-offs between FEW nexus components. This suggests that achieving multiple SDGs will require balancing societal demands in the context of finite natural resources (Jägermeyr et al., 2017; Amjath-Babu et al., 2019; Momblanch et al., 2019).

Despite concluding that integrated solutions addressing the systemic connections between the FEW nexus would improve development and environmental outcomes, there are limitations of integrating multiple frameworks, both in terms of describing the complexities and in finding solutions (Leck et al., 2015; Weitz et al., 2017; Wichelns, 2017; Shannak et al., 2018). Leck et al. (2015) and Weitz et al. (2017) indicate that evidence of successful implementation and improved outcomes based on the application of nexus concepts is rare.

5.14 Implementation Pathways to Adaptation and Co-benefits

5.14.1 State of Adaptation of Food, Feed, Fibre, and Other Ecosystem Products

Since AR5, several adaptation reviews have been done (Ford et al., 2015; Lesnikowski et al., 2016). In a review of 1159 peer-reviewed sources, Berrang-Ford et al. (2021b) found that observed adaptations in food, fibre and other ecosystem products has consisted mainly in changes in autonomous behaviour changes, such as changing planting time, followed by technological/infrastructure and ecosystem-based adaptation approaches, the majority of which have occurred in Africa and Asia (Figures 5.20-5.21, Table 5.22). Several adaptation options addressed multiple SDGs (e.g. 2, 6 8, 12) (Figure 5.21).

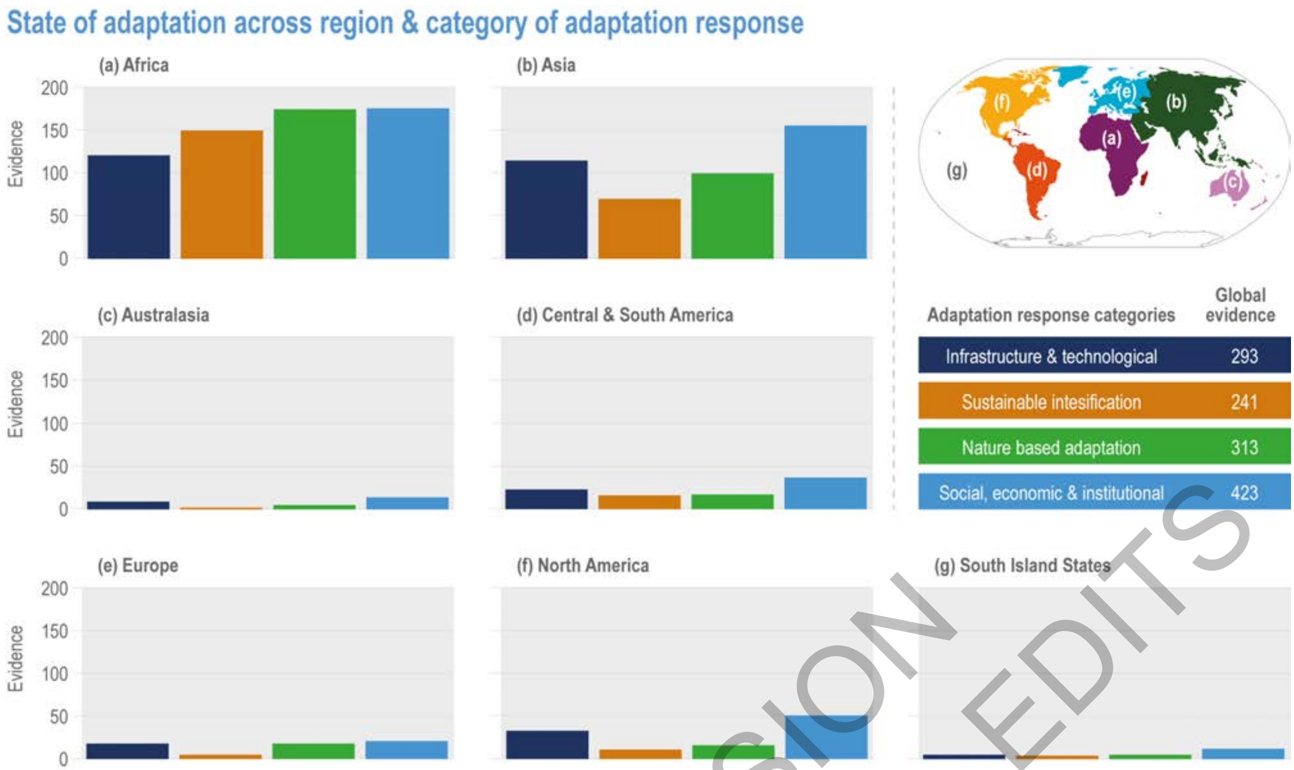

Figure 5.19: State of adaptation by region and type of response (based on 1159 peer-reviewed references that addressed adaptation in food, fibre, and other ecosystem products sector; source: Global Adaptation Mapping Initiative (GAMI) database (Berrang-Ford et al., 2021a). The bars indicate the number of evidence for the category x region.

Table 5.23: State of adaptation in food, fibre and other ecosystem products by actor and vulnerability (planned and targeted) (source: Global Adaptation Mapping Initiative (GAMI) database (Berrang-Ford et al., 2021a)).

Actors	N (%)	Equity/justice	Planned – N (%)	Targeted – N (%)
International or multinational governance institutions	72 (6%)	*Women*	134 (12%)	118 (10%)
National government	264 (23%)	*Youth*	22 (2%)	24 (2%)
Local government	267 (23%)	*Elderly*	31 (3%)	28 (2%)
Sub-national government	89 (8%)	*Low-income*	201 (17%)	258 (22%)
Private sector corporations	56 (5%)	*Disabled*	2 (0%)	3 (0%)
Private sector SMEs	80 (7%)	*Migrants*	12 (1%)	18 (2%)
Civil Society-international/multinational/national	117 (10%)	*Indigenous*	95 (8%)	85 (7%)
Civil Society- sub-national or local	257 (22%)	*Ethnic minorities*	32 (3%)	32 (3%)
Individuals or households	1087 (94%)			

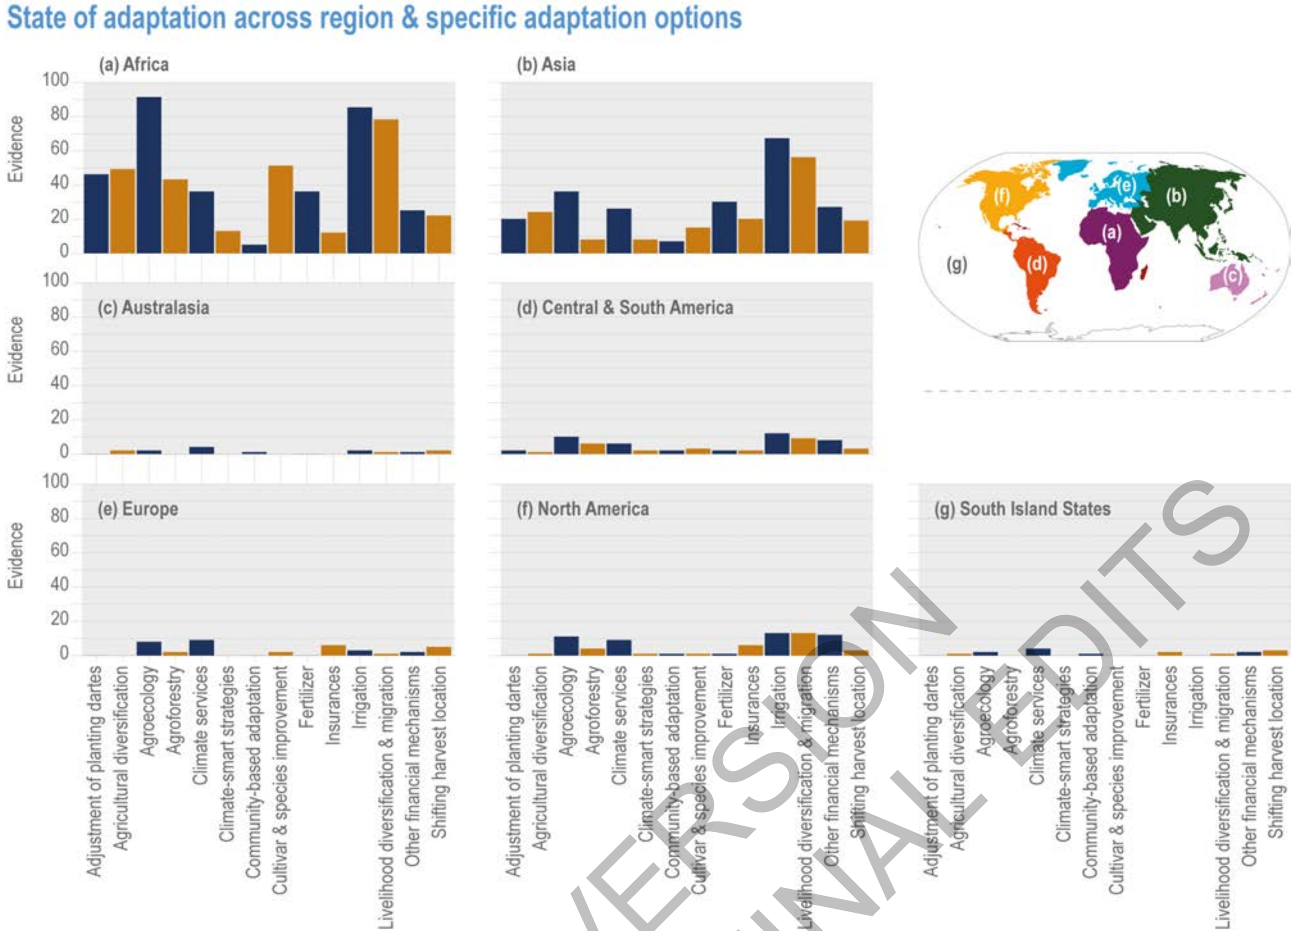

Figure 5.20: Observed adaptation across regions in food, fibre, and other ecosystem products. Stage of implementation; Type of adaptation; Inclusion of Indigenous knowledge and local knowledge (IK and LK) based on Global Adaptation Mapping Initiative (GAMI) database – (Berrang-Ford et al., 2021a). The bars indicate the number of evidence for the options x region.

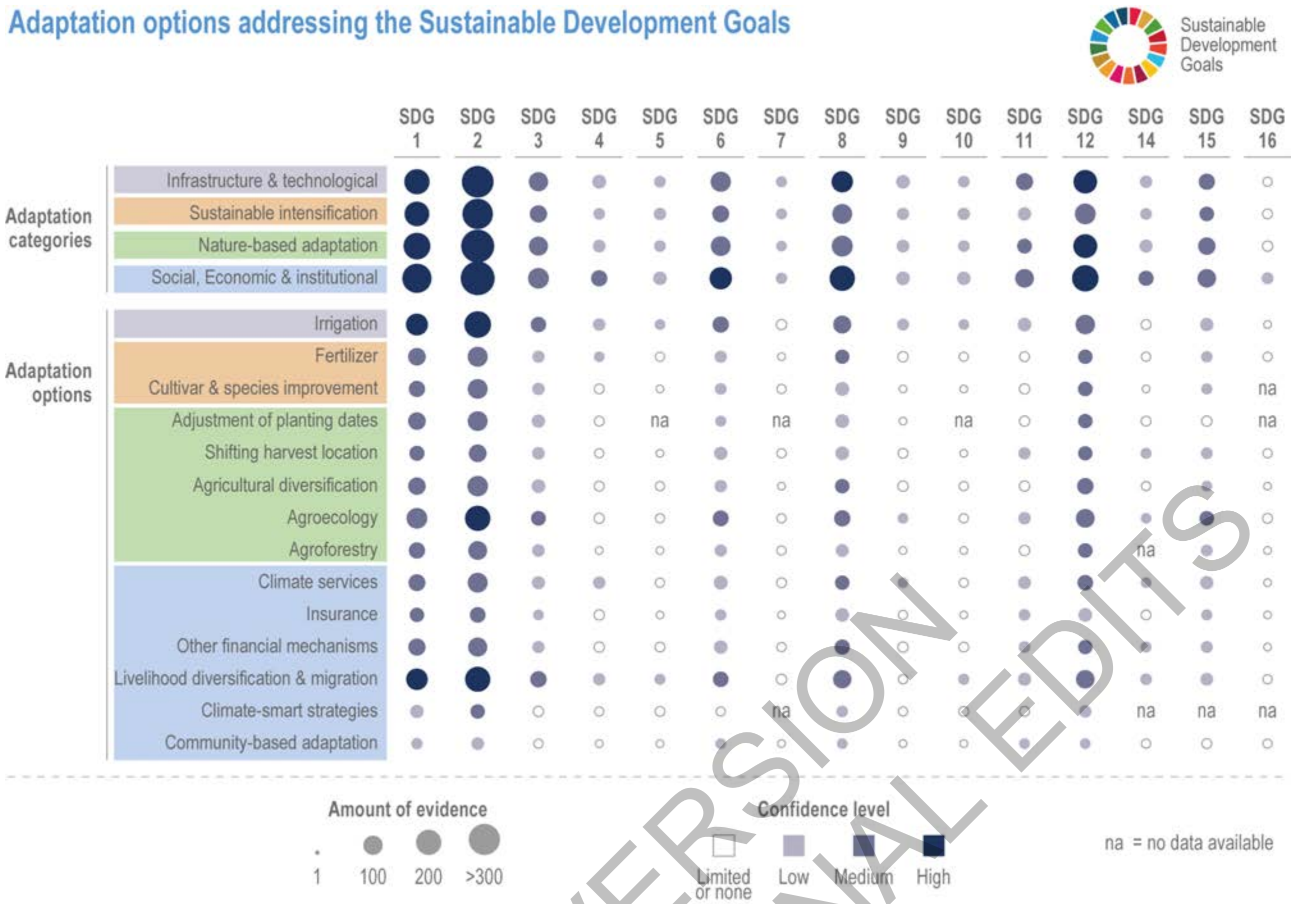

Figure 5.21: How different response types address the SDGs based on GAMI

Assessment of adaptation options was done for 15 potential options for land and ecosystem transitions (SM5.7, Figure 5.22a). Several adaptation options have high to medium feasibility, with *robust evidence, high agreement* about the adaptive capacity resilience building potential of options in relation to climate change impact drivers (*high confidence*). Policy and planning and production shifts have limited evidence for feasibility. Most options are technically and physically feasible, with generally high political and social acceptability and environmental feasibility, but have limited evidence for institutional feasibility. Most adaptation options have medium to high microeconomic feasibility (*high confidence*), but *limited evidence* for macroeconomic viability.

Among five effectiveness indicators (SM5.7, Figure 5.22b), most options have *robust evidence* of reduced risk vulnerability to climate change, with low scores for local governance, substitution of plant or animal type, community forest management, livelihood diversification and climate services. Higher scored options to reduce risk included increasing biodiversity (at landscape and field level), community seed banks, conventional breeding (plant and animals), mixed systems and agroecological approaches (*medium confidence*), suggesting multiple co-benefits of these options. Most options have high scores for enhancing social well-being, economic and environmental benefits (*medium confidence*) but limited evidence for strengthening institutions for most options. There were low scores for potential maladaptation (*medium confidence*).

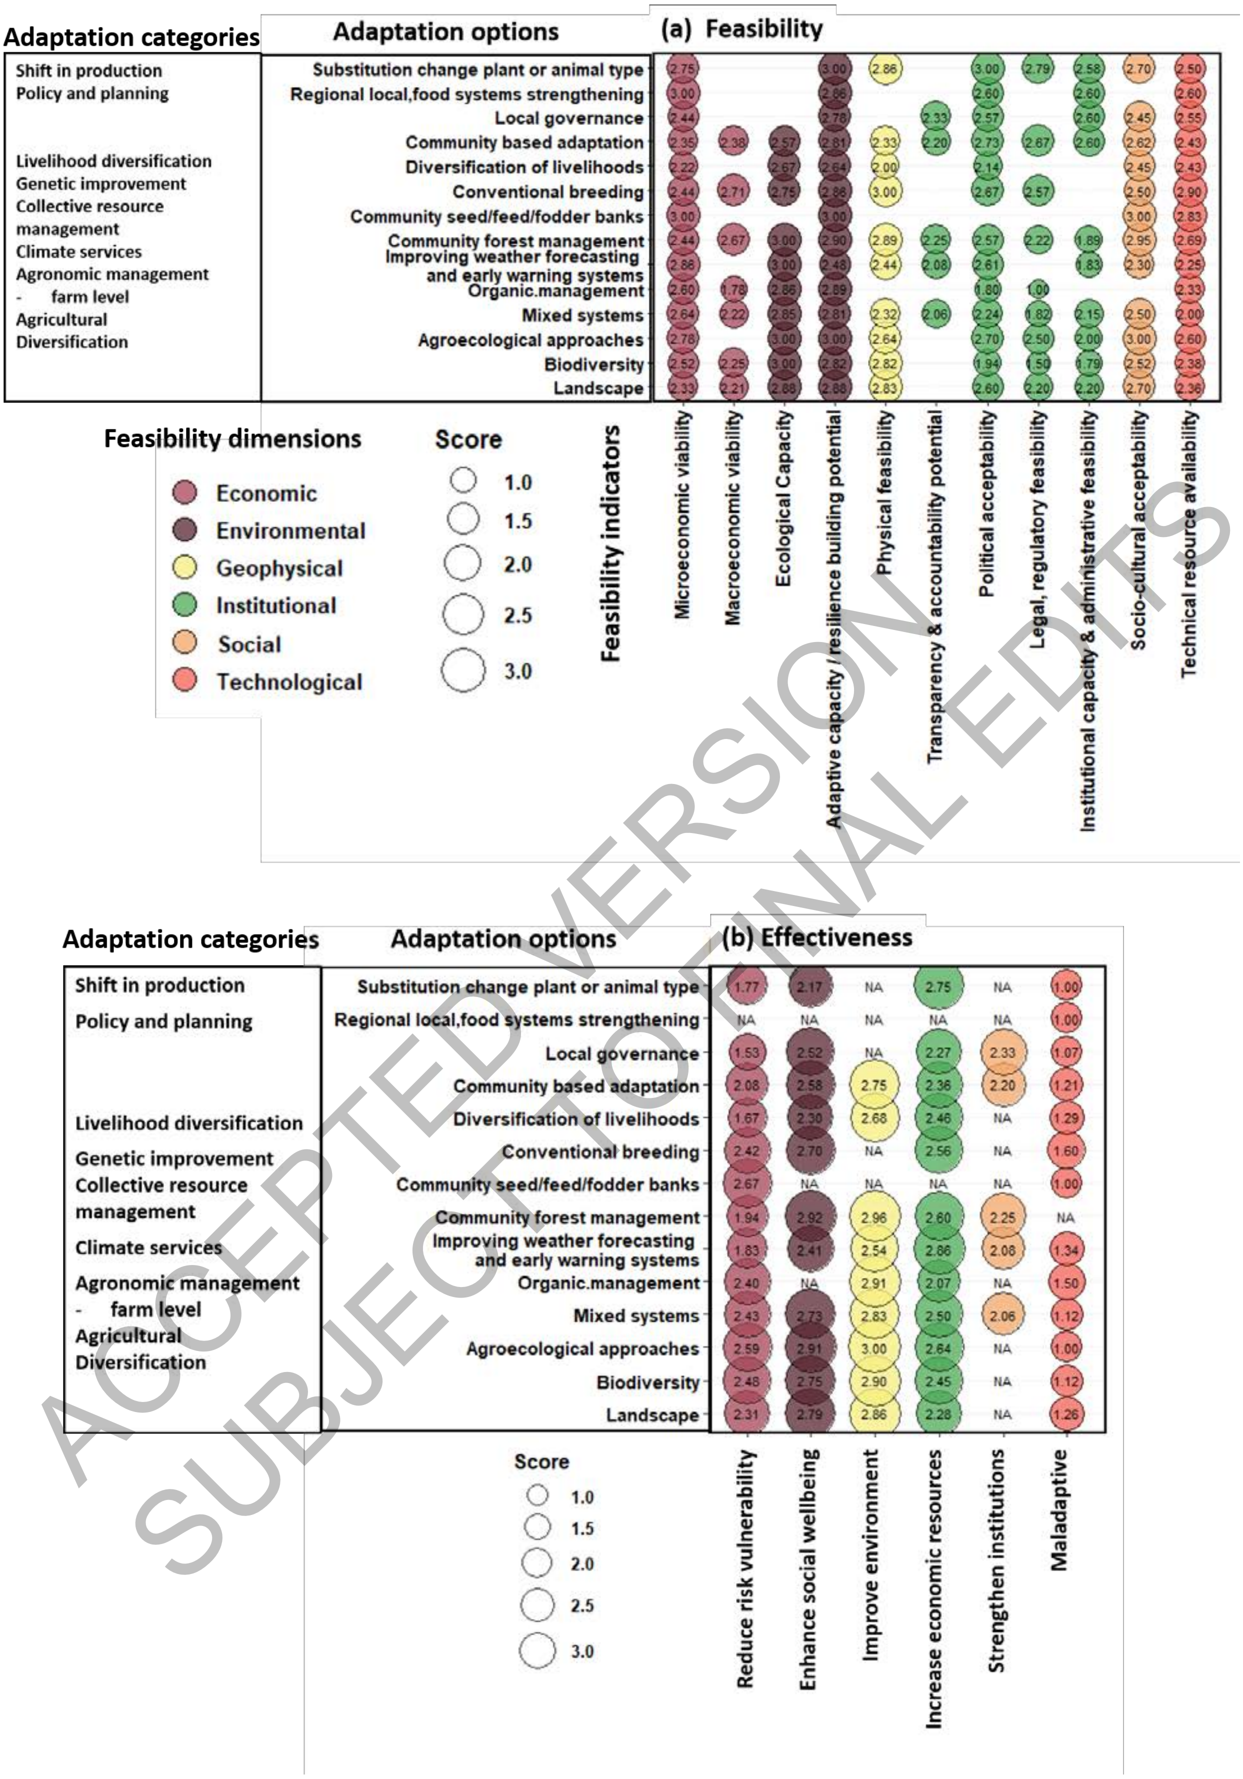

Figure 5.22: Assessment of 11 feasibility indicators (six categories) (a) and five effectiveness indicators and maladaptation (b) of adaptation options based on 287 peer-reviewed papers. See SM5.7 for methods and data. Scores ranging from 1 (low) to 3 (high) were obtained by averaging five or more papers for each option and indicator.

5.14.1.1 Nature-based solutions or ecosystem-based adaptation

There is growing evidence that nature-based solutions (NBS), which emphasise ecological approaches and biodiversity conservation (Chapter 1), have high potential to transform land and aquatic systems into climate-resilient systems *(medium evidence, high agreement*) (Albert et al., 2017; Brugère et al., 2019; Galappaththi et al., 2020b; Snapp et al., 2021; Cross-Working Group Box BIOECO; Cross-Chapter Box - NATURAL in Chapter 2).

[START BOX 5.11 HERE]

Box 5.11: Agroecology as a Transformative Climate Change Adaptation Approach

Agroecological approaches can increase food system resilience (*robust evidence, medium agreement*), while some agroecological practices such as agroforestry can provide mitigation measures (*medium confidence*) (Section 5.10.4.2, Table Box 5.11.1, Altieri et al., 2015; Martin and Willaume, 2016; HLPE, 2019; Bezner Kerr et al., 2021; Snapp et al., 2021). Studies testing agroecological approaches have shown *robust evidence, medium agreement* of increasing adaptation effectiveness through reducing risk, improving food security, yield stability, reducing input costs, and other supporting and provisioning ecosystem services (Section 5.4.4.4 Diacono et al., 2017; Pandey et al., 2017; Schulte et al., 2017; Calderón, 2018; Bezner Kerr et al., 2019; Côte et al., 2019; Rosa-Schleich et al., 2019; Bezner Kerr et al., 2021; Snapp et al., 2021). Effective locally relevant agroecological approaches involves participatory processes, co-creation of knowledge with farmers and attention to social inequities (Bezner Kerr et al., 2021; Santoso et al., 2021; Snapp et al., 2021). To address smallholder vulnerability to climate change impacts, however, additional policy support beyond agroecology will be needed that is context specific; for example, addressing farmer capacity, limited political power to access land, water, seeds and other key natural resources, structural gender inequalities, policy and market disincentives that support large-scale monocultures (*high confidence*) (Anderson et al., 2019a; HLPE, 2019; Holt-Giménez et al., 2021; Snapp et al., 2021).

Table Box 5.11.1: Dimensions of agroecological transitions as a transformative climate change adaptation strategy, benefits, tradeoffs and constraints to implementation

Different dimensions of agroecological transitions as a transformative climate change adaptation strategy	**Links to climate change impacts, benefits, tradeoffs and constraints to implementation with examples.**
Environmental: Agroecology can support long-term productivity and resilience of food systems by sustaining ecosystem services such as pollination, soil organic carbon, pest and weed control, soil microbial activity, crop yield stability, water quality and biodiversity (*high confidence,* see Section 5.4.4.4, Cross-Working Group Box BIOECONOMY this chapter and Cross-Chapter Box NATURAL in Chapter 2). (Isbell et al., 2017; Kremen and Merenlender, 2018; LaCanne and Lundgren, 2018; Beillouin et al., 2019b; Dainese et al., 2019; Rosa-Schleich et al., 2019; Snapp et al., 2021).	• Biodiversity of functional species groups and responses to climate hazards play an important role in building stability and productivity in agroecological systems (5.4.4.4). A 5-year study, for example, in Asia, Africa and Latin America found that smallholder farmers (< 2 ha) increased yields by 25% through promoting pollination (Garibaldi et al., 2016). • Landscape complexity is an important feature of agroecology which can increase resilience to extreme events, such as pest and disease outbreaks or floods, and provide multipurpose benefits (Sections 5.4.4; 5.10.4.2) (Paolotti et al., 2016; Reed et al., 2016; Kremen and Merenlender, 2018; LaCanne and Lundgren, 2018; Rosa-Schleich et al., 2019; Holt-Giménez et al., 2021). • Context-specific: some agroecological systems and practices have lower average crop productivity than conventional systems, while others can have higher overall crop productivity and farm profitability (LaCanne and Lundgren, 2018; Barbieri et al., 2019; Rosa-Schleich et al., 2019).
Socio-cultural: Effective locally relevant agroecological approaches involves participatory processes, co-creation of knowledge with farmers and attention to	• Agroecology can emphasize social justice concerns, including gender inequities, considered crucial for climate change adaptations in food production to have positive impacts on food

social inequities, in doing so building farmer capacity (HLPE, 2019; Bharucha et al., 2020; Holt-Giménez et al., 2021; Snapp et al., 2021).	security and nutrition (Cross-Chapter Box GENDER in Chapter 18; (Smith and Haddad, 2015; HLPE, 2019; Sylvester and Little, 2020). • In some contexts, agroecological systems can draw on and support Indigenous knowledge, farming systems, networks and socio-cultural values(Catacora-Vargas et al., 2017).
Food security and nutrition: Agroecological practices can increase household food security and nutrition for producer households, with more evidence in low- and medium-income countries *(high confidence*) (Darrouzet-Nardi, 2016; Demeke et al., 2017; Jones, 2017a; Kangmennaang et al., 2017; Pandey et al., 2017; Luna-Gonzalez and Sorensen, 2018; Bezner Kerr et al., 2019; Boedecker et al., 2019; Mulwa and Visser, 2020; Bezner Kerr et al., 2021; Santoso et al., 2021).	• Combinations of practices, such as intercropping, crop rotation and crop diversification, often outperform individual practices for yield and food security outcomes (Beillouin et al., 2019b; Bezner Kerr et al., 2021). • Agroecological systems more effectively support food security and nutrition when complemented by nutrition and health education, participatory research and other public policies and programs which address access to knowledge (*high confidence;* (HLPE, 2019; Bezner Kerr et al., 2021; 7.4).
Economic: Agroecology can support socio-economic resilience, through reducing reliance on purchased inputs, enhancing local and regional economies (HLPE, 2019; Bharucha et al., 2020; Holt-Giménez et al., 2021).	• Multi-level policies and programs that support urban and peri-urban networks with agroecological producers, including farmers' markets, public procurement (e.g.school meals, hospitals), incentives for short food value chains, and participatory guarantee certification schemes which build producer-consumer networks are all ways to support agroecological transitions by consumers (*high confidence*) (Catacora-Vargas et al., 2017; Pérez-Marin et al., 2017; Mier y Terán Giménez Cacho et al., 2018; Anderson et al., 2019a; HLPE, 2019; Borsatto et al., 2020; González de Molina, 2020). • Transitions to agroecology at a global scale, however, may require considerable dietary shifts which vary by region, have implications for total food production and farm level revenues, especially in the short term (medium confidence, (Muller et al., 2017; Seufert and Ramakutty, 2017; Barbieri et al., 2019; Rosa-Schleich et al., 2019; Smith et al., 2019b; Smith et al., 2020a). • To address smallholder vulnerability to climate change impacts additional policy support beyond agroecology will be needed that is context specific; for example addressing farmer capacity, limited political power to access land, water, seeds and other key natural resources, structural gender inequalities, policy and market disincentives that support large-scale monocultures (Anderson et al., 2019a; Holt-Giménez et al., 2021; Snapp et al., 2021).
Long-term investment: Timeframes are an important consideration, as an agroecological transition involves multiple overlapping stages, of reducing chemical inputs, experimenting with and applying new agroecological practices and adjusting them, redesigning the farm, strengthening short value chains and producer networks (Gliessman, 2014; Padel et al., 2020).	• In the short term, without policy support the costs of implementing agroecological practices at the farm scale can outweigh ecological and adaptation benefits, although the timeframe required is context-specific (Padel et al., 2020). • In the long-term, implementing agroecological practices can increase yields, yield stability, farm profitability, reduce risks and build resilience alongside ecological, health and social co-benefits, but impacts are context-specific (Section 5.4.4.4, Rosa-Schleich et al., 2019; Bezner Kerr et al., 2021; Snapp et al., 2021).

	• In Malawi, for example, studies indicate that smallholder producers using agroecological practices improved food security and nutrition, livelihoods and provisioning ecosystem services after 2 years (Kangmennaang et al., 2017; Bezner Kerr et al., 2019; Kansanga et al., 2021), while in the UK, farmers transitioning to agroecological practices took 3 or more years to realize benefits (Padel et al., 2020).
Policy tools: Investment in agroecological approaches that are designed for socio-ecological context, farmer-led schools, co-learning platforms, and networks of farmers, scientists, private sector and civil society can support agroecological transitions at a regional scale (*high confidence*) (Coe et al., 2014; Catacora-Vargas et al., 2017; Pérez-Marin et al., 2017; Mier y Terán Giménez Cacho et al., 2018; Anderson et al., 2019a; González de Molina, 2020; Lampkin et al., 2020; Padel et al., 2020; Snapp et al., 2021). Policies can provide incentives (e.g., price premiums, access to credit, extension service, taxes, regulation) to support agroecological transitions by producers (HLPE, 2019; Rosa-Schleich et al., 2019; Gerard et al., 2020; SAPEA, 2020).	• Farm scale and landscape diversity can affect the capacity for producers to implement agroecological systems. Small to mid-sized farms can more effectively integrate agroecological methods such as increasing landscape diversity, on-farm diversity and intercrops (*medium confidence)* (Garibaldi et al., 2016; Herrero et al., 2017; HLPE, 2019). Barriers to adopting agroecological practices for small to mid-sized farms include limited market options, subsidy and policy disincentives, lack of extension support, knowledge and insecure land tenure (Jacobi et al., 2017; Kongsager, 2017; Hernández-Morcillo et al., 2018; Iiyama et al., 2018; Anderson et al., 2019a; Gerard et al., 2020). • Barriers for large farms to transition to agroecological practices include knowledge gaps, cost, significant infrastructure and farm design changes, labour, psycho-social adjustments, policy disincentives and market lock-ins (Hill, 2014; Rosa-Schleich et al., 2019; Lampkin et al., 2020). • Some policies and initiatives support large-sized farms to transition to agroecology (Zhou et al., 2014; Liebman and Schulte, 2015; Ajates Gonzalez et al., 2018; Bellon and Ollivier, 2018; Lampkin et al., 2020; Padel et al., 2020)
Other drivers of agroecological transitions can include crises (environmental, economic, or social), social movements, changing socio-cultural values, addressing social inequities, and discourse (Pérez-Marin et al., 2017; Mier y Terán Giménez Cacho et al., 2018; Anderson et al., 2019a).	Further research could provide context-specific information about economic and ecological benefits of some practices and combinations, with effective policies to support their implementation (*high confidence*) (HLPE, 2019; Rosa-Schleich et al., 2019; Snapp et al., 2021). Institutional support to monitor the ecosystem services climate change mitigation and adaptation impact of agroecological systems can inform policy, using systematic methods and indicators (e.g. Barrios et al., 2020; Mottet et al., 2020) including annual reporting to the UNFCCC (Snapp et al., 2021).

5.14.1.2 Climate services

Climate services, understood as the production, translation, communication and use of climate information in decision-making processes, can contribute to adaptation efforts in agricultural systems (*medium agreement, low evidence*). Climate services can support decision-makers in agriculture by providing tailored information that can inform the implementation of specific adaptation options (Vaughan, 2018; Buontempo et al., 2019; Dobardzic et al., 2019; Hank et al., 2019).

For some high- and medium-income countries, evidence suggests that climate services have been underutilized (Mase and Prokopy, 2014), with *limited evidence* in these countries of the impact of climate services on yields, income, and food security and nutrition. In low-income countries, use of climate services can increase yields, incomes and promote changes in farmers' practices (*low confidence*) (Roudier et al., 2014; Roudier et al., 2016; Tarchiani et al., 2017; Ouedraogo et al., 2018). There is *low confidence* that climate services are delivering on their potential, whether they are being accessed by the vulnerable, and how these services are contributing to food security and nutrition (Ouedraogo et al., 2018; Vaughan et al., 2019).

Improved design and delivery of climate services can enhance effectiveness (*medium confidence*). Ways to enhance the impact of climate services include integrating information from multiple sources at different scales (Bouroncle et al., 2019), participatory collection and analysis of climate information (Loboguerrero AM, 2018; Tesfaye et al., 2019; Rossa, 2020), and making forecast information available in local languages and as verbal communications for farmers who cannot read (Nkiaka et al., 2019).

In countries with limited climate data, crowd sourcing (outsourcing data collection to the public) (Minet et al., 2017) and digital tools present an opportunity for addressing climate risk (*medium confidence*) (Osgood et al., 2018; Thornton, 2018; Partey et al., 2020; Sotelo et al., 2020). Bundling additional services such as market information with climate information may be effective at plugging information gaps (*low confidence*) (Chatuphale and Armstrong, 2018; Dalberg, 2019; Tesfaye et al., 2019)

There may be inequality in access to climate services; their use may tend to benefit large-scale operations and disadvantage small-and medium-scale farmers and others who face issues of access due to social and economic inequity; also some groups such as pastoralists have not yet benefitted from climate services (*high confidence*) (Furman et al., 2014; Muema et al., 2018; Awazi et al., 2019; Nyantakyi-Frimpong, 2019; Paudyal et al., 2019; Vaughan et al., 2019; Nidumolu et al., 2020; Partey et al., 2020). Other challenges include technology ignorance, data privacy and security, data access permissions, software and system compatibility, and understanding how to use and derive value from accessed data (Chatuphale and Armstrong, 2018; Drewry et al., 2019). More work is needed to understand the factors that prevent farmers and fishers from benefiting from this new information. Recent assessments suggest that access to, and value of, climate and weather information can be enhanced by the development of digital tools (including radio, text messages, etc.) appropriate to the specific needs of different vulnerable groups, as well as by including these groups in their development and building their capacity (*medium confidence*) (Camacho and Conover, 2019; Gumucio et al., 2020; Sultan et al., 2020).

5.14.1.3 Insurance as a climate impact risk management tool

Insurance is a financial adaptation strategy increasingly used in agriculture and aquaculture. A relatively new approach to agricultural insurance risk is the use of financial derivative products, such as index-based agricultural insurance (IBAI), marketed by financial institutions to farmers to help them deal with weather-related production risks (Isakson, 2015; Jensen and Barrett, 2017). The basic idea is to rely on easily observed weather indices, such as precipitation or temperature, that co-vary with farm production. Insurance payments are received when the metric trigger for a region is reached, eliminating the need to collect farm-specific information. Proponents of index insurance argue that it can resolve the information costs and incentive problems inherent in rural financial markets, such as adverse selection, and allow provision of insurance coverage at a fraction of the costs of loss-based polices (Jensen and Barrett, 2017). Buyers of index policies do not have to prove their ownership of assets with weather-related losses. This lowers transactions costs and makes it more affordable to insure small plots of land.

The creation of index insurance requires significant prior research and extensive data that may not be available or sufficient in lower income countries, including identifying the most appropriate farm and climate variables to include and financial and regulatory support from the public sector (Economic Commission for Latin America and the Caribbean and Central American Agricultural Council of the Central American Integration System, 2013; Economic Commission for Latin America and the Caribbean and System, 2014). Some insurance providers bundle it with other services, such as fertilizer use or seeds that may not be useful to particular farmers and can increase their overall capital costs (Isakson, 2015). Although proponents see IBAI as a way to mitigate farmers' risks associated with more variable weather patterns (Greatrex et al., 2015), critics argue that derivative-based insurance products tend to benefit wealthier farmers and fail in assisting the poorest and most marginalized farmers (Isakson, 2015; Taylor, 2016). Thus far, there is *low agreement and medium evidence* regarding the adaptation potential of derivatives-based insurance products, signaling a need for further research in this area.

5.14.1.4 Community-based adaptation approaches

Community-based adaptation (CbA) strategies, which involve locally-driven, place-based adaptation approaches, can help build adaptive capacity to climate change impacts, but require explicit attention to power dynamics, respect for local and Indigenous knowledge systems, adequate resources, future climatic trends and coordination at multiple levels of governance to be effective (*high confidence*) (Spires et al., 2014; Fernández-Giménez et al., 2015; Nagoda, 2015; Ashley et al., 2016; Berner et al., 2016; Ensor et al., 2016; Avtar et al., 2019; Lam et al., 2019; Silwal et al., 2019; McNamara et al., 2020; Piggott-McKellar et al., 2020; Rossa, 2020; Uchiyama et al., 2020). Since AR5, there is strong evidence that participation of local stakeholders in adaptation planning and implementation improve communities' capacity to monitor and respond to climate change impacts on food, fibre, and forestry systems, provided that adequate resources and local knowledge on climate change exist. Participatory monitoring of climate change impacts, and participatory scenario development to develop community action plans are examples, which can help strengthen community preparation for and response to climate impacts.

Community-based monitoring of forests, coral reefs, seagrass and mangroves are examples of local natural resource assessment that can support food security and livelihoods while informing regional and national climate change planning tools (Carter et al., 2014; Gevaña et al., 2018; Avtar et al., 2019). Negotiation amongst many stakeholders at multiple scales, including inclusive mechanisms to address power inequities in governance structures and communities, may be needed for CbA to be effective (Avtar et al., 2019; McNamara et al., 2020). Indigenous knowledge and community-based management of fisheries and aquaculture in the Arctic and Asia (Roux et al., 2019; Chen and Cheng, 2020; Galappaththi et al., 2020a; Schott et al., 2020; Galappaththi et al., 2021) provide adaptive strategies for sustainable use. (Iticha and Husen, 2019). Community-based climate services in the Andes (managed through a collaboration of smallholder producers and an international partnership) built capacity and knowledge of climate change dynamics as well as trust in local climate institutions, providing meaningful information for regional responses to climate change impacts (Rossa, 2020). Community-based participatory scenario planning can help identify multiple climate stressors and vulnerabilities to develop effective adaptation plans (Fernández-Giménez et al., 2015; Bennett et al., 2016; Cross-Chapter Box MOVING PLATE this Chapter).

An assessment of 32 different CbA initiatives in the Pacific Islands, including addressing risks to food security, found high performing projects had 6 key entry points: effective methods to improve adaptive capacity, appropriate to the local context, which moved beyond narrow geographical definitions of community to consider equity of impact, and ecosystem-based approaches, jointly addressing climatic and non-livelihood pressures and consideration of future climatic trends (McNamara et al., 2020). Low-performing initiatives, in contrast, were not sustained; these overlooked future climatic trends in their initiatives, such as beehive susceptibility to climate extremes, and had dependent, unequal relationships that lacked genuine local approval or ownership and did not fit local values and context (Spires et al., 2014; McNamara et al., 2020; Piggott-McKellar et al., 2020). CbA initiatives can also suffer from not having adequate local knowledge of potential strategies to address future climatic scenarios, and may lead to maladaptation, increasing socio-economic inequities in communities (Nagoda, 2015). Addressing inequity in power dynamics and building technical adaptive capacity of local people are some of the ways that CbA initiatives can support more resilient food systems (McNamara et al., 2020).

5.14.1.5 Local and regional food systems' strengthening and food sovereignty

Food sovereignty brings together adaptation options based on agroecological methods, access to resources, collective and CbA (HLPE, 2019). Addressing food security and nutrition in light of climate change impacts and vulnerabilities is considered to arise from a mixture of globalised supply chains and local production, not one or the other (Blesh et al., 2019; Stringer et al., 2020). Evidence on strengthening local and regional food systems with a food sovereignty approach, in terms of access to resources (land, seeds, water), shortened food chains and CbA strategies suggest that these strategies can positively contribute to climate change adaptation in many contexts (*medium confidence)*(SRCCL) but can also lead to conflict especially regarding management of mobile resources such as fisheries (Section 5.8, Cross-Chapter Box MOVING PLATE this Chapter). All these options can build adaptation through actions that strengthen local capacities and the power to act within food systems. Securing and recognising tenure for Indigenous Peoples (Hurlbert et al., 2019) and local communities (Oates et al., 2020) can improve their ability to adapt by increasing the incentive to invest in resilient infrastructure and sustainable land management practices. Community seed banks and networks strengthen local seed systems and realize farmers' rights favouring access to a variety of local genetic resources, with landraces often more adapted to the local social, cultural, and ecological environment and needs, and better adapted to harsh environments without external inputs (Mousseau, 2015; Bisht et al., 2018; Maharjan and Maharjan, 2018; Otieno et al., 2018; Mbow et al., 2019). This plays a key role in participatory plant breeding (section 5.4.4.5; FAO, 2019e). The integration of informal and formal seed system elements is important for the adaptive capacity of smallholder farmers (Westengen and Brysting, 2014; Westengen and Berg, 2016; FAO, 2019e).

Strengthening both local and regional food systems is a strategy to increase resilience (Schipanski et al., 2016; Palmer et al., 2017)resource use efficiency (Mu et al., 2019) and self-reliance (*medium evidence, low agreement*) (Griffin et al., 2015; Chapin et al., 2016; Karg et al., 2016). Collective trademarks (Quiñones-Ruiz et al., 2015) and participatory guarantee systems (Niederle et al., 2020) are examples of innovative institutional strategies to strengthen local and regional food systems. In the urban context, the city-region food system (CRFS) approach is motivated by reducing dependence on international trade and associated instability and to facilitate local decision-making (Karg et al., 2016). CRFS includes a network within a regional landscape around one urban center and surrounding peri-urban and rural regions (Blay-Palmer et al., 2018). Urban and peri-urban agriculture are promoted as effective strategies to adapt to climate change in different contexts (see Section 5.12.5.3, Dubbeling, 2015; Lwasa et al., 2015). In order to cope with the effects of climate change, strengthening regional food systems is becoming an explicit part of urban and regional policy, being tested in many different cities worldwide (Dubbeling et al., 2017; Blay-Palmer et al., 2018; Berner et al., 2019; Sellberg et al., 2020; van der Gaast et al., 2020). Strengthening both local and regional food systems has to be balanced against limitations and tradeoffs, since modelling exercises of regionalization scenarios show urban agriculture cannot achieve food security in areas with rapid population growth (Le Mouël et al., 2018). Furthermore, international trade can compensate in cases where the regional system fails due to extreme events or other related climate shocks (Section 5.11.8).

5.14.2 Enabling Conditions for Implementing Adaptation

5.14.2.1 Addressing social inequalities in food systems

Addressing gender and other social inequalities (e.g., racial, ethnicity, age, income, geographic location) in markets, governance and control over resources is a key enabling condition for climate resilient transitions in land and aquatic ecosystems (*high confidence*) (Pearse, 2017; Vermeulen et al., 2018; Blesh et al., 2019; Rao et al., 2019b; Cross-Chapter Box GENDER in Chapter 18, Section 5,13,1; Tavenner et al., 2019). Adaptation strategies can have negative impacts on marginalized social groups and worsen socio-economic inequities unless explicit efforts are made to address unequal power dynamics and differences in access to resources in agricultural, fisheries, aquaculture, livestock and forestry systems (*high confidence*) (Glemarec, 2017; Haji and Legesse, 2017; Nagoda and Nightingale, 2017; Nightingale, 2017; Rao et al., 2019b; Huyer and Partey, 2020; Mikulewicz, 2020; Taylor and Bhasme, 2020; Eriksen et al., 2021). Technical approaches to adaptation that ignore inequities can worsen them, see for example the case study on Climate Smart Agriculture (Box 5.12). Enabling environments support inclusive decision-making, capacity-building, shifts in social rules, norms and behaviours and access to resources for marginalized groups for climate change adaptation (e.g., Tschakert et al., 2016; Ziervogel, 2019; Eriksen et al., 2021; Garcia et al., 2021).

[START BOX 5.12 HERE]

Box 5.12: Is Climate-smart Agriculture Overlooking Gender and Power Relations?

Climate-smart agriculture (CSA) is an approach that aims to increase agricultural productivity, enhance food security, adapt to climate change and, where possible, reduce GHG emissions. The effective implementation of climate-smart practices is conceptually linked to an enabling environment in which policies, institutions and finance can reorient agricultural systems, thereby supporting development and enhancing food security in a changing climate (Lipper et al., 2014; Karttunen et al., 2017). However, the concept has received criticism based on the absence of conceptual clarity of the interrelations between productivity, food security, adaptation and mitigation (Arenas-Sanchez et al., 2019) and because of limited evidence on the efficacy of

CSA for achieving adaptation and mitigation outcomes at a global scale (Arslan et al., 2015; Lamanna et al., 2016; Chandra et al., 2018). Some argue that CSA operates within an apolitical framework that tends to minimize issues concerning power, inequality, and access, and is overly focused on technical approaches (Taylor, 2017; HLPE, 2019). CSA is explicitly referenced by more than 30 countries in their Intended Nationally Determined Contributions (INDCs) (Ross et al., 2016), but measuring the degree of its implementation still represents a challenge.

There is *low agreement, medium evidence* on the relationship between CSA and equity (Allen, 2018; Karlsson et al., 2018). CSA can potentially benefit women if they are able to take advantage of improvements in productivity, food security and adaptation decision making as a result of the implementation of CSA practices. Nevertheless, these advantages can be unequally realized given male domination in receiving information and extension services, as well as financial or resource access (Jost et al., 2016). Some argue that CSA may undermine gender equity (Collins, 2018), entrench and solidify power (Haapala, 2018), and result in the disproportional allocation of new labour-intensive activities to women (Jost et al., 2016). Uptake of some climate-smart technologies can further marginalize the most disadvantaged local groups (Roncoli et al., 2009; Haapala, 2018). Unequal sharing of benefits and burdens with respect to emission reduction costs among different agricultural groups have also been observed (Budiman, 2019).

In contrast, emerging research points to the potential of CSA as a supporting condition for gender equity, provided that equity and power concerns are explicitly included in the approach (Chanana-Nag and Aggarwal, 2020). Some CSA technologies and practices, such as direct seeding, green manuring, and laser land levelling, can have a significant role in reducing the gender gap in labour burden for women in agriculture, (Khatri-Chhetri et al., 2020). The use of participatory approaches can facilitate community-based adaptation of gender-sensitive CSA practices (Rosimo, 2018). CSA may also empower both men and women: in two villages in India, CSA adoption empowered both sexes in decision making and use and control of income (Hariharan et al., 2018).

In general CSA programs have tended to overlook questions of inequity (*medium confidence)*, including limited attention to social conditions that promote business-as-usual pathways, although this is now changing. Addressing questions of rights, social injustice, unequal power relations and inequality would help make CSA-related policy responses more effective in addressing vulnerability (Chandra et al., 2017; Clapp and Isakson, 2018; Karlsson et al., 2018; Westengen et al., 2018; Ellis and Tschakert, 2019; Eriksen et al., 2019; Westengen et al., 2019).

[END BOX 5.12 HERE]

[START BOX 5.13 HERE]

Box 5.13: Supporting youth adaptation in food systems

Young people are key agents in agri-food systems: both a vulnerable group, and one that can foster systemic change (*high confidence*) (Brooks et al., 2019; Figure X; IFAD, 2019; Flynn and Sumberg, 2021; HLPE, 2021). Food systems are the largest source of employment for young people, but do not always provide adequate livelihoods or decent working conditions (HLPE, 2021). Regions with more youthful populations – such as Sub-Saharan Africa, South Asia, and Central America - are both highly vulnerable to climate change impacts, and reliant on agriculture, forestry, aquaculture, and fisheries for livelihoods (Brooks et al., 2019; IFAD, 2019; HLPE, 2021). Rural youth in these sectors are particularly vulnerable, often with less access to land, water, capital, and other resources, shaped by family and social relations, and fewer opportunities (*high confidence*) (Chingala et al., 2017; Ricker-Gilbert and Chamberlin, 2018; IFAD, 2019; Yeboah et al., 2020; Flynn and Sumberg, 2021; Nhat Lam Duyen, 2021). In these vulnerable regions, climate change compounds other drivers such as poverty to increase youth out-migration to urban areas or other regions (*medium confidence*) (Zin et al., 2019; Weinreb et al., 2020; HLPE, 2021; Stoltz et al., 2021; Voss, 2021), which can further worsen rural economies. Young low-income rural women may be particularly marginalized and vulnerable due to systemic gender inequities in access to land, credit, employment, institutions, and other resources (*medium confidence*) (Sah Akwen, 2017; IFAD, 2019; Flynn and Sumberg, 2021).

Youth play a critical role in all sectors of the food system (HLPE, 2021; Figure Box 5.13.1) and some are actively pursuing work and innovation in agri-food systems (*medium confidence*) (Sah Akwen, 2017; 2019; Yeboah et al., 2020; Flynn and Sumberg, 2021). Climate change impacts may reduce youth employment options in food systems in some regions, while they are often politically marginalized (Brooks et al., 2019; IFAD, 2019; HLPE, 2021). At the same time, due to heightened awareness about climate change, youth may be more willing to apply climate adaptation strategies (*medium confidence*) (Ali and Erenstein, 2017; Jiri et al., 2017; Sah Akwen, 2017; Chamberlin and Sumberg, 2021; Doherty et al., 2021). Agri-food policy implementation of adaptation strategies could increase inclusive participation of youth to meet their needs (HLPE, 2021). Inclusive investments in water management, infrastructure, agri-food science, and policies that increase youth access to land, credit, knowledge, education, skills, and other crucial resources can support dignified and rewarding agri-food employment (Ahsan and Mitra, 2016; Brooks et al., 2019; HLPE, 2021). Digital technologies can support agrifood adaptations, but digital divides must be overcome to avoid worsening inequities (HLPE, 2021). Initiatives which protect and strengthen youth engagement and employment in the all points of the food system, including recognition of youth's critical role and agency through rights-based approaches, can support sustainable food transitions (HLPE, 2021). Harnessing youth innovation and vision to address climate change alongside other SDGs such as gender inequity and rural poverty, will be a crucial strategy to ensure resilient economies in food systems (*high confidence*) (Laube, 2016; Brooks et al., 2019; IFAD, 2019; Abay et al., 2021; HLPE, 2021).

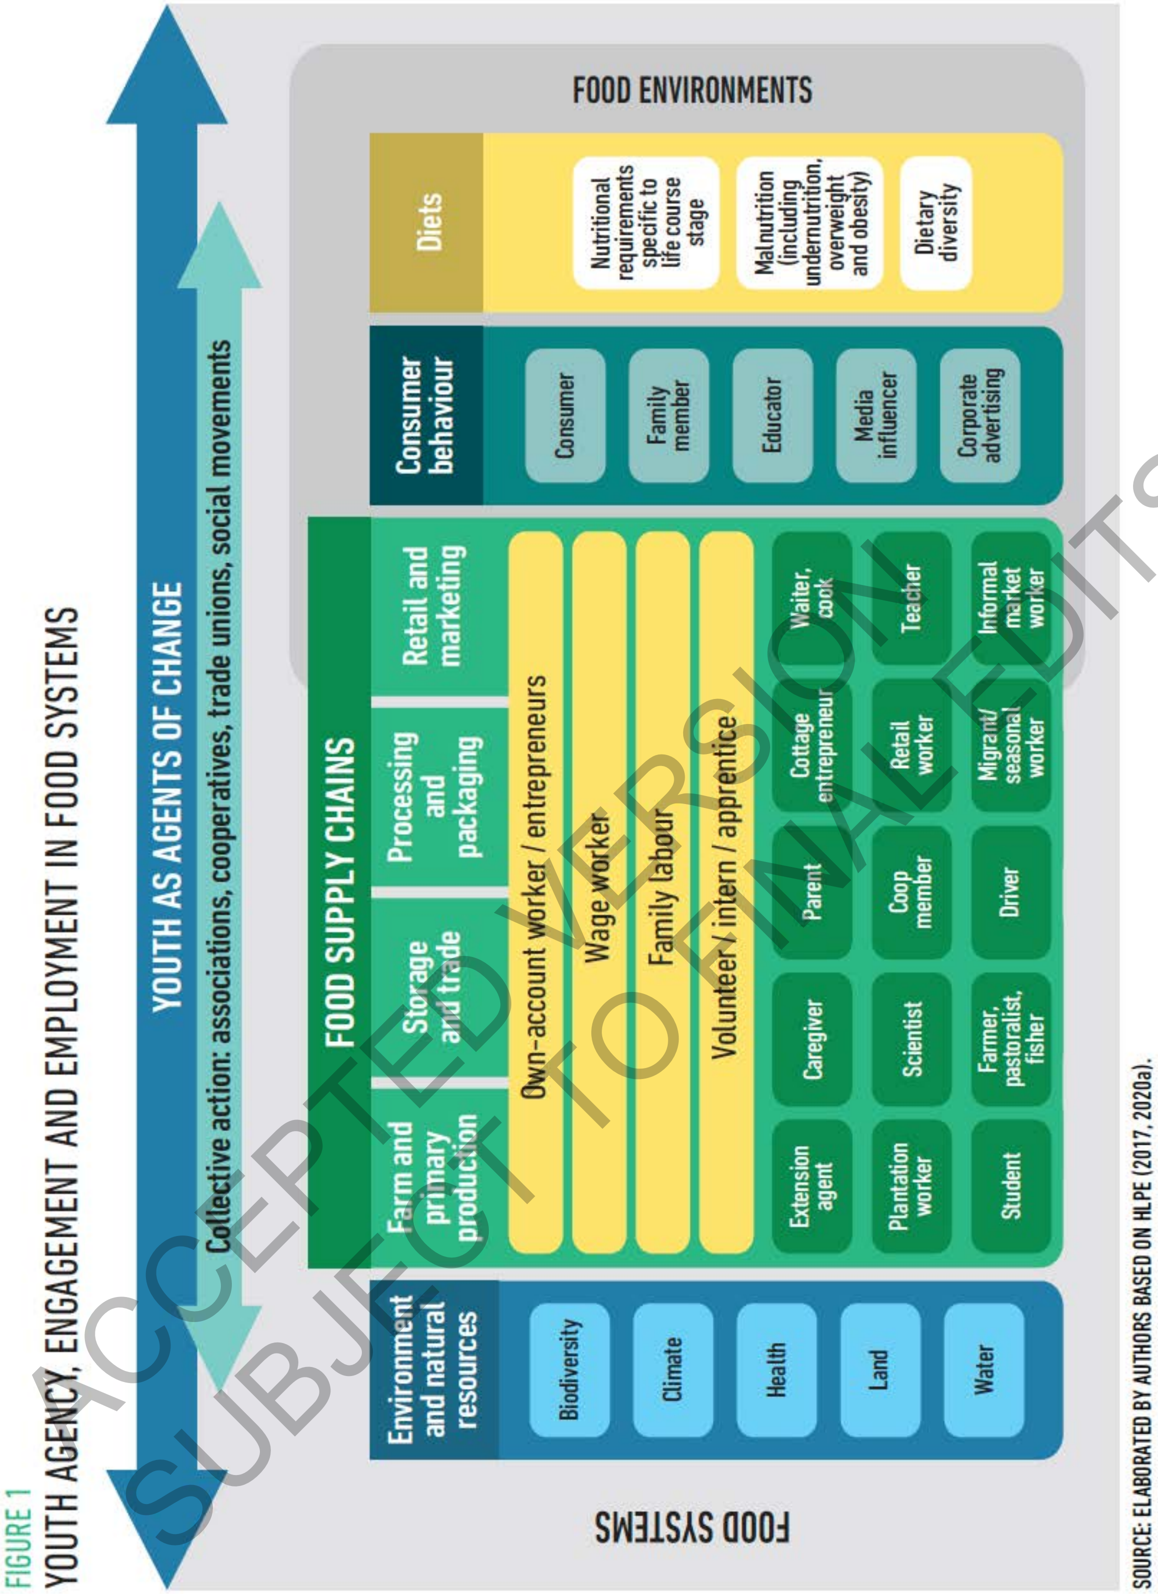

Figure Box 5.13.1: Youth agency, engagement, and employment in food system (HLPE, 2021)

[END BOX 5.13 HERE]

5.14.2.2 Incorporating Indigenous knowledge and local knowledge

Indigenous knowledge (IK) and local knowledge (LK), while an important component of many adaptation strategies (Reyes-García, 2014; Roue, 2018), continues to be marginalized in food systems; greater integration will increase effectiveness (*high confidence*) (Ford et al., 2015; Brugnach et al., 2017; Figueroa-Helland et al., 2018). Where Indigenous Peoples have access to and control over their lands and natural resources, food systems can potentially be more sustainably managed and more resilient (*high confidence*) (Rumbach and Foley, 2014; O'Connell-Milne, 2015; Camacho et al., 2016; Janhiainen, 2017; Kihila, 2018). For example, Solomon Islands, community-based adaptation combining with IK-informed community mapping helped boost agricultural yields sustainably (Leon et al., 2015), and in China people living in rich plant resource regions have used their wild plants IK to complement the decrease of crop yields during extreme droughts to ensure food security (Zhang et al., 2016). These cases have led scientists and local communities to call for more practical actions to bridge local knowledge, Indigenous knowledge, and formal science (Borquez et al., 2017; Klenk et al., 2017; Mukhopadhyay, 2017; Olorunfemi, 2017; Reyes-Garcia et al., 2019). Despite this increased public and scientific recognition, Indigenous knowledge is often not acknowledged or used.

Effective adaptation requires a more holistic approach that includes the recognition of Indigenous rights, governance systems and laws (*high confidence*) (Robinson et al., 2016a; Brugnach et al., 2017; Magni, 2017; McMillen et al., 2017; McNeeley, 2017; Pearce et al., 2018), and to couple IK with proactive and regionally coherent adaptation plans, actions, and cooperation (Shaffer, 2014; Melvin et al., 2017; Forbis Jr. and Hayhoe, 2018; Makondo and Thomas, 2018).

Supporting Indigenous groups' knowledge and other excluded social groups can help preserve and harness underutilized resources to enhance nutritional and economic security, with careful measures in protecting Indigenous intellectual rights and avoiding commodification exploitation (Nakashima et al., 2012; Nandal and Bhardwaj, 2014; Ghosh-Jerath et al., 2015; Ebert, 2017). In some regions there has been a loss of Indigenous knowledge about food systems, reducing adaptive capacity (Richards et al., 2019; Panikkar and Lemmond, 2020). Knowledge exchange between Indigenous elders and youth can support adaptive capacity (Osterhoudt, 2018; Richards et al., 2019; Zin et al., 2019). Education utilizing Indigenous knowledge and local knowledge can help prevent maladaptation options (*high confidence*) (Melvin et al., 2017; Taremwa, 2017; Forbis Jr. and Hayhoe, 2018; Narayan et al., 2020). There are examples of integrating IK and LK into resource management systems, school curricula and in local institutions with existing decision-making process to strengthen their capacity to address climate change (Huaman and Valdiviezo, 2014; McNamara and Prasad, 2014; Abah et al., 2015; Mistry and Berardi, 2016; Tschakert et al., 2017; McNeeley et al., 2018; McNeeley et al., 2020). However, there are limitations of IK and LK to address future climate impacts. Therefore, it is important that science-based knowledge and other knowledge coalesce to produce solutions that are sustainable and viable in the face of projected impacts of climate change. Community-based adaptation approaches can integrate IK and LK and more formal knowledge systems, provided efforts to establish relationships of respect, trust and common understanding between different stakeholders involved (Herath et al., 2015; Camacho et al., 2016; Fidelman et al., 2017; Inaotombi and Mahanta, 2019; Lam et al., 2019).

5.14.2.3 System transformation and policy enablers

Recent literature highlights the future challenges of producing the quantities of food needed to feed a growing world population in a way that satisfies nutritional needs, benefits everyone equally and equitably, and minimises the negative impacts of food systems on the environment and the natural resource base. There is broad agreement that current trajectories towards the SDGs and countries' commitments under the Paris Agreement are slow and that transformation of food systems is needed (*medium agreement, robust evidence*) (Campbell et al., 2018; Brondizio et al., 2019; Dury et al., 2019; EAT-LANCET, 2019; FAO, 2019f; Food and Land Use Coalition, 2019; Sachs et al., 2019; Searchinger, 2019a; Searchinger T, 2019b; Loboguerrero et al., 2020; Meridian Institute, 2020; Steiner A, 2020).

Recent reviews have summarised literature on production system transformations, driven at least in part by a changing climate or changing climate variability. Such transformations may involve sometimes substantial shifts in farm and livelihood enterprises and land configurations, including intensification, diversification, sedentarisation, as well as abandonment of agriculture (Vermeulen et al., 2018; Thornton et al., 2019). Relevant literature is summarised in Table 5.24, showing reported farmers' perceptions of the drivers of change and the different outcomes of these changes. The consequences of these production system transitions have been mixed; in about 40% of cases, the outcomes at household level have been unequivocally beneficial. In the other cases, there were detrimental effects on livelihoods, or a mixture of positive and negative effects. The effects on nutritional security reported in these studies were limited. Different enablers of change appear critical if transitions are to have positive outcomes. Policy environments, defined in terms of multi-level governance structures and institutions, are a key driver of systems change, as well as being enablers of and barriers to adaptation responses (Xu et al., 2008; Namgay et al., 2014; Galvin et al., 2015; Schmidt and Pearson, 2016; Liao and Fei, 2017). Policies around property and grazing rights are directly linked to small-scale food producer vulnerability, and land ownership changes will pose a key challenge as climate change impacts in the marginal lands intensify (Reid et al., 2014). Collective action at multiple scales and effective governance structures are also a key enabler of transformational change, for helping community initiatives overcome economic, social, and technical barriers, and to strengthen social capital and farmer knowledge (Haglund et al., 2011; Reed et al., 2017; Vermeulen et al., 2018; Fedele et al., 2019). Market development has been shown to be a critical factor for successful adaptation at scale in sub-Saharan Africa (Ouédraogo et al., 2017; Iiyama et al., 2018; Totin et al., 2018). At the same time, financing mechanisms may be a crucial enabler for different food system actors: de-risking agricultural production and food system investments for producers and input suppliers, for example, that address core market failures and compensate actors for extra short-term costs that can lead to longer-term benefits, particularly for small-scale producers and businesses with comparatively low access to technologies and services (Vermeulen et al., 2018; Millan, 2019; see Section 5.14.2.5).

The examples in Table 5.24 highlight the uneven impact of adaptation programs and projects in general, due in part to differences in institutional support and failure of policies to take into account inequalities (Clay and King, 2019; Nightingale et al., 2020). Focusing on transformational adaptation, Vermeulen(2018) suggested the need to expand the remit of adaptation planning to consider the multi-functionality of agriculture and a system-wide view of food production and consumption. Several authors argue that transformational change must address the personal, practical, and political spheres, in view of the role of power relations and worldviews in shaping practices, food security and inequity (O'Brien, 2015; Nightingale, 2017; O'Brien, 2018; Eriksen et al., 2019; Gosnell et al., 2019). If it involves new or unfamiliar technology, transformation may also be highly disruptive, and the added vulnerabilities of food system actors at risk will need to be addressed (Herrero et al., 2020; see Box5.5).

"Transformation", defined by IPCC (2019a) as 'b a change in the fundamental attributes of natural and human systems', is defined here as a redistribution of at least a third in the primary factors of production (land, labor, capital) and/or the outputs and outcomes of production (the types and amounts of production and consumption of goods and services arising from multifunctional agricultural systems) (Vermeulen et al., 2018; Thornton et al., 2019).

Table 5.24: Agricultural and livelihood system transformations from systematic searches of the literature, which are at least partially attributable to climatic factors and that involve increased or decreased system integration, and major consequences of the change. Information in the table is from the references cited. Sources: updated from (Vermeulen et al., 2018; Thornton et al., 2019).

Underlying Production System	Primary Drivers of Change as Stated	Major Processes of Change as Reported	Consequences of Change, if Reported	Reference
Extensive grassland-based systems				
Extensive grassland-based, NW China	Government policy, climate	Sedentarisation Diversification (crops, wages)	Income decline, asset holding decline	Liao and Fei, (2017)
Extensive grassland-based, Peruvian Andes	Multiple climatic and non-climatic drivers	Diversification (wages, livestock assets, land) Extensification	Livestock accumulation in wealthy households, asset diversification in poorer households	López-i-Gelats et al., (2015)

Extensive grassland-based, Bhutan	Government policy, labour constraints, climate	Sedentarisation Diversification (crops) Exit	Increased risk, loss of cultural identity, improved market access, livelihood "lock-in" (inability to change rapidly)	Namgay et al., (2014)
Extensive grassland-based, Borana, Ethiopia	Increase in climate variability, resource degradation	Livestock herd diversification (more small stock and camels, fewer cattle)	Enhanced household resilience	Megersa et al., (2014)
Extensive grassland-based, Tibet	Government policy, climate	Sedentarisation Diversification (crops, off-farm wages, trade)	Increased food production, increased disease burden	Xu et al. (2008)
Extensive grassland-based, Afar, Ethiopia	Government policy, climate	Sedentarisation Diversification (crops)	Weakened institutions and cultural practices, deteriorating natural resources	Schmidt and Pearson (2016)
Extensive grassland-based, Kajiado, Kenya	Government policy, climate, population growth	Sedentarisation Diversification (crops, wages, remittances) Intensification	Nutritional status remains poor	Galvin et al. (2015)
Extensive grassland-based, Mongolian Altai	Government policy, climate	Sedentarisation Diversification (cashmere sales, forest products)	Fodder shortages, forest over-use, unsustainable land-use system	Lkhagvadorj et al. (2013)
Extensive grassland based, Mongolia	Increasing drought, grassland degradation	Diversification (decreases in sheep and goats, increases in cattle, decreases in grain production, increases in fruit and vegetable production) Exit from agriculture	Increased household income from off-farm employment, more diverse diets	Du et al. (2016)
Extensive grassland-based, northern Kenya	Climate change and variability	Diversification (crops, wages, migration)	Decreasing adaptive capacity, over-dependence on local knowledge for adaptation	Ogalleh et al. (2012)
Extensive systems with crops				
Extensive with crops, Eastern Cape, South Africa	Multiple	Intensification (richer households) Exit and abandonment (poorer households) Livelihood diversification	Wildlife conflicts, loss of cultural identity	Shackleton et al. (2013)
Extensive with crops, Peruvian highlands	Economic globalisation, climate change	Diversification (dairy production, wage migration) Conversion (away from staple crops to feed production) Intensification (feed production)	Reduced vulnerability to climate change, but potential loss of both agrobiodiversity and food self-sufficiency identified by the author	Lennox (2015)
Extensive with crops, East Africa	Climate	Diversification (crops, livestock, wages) Intensification (crops, intercrops)	Increasing household vulnerability	Rufino et al. (2013)
Extensive with crops, Ghana	Climate variability, temperature change	Diversification (off-farm activities)	Reduced vulnerability	Antwi-Agyei et al. (2018)

Extensive smallholder cropping, Nepal	Annual and seasonal warming. Increased precipitation with changes in patterns.	Diversification and integration (from growing buckwheat and barley to vegetables and fruit trees)	Increased household resilience owing to diversification of production	Konchar et al. (2015)
Extensive smallholder mixed system, Niger	Droughts and famines, and land degradation	Large-scale regeneration of native trees and shrubs in the arable landscape	Increased household income, effects on household food security not yet know	Haglund et al. (2011)
Other mixed coastal and forest systems				
Coastal rice-based, Bangladesh	Increased salinity due to reduced dry season flows from rivers in India, use of groundwater for irrigation	Diversification (from rice cultivation to aquaculture of shrimp and prawn)	Increased household income, increased engagement of women, increased human disease vulnerability	Faruque et al. (2017)
Smallholder cropping systems, coastal Bangladesh	Increasing frequency and severity of floods since 2008	Diversification (reallocation of land from crops to aquaculture) Exit (migration away from village)	Mixed impacts on household incomes and seasonal migration frequency	Fenton et al. (2017)
Smallholder mixed cropping in forested landscapes in Indonesia	Floods, drought, crop and livestock disease	Diversification (reallocation of land from forests to rubber plantations and rice) Intensification (agroforestry) Extensification (reforestation, forest protection)	Locally, increased household incomes in general; more widely, some trade-offs with biodiversity, water, carbon stocks	Fedele et al. (2018)

5.14.2.4 Finance needs and strategies for adaptation

Current understanding of finance flows and needs for adaptation in crop agriculture, livestock, fisheries, aquaculture, and forest products relies primarily on top-down projections, with limited data (UNFCCC, 2018; Buchner et al., 2019; Jachnik et al., 2019). By one estimate, in 2017/2018, agriculture, forestry, and land use received 24% of public adaptation finance (totaling USD 7 billion; half via multilateral development finance institutions and one-quarter from governments) and 35% of international grants (with 71% used for adaptation) (Buchner et al., 2019). According to data from OECD (2020), finance flows for agriculture, forestry and fisheries have risen fairly linearly from ca. USD 1.46 billion in 2010 (the year the Rio marker on climate change adaptation was introduced) to ca. 5.5 billion in 2018. Over the entire tracked period the three subsectors combined received a total of USD 29.82 billion for activities with principal and significant adaptation components.[4] However, the dataset only includes climate-related development finance from bilateral, multilateral, and private philanthropic sources, whereas private sector finance flows are not captured as this is notoriously difficult to track (UNEP, 2016; OECD, 2020; cross-ref to Cross-Chapter Box FINANCE in Chapter 17). Most of the funding (85%) was directed towards agriculture with forestry (12%) and fisheries (3%) receiving significantly less, but across the subsectors, there is consistency in the sense that policy and administrative management and development receive the lion's share of support, which is predominantly given in the form of grants (72%) while debt instruments (26%) and equity and shares in collective investment vehicles (2%) contribute less. From a regional perspective, 80% were directed to Africa (47%), Asia-Pacific (27%), and Latin America and Caribbean States (7%), whereas Eastern Europe and Western Europe and Other States received (2%) each and 17% were destined for 'developing countries'

[4] For reference, the SEI Aid-Atlas (https://aid-atlas.org) only reports flows where adaptation is the principal objective, and therefore adaptation spending on agriculture, forestry and fisheries for the same period is significantly lower with USD 16.52 billion, i.e., 21.4% of total adaptation spending.

without regional tags. Finally, it is noteworthy that 38% of adaptation finance in agriculture, forestry and fisheries is marked as also having mitigation benefits and roughly a quarter of funding is reported as having principal or significant gender objectives.

Whether current levels of growth in adaptation finance for agriculture, forestry and fisheries is keeping up with estimated needs cannot be assessed because of the large uncertainties that surround adaptation cost estimates (Cross-Chapter Box FINANCE in Chapter 17). There is hence high agreement that better assessment of adaptation costs of climate impacts requires considerably more research (Watkiss, 2015; Diaz and Moore, 2017). A recent study focusing on investments needed to offset the effects of climate change on the prevalence of hunger concludes that investments in agricultural R+D have to increase from USD 1.62 billion to USD 2.77 billion per year between 2015 and 2050 (Sulser et al., 2021a). In addition to agricultural R+D, significant investment increases in water and infrastructure in the range of USD 12.7 billion and USD 10.8 billion are required, respectively, a considerable portion of which is relevant to the food system. In total, Sulser et al. (2021a) estimate that annual investment between USD 21.47 billion and USD 29.8 billion are needed to avoid sliding back from climate-change related increases in the prevalence of hunger but recognize the shortcomings of their approach and acknowledge that "a full analysis of adaptation to climate change in agriculture would require including many other social, economic, and environmental dimensions". For comparison, World Bank (2010) estimated global costs of USD 70-100 billion per year for agriculture, forestry and fisheries, infrastructure, water resources, health, ecosystem services, coastal zones, and extreme weather events to adapt to an approximately 2°C warmer world between 2010 and 2050. While the World Bank includes more sectors, more recent publications consider the resulting figures to be significantly too low (Baarsch et al., 2015; UNEP, 2016; Rossi and Miola, 2017; Hallegatte et al., 2018; Markandya and González-Eguino, 2019; Chapagain et al., 2020; cross-ref to WGII Cross-Chapter Box FINANCE in Chapter 17). Therefore, despite the methodological and data challenges, further efforts are needed to better capture the economic risks of climate change and provide estimates of adaptation costs at global to national scales as well as across sectors (Watkiss, 2015; Diaz and Moore, 2017).

Financial barriers limit implementation of adaptation options in agriculture, fisheries, aquaculture, and forestry (*high confidence*) (Shukla et al., 2019; FAO et al., 2020). Finance strategies can contribute to adaptation in these sectors in different ways (Table 5.25) and to different degrees. Standardized strategies have not yet been developed for specific adaptation needs and, in current practice, finance strategies are opportunistically deployed, with developing countries facing particular challenges due to under-developed financial mechanisms (Omari-Motsumi et al., 2019).

Table 5.25: Potential adaptation finance strategies for categories of climate-related risks in the agriculture, fisheries, aquaculture, and forestry sectors.

Finance strategies	Reduced food availability	Low food safety / dietary health	Diminished livelihoods	Declining ecosystem services
Reduce vulnerability	▪ *Avoid staple failure:* Vouchers to producers for improved production inputs	▪ *Diversify production strategies:* Invest in alternative crops / species / harvest methods	▪ *Increase producer capacity:* Fund technical assistance programs	▪ *Incentivize improved management:* Improved access to credit based on environmental performance
Anticipate / minimize impacts	▪ *Minimize impact of extreme weather:* Fund early warning systems	▪ *Diversify products in supply chains:* Finance processing equipment for alternative food products	▪ *Moderate food price spikes:* National food reserves	▪ *Minimize resource depletion:* Subsidize micro-lending for water-efficient technologies
Steer capital toward climate resilience	▪ *Develop climate-resilient production technologies:* Fund	▪ *Build nutrition-sensitive food systems:* Finance early-stage	▪ *Increase resilience of supply chain infrastructure:* Finance improved	▪ *Disincentivize low-resilience production:* Screen investments based

Finance strategies	Reduced food availability	Low food safety / dietary health	Diminished livelihoods	Declining ecosystem services
	R&D for improved genetics (crops, fish, livestock) and management	market building for diversified food products	storage and transport facilities	on climate risk disclosures
Pool climate-related risks	▪ *Distribute climate-related risks:* Securitize investments in production systems	▪ *De-risk diversified food supply chains:* Invest in producer aggregation to improve supply chain efficiency	▪ *Insure against supply chain risks:* Subsidized index insurance programs	▪ *Detect high-risk production systems:* Invest in supply chain monitoring / traceability mechanisms
Compensate for climate-related impacts	▪ *Compensate for production losses:* Financial transfers to affected producers	▪ *Avoid food shortages:* Subsidize food importation	▪ *Avoid selling off productive assets:* Fund social support for low-income households	▪ *Ecological restoration:* Direct development aid to land rehabilitation projects

Many types of financial instruments are employed by diverse actors (Table 5.26) guided by their mandates (e.g., development, commerce), capacity (investor, intermediary, donor), and risk appetite. Actors within a sector or local production area can coordinate their financial strategies toward common objectives (e.g., reduced supply chain loss) or participate in joint financial action such as blended finance structures that combine commercial and concessionary finance to catalyze additional private investment, enrich the pipeline of bankable projects, and test business models (FAO, 2020b).

Table 5.26: Potential adaptation finance objectives for major actors in agriculture, fisheries, aquaculture, and forestry sectors.

Actors	Potential adaptation finance objectives
Private sector –Focused on capturing positive externalities (i.e., lower risks or costs) from adaptation investments (Woodard et al., 2019). Major considerations include fiduciary responsibilities; expected rates of return (i.e., risk-adjusted; benchmarked to comparable investments); investment characteristics (e.g., liquidity, structure, size) and contribution to investor portfolio; material business risks (e.g., supply chain reliability; stranded assets); cost control (e.g., product losses; insurance); legal compliance; and sectoral requirements (e.g., climate risk disclosure) (Havemann et al., 2020).	
Production companies or cooperatives	▪ Supply chain transactions (e.g., trade finance) ▪ Sustainable agricultural infrastructure (e.g., capital investment in storage or processing facilities to reduce exposure to climate risks) ▪ Developing or accessing advisory services (weather data; agronomic information) (Orchard, 2019) ▪ Risk management (e.g., insurance / reinsurance; budget reserves)
Financial investors and intermediaries (e.g. banks, asset managers, venture capital; non-bank financial institutions)	▪ Ownership shares in established companies (i.e., private equity) or large publicly traded companies (i.e., listed equities) ▪ Debt issuance (e.g., working capital; catastrophe bonds; emergency loans) ▪ Real estate investment ▪ Financial derivatives ▪ Technological research and development ▪ (Impact investors) Bespoke non-financial sustainability objectives (e.g., fairtrade products; financial inclusion) (Havemann et al., 2020)
Public sector – Encompassing nearly-commercial (e.g., specialized commodity boards; bond issuances), partially subsidized (e.g., low-interest loans), and fully subsidized (e.g., R&D; grants) investments. Major considerations include avoiding negative impacts to citizens (e.g., food price spikes) and specific constituencies (e.g., catastrophic losses to producers) and maintaining / enhancing public revenues (i.e., taxes from economic activity in agriculture, fisheries, aquaculture, and forestry).	

Actors	Potential adaptation finance objectives
Government agencies and multilateral institutions	▪ Strengthen enabling environments for sustainable production and ecosystem protection (e.g., price transparency; information exchange; international coordination) ▪ Support demonstration projects for sustainable land and resource management (e.g., grants) ▪ Disaster risk reduction (e.g., national disaster funds; social protection programs; contingent credit lines; sovereign / subsovereign insurance (Global Commission on Adaptation, 2019) ▪ Increase resilience through early warning systems, infrastructure, and capacity building (e.g., climate change adaptation funds) ▪ Increase revenues for adaptation activities (e.g., income / luxury taxes) ▪ Reduce production risks (e.g., agricultural subsidies) ▪ Promote advanced technology implementation (e.g., tax incentives) ▪ Coordinate and align donor funding with national priorities (e.g., multi-donor national climate change funds) ▪ Incentivize and de-risk commercial investments (e.g., interest rate reduction programs, structured financing, guarantee funds) (Woodard et al., 2019)

Expanding access to financial services and pooling climate risks can enable and incentivize climate change adaptation (*medium confidence*) (Shukla et al., 2019). To mobilize financial instruments (Table 5.27) toward adaptation needs, individual actors can apply an adaptation lens to existing or new activities, accounting for investment characteristics (e.g., development stage; cash flow profile), requirements (e.g., amount; risk-return), and context (e.g., regulatory landscape) (Havemann et al., 2020). Risk-layering can match financial instruments to severity and probability climate risks (Chatterjee, 2019).

Table 5.27: Major types of financial instruments suitable to adaptation finance in agriculture, fisheries, aquaculture, and forestry sectors (adapted from (Havemann et al., 2020))

Financial instrument	Description
Equity – Ownership stake in a company (e.g., agricultural technology company; processing company) or collective investment vehicle (e.g., agriculture fund; Timber Investment Management Organization; commodity index fund) providing returns (via dividends and / or sale of equity shares) corresponding to business-related risk (e.g., higher return for higher risk and / or lower liquidity)	
Listed equities	Ownership of shares in a company listed in a public market
Private equity	Ownership of shares in a company or other assets
Junior or risk-absorbing equity	Ownership of lower-tier shares in a company (e.g., Common stock) or collective investment vehicle (e.g., first-loss tranche)
Debt – Capital provided directly or indirectly (via banks or other third-party institutions) to users with defined repayment terms (i.e. timeframe, interest rate); more likely to deliver adaptation benefits when coupled with capacity building (e.g. technical assistance, education, analytics) (Woodard et al., 2019)	
Loan, bond, note, credit line	Direct or indirect provision of capital (e.g., operating loans; dedicated credit line for agricultural trade); concessionary loans may allow for below-market interest rates
Soft loan	Direct interest-free loan (e.g., funds provided in advance of good / service delivery)
Emergency loan	Lending in response to climate risks or impacts with repayment terms (e.g., return period) that consider necessary relief, recovery, and reconstruction
Catastrophe bond	Risk transfer instrument in which insurers or reinsurers provide high interest payments to investors in exchange for a payout (and repayment deferment or forgiveness) activated by specific events (e.g., extreme weather)
Impact bond	Subsidized investment providing capital upfront or based on defined outcomes
Subordinated loan	Concessionary capital with a junior position (i.e., accepting higher risk of non-repayment and / or lower rate of return on investment) relative to other investors
Securitized investments	Aggregation of equity or debt to offer marketable securities to a wider pool of investors with different risk-return appetites
Guarantees – Commercial and concessionary guarantees that provide compensation for losses due to specified risks (e.g., political risk, performance risk); more likely to deliver adaptation benefits when linked to robust underwriting standards and verification protocols (Woodard et al., 2019)	

Financial instrument	Description
Credit guarantee	Compensation for specified losses incurred by agricultural lenders
Payment, performance, surety bonds	De-risking mechanism for transactions between providers and buyers of goods / services; may be used in trade finance and other forms of intermediation
Insurance – Policies and other financial instruments that provide compensation for losses based on defined terms and conditions.	
Production insurance	Compensation for specified losses related to production (e.g., insurance indexed to specific weather events) or supply chains (e.g., shipping insurance)
Market and price insurance	Compensation for specified market-related losses (e.g., price or currency fluctuation)
Grants – Concessionary funding provided by public or philanthropic entities to support climate adaptation costs or outcomes (no expectation of repayment)	
Direct support	Funding for provision of goods (e.g., fertilizer, seeds, nursery stock) or services (e.g., technical assistance; product storage) to producers, local companies, or intermediaries (e.g., for agronomic or business management expertise); can reduce credit risk when part of blended finance arrangements
Performance-based grants	Grants or other concessionary funding contingent on achievement of defined adaptation outcomes (with possible third-party verification requirement); may support development and testing of new approaches (i.e., design funding; challenges / prizes)
Governmental instruments –	
Policy incentives	Public policies designed to stimulate adaptation action among targeted groups (e.g., producers; consumers; agri-businesses; financiers) including direct or indirect subsidies (e.g., producer payments; tax breaks; health insurance), procurement policies (e.g., low carbon and sustainability criteria; nutrition-sensitive school feeding programs) and other fiscal measures (e.g., infrastructure development; funding R&D in climate-resilient practices or technologies) (Shukla et al., 2019)
Development aid	International or domestic programs that directly or indirectly fund adaptation actions including financial transfers (e.g., producer support or anti-poverty programs) and subsidized credit (*medium confidence*) (Shukla et al., 2019)
Planning grants	Financial support to governments for adaptation planning (e.g., via readiness programs)
Other instruments –	
Fintech	Data analytics and risk analysis models used to better assess borrowers' repayment risk (e.g., due to crop failure) and reduce transaction costs (e.g., streamlined lending processes); applications may include financial inclusion (e.g. micro-financing; lending to small- and mid-size operators), alternative repayment programs (e.g., for larger capital borrowing), insurance (e.g., more granular risk assessment), or digital strategies (e.g., crowdfunding; smallholder credit) (Agyekumhene et al., 2018)
Payment for Ecosystem Services (PES)	Funds delivered to land and resource managers in exchange for compliance with specified sustainability practices or environmental outcomes; PES depends on willing payers (i.e., direct and indirect beneficiaries of ecosystem services such as governments, companies, conservation groups, philanthropies)

5.14.2.5 Constraints on adaptation finance for food, feed, fibre, and other ecosystem products

Flow of adaptation finance in the agriculture, fisheries, aquaculture, and forestry sectors is impeded by weak measurement and benchmarking of financial and resilience outcomes (Kramer et al., 2019; Negra et al., 2020), and challenges in assessing repayment capacity of investee producers and companies (*medium confidence*). Immature information systems (e.g., weak analytics; fragmented standards) (Woodard et al., 2019; Negra et al., 2020) inhibit effective due diligence and impact assessment, contributing to uncertainty and low investor confidence (Havemann et al., 2020; NGFS, 2020). Improved characterization of adaptation finance strategies (e.g., insurance, subsidies, blended finance) requires increased transaction volume (Millan et al., 2019) and analysis of financial (e.g., risk-return profile; investor demand) and resilience (e.g., reduced vulnerability) effects.

Use of climate-resilient financial strategies and instruments is limited by weak incentives, which commonly take the form of high upfront costs (Verdolini et al., 2018), high transaction and intermediation costs

(Havemann et al., 2020), and relatively long pay-off time. Tenant producers may not experience benefits from adaptation investments (Woodard et al., 2019). Investors seek low-risk, liquid investments, and credit-worthy counterparties (Havemann et al., 2020) yet small- and medium-sized producers and supply chain actors often lack access to formal credit. Given limited experience and weak information for adaptation finance, sub-optimal outcomes may include imbalanced allocation of public and private finance (e.g., to less vulnerable regions and producers; to lower-resilience investments; to short-term benefits) as well as inequitable division of risks and returns (e.g., within blended finance structures) (Clapp, 2017; World Bank, 2018; Attridge and Engen, 2019). Additionally, while risk-sharing finance strategies can deliver adaptation benefits, they do not inherently reduce overall risk and commonly cover only specified types of risks (Kellett and Peters, 2014; Watson et al., 2015).

Methods to strengthen adaptation finance include updating regulations and policies to support adaptation finance instruments (e.g., climate accounting standards), requiring climate-risk disclosure, improved information-sharing among public and private sector actors and devolving funding to local actors (*medium confidence*) (Global Commission on Adaptation, 2019; Millan et al., 2019).

5.14.3 Climate-resilient Development Pathways

Climate-resilient development pathways (CRDPs) introduced in AR5 (Denton, 2014) can briefly be described as “development trajectories that integrate adaptation and mitigation to realize the goal of sustainable development” (see IPCC (2019a)) for a more extensive definition). Several characteristics were proposed in SR1.5 by which such CRDPs could be identified: consistency with principles of sustainable development; ability to deliver poverty reduction; ability to enhance social, gender, racial, ethnic, and intergenerational equity; ability to deliver resilience to climate change and other shocks and stresses; and ability to protect species, biodiversity, and ecosystem goods and services. There is an increasing literature, assessed in SR1.5, on adaptation pathways approaches, generally for specific regions, locations, and subsectors.

Two recent examples directly related to agriculture and food are the following: sustaining agrarian livelihoods to mid-century of Nicaraguan small-scale coffee producers using analyses of suitability and coffee quality changes under a SRES A2 emissions scenario (Läderach et al., 2017); and development of participatory pathways to mid-century under RCPs 4.5 and 8.5 support regional adaptation planning in Hawke’s Bay, New Zealand for agricultural producers and rural communities (Cradock-Henry et al., 2020). CRDPs mentioned in SROCC include shifting from providing coastal defences to adapting to seawater inundation in coastal regions (Renaud et al., 2015) and retreating coastal megacities (Solecki et al., 2017). Pathways frameworks continue to be used to frame the broad-scale challenges of development and climate change, thereby linking different types of food system actor with different responses through time using a variety of approaches, top down and participatory, qualitative, and quantitative (Butler et al., 2016; Antle et al., 2017; Thornton and Comberti, 2017; Collste et al., 2019; Loboguerrero et al., 2020; Stringer et al., 2020).

While there is consensus that the concept of CRDPs is useful, there are major challenges in identifying, operationalising, monitoring, and evaluating them (Lin et al., 2017; Bloemen et al., 2018). Management approaches seldom integrate across spatio-temporal scales and may be unable to address unidirectional change and extreme events (Holsman et al., 2019). The socio-economic complexities and implications of pursuing integrated outcomes make it difficult to evaluate synergies and trade-offs associated with different actions in local contexts through time (Thornton and Comberti, 2017; Ellis and Tschakert, 2019; Holsman et al., 2019; Orchard, 2019). Case studies by Lo (2019) of transformation in a fishing town in south China and by Gajjar (2019) on undesirable path dependencies in development trajectories in urban and rural India show that overall adaptive capacity of populations may be decreased though politicization and entrenchment of existing inequalities, severely limiting the possibilities for future adaptation. A further challenge of implementation is timely detection of tipping points and abrupt exposure events in both climate and environmental systems (Lenton et al., 2019; Trisos et al., 2020), which may alter the efficacy of current and planned adaptation actions, necessitating a switch to other, more transformational strategies; in such cases, re-energizing food system actors’ commitment to adaptation action may well be needed (Bloemen et al., 2018).

Integrated modelling of CRDPs will increasingly be needed to throw light on key SDG synergies and trade-offs into the future (Bleischwitz et al., 2018). In investigating possible future pressures on land under the Shared Socio-economic Pathways (SSP), Doelman (2018) projected that the largest changes take place in sub-Saharan Africa in SSP3 and SSP4, mostly because of continued high population growth coupled with (projected) sluggish increases in agricultural efficiency, among other things, leading to expansion of agricultural land for crop and livestock production and reduced food security. Lassaletta (2019) evaluated global pig production in the SSPs and concluded that the future sustainability of pig systems will depend on production efficiency improvements coupled with other factors such as use of alternative feed sources and use of slurries on cropland. Such studies will be increasingly important for quantifying the potential trade-offs and synergies between different SDGs, to guide adaptation (and mitigation) action along CRDPs in the future. The current lack of widely accepted and simple-to-measure indicators for tracking progress in adaptation is a significant hurdle to overcome. There is a large literature on the desirable characteristics of future global food systems, but much less on robust analysis that explicitly addresses and evaluates the pathways towards these desired futures. Gerten (2020) estimate that 10.2 billion people can be supported within key planetary boundaries via spatially redistributed cropland and dietary changes, among other actions. There are few if any analyses for detailing the plausible pathways to move towards such a future in ways that are socially, economically, and environmentally acceptable through time; whether such pathways could indeed be made climate-resilient is unknown. Appropriate monitoring and rapid feedback to food system actors on what is working and why, will be critical to the successful operationalisation of adaptation actions within CRDPs (Bosomworth and Gaillard, 2019).

Cross-Working Group Box BIOECONOMY: Mitigation and Adaptation via the Bioeconomy

Authors: Henry Neufeldt (Denmark/Germany), Göran Berndes (Sweden), Almut Arneth (Germany), Rachel Bezner Kerr (USA/Canada), Luisa F Cabeza (Spain), Donovan Campbell (Jamaica), Jofre Carnicer Cols (Spain), Annette Cowie (Australia), Vassilis Daioglou (Greece), Joanna House (UK), Adrian Leip (Italy/Germany), Francisco Meza (Chile), Michael Morecroft (UK), Gert-Jan Nabuurs (Netherlands), Camille Parmesan (UK/USA), Julio C Postigo (USA/Peru), Marta G. Rivera-Ferre (Spain), Raphael Slade (UK), Maria Cristina Tirado von der Pahlen (USA/Spain), Pramod K. Singh (India), Peter Smith (UK)

Summary statement

The growing demand for biomass offers both opportunities and challenges to mitigate and adapt to climate change and natural resource constraints (high confidence). Increased technology innovation, stakeholder integration and transparent governance structures and procedures at local to global scales are key to successful bioeconomy deployment maximizing benefits and managing trade-offs (high confidence).

Limited global land and biomass resources accompanied by growing demands for food, feed, fibre, and fuels, together with prospects for a paradigm shift towards phasing out fossil fuels, set the frame for potentially fierce competition for land[5] and biomass to meet burgeoning demands even as climate change increasingly limits natural resource potentials (*high confidence*).

Sustainable agriculture and forestry, technology innovation in biobased production within a circular economy and international cooperation and governance of global trade in products to reflect and disincentivize their environmental and social externalities, can provide mitigation and adaptation via bioeconomy development that responds to the needs and perspectives of multiple stakeholders to achieve outcomes that maximize synergies while limiting trade-offs (*high confidence*).

Background

[5] For lack of space the focus is on land only although the bioeconomy also includes sea-related bioresources.

There is *high confidence* that climate change, population growth and changes in per capita consumption will increase pressures on managed as well as natural and semi-natural ecosystems, exacerbating existing risks to livelihoods, biodiversity, human and ecosystem health, infrastructure, and food systems (Conijn et al., 2018; IPCC, 2018; IPCC, 2019b; Lade et al., 2020). At the same time, many global mitigation scenarios presented in IPCC assessment reports rely on large GHG emissions reduction in the AFOLU sector and concurrent deployment of reforestation/afforestation and biomass use in a multitude of applications (Rogelj et al., 2018; Hanssen et al., 2020; AR6 WGIII Chapter 3 and Chapter 7; Canadell et al., 2021; Lee et al., 2021)

Given the finite availability of natural resources, there are invariably trade-offs that complicate land-based mitigation unless land productivity can be enhanced without undermining ecosystem services (e.g.,Obersteiner et al., 2016; Campbell et al., 2017; Caron et al., 2018; Conijn et al., 2018; Heck et al., 2018; WRI, 2018; Smith et al., 2019c). Management intensities can often be adapted to local conditions with consideration of other functions and ecosystem services, but at a global scale the challenge remains to avoid further deforestation and degradation of intact ecosystems, in particular biodiversity-rich systems (cross-ref to Cross-Chapter Box on NBS-NATURAL in Chapter 2), while meeting the growing demands. Further, increased land-use competition can affect food prices and impact food security and livelihoods (To and Grafton, 2015; Chakravorty et al., 2017), with possible knock-on effects related to civil unrest (Abbott et al., 2017; D'Odorico et al., 2018).

Developing new biobased solutions while mitigating overall biomass demand growth

Many existing biobased products have significant mitigation potential. Increased use of wood in buildings can reduce GHG emissions from cement and steel production while providing carbon storage (Churkina et al., 2020). Substitution of fossil fuels with biomass in manufacture of cement and steel can reduce GHG emissions where these materials are difficult to replace. Dispatchable power based on biomass can provide power stability and quality as the contribution from solar and wind power increases (cross-ref WGIII-Chapter 6), and biofuels can contribute to reducing fossil fuel emissions in the transport and industry sectors (cross-ref WGIII-Chapter10 and Chapter11). The use of biobased plastics, chemicals and packaging could be increased, and biorefineries can achieve high resource-use efficiency in converting biomass into food, feed, fuels, and other biobased products (Aristizábal-Marulanda and Cardona Alzate, 2019; Schmidt et al., 2019). There is also scope for substituting existing biobased products with more benign products. For example, cellulose-based textiles can replace cotton, which requires large amounts of water, chemical fertilizers, and pesticides to ensure high yields.

While increasing and diversified use of biomass can reduce the need for fossil fuels and other GHG-intensive products, unfavourable GHG balances may limit the mitigation value. Growth in biomass use may in the longer term also be constrained by the need to protect biodiversity and ecosystems' capacity to support essential ecosystem services. Biomass use may also be constrained by water scarcity and other resource scarcities, and/or challenges related to public perception and acceptance due to impacts caused by biomass production and use. Energy conservation and efficiency measures and deployment of technologies and systems that do not rely on carbon, e.g., carbon-free electricity supporting, inter alia, electrification of transport as well as industry processes and residential heating (IPCC, 2018; UNEP, 2019), can constrain the growth in biomass demand when countries seek to phase out fossil fuels and other GHG-intensive products while providing an acceptable standard of living. Nevertheless, demand for biobased products may become high where full decoupling from carbon is difficult to achieve (e.g., aviation, biobased plastics, and chemicals) or where carbon storage is an associated benefit (e.g., wood buildings, BECCS, biochar for soil amendments), leading to challenging trade-offs (e.g., food security, biodiversity) that need to be managed in environmentally sustainable and socially just ways.

Changes on the demand side as well as improvements in resource-use efficiencies within the global food and other bio-based systems can also reduce pressures on the remaining land resources. For example, dietary changes toward more plant-based food (where appropriate) and reduced food waste can provide climate change mitigation along with health benefits (Cross-ref WGIII-Chapter 7.4 and 12.4, Willett et al., 2019) and other co-benefits with regard to food security, adaptation and land use (Mbow et al., 2019; Smith et al., 2019c; cross-ref WGII chapter 5). Advancements in the provision of novel food and feed sources (e.g., cultured meat, insects, grass-based protein feed and cellular agriculture) can also limit the pressures on finite natural resources (WGIII Chapter 12.4, Parodi et al., 2018; Zabaniotou, 2018).

[START BOX CROSS-WORKING GROUP BOX BIOECONOMY.1 HERE]

Box Cross-Working Group Box BIOECONOMY.1: Circular bioeconomy

Circular economy approaches (Cross ref WGIII-12.6) are commonly depicted by two cycles, where the biological cycle focuses on regeneration in the biosphere and the technical cycle focuses on reuse, refurbishment, and recycling to maintain value and maximize material recovery (Mayer et al., 2019a). Biogenic carbon flows and resources are part of the biological carbon cycle, but carbon-based products can be included in, and affect, both the biological and the technical carbon cycles (Kirchherr et al., 2017; Winans et al., 2017; Velenturf et al., 2019). The integration of circular economy and bioeconomy principles has been discussed in relation to organic waste management (Teigiserova et al., 2020), societal transition and policy development (Directorate-General for Research Innovation, 2018; Bugge et al., 2019) as well as COVID-19 recovery strategies (Palahi et al., 2020). To maintain the natural resource base, circular bioeconomy emphasizes sustainable land use and the return of biomass and nutrients to the biosphere when it leaves the technical cycle.

Biomass scarcity is an argument for adopting circular economy principles for the management of biomass as for non-renewable resources. This includes waste avoidance, product reuse and material recycling, which keep down resource use while maintaining product and material value. However, reuse and recycling is not always feasible, e.g., when biofuels are used for transport and biobased biodegradable chemicals are used to reduce ecological impacts where losses to the environment are unavoidable. A balanced approach to management of biomass resources could take departure in the carbon cycle from a value-preservation perspective and the possible routes that can be taken for biomass and carbon, considering a carbon budget defined by the Paris Agreement, principles for sustainable land use and natural ecosystem protection.

[END BOX CROSS-WORKING GROUP BOX BIOECONOMY.1 HERE]

Land use opportunities and challenges in the bioeconomy

Analyses of synergies and trade-offs between adaptation and mitigation in the agriculture and forestry sectors show that outcomes depend on context, design, and implementation, so actions have to be tailored to the specific conditions to minimize adverse effects (Kongsager, 2018). This is supported in literature analyzing the nexus between land, water, energy, and food in the context of climate change which consistently concludes that addressing these different domains together rather than in isolation would enhance synergies and reduce trade-offs (Obersteiner et al., 2016; D'Odorico et al., 2018; Soto Golcher and Visseren-Hamakers, 2018; Froehse and Schilling, 2019; Momblanch et al., 2019).

Nature-based solutions addressing climate change can provide opportunities for sustainable livelihoods as well as multiple ecosystem services, such as flood risk management through floodplain restoration, saltmarshes, mangroves or peat renaturation (Cross-Chapter Box NATURAL in Chapter 2; UNEP, 2021). Climate-smart agriculture can increase productivity while enhancing resilience and reducing GHG emissions inherent to production (Lipper et al., 2014; Nabuurs et al., 2018; Verkerk et al., 2020; Singh and Chudasama, 2021). Similarly, climate-smart forestry considers the whole value chain and integrates climate objectives into forest sector management through multiple measures (from strict reserves to more intensively managed forests) providing mitigation and adaptation benefits (WGIII Section 7.3).

Agroecological approaches can be integrated into a wide range of land management practices to support a sustainable bioeconomy and address equity considerations (HLPE, 2019). Relevant land-use practices, such as agroforestry, intercropping, organic amendments, cover crops and rotational grazing, can provide mitigation and support adaption to climate change via food security, livelihoods, biodiversity and health co-benefits (Ponisio et al., 2015; Garibaldi et al., 2016; D'Annolfo et al., 2017; Bezner Kerr et al., 2019; Clark et al., 2019; Córdova et al., 2019; HLPE, 2019; Mbow et al., 2019; Renard and Tilman, 2019; Sinclair et al., 2019; Bharucha et al., 2020; Bezner Kerr et al., 2021;WGII Cross-Chapter Box NATURAL in Chapter 2). Strategic integration of appropriate biomass production systems into agricultural landscapes can provide biomass for bioenergy and other biobased products while providing co-benefits such as enhanced landscape diversity, habitat quality, retention of nutrients and sediment, erosion control, climate regulation, flood regulation, pollination and biological pest and disease control (WGIII Chapter12 Box on UNCCD-LDN, Christen and Dalgaard, 2013; Asbjornsen et al., 2014; Holland et al., 2015; Ssegane et al., 2015; Dauber and Miyake, 2016; Milner et al., 2016; Ssegane and Negri, 2016; Styles et al., 2016; Zumpf et al., 2017; Cacho et al., 2018; Alam and Dwivedi, 2019; Cubins et al., 2019; HLPE, 2019; Olsson et al., 2019; Zalesny et al., 2019; Englund et al., 2020). Such approaches can help limit environmental impacts from intensive agriculture while maintaining or increasing land productivity and biomass output.

Figure Cross-Working Group Box BIOECONOMY.1: Left: High-input intensive agriculture, aiming for high yields of a few crop species, with large fields and no semi-natural habitats. Right: Agroecological agriculture, supplying a range of ecosystem services, relying on biodiversity and crop and animal diversity instead of external inputs, and integrating plant and animal production, with smaller fields and presence of semi-natural habitats. Credit: Jacques Baudry (left); Valérie Viaud (right), published in van der Werf et al. (2020)

Transitions from conventional to new biomass production and conversion systems include challenges related to cross-sector integration and limited experience with new crops and land use practices, including needs for specialized equipment (WGII Chapter 5.10, Thornton and Herrero, 2015; HLPE, 2019). Introduction of agroecological approaches and integrated biomass/food crop production can result in lower food crop yields per hectare, particularly during transition phases, potentially causing indirect land use change, but can also support higher and more stable yields, reduce costs, and increase profitability under climate change (Muller et al., 2017; Seufert and Ramakutty, 2017; Barbieri et al., 2019; HLPE, 2019; Sinclair et al., 2019; Smith et al., 2019c; Smith et al., 2020a). Crop diversification, organic amendments, and biological pest control (HLPE, 2019) can reduce input costs and risks of occupational pesticide exposure and food and water contamination (Gonzalez-Alzaga et al., 2014; European Food Safety Authority Panel on Plant Protection Products and their Residues et al., 2017; Mie et al., 2017), reduce farmers' vulnerability to climate change (e.g., droughts and spread of pests and diseases affecting plant and animal health (Delcour et al., 2015; FAO, 2020a)) and enhance provisioning and sustaining ecosystem services, such as pollination (D'Annolfo et al., 2017; Sinclair et al., 2019).

Barriers toward wider implementation include absence of policies that compensate landowners for providing enhanced ecosystem services and other environmental benefits, which can help overcome short term losses during the transition from conventional practices before longer term benefits can accrue. Other barriers include limited access to markets, knowledge gaps, financial, technological, or labour constraints, lack of extension support and insecure land tenure (Jacobi et al., 2017; Kongsager, 2017; Hernández-Morcillo et al., 2018; Iiyama et al., 2018; HLPE, 2019). Regional-level agroecology transitions may be facilitated by co-learning platforms, farmer networks, private sector, civil society groups, regional and local administration, and other incentive structures (e.g., price premiums, access to credit, regulation) (Coe et al., 2014; Pérez-Marin et al., 2017; Mier y Terán Giménez Cacho et al., 2018; HLPE, 2019; Valencia et al., 2019; SAPEA, 2020). With the right incentives, improvements can be made with regard to profitability, making alternatives more attractive to landowners.

Governing the solution space

Literature analyzing the synergies and trade-offs between competing demands for land suggest that solutions are highly contextualized in terms of their environmental, socioeconomic, and governance-related characteristics, making it difficult to devise generic solutions (Haasnoot et al., 2020). Aspects of spatial and temporal scale can further enhance the complexity, for instance where transboundary effects across jurisdictions or upstream-downstream characteristics need to be considered, or where climate change trajectories might alter relevant biogeophysical dynamics (Postigo and Young, 2021). Nonetheless, there is broad agreement that taking the needs and perspectives of multiple stakeholders into account in a transparent process during negotiations improves the chances of achieving outcomes that maximize synergies while limiting trade-offs (Ariti et al., 2018; Metternicht, 2018; Favretto et al., 2020; Kopáček, 2021; Muscat et al., 2021). Yet differences in agency and power between stakeholders or anticipated changes in access to or control of resources can undermine negotiation results even if there is a common understanding of the overarching benefits of more integrated environmental agreements and the need for greater coordination and cooperation to avoid longer-term losses to all (Aarts and Leeuwis, 2010; Weitz et al., 2017). There is also the risk that strong local participatory processes can become disconnected from broader national plans, and thus fail to support the achievement of national targets. Thus, connection between levels is needed to ensure that ambition for transformative change is not derailed at local level (Aarts and Leeuwis, 2010; Postigo and Young, 2021).

Decisions on land uses between biomass production for food, feed, fibre, or fuel, as well as nature conservation or restoration and other uses (e.g., mining, urban infrastructure), depend on differences in perspectives and values. Because the availability of land for diverse biomass uses is invariably limited, setting priorities for land-use allocations therefore first depends on making the perspectives underlying what is considered as 'high-value' explicit (Fischer et al., 2007; Garnett et al., 2015; de Boer and van Ittersum, 2018; Muscat et al., 2020). Decisions can then be made transparently based on societal norms, needs and the available resource base. Prioritization of land-use for the common good therefore requires societal consensus-building embedded in the socioeconomic and cultural fabric of regions, societies, and communities. Integration of local decision-making with national planning ensures local actions complement national development objectives.

International trade in the global economy today provides important opportunities to connect producers and consumers, effectively buffering price volatilities and potentially offering producers in low-income countries access to global markets, which can be seen as an effective adaptation measure (Baldos and Hertel, 2015; Costinot et al., 2016; Hertel and Baldos, 2016; Gouel and Laborde, 2021; WGII Section 5.11). But there is also clear evidence that international trade and the global economy can enhance price volatility, lead to food price spikes and affect food security due to climate and other shocks, as seen recently due to the COVID-19 pandemic (WGII Chapter 5.12, Cottrell et al., 2019; WFP-FSIN, 2020; Verschuur et al., 2021). The continued strong demand for food and other biobased products, mainly from high- and middle-income countries, therefore, requires better cooperation between nations and global governance of trade to more accurately reflect and disincentivize their environmental and social externalities. Trade in agricultural and extractive products driving land-use change in tropical forest and savanna biomes is of major concern because of the biodiversity impacts and GHG emissions incurred in their provision (CCP7, Hosonuma et al., 2012; Forest Trends, 2014; Henders et al., 2015; Curtis et al., 2018; Pendrill et al., 2019; Seymour and Harris, 2019; Kissinger et al., 2021).

In summary, there is significant scope for optimizing use of land resources to produce more biomass while reducing adverse effects (*high confidence*). Context-specific prioritization, technology innovation in biobased production, integrative policies, coordinated institutions and improved governance mechanisms to enhance synergies and minimize trade-offs can mitigate the pressure on managed as well as natural and semi-natural ecosystems (*medium confidence*). Yet, energy conservation and efficiency measures, and deployment of technologies and systems that do not rely on carbon-based energy and materials, are essential for mitigating biomass demand growth as countries pursue ambitious climate goals (*high confidence*).

[END CROSS-WG BOX BIOECONOMY HERE]

[START FAQ5.1 HERE]

FAQ5.1: How is climate change (already) affecting people's ability to have enough nutritious food?

Climate change has already made feeding the world's people more difficult. Climate related hazards have become more common, disrupting the supply of crops, meat, and fish. Rapid changes in weather patterns have put financial strain on producers, while also raising prices and limiting the choices and quality of produce available to consumers.

Most of our food comes from crops, livestock, aquaculture, and fisheries. Global food supply increased dramatically in the last century, but ongoing climate change has begun to slow that growth, reducing the gains that would have been expected without climate change. Regionally, negative effects are apparent in regions closer to the equator, with some positive effects further north and south.

Climate impacts are also negatively affecting the quality of produce, from changes in micronutrient content to texture, colour, and taste changes that reduce marketability. With warmer and more humid condition, many food pests thrive, food decays more quickly and food contains more toxic compounds produced by fungi and bacteria.

Warming of the oceans has reduced potential fish catch. The increased carbon dioxide in the atmosphere has led to ocean acidification, which is already impacting the production of farmed fish and shellfish. Changes in local climate have forced producers to shift to new locations, change what they grow or where they work (e.g., pole-ward shifting fishing grounds).

Climate hazards have increased over the past 50 years and are the major cause of sudden losses of production (food production shocks). Food shocks occur following droughts, heatwaves, floods, storms, and outbreaks of climate-related pests and combine to cause multiplying impacts. Climate hazards sometimes disrupt food storage and transport, which impairs the food supply.

All of these negative impacts can lead to increased food prices, and reduced income for producers and retailers as there are fewer products to sell. Together, these impacts threaten to reduce the supply of varied, nutrient-rich foods to poor populations that already suffer ill health.

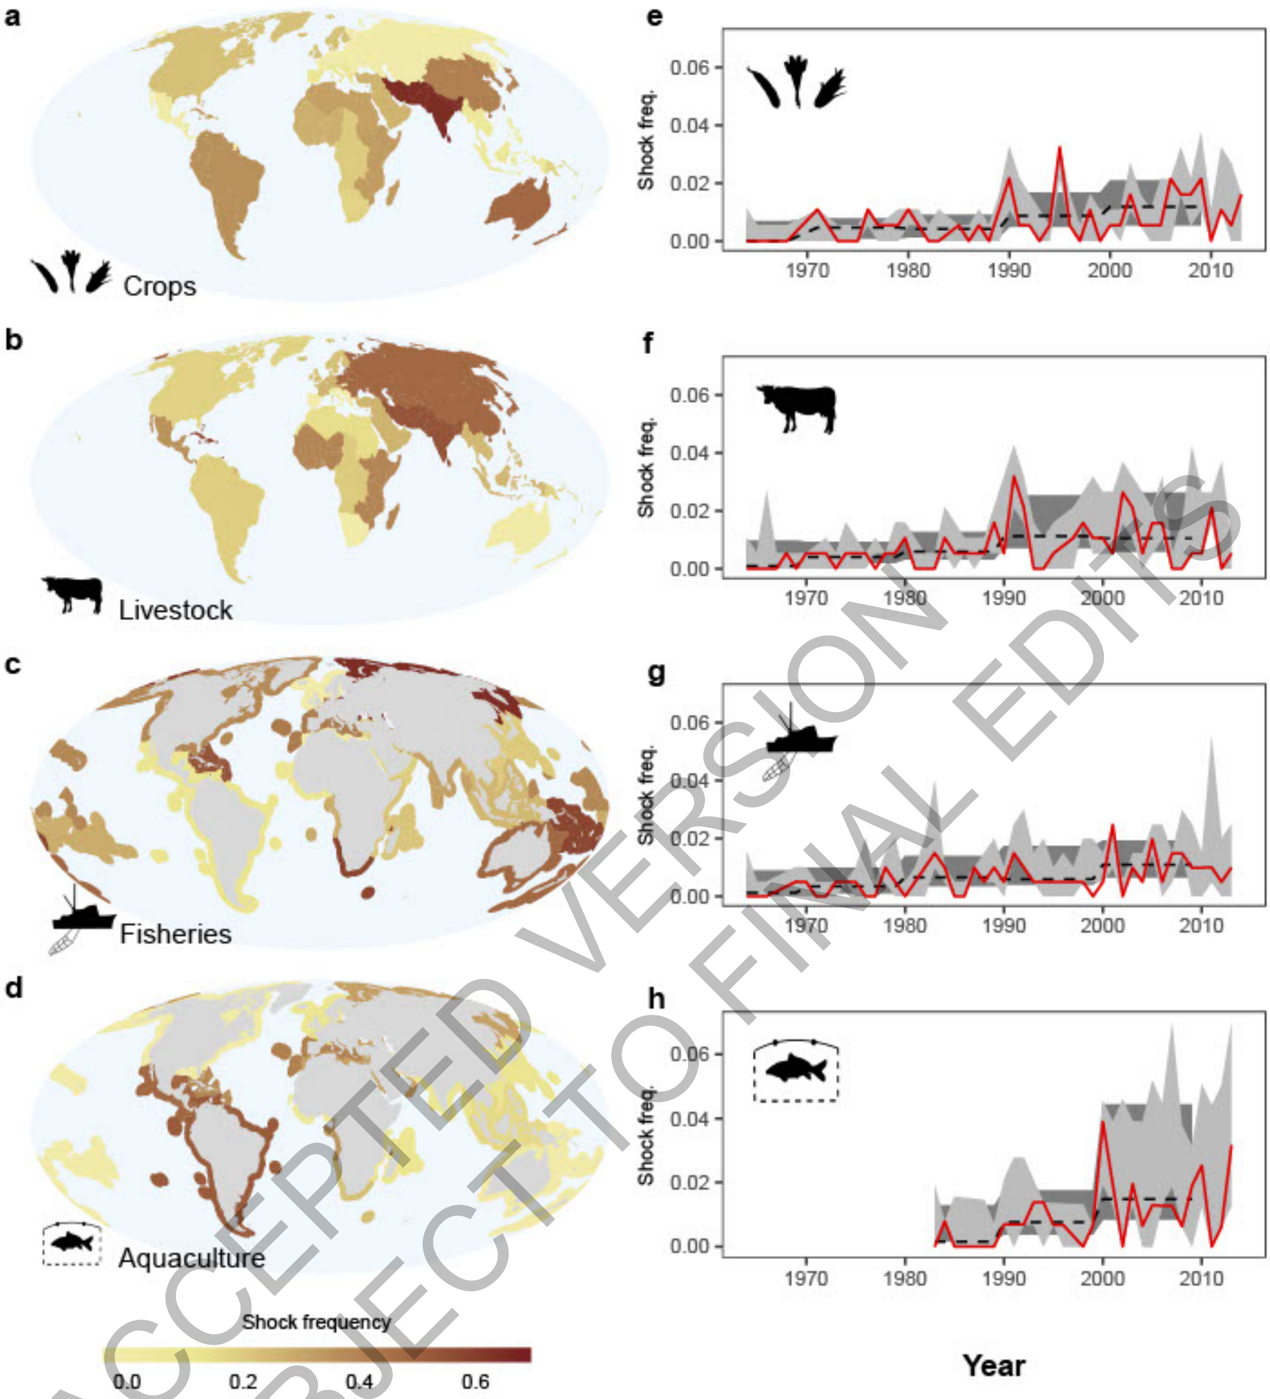

Figure FAQ 5.1.1: Trends in food production shocks in different food supply sectors from 1961-2-13 (Cottrell et al., 2019). The red lines in the time series are the annual shock frequency and the dashed line is the decadal mean.

[END FAQ5.1 HERE]

[START FAQ5.2 HERE]

FAQ5.2: How will climate change impact food availability by mid and late century and who will suffer most?

Climate change impacts will worsen over time with the period after mid-century seeing more rapid growth in negative impact than in the early part of this century. The impacts will be global but people with fewer resources, and those who live in regions where impacts will worsen more rapidly, will be hurt the most.

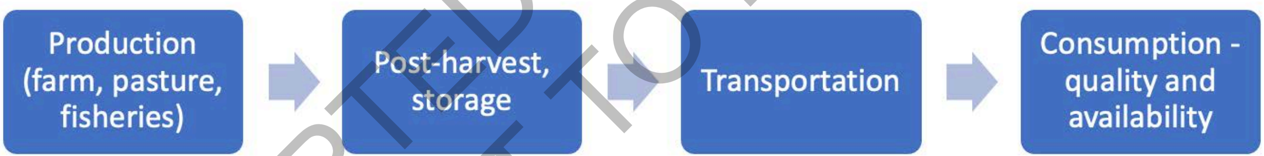
Climate change impacts will worsen over time, but the extent depends on how rapidly greenhouse gas emissions grow. If the current rate of emissions continues, the impacts will worsen, especially after mid-century with rapid growth in the number and severity of extreme weather events. Yields of plants, animals and aquaculture will decline in most places and marine and inland fisheries will suffer. Food production in some regions will become impossible, either because the crops or livestock there can't survive in the new climatic conditions, or it is too hot and humid for farm workers to be in the fields.

After harvest, agricultural production passes through the agricultural value chain, supplying animal feeds, industrial uses, and international markets, with some stored for use in the future. Each of these transitions will be affected by climate change. Food storage facilities will face more challenges in dealing with spoilage. Transportation of perishable fruits, vegetables, and meats will become costlier to maintain quality. Households and food services will need to spend more on food preservation.

Low-income countries and poor people are at higher risk, as they have limited social safety nets, suffer more from rising food prices, and an unstable food supply. But large famers will also be hurt. Rural communities, especially smallholder farmers, pastoralists, and fishers, are extremely vulnerable because their livelihoods mainly depend on their production. The urban poor will have to spend more on food.

A flood, for example, may force low-income families out of their homes, affect their employment and reduce their access to food supplies, with prices often rising after natural disasters. Families will have less access to safe water supplies, and this combination of lower food supplies, uncertain employment, displacement from home and rising food costs will increase the number of children who are undernourished.

Yields reduced Producer income falls	Pests and disease damage reduce quality and quantity	Losses of perishable items to higher temperatures/humidity More expense to marketing system	More spoilage, reduced availability Impacts in other sectors reduce income available



Examples [take from individual sections of ch 5]

Maize yields fall by 23 % in the 21st century with high GHG emissions (SSP5-8.5)	aflatoxin contamination will increase in maize in a + 2°C temperature scenario in Europe.	Increase in temperature from 17 °C to 25°C increases cold storage power consumption by about 11%	Uptake of methyl mercury in fish and mammals has been found to increase by 3–5% for each 1°C rise in water temperature

Figure FAQ5.2.1: Impacts of climate change in the food system

[END FAQ5.2 HERE]

[START FAQ5.3 HERE]

FAQ5.3: Land is going to be an important resource for mitigating climate change: How is the increasing competition for land threatening global food security and who will be affected the most?

Climate change will affect food production. To meet future food needs requires greater land shares unless we change what we eat and how we grow food. Additionally, large scale land projects that aim to mitigate *climate change will increase land competition. Less land will then be available for food production, increasing food insecurity. People at greater risk from land competition are smallholder farmers, Indigenous Peoples, and low-income groups.*

Why is land important?

Land is a limited resource on which humans and ecosystems depend on to grow plants, which capture carbon dioxide and release oxygen, provide food, timber, and other products. We also have cultural, recreational, and spiritual connections to land.

Why will climate change affect land use?

Climate change results in more frequent heat waves, extreme rainfall, drought, and rising sea levels, which negatively affect crop yields. More land is thus needed to grow crops, increasing land competition with other food systems that use crops to feed their animals (e.g., livestock, fish). Where land will be flooded, humans cannot grow crops, but food production could be adapted to grow seafood instead. Extensive land allocations aiming at reducing carbon emissions e.g., afforestation, reduce land availability for food. Unless carefully managed, competition for land will increase food prices and food security.

Solutions to reduce land competition and protect food security

Sustainable land management allows land to remain productive and support key functions. Other land practices include growing cover crops to improve soil quality. Governments can provide incentives to producers to grow alternative foods and use sustainable practices. Making sure that vulnerable groups (e.g. low-income communities, Indigenous people, and small-scale producers) strengthen land tenure rights will help protect food security.

Food by-products used as alternative food sources and other products reduce waste and increase sustainability. Dietary changes are another important solution. People that eat high amounts of meat or unhealthy foods could reduce consumption of these foods and have more diverse diets. These dietary changes will benefit their health and reduce pressure on land. Regulated labelling, education and other policies which encourage healthy diets can support these shifts.

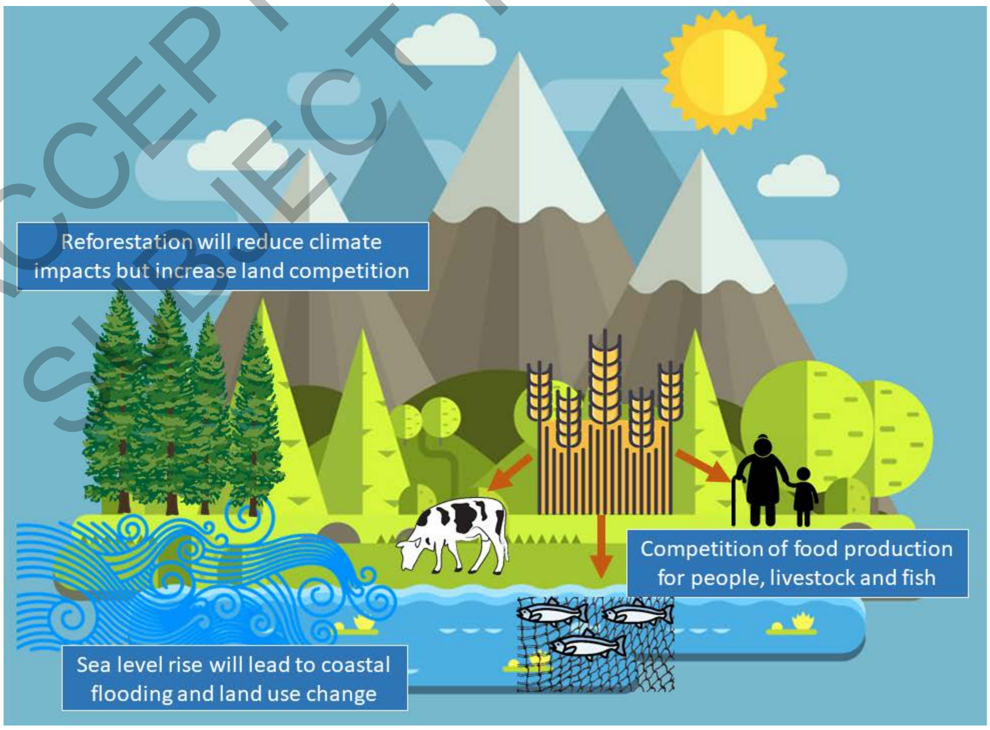


Figure FAQ5.3.1: Climate impacts will increase competition for land use reducing coastal land for crops, affecting food security for vulnerable groups. Adaptation methods like coastal aquaculture and mangrove reforestation reduce climate effects but may increase land competition.

[END FAQ5.3 HERE]

[START FAQ5.4 HERE]

FAQ5.4: What are effective adaptation strategies for improving food security in a warming world?

A variety of adaptation options exist to improve food security in a warming world. Examples of adaptation for crop production include crop management and livelihood diversification. For livestock-based systems, an example is matching number of animals with the production capacity of pastures. For fisheries, eliminating overfishing is an effective adaptation practice. For mixed cropping and nature-based systems, an appropriate adaptation is agroforestry.

Adaptation strategies to enhance food security vary from farm-level interventions to national policies and international agreements. They cover the following dimensions of food security: availability, access, utilization (food quality and safety), and stability.

For the production of crops, adaptation strategies include field and farm-level options such as crop management, livelihood diversification, and social protection such as crop insurance. The most common field management options are changes in planting schedules, crop varieties, fertilisers, and irrigation. For example, farmers can shift their planting schedules in response to the early or late onset of the rainy season. Moreover, there are new crop insurance schemes that are based on changes in weather patterns.

For livestock-based systems, adaptation options include matching the number of animals with the production capacity of pastures; adjusting water management based on seasonal and spatial patterns of forage production; managing animal diet; more effective use of fodder, rotational grazing; fire management to control woody thickening of grass; using more suitable livestock breeds or species; migratory pastoralist activities; and activities to monitor and manage the spread of pests, weeds, and diseases.

For ocean and inland fisheries, adaptation options are primarily concentrated in the socio-economic dimension and governance and management. In general, eliminating overfishing could help rebuild fish stocks, reduce ecosystem impacts, and increase fishing's adaptive capacity. Aquaculture is often viewed as an adaptation option for fisheries declines. However, there are adaptation strategies specific to aquaculture such as proper species selections at the operational level, such as the cultivation of brackish species (shrimp, crabs) in inland ponds during dry seasons and rice-freshwater finfish in wetter seasons.

For so-called mixed farming systems that produce a combination of crops, livestock, fish, and trees, these systems' inherent diversity provides a solid platform for adaptation. A good example is agroforestry, the purposeful integration of trees or shrubs with crop or livestock systems, increases resilience against climate risks.

Overall, nature-based systems or ecosystem-based strategies in food systems, such as agroecology, can be a useful adaptation method to increase wild and cultivated food sources. Agroecological practices include agroforestry, intercropping, increasing biodiversity, crop and pasture rotation, adding organic amendments, integration of livestock into mixed systems, cover crops and minimizing toxic and synthetic inputs with adverse health and environmental impacts.

[END FAQ5.4 HERE]

[START FAQ5.5 HERE]

FAQ5.5: Climate change is not the only factor threatening global food security: other than climate action, what other actions are needed to end hunger and ensure access by all people to nutritious and sufficient food all year round?

Our food systems depend on many factors other than climate change, such as food production, water, land, energy, and biodiversity. People's access to healthy food can be also be affected by factors such as poverty and physical insecurity. We are all stakeholders in food systems, whether as producers or consumers, and we can all contribute to the goal of a food-secure world by the choices we make in our everyday lives.

Today more than 820 million people are hungry, and hunger is on the rise in Africa. Two billion people experience moderate or severe food shortages and another 2 billion suffer from overnutrition, a state of obesity or being overweight from unbalanced diets, with related health impacts such as diabetes and heart disease. The changing climate is already affecting food production. These effects are worsening, affecting food production from crops, livestock, fish, and forests in many places where people already don't have enough to eat. Food prices will be affected as a result, with increasing risk that poorer people will not be able to buy enough for their families. Food quality will increasingly be affected too.

Our ability to grow and consume food depends on many factors other than climate change. There are tight connections between food production, water, land, energy, and biodiversity, for example. Other factors like gender inequality, poverty, political exclusion, remoteness from urban centres and physical insecurity can all affect people's access to healthy food.

Food systems are complicated **(**Figure FAQ5.5). To improve food production, supply, and distribution, we need to make changes throughout the food supply chain. For instance: improving the way farmers access the inputs needed to grow food; improving the ways in which food is grown, with climate and market information, training and technical know-how, water-saving and water-harvesting technologies; adopting new low-cost and less carbon-intensive storage and processing methods; and creating local networks of producers and processors For food consumers, we could consider shifts to different diets that are healthier and make more efficient use of natural resources; depending on context, these could involve rebalancing consumption of meat and highly processed foods, reducing food loss and waste, and preparing food in more energy-efficient ways. Policy makers can enable such actions through appropriate price and trade policies, implementing policies for sustainable and low-emission agriculture, providing safety nets where needed, and empowering women, youth, and other socially disadvantaged groups.

Our food systems need to be robust and sustainable, otherwise we won't be able to manage the additional pressures imposed on them by climate change. We can all contribute to this goal.

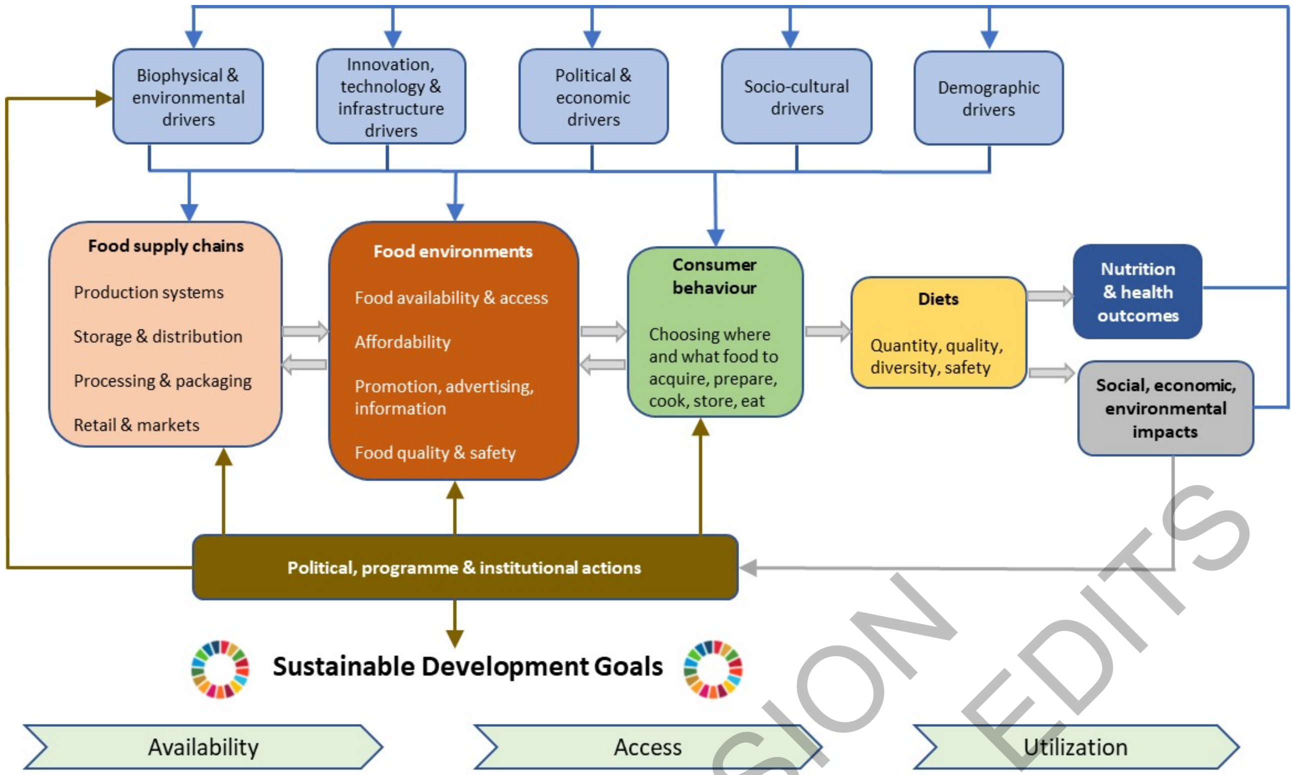

Figure FAQ5.5.1: Conceptual framework of food systems for diets and nutrition (modified from (HLPE, 2017a)

Executive Summary

In all cities and urban areas, the risk faced by people and assets from hazards associated with climate change has increased (*high confidence*[1]). Urban areas are now home to 4.2 billion people, the majority of the world's population. Urbanization processes generate vulnerability and exposure which combine with climate change hazards to drive urban risk and impacts (high confidence). Globally, the most rapid growth in urban vulnerability and exposure has been in cities and settlements where adaptive capacity is limited – especially in unplanned and informal settlements in low- and middle-income nations and in smaller and medium-sized urban centres (high confidence). Between 2015 and 2020, urban populations globally grew by more than 397 million people, with more than 90 percent of this growth taking place in Less Developed Regions. {Box 6.1; 6.1.4; 6.2.1; 6.3.2; 6.3.3.4; 6.2.2.2; 6.4.4}

The documentation of climate related events and observed human and economic losses have increased since AR5 for urban areas and human settlements. Observed losses arise from single, compound, cascading and systemic events (*medium evidence, high agreement*). Losses from single events include the direct impact of heat stress on human health. Compound event losses arise from the interaction of single climate hazards with at least one other hazard driver such as heat with poor air quality (e.g. from traffic fumes or wildfire), flooding with poor water quality (e.g. from contaminated run-off and flood water), or land subsidence. Cascading impacts are observed when damages in one place or system reduce resilience and generate impacts elsewhere (e.g. when flood waters damage energy infrastructure causing blackouts and knock on financial and human impacts). Losses become systemic when affecting entire systems and can even jump from one system to another (e.g. drought impacting on rural food production contributing to urban food insecurity) (medium confidence). In some cases, maladaptive responses to hazards have exacerbated inequality in the distribution of impacts, for example shifting risk from one community to another. {Figure 6.2; 6.2.6; 6.3.4.1; 6.4.5; Cross-Chapter Paper 2; Cross-Working Group Box URBAN in Chapter 6}

Evidence from urban and rural settlements is unequivocal; climate impacts are felt disproportionately in urban communities with the most economically and socially marginalized, most affected (*high confidence*). Vulnerabilities are shaped by drivers of inequality - including gender, class, race, ethnic origin, age, level of ability, sexuality and nonconforming gender orientation - framed by cultural norms, diverse values, and practices (high confidence). Intersections between these drivers shape unique experiences of vulnerability and risk and the adaptive capacities of groups and individuals. Robust adaptation plans are those developed in inclusive ways. However, few adaptation plans for urban areas and infrastructure are being developed through consultation and coproduction with diverse and marginalized urban communities. The concerns and capacities of marginalised communities are rarely considered in planning (medium confidence). {Box 6.3, Box 6.4; 6.4.3.1; 6.4.5.2, Case study 6.7; Cross-Working Group Box URBAN in Chapter 6}.

The COVID-19 pandemic has had a substantial impact on urban communities and climate adaptation (*medium evidence, high agreement*). The pandemic has revealed both systemic underinvestment resulting in multiple, persistent health related vulnerabilities (many of which also exacerbate climate change risk) and co-benefits for urban interventions to reduce future pandemic and climate change risk. The COVID-19 pandemic is estimated to have pushed an additional 119 to 124 million people into poverty in 2020, with South Asia and Sub-Saharan Africa each contributing roughly two-fifths of this total (medium confidence). At city level, community groups, NGOs and local governments face challenges to bring agencies already working on social and economic development into coordinated action to reduce urban vulnerabilities and manage risks. COVID-19 and climate change impacts are exacerbated by widening social inequality. Addressing the causes of social vulnerability creates opportunity for transformative adaptation. {Box 6.4; 6.1.4; 6.2.2.4; 6.2.5; 6.4.1.3; case study 6.4; Cross-Chapter Box COVID in Chapter 7}

The number of people expected to live in urban areas highly exposed to climate change impacts has increased substantially (*high confidence*). An additional 2.5 billion people are projected to be living in

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

urban areas by 2050, with up to 90 percent of this increase concentrated in the regions of Asia and Africa. Projections of the number of people expected to live in urban areas highly exposed to climate change impacts have increased. Sea level increase and increases in tropical cyclone storm surge and rainfall intensity will increase the probability of coastal city flooding, with more than a billion people located in low-lying cities and settlements expected to be at risk from coastal-specific climate hazards by 2050 (*high confidence*). Sea level rise, increases in tropical cyclone storm surge, and more frequent and intense extreme precipitation will increase the number of people, area of urban land, and damages from flood hazard (*high confidence*). The main driver for increased heat exposure is the combination of global warming and population growth in already-warm centres, and the majority of the population exposed to heatwaves will live in urban centres. An additional 350 million people living in urban areas are estimated be exposed to water scarcity from severe droughts at 1.5°C warming, and 410.7 million at 2°C warming. {6.1; 6.2.2; CCP2}

Many more cities have developed adaptation plans since AR5, but only a limited number of these have been implemented (*medium confidence*). Many of these plans focus narrowly on climate risk reduction, missing opportunities to advance co-benefits of climate mitigation and sustainable development, compounding inequality and reducing wellbeing (*medium confidence*). However, an increasing array of adaptation options are available. Nature-based solutions are now mainstream urban adaptation options and there remains considerable scope for their wider application. Social policy based adaptation, including education and the adaptation of health systems offers considerable future scope. Options of adapting physical infrastructure are similarly advancing though at times constrained by existing infrastructure design and location. The greatest gaps between policy and action are in failures to manage adaptation of social infrastructure (community facilities, services and networks) and failure to address complex interconnected risks for example in the food-energy-water-health nexus or the inter-relationships of air quality and climate risk (*medium confidence*). Barriers to implementing plans include lack of political will and management capacity, limited financial means and mechanisms (especially for smaller urban settlements) and competing priorities (*limited evidence, high agreement*). {6.3.1, 6.4.3; 6.4.5; 6.4.5.1; 6.4.5.2; Figure 6.5}

The shift from urban planning to action in ways that identify and advance synergies and co-benefits of mitigation, adaptation and Sustainable Development Goals (SDGs) has occurred slowly and unevenly (*high confidence*). While there is ambition for joined up policy, action and research, this is still the exception. One area of sustained effort is community-based adaptation planning and resilience actions which have potential to be better integrated to enhance wellbeing and create synergies with the Sustainable Development Goal ambitions of leaving no-one behind. Complex trade-offs and gaps in alignment between mitigation and adaptation over scale and across policy areas where sustainable development is hindered or reversed also remain. {6.1.1, Table 6.2; 6.1.5; 6.4.1.4; 6.4.3; 6.4.4}

Urban adaptation gaps exist in all world regions and for all hazard types, although exposure to the limits to adaptation are unevenly distributed. Governance capacity, financial support and the legacy of past urban infrastructure investment constrain how all cities and settlements are able to adapt (*high confidence*). Critical capacity gaps exist at city and community levels that hinder adaptation. These include the limited ability to identify social vulnerability and community strengths; the absence of integrated planning to protect communities; and the lack of access to innovative funding arrangements and limited capability to manage finance and commercial insurance (medium confidence). These can be addressed through enhanced locally accountable decision-making with sufficient access to science, technology and local knowledge to support widespread application of adaptation solutions. {6.3.1, 6.4.3; 6.4.5; 6.4.5.1; 6.4.5.2; Figure 6.4; Figure 6.5}

Slow uptake of monitoring and evaluation frameworks constrains potential for developing climate resilient urban development pathways (*medium confidence*). A lack of agreement on metrics and indices to measure urban adaptation investment, impacts and outcomes, reduces the scope for sharing lessons and joined-up action across interconnected sectors and places in the face of compound and systemic risks. These constraints affect the potential for climate resilient development pathways. Limits to adaptation are often most pronounced in rapidly growing towns and cities and smaller settlements including those without dedicated local government. At the same time, legacy infrastructure in large and mega-cities, designed without taking climate change risk into account, constrains innovation leading to stranded assets and with increasing numbers of people unable to avoid harm, including heat stress and flooding, without transformative adaptation. {6.2.5; 6.3.3.3; 6.3.7; Figure 6.4; 6.4.4; 6.4.6 FAQ6.5}

City and local governments are key amongst multiple actors facilitating climate change adaptation in cities and settlements (*medium confidence*). City and local governments can invest directly and work in partnership with community, private sector and national agencies to address climate risk. Private and business investment in key infrastructure, housing construction and through insurance requirements can also drive widespread adaptive action, though at times excluding the priorities of the poor (*medium confidence*). Networked community actions can also go beyond neighbourhood-scale improvements to address widespread vulnerability. Such actions include fostering roles of intermediaries and multiple spaces for networked governance across scales of decision making, improving development processes through an understanding of social and economic systems, foresight, experimentation and embedded solutions, and social learning. Transnational networks of local government can also enhance city level capacity, share lessons and advocacy (medium confidence). {Table 6.2, 6.3.3.4; 6.3.3.5; 6.4.1; 6.4.1.1; case study 6.2; FAQ6.5}

Globally, decisions about key infrastructure systems and urban expansion drive risk creation and potential action on climate change (*high confidence*). Urban infrastructure concentrates and connects populations, physical assets and energy use. Urban expansion and the compromising of green infrastructure and ecosystem services reduces adaptive capacity and can increase risk: the urban heat island – a product of expansion – can add 2°C to local warming. How settlements and key infrastructure are planned, designed and maintained determines patterns of exposure, social and physical vulnerability and capacity for resilience. Unplanned rapid urbanization including peri-urban development is a major driver of risk, particularly where cities and settlements are expanding into land that is prone to coastal flooding or landslides, or where there is inadequate water to meet the needs of growing populations. Urban decision-making processes equally shape how far low- and zero-carbon development can meet social needs – enhancing wellbeing while enabling climate change mitigation and advancing the Sustainable Development Goals. {6.1.3; 6.2.3; 6.2.4; 6.3.3; 6.3.4; 6.3.5; 6.4.6; Cross-Working Group Box URBAN in Chapter 6}

Investment in urban adaptation has not kept pace with innovations in policy and practice (*medium confidence*). Knowledge transfer and innovation in adaptation has broadened advances in social and ecological infrastructures including disaster risk management, social policy and green/blue infrastructure, especially where these are integrated with grey/physical infrastructure (medium evidence, high agreement). Innovation has also taken pace at the interface of difference systems, for example ICT and water or energy although financial investment has been slow to recognize and support these activities. Adaption finance continues to be directed at large-scale grey/physical engineering projects, neglecting maintenance and reproducing risk of stranded assets if climate change risk accelerates beyond planned-for levels. Finance deployed at the interface of multiple, integrated adaptation measures can support climate resilient development (high confidence). Access to finance is most difficult for city, local and non-state actors and in conditions where governance is fragile. {6.3.3; 6.3.4; 6.3.6; 6.4.5; 6.4.5.2; Table 6.10; Table 6.11; Box 6.8; case study 6.2; case study 6.3; case study 6.5}

Global urbanization offers a time-limited opportunity to work towards widespread and transformational adaptation and Climate Resilient Development (*high confidence*). Current dominant models of energy intensive and market-led urbanization build high carbon dependency and high vulnerability into cities, but this need not be the case. Integrated development planning that connects innovation and investment in social, ecological and grey/physical infrastructures can significantly increase the adaptive capacity of urban settlements and cities. Transitioning cities to low carbon development and equitable resilience may lead to trade-offs with dominant models of economic growth based on housing and infrastructure investment. Integrated planning approaches are important for Climate Resilient Development to enable planning and monitoring of interactions between development, mitigation and adaptation. Urban adaptation measures can offer a considerable contribution to Climate Resilient Development. This potential is realised by adaptations that extend predominant physical infrastructure approaches to also deploy nature based solutions and social interventions. The most consistent limit for all infrastructure types is in risk transfer. Current adaptation approaches in cities, settlements and key infrastructure have a tendency to move risk form one sector or place to others. Multi-level leadership, institutional capacity together with financial resources (including climate finance) to support inclusive and sustainable adaptation in the context of multiple pressures and interconnected risks, can help to ensure that global urbanization of an additional 2.5 billion people by 2050; reduces rather than generates climate risk (medium confidence). {Table 6.7; Table 6.5; 6.1.3; 6.3.6; 6.3.5.2; 6.4.7; Box 6.5; Cross-Working Group Box URBAN in Chapter 6; CCP2}

Intersectional, gender-responsive and inclusive action can accelerate transformative climate change adaptation. The greatest gains in wellbeing in urban areas can be achieved by prioritising investment to reduce climate risk for low-income and marginalised residents and targeting informal settlements (*high confidence*). These approaches can advance equity and environmental justice over the long term in ways more likely to lead to outcomes that reduce vulnerability for all urban residents. Participatory planning for infrastructure provision and risk management to address climate change and underlying drivers of risk in informal and underserviced neighbourhoods, the inclusion of Indigenous Knowledge and Local Knowledge, communication and efforts to build local leadership especially amongst women and youth are examples of inclusive approaches with co-benefits for equity. Providing opportunities for marginalised people, including women, to take on leadership and participation in local projects can enhance climate governance and its outcomes (high confidence). Since AR5, social movements in many cities, including movements led by youth, Indigenous and ethnic communities have also heightened public awareness about the need for urgent, inclusive action to achieve adaptation that can also enhance wellbeing. {6.1.5; 6.3.5; 6.4.1.2; 6.4.7; Box 6.6, case studies 6.2; 6.4 FAQ6.3}

City and infrastructure planning approaches that integrate adaptation into everyday decision-making are supported by the 2030 Agenda (the Paris Agreement, the Sustainable Development Goals, the New Urban Agenda and the Sendai Framework for Disaster Risk Reduction) (*high confidence*). The 2030 Agenda provides a global framework for city and community level action to be points of alignment between Nationally Determined Contributions, National Adaptation Plans of Action, and the Sustainable Development Goals. City and local action can complement – and at times go further than national and international interventions. Similarly, the Convention on Biological Diversity offers a global agreement through which nature-based solutions can be viewed as benefits for biodiversity, social justice and climate resilience. However, there is no specific global agreement that addresses informality and city level climate adaptation. More comprehensive and clearly articulated global ambitions for city and community adaptation will contribute to inclusive urbanization, by addressing the root causes of social and economic inequalities that drive social exclusion and marginalization, so that adaptation can directly support the 2030 Sustainable Development Agenda (high confidence). {6.1.1; Table 6.2; 6.2.3.2; 6.4.1.4; case study 6.4}

6.1 Introduction and Points of Departure

6.1.1 Background and Chapter Outline

Cities and urbanising areas are currently home to over half the world's population. What happens in cities is crucial to successful adaptation (Grafakos et al., 2019). By 2050 over two thirds of the world's population is expected to be urban, many living in unplanned and informal settlements and in smaller urban centres in Africa and Asia (*high confidence*) (UNDESA, 2018). Between 2015 and 2020, urban populations globally have grown by about 397 million people, with more than 90 percent of this growth taking place in Less Developed Countries (UNDESA, 2018). Projections of the number of people expected to live in urban areas highly exposed to climate change impacts have also increased, exacerbating future risks under a range of climate scenarios. Rates of population growth are most pronounced in smaller and medium sized settlements of up to 1 million people (UNDESA, 2018).

Since AR5 there has been increasing understanding of the interdependence of meta-regions, large, small and rural settlements which may be connected through key infrastructure (Lichter and Ziliak, 2017) including national and trans-national infrastructure investments (Hanakata and Gasco, 2018). Almost all the world's non-urban population and its provisioning ecosystems are impacted by urban systems through connecting infrastructure and family and kinship ties, remittances and trade arrangements that influence flows of water, food, fibre, energy, waste and people (Trundle, 2020; McIntyre-Mills and Wirawan, 2018; Zhang et al., 2019; Nerini et al., 2019; Friend and Thinphanga, 2018). Many rural places are so deeply connected to urban systems that risks are observed to cascade from one to the other – for example when drought in arable zones leads to food insecurity in cities, or where flood damage to urban transport infrastructure leads to prolonged isolation of small towns and rural settlements (Friend and Thinphanga, 2018; McIntyre-Mills and Wirawan, 2018). A focus of this chapter is the experience of a range of urban settlements, from small to large, and the connecting infrastructure and formal and informal networks and systems that join them to each other. There are close synergies with chapters 7 (Health, wellbeing and the changing structure of communities) and 8 (Poverty, livelihoods and sustainable development). There are further important synergies with Working Group III Chapter 8 (Urban systems and other settlements) and the Cross-Chapter Paper 2: Cities and Settlements by the Sea.

Well planned climate adaptation can have far reaching co-benefits for sustainable development, and community wellbeing (Nerini et al., 2019; Tonmoy et al., 2020). However the varied success of cities' responses to the global COVID-19 pandemic underscores how social and economic conditions, built environments and local planning can exacerbate or reduce vulnerability and long term sustainable, community wellbeing (Megahed and Ghoneim, 2020; Plastrik et al., 2020; Hepburn et al., 2020; Sarkis et al., 2020).

Many of the significant sustainable development initiatives that have been proposed and implemented in the last five years recognise the critical importance of cities, settlements and key infrastructure in responding to the crisis of climate change (Zhang et al., 2019; Nerini et al., 2019). There is widespread acceptance of the need for far-reaching responses by actors from the local to the global scales to make human settlements and infrastructure more resilient (UNDP, 2021). There is recognition also of the considerable capacity in settlements to meet climate change challenges, if the governance, financial and social conditions are in place (Carter et al., 2015; MINURVI, 2016). And yet the implementation of climate adaptation planning lags behind climate mitigation efforts in urban communities (Sharifi, 2020; Grafakos et al., 2019; Nagendra et al., 2018).

Since the publication of AR5, there has been rapid expansion in policy, practice and research related to climate change and human settlements. The 2030 Agenda for Sustainable Development (the Sustainable Development Goals) agreed in September 2015, was preceded by the Sendai Framework for Disaster Risk Reduction 2015-30 and followed shortly afterwards by the Paris Agreement (December 2015) (United Nations, 2015b). These make explicit mention of "mainstreaming of disaster risk assessments into land-use policy development and implementation, including urban planning" (Sendai Framework) (UNISDR, 2015). The agreements identify "sustainable cities and communities" (SDG11) and "cities and subnational authorities" (Paris Agreement) as important actors in integrating climate and development goals (Sanchez Rodriguez, Ürge-Vorsatz and Barau, 2018). However not all urban SDGs have measurable targets yet, or data particularly in regard to children and youth, the elderly and disabled (Klopp and Petretta, 2017; Reckien et al., 2017; Nissen et al., 2020). Clear procedures for linking climate adaptation in communities at all scales to the SDGs is lacking (Major, Lehmann and Fitton, 2018; Sanchez Rodriguez, Ürge-Vorsatz and Barau, 2018).

The New Urban Agenda (NUA) (October 2016), with its focus on housing and sustainable urban development, commits its signatories to building resilient and responsive cities that foster climate change mitigation and adaptation (United Nations, 2016b). This agreement followed the Geneva UN Charter on Sustainable Housing, endorsed by 56 member states of the United Nations Economic Commission for Europe (United Nations, 2015d). The NUA aims to ensure access to decent, adequate, affordable and healthy housing for all while reducing the impact of the housing sector on the environment and increasing resilience to extreme weather events (United Nations, 2016b). Voluntary, networked action led by cities was also illustrated by a November 2019 call to Mayors and youth climate activists to sign a voluntary pledge in a "Race to Zero" ahead of the Conference of the Parties 26, which included endorsing principles of a New Green Deal (C40, 2019). Other voluntary, global, urban efforts have been led by the scientific community including the Research and Action Agenda on Cities and Climate Change Science which aims to promote research and reports (Prieur-Richard, Walsh and Craig, 2019).

These collaborative global changes are reflected in the bodies of literature assessed for this report. In AR5, the section on 'human settlements, industry, and infrastructure' contained three chapters: urban areas; rural areas; and key economic sectors and services. This chapter covers the full range of human settlements: from small settlements in predominantly rural areas, to large metropolises in both high-income and low-income countries. It also assesses evidence of climate change impacts, vulnerability and adaptation on a range of urban infrastructures including infrastructure that incorporates socio-economic, and ecosystem dimensions (see 6.1.3).

This assessment also considers new literature about how enabling environments can support adaptation in ways that are also sensitive to Indigenous knowledge and local knowledge (see below 6.1), social justice (6.4.3.d) and climate mitigation (6.3.5.2). It builds on the findings of AR5 which highlighted the concentration of global climate risks in urban areas, the complex causal chains that mediate climate impacts for smaller settlements and rural areas, and the multiple issues shaping and influencing economic sectors and infrastructure. This integrated chapter enables a more detailed analysis of the inter-connected drivers of risk that affect urban people and settlements of different sizes. This discussion also highlights the inter-connections within and between urban areas, and between different types of infrastructure and how these complex relationships accentuate or limit the effects of climate change and the institutional structures that play a critical role in mediating and govern these relationships.

This chapter has five main sections. The first elaborates on changes in the international policy context since 2014, highlighting the implications that this has for responses to climate change in cities, settlements and key infrastructure. Section 6.2 is focused on observed and projected climate risks, paying particular attention to the ways in which these are created through processes of urbanization and infrastructural investment. Section 6.3 takes an integrated and holistic approach to an assessment of adaptive actions relevant to key infrastructures (those that form the material basis for resilience in cities and settlements, drive economies, and are essential for human wellbeing). Section 6.4 assesses the enabling conditions and leadership qualities associated with adaptation processes that can also meet the equity agenda of the Sustainable Development Goals – to leave no-one behind including the role of governance, finance, institutions and emerging literature around the limits of urban adaptation.

Case studies highlight how climate and other issues interrelate to create (or reduce) urban risk within and between scales of decision-making. They illustrate how multiple levels of governance and formal and informal decision-making sectors influence how risk production/reduction plays out across a range of urban contexts and networks.

6.1.2 Points of Departure

The AR5 conceptualised cities and settlements as complex interdependent systems that could be engaged in supporting climate change adaptation (Revi et al., 2014 8.8.2). Effective municipal governance systems and cooperative multilevel governance supported adaptation action. The AR5 report expressed *medium confidence* that governance interventions can help develop synergies across geographical and institutional scales. Urban areas face challenges of infrastructure investment and maintenance, land use management, livelihood creation, and ecosystem services protection. AR5 also considered how urban localities can encourage incremental and transformative adaptation, build resilience and support sustainable development. The assessment identified the need for multi-level and multi-partner action in rapidly growing cities where institutions and infrastructure are still not established to meet the growing demands of the cities. However, there was only *medium confidence* that adaptation action was happening in the AR5 review period.

The framing of 'key economic sectors and services' in AR5 focused primarily on three infrastructural areas (energy, water services, transport) and on primary and secondary economic activities (including recreation and tourism, insurance and financial services). Cities, settlements and key infrastructure are also referred to in the IPCC special reports released since AR5. The Special Report on Global Warming of 1.5°C examines impacts of global warming on urban systems and infrastructure in the context of advancing sustainable development and eradicating poverty. It highlights the risks facing residents of unplanned and informal urban settlements, many of which are exposed to a range of climate-related hazards (Sections 3.4.8 and 4.4.1.3). The Special Report on Global Warming of 1.5°C also identifies green infrastructure, sustainable land use and planning, and sustainable water management as key adaptation options that can reduce risks in urban areas (SPM C2.4; C. 2.5), and highlights "urban and infrastructure" as one of four system transitions required to limit warming to 1.5°C to create an enabling environment for adaptation (Section 4.3.3). Innovative governance arrangements that go beyond formal 'government' and political arrangements and that include non-state actors, networks and informal institutions were identified as important in addressing climate change and implementing responses to 1.5°C-consistent pathways (Special Report on Global Warming of 1.5°C (Section 4.4.1 and 5.6.2). In addition, the Special Report on Global Warming of 1.5°C mentions, with *high confidence*, the climate related health effects of urban heat islands, urban heatwaves and increasing risks from some vector-borne diseases (illnesses caused by pathogens and parasites in human populations) (SPM B 5.2). The report also notes both trade-offs and important co-benefits of sustainable development in pursuit of climate-resilient development pathways that achieve ambitious mitigation and adaptation in conjunction with poverty eradication and efforts to reduce inequalities (SPM D6).

The Special Report on Oceans and Cryosphere (SROCC) similarly emphasises the role governance plays in reducing disaster risk, through planning, and zoning. It identifies vulnerability factors such as poverty, which can undermine resilience and sustainable development in urban communities (SPM C31, Section 2.3.2.3; pp. 135; 164). The SROCC report shows that the emerging climate related challenges are impacting the accessibility and availability of vital resources and blurring the public and private boundaries of risk and responsibility (Cross-Chapter Box 3 p 99). According to the SROCC report, new governance arrangements are emerging to address these challenges, including participatory and networked structures, and institutions linking formal and informal networks involving state, private sector, Indigenous and civil society actors (Cross-Chapter Box 3 p 99). The SROCC report calls for place-specific action because there is no single climate governance panacea for the ocean, coasts, and cryosphere Cross Chapter box 3 p 99). The SROCC report highlights evidence of the importance of inclusivity, fairness, deliberation, reflexivity, responsiveness, social learning, the co-production of knowledge, and respect for ethical and cultural diversity in climate related urban decision-making (Cross-Chapter Box 3). In addition, the Special Report on Climate Change and Land notes that urbanisation can intensify extreme rainfall events over the city or downwind of urban areas and have can significant consequences for heat island effects loss of food production posing additional risks to the food system (SPM A5.3 and Cross-Chapter Box 4 in Chapter 2).

An additional research bridge between AR5 and AR6 was the IPCC Cities and Climate Change Science conference in Edmonton, Canada March 2018. This generated a 'Global Research and Action Agenda on Cities and Climate Change Science' (Prieur-Richard, Walsh and Craig, 2019), which highlights six topical research areas where more evidence is needed to inform action: finance; informality; uncertainty; urban planning and design; built and green/blue infrastructure; and sustainable consumption and production. These areas are addressed in specific sections of this chapter or as cross-cutting themes. The Cross-Working Group Box provides a linkage with perspectives from Working Group III.

6.1.3 Terminology and Definitions

This chapter covers both 'cities and settlements' and 'key infrastructure'.

Definitions of 'urban' have become more nuanced since the AR5 review with the publication of the OECD report 'A new perspective on urbanisation' (OECD and European Commission, 2020). This report presents two new global definitions of urbanisation reflecting the degree of urbanisation on a continuum of cities, towns & semi-dense areas, and rural areas. The OECD estimates almost half the world's population (48%) live in cities, while just 24% live in rural areas and 28% live in towns & semi-dense areas (28%). In addition, the OECD report defines metropolitan areas as functional urban areas together with their surrounding commuting zones 'to capture the full extent' of a city's working population. Metropolitan areas account for 54% of total world population, with the OECD estimating that commuting zones representing 17% of the overall metropolitan population, rising to 31% in high-income countries. In the context of these global definitions, this chapter identifies 'cities and settlements' as concentrated human habitation centres (along a dynamic continuum from rural to urban (Murali et al., 2019; Ward and Shackleton, 2016) (Figure 6.1) and that are fundamentally inter-connected to other urban centres and rural areas as nodes within broader networks.

Key infrastructure is used here to refer to 'critical nodes and arteries' that comprise urban energy, food, water, sewerage, health, transport and communication systems (Steele and Legacy, 2017; Maxwell et al., 2018; Bassolas et al., 2019). Key or critical infrastructure provides much of the material basis of cities and settlements, as well as the mechanisms for enabling flows of people, goods, data, waste, energy (through urban metabolism processes of consumption and production) and capital, between urban regions and rural areas (Blay-Palmer et al., 2018; Dijst et al., 2018). An overview of this process of 'planetary' urbanization is provided in Box 6.1. The balance of accumulated scientific knowledge on climate risks, impact and adaptation has been generated from studies in large and medium sized cities of 1 million or more. While these larger cities continue to grow rapidly (UNDESA 2018), settlements of more than 5 million people contain less than a quarter of the world's urban population, and more than half of the world's urban residents live in settlements of 1 million or less (Table 6.1). There is a key gap in knowledge, especially concerning urban enabling environments and how smaller settlements can be supported to accelerate equitable and sustainable adaptation in the face of financial and governance constraints (Birkmann et al., 2016; Shi et al., 2016; Dulal, 2019; Rosenzweig et al., 2018b).

Table 6.1: Proportion of the urban population in different size class urban areas (UN-DESA 2018). Each column indicates the percentage of urban residents in that region living in cities of that size class.

Proportion (by region) of urban population living in cities with population size:	Africa	Asia	Latin America and the Caribbean	Europe	Northern America	Oceania	World
10 million +	8	15	17	4	10	0	13
5-10 million	6	9	3	5	17	0	8
1-5 million	22	22	25	16	30	60	22
500,000-1 million	9	10	8	11	13	2	10
300,000-500,000	6	6	6	8	7	11	6
Under 300,000	48	38	40	57	24	27	41

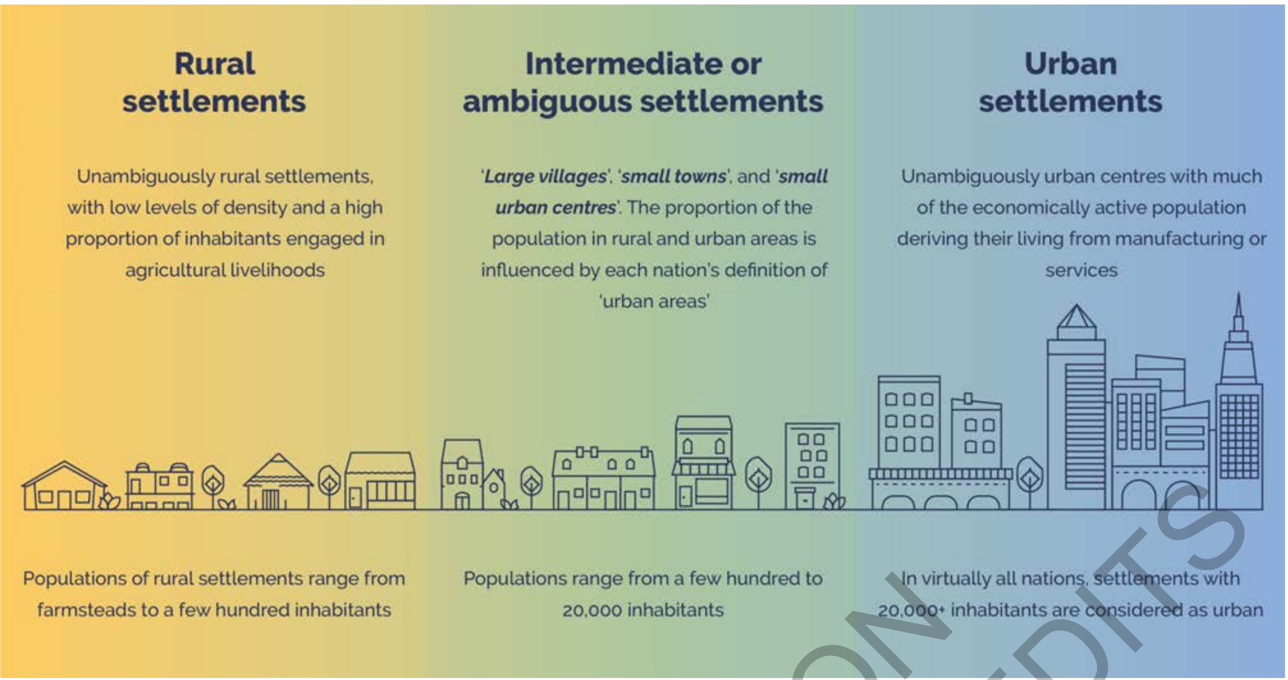

Figure 6.1: Defining 'urban' and 'rural' in relation to cities and settlements

The chapter takes a comprehensive approach to understanding 'key infrastructure' as expressed in social, nature-based and physical infrastructure. Social infrastructure includes the social, cultural, and financial activities and institutions as well as associated property, buildings and artefacts and policy domains such as social protection, health and education that support wellbeing, public life (Frolova et al., 2016; Latham and Layton, 2019). Nature-based infrastructure focusses on solutions to risk applying natural assets such as trees or open water, physical infrastructure describes engineering approaches. Grey/physical infrastructure refers to engineered assets that provide one or multiple services required by society, such as transportation or wastewater treatment ((IISD, N.D.); see also IPCC glossary).

This approach is based on a framing of cities and settlements as complex systems where social, ecological and physical processes interact in planned and unplanned ways. The chapter therefore builds on the AR5 chapter 10 conception of key economic sectors and services (e.g. energy, water, transport, waste, sanitation and drainage) by positioning these within three major categories of infrastructure: social, nature-based and physical (see Section 6.3). Where adaptation challenges can be responded to by more than one approach, sometimes working together, this is noted (see also Chapter 17.2; 17.4). This approach allows an understanding of adaptation that is not constrained to the administrative boundaries of cities and settlements, but that includes the networks and flows that connect peri-urban communities, metropolitan regions, suburban settlements and more rural places (See Box 6.1). Both formal provision of infrastructure services by government and informal provision by communities and individuals are considered at risk from climate change as are existing adaptation pathways and actions.

Cities are complex entities where social, ecological and physical systems interact in planned and unplanned ways (Markolf et al., 2018). The complexity of cities, settlements and key infrastructure (Figure 6.2) where multiple functional systems continuously interact, makes it difficult to distinguish risks (Box 6.1). The literature often resolves this by offering discrete assessments for specific sectors (see Section 6.3). This fragmented approach to understanding climate change associated impacts and risks is then reflected also in siloed approaches to risk management and adaptation financing (see Section 6.4). Recent literature notes that resilience planning has begun to overcome this tendency by presenting climate change impacts, losses and damages, and urban processes, as unfolding together in interacting and cascading pathways (Fraser et al., 2020; Eriksen et al., 2020) (Figure 6.2). The chapter reflects this change in the literature by presenting climate change impacts through a series of risk assessments, including by hazard type, through indirect impacts on: health or food security, key infrastructure systems, land-use and human mobility; water flows and on structural conditions, like poverty and justice in the city (see Sections 6.3 and 6.4). In a departure from AR5 we also consider the consequential interactions of climate risks, impacts, adaptation and climate mitigation (see also Cross Working Group Box URBAN in Chapter 6).

The IPCC 1.5°C Special Report commented that “The extent of risk depends on human vulnerability and the effectiveness of adaptation for regions (coastal and non-coastal), informal settlements, and infrastructure sectors (energy, water, and transport) (*high confidence*)” (Masson-Delmotte and Waterfield, 2018).We take this statement as a starting point for assessing the risks to cities, settlements and key infrastructure, with infrastructure extended as noted above. Risks from climate change are understood as the product of climate change associated hazards impacting on exposed and vulnerable people and assets (including biodiversity). Adaptation can in some cases reduce exposure and susceptibility and enable recovery and scope for transformation towards long-term equitable and sustainable development. Risks describe both present conditions and also future prospects. Direct attribution of hazards to climate change remains limited to temperature extremes and sea-level rise, though we consider all hydrometeorological hazards as systems associated with climate change processes.

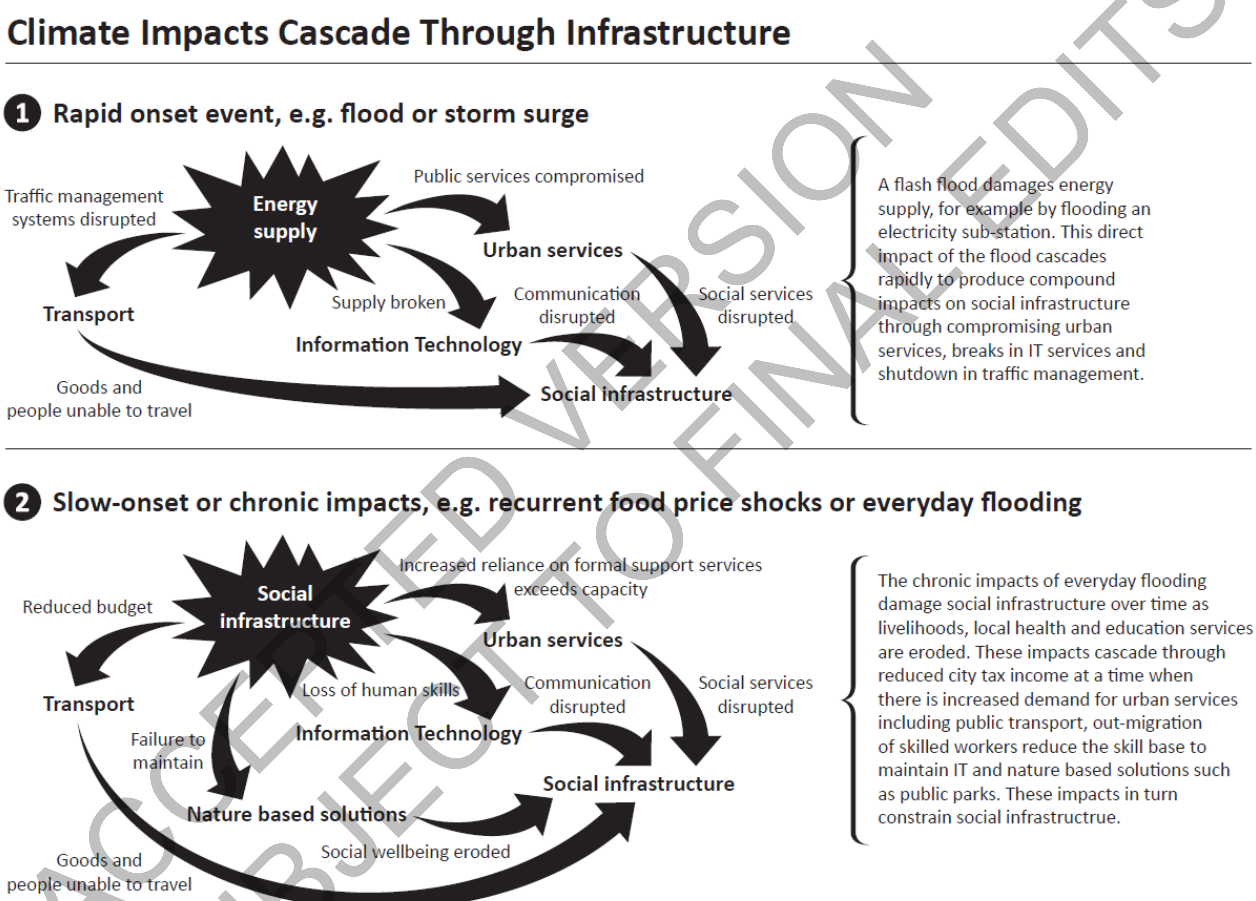

Figure 6.2: The interconnected nature of cities, settlements and infrastructure.

The chapter also assesses conditions supporting incremental and transformative adaptation (6.4). Incremental and transformative adaptation are both important but serve distinct roles in the interaction of urban systems, climate risk and risk management and in advancing social justice, just-transitions and climate resilient development (see 6.4). Climate resilient development pathways are an emerging concept in literature since the AR5 (Schipper et al., 2020). Climate resilient development is an iterative process of systemic change that integrates both mitigation and adaptation efforts (see Glossary). Initial studies highlight the way rapid urbanization and precarious urban housing and land tenure can undermine climate resilient development while human settlements that are managed to protect housing tenancy and land tenure rights, can advance land-use planning and social learning while reducing inequalities, and vulnerability, and enhancing resilient development (Mitchell, Enemark and Van der Molen, 2015; Bellinson and Chu, 2019; Ürge-Vorsatz et al., 2018). The benefits of integrating decision-making across scales for climate resilient development is also highlighted in 6.4. How households engage with communities and neighbourhoods and larger units within cities and how cities (both formal and informal) interact with sub national and national actors is also discussed as is the role of finance, and CBOs/NGOs in the governance process.

6.1.4 Global Urban Trends

Since AR5, many cities and other settlements, particularly unplanned and/or informal in Asia and Africa, have continued to grow at rapid rates (van den Berg , Otto and Fikresilassie 2021). Elsewhere, in Latin America in particular, while growth is less rapid, inequality persists. As a result, cities and settlements are crucial both as sites of potential action on climate change, and sites of increased exposure to risk (medium evidence, high agreement).

Patterns and trends for urban population growth were described in detail in AR5. Between 2015 and 2020, urban populations globally have grown by more than 397 million people, with more than 90 percent of this growth taking place in Less Developed Regions (UNDESA, 2018). The latest population projections from UNDESA (2018) reinforce the trends identified previously, with even higher estimates for global urban populations. The 2012 data used in AR5 projected a global urban population of 4,984 million in 2030 and 6,252 million in 2050; the 2018 revisions project 5,167 million and 6,680 million respectively. Particularly noteworthy is the higher projection provided for sub-Saharan Africa's urban population: increasing from 596 million to 666 million in 2030, and from 1,069 million to 1,258 million in 2050. These figures highlight the continued trend towards larger urban populations, and the particular significance of this in areas which currently have relatively small proportions of their populations living in towns and cities – this is also true in some Small Island States (e.g. Solomon Islands) (McEvoy et al., 2020). The proportion of the global urban population living in megacities (with populations of more than 10 million people) is expected to continue growing slowly (to 16% of the urban total, or 862 million people, living in 48 agglomerations) by 2035 (UNDESA, 2018). The size and form of these megacities presents particular challenges with climate change impacts, in areas including air quality (Baklanov, Luisa and Molina, 2016), flooding (Januriyadi et al., 2018), and temperature increase (Darmanto et al., 2019) (see 6.2.3).

While there are few analyses of urban trends at the global scale, an additional 2.5 billion people are projected to be living in urban areas by 2050, with up to 90 percent of this increase concentrated in the regions of Asia and Africa, particularly in India, China and Nigeria where 35 percent of this urban growth is projected to occur (UNDESA, 2018). Growth rates are slowing down in North America, South America and Europe (UNDESA, 2018). Much global growth continues to outstrip the ability of governments or the private sector to plan, fund and provide for sustainable urban infrastructure and this is most marked in low-income and informal settlements (Angel et al., 2016). Rural migration as a driver of urbanisation is discussed in 6.2.4.3, and literature has documented the way urban expansion, and the conversion of agricultural land is also driven by investment incentives and weak planning policies (Colsaet, Laurans and Levrel, 2018; Woodworth and Wallace, 2017). At the same time, early evidence suggests that – at least in some locations – out-migration from cities occurred as a result of the COVID-19 pandemic (Rajan, Sivakumar and Srinivasan, 2020) but the evidence is not clear and in some cases may have increased migration to other megacities (Chow et al., 2021). There is also growing recognition that poor planning has exacerbated the concentrated of deprivation in specific locations deepening a cycle of exclusion and marginalization (UNDESA, 2020).

One critical element of global urban trends, which has received growing attention is informality (see also Prieur-Richard, Walsh and Craig, 2019). Informality is one of the key defining features of cities and settlements in the Global South (See Glossary; Banks, Lombard and Mitlin, 2020; Myers, 2021; UNHABITAT, 2016). In almost all nations in the Global South, more than half the urban workforce work in informal employment; the proportions are particularly high in South Asia (82 percent in informal employment) and sub-Saharan Africa (66 percent) (Chen, Roever and Skinner, 2016; Chen, 2014). The term 'informal settlement' refers to urban settlements or neighbourhoods that developed outside the formal system that is meant to record land ownership and tenure and without meeting a range of regulations relating to planning and land use, built structures and health and safety. Informality is a broader concept than 'slums', which are usually defined using measures of housing quality, provision of services and overcrowding. While most countries do not generate formal statistics on the number of people living in informal settlements, UN Habitat provides regional and global estimates of the number of urban households that are 'slum' households and therefore likely to include most residents of informal settlements. These estimates suggest that there were 1034 million slum dwellers in 2018, including some 56 per cent of the urban population in sub-Saharan Africa and more than 30 percent of the urban population of South Asia (UN-Habitat, 2020). Informality is particularly important in understanding climate risks and responses in cities and settlements, and also in relation to key infrastructure (Trundle, 2020; Taylor et al., 2021).

Evidence since AR5 confirms that occupants of informal settlements are particularly exposed to climate events given low-quality housing, limited capacity to adapt, and limited or no risk-reducing infrastructure (*high confidence*) (Melore and Nel, 2020; Twinomuhangi et al., 2021; Satterthwaite et al., 2020; Patel et al., 2020a)(see 6.2 and case study). The impacts of COVID-19 are also increasingly impacting high-density informal and slum settlements where social distancing and access to water for handwashing are limited (Bhide, 2020; Pinchoff et al., 2021; Tagliacozzo, Pisacane and Kilkey, 2021; Wilkinson, 2020). This compounds pre-existing vulnerability to climate change associated hazards. Box 6.1 expands on trends in informality as part of global urbanism, peri-urbanization and suburbanization with implications for the global distribution of climate risks and adaptive capacity.

[START BOX 6.1 HERE]

Box 6.1: Planetary Urbanisation and Climate Risk

The scale, reach, and complexity of contemporary urbanization compounds climate risks and conditions adaptation (*high confidence*) (Miller and Hutchins, 2017; Rosenzweig et al., 2018b). Urbanization manifests as a heterogeneous and plural process with varied spatial manifestations (Oswin, 2018) that extends beyond cities and settlements, defining actions elsewhere in what has been called 'planetary urbanization' (Brenner, 2014b). While the concept of Planetary urbanisation is contested for example for a predominantly Eurocentric focus (Vegliò, 2021) the concept has reflected human urbanisation as a mega-trend of urban expansion and landuse intensification (Capon, 2017; Lauermann, 2018). Three dimensions of planetary urbanization are currently shaping adaptation actions: the new forms and scales of urbanization, the blurring of boundaries around clearly demarcated territories, and the fragmentation of the urban hinterland into units that serve productive functions for the reproduction of urban space under capitalism (Brenner and Schmid, 2017).

Planetary scale urbanization challenges current understandings of spatial settlements and how risk affects urban communities (*limited evidence, medium agreement*) (Ruddick et al., 2018). Massive urbanization manifests in large agglomerations such as metropolitan areas and urban regions, conurbations with unique risk challenges, particularly when interacting with other drivers of vulnerability (Adetokunbo and Emeka, 2015; Maragno, Pozzer and Musco, 2021). Experiences of regional collaboration to scale adaptation to metropolitan areas have shown to be effective, particularly facilitating information and technology exchanges and institutional cooperation (Shi, 2019; Lundqvist, 2016), but may face challenges such as addressing administrative and fiscal requirements and enrolling local populations in a meaningful participation process (Shi, 2019). For example, the coordination of planning policies in the Vienna-Bratislava metropolitan region, further divided by an international border, demonstrates that institutional coordination alone is not sufficient to deliver effective spatial governance: instead, meaningful spatial policies required the involvement of multiple actors (Patti, 2017). In addition to institutional coordination, adaptation in rapidly urbanizing areas requires understanding how these processes magnify risk and condition urban responses (see also 6.3).

Urban expansion processes affect human settlements everywhere, regardless of their size. Figure 6.1 represents a continuum of settlements from high to low-density areas (Ward and Shackleton, 2016). Urban and rural areas are not always clearly differentiated (Brenner, 2014a; Brenner and Schmid, 2017). For example, in 2010/2011, drought-exacerbated wildfires across Russia's agricultural hinterland not only led to increased air pollution in Moscow and other large cities in the region it also disrupted global supply chains of wheat and caused skyrocketing global food prices (Zscheischler et al., 2018). Floods in Bangkok, Thailand, in 2011 destroyed many foreign-owned factories, leading to a global shortfall in different types of IT equipment (Levermann, 2014).

Rural areas provide ecosystem services that benefit cities directly including thorugh reducing hazard (run-off, and temperature) and thorugh carbon storage – and can be maintained through urban markets and other inputs (Gebre and Gebremedhin, 2019). Most urban areas extend into dispersive peri-urban areas where urban and rural land uses coexist (Simon, 2016) and/or suburban areas which are lower density and primarily residential in function. Moreover, the urban and rural differentiation creates normative expectations at the heart of planning conflicts and constraints urban governance (Taylor, Butt and Amati, 2017). Expanding peri-urban areas pose specific structural constraints to addressing risks. In Bogotá, Colombia, a study found marked inequalities as more impoverished families had restricted access to peri-urban forests, trees, and tree services (Escobedo et al., 2015). Factors like limited land ownership and tenure insecurity in peri-urban areas hinder people's ability to invest in permanent infrastructure to buffer themselves from flood events, as witnessed in the slums in Nairobi (Thorn, Thornton and Helfgott, 2015). Building resilience and adaptation via community mobilization may not be effective in peri-urban areas shaped by migration, agricultural intensification, and industrialization (Wandl and Magoni, 2017).

At the same time, actions to improve access to peri-urban services almost always improve resilience (Simon, 2016) Evidence from Kampala, Addis Ababa, Dar es Salaam, Douala, Ibadan, Nairobi, Dakar and Accra shows that urban and peri-urban agriculture and forestry can support adaptation (Lwasa et al., 2014). In the metropolitan area of Milan, multifunctional agriculture supports a local, more sustainable food chain (Magoni and Colucci, 2017). Since communities in peri-urban areas are often transitory, efforts towards creating social capital by promoting civic engagement are crucial to facilitate collective action (Narain et al., 2017). For example, adaptation actions can help to build the capacity of the community to engage with service providers (Harris, Chu and Ziervogel, 2018; Ziervogel et al., 2017), as demonstrated in parts of peri-urban Kolkata, India, and Khulna, and Bangladesh (Gomes and Hermans, 2018; Gomes, Hermans and Thissen, 2018).

Urbanization on an immense scale blurs the boundaries that previously defined cities and settlements (Arboleda, 2016a; Shaw, 2015; Brenner, 2014a; OECD and European Commission, 2020; Schmid, 2018; Davidson et al., 2019; Wu and Keil, 2020). For example, peri-urban areas typically extend over multiple government jurisdictions (Wandl and Magoni, 2017). Adaptation actions can be difficult to plan, coordinate, implement and evaluate in these transboundary contexts (Solecki et al., 2018; Srivastava, 2020; Fünfgeld, 2015; Rukmana, 2020; Carter et al., 2018). In Medellín, Colombia, a 46-mile-long green belt is being built to stop urban expansion while also protecting urban forests, providing access to green spaces, and reducing urban heat island effects (Anguelovski et al., 2016). However, large-scale infrastructure projects like this one require coordination between regional transport authorities and the different municipalities in charge of housing and public services, in addition to consulting communities on their social impact (Chu, Anguelovski and Roberts, 2017). Local and regional authorities have competing mandates – such as a competition for taxpaying residents in peri-urban, commuting zones – and different infrastructure investment logics, political drivers, and constituent needs. Smaller discrete infrastructure projects that actively engage local populations may provide better opportunities to build resilience across fragmented spaces (Santos, 2017; Kamalipour and Dovey, 2020).

Suburbanization follows a gradual movement of citizens from high-density urban centres to the suburbs (Pieretti, 2014). Suburbanization generates new ways of appropriating space where, again, inequality (both in terms of limited access to access and limited capacity to respond to external changes) seems to be the main driver and a magnifier of its impacts (Keil and Macdonald, 2016). The development of enclaves for higher-income people, that appropriate resources and constraint the access to those resources for disadvantaged populations has been recorded in places as distant as Santiago de Chile, People's Republic of China, India, Indonesia, or the Philippines (Calvet and Castán Broto, 2016; Phelps, Miao and Zhang, 2020; Bulkeley, Castán Broto and Edwards, 2014; Buchori et al., 2021; Kleibert, 2018). The appropriation of land and resources in enclaves defends exclusive, privileged communities at the expense of everyone else. Enclaves exacerbate inequalities because those who cannot afford to live in the enclave suffer the fragmentation of public services, restrictions in access to resources, and greater exposure to climate risks (Hodson, 2010; Haase et al., 2017a). Moreover, suburbanization is linked to the privatization of public spaces and the decline of public infrastructures, collective spaces, and green projects (Long and Rice, 2019; North, Nurse and Barker, 2017). Climate gentrification, whereby vulnerable communities are displaced from urban areas with lower climate risks (UN-Habitat, 2020), reconfigures urban areas, for example, as higher-income populations move away from the city centers, as shown in North American cities that have already suffered climate-related impacts such as Miami, Philadelphia and New Orleans (Keenan, Hill and Gumber, 2018; Shokry, Connolly and Anguelovski, 2020; De Koning and Filatova, 2020; Aune, Gesch and Smith, 2020).

Urbanization leads to the spatial fragmentation of the hinterland, divided alongside functional units to serve the demands of the capitalist urban economy (Brenner and Schmid, 2017). Urbanization is thus linked to new intensities of resource exploitation that threaten vulnerable land and ecosystems, as shown in the Amazon and that extend across scales (Arboleda, 2016b; Wilson, 2018). The fragmentation of the hinterland for extractivist purposes depletes ecosystem services and further exacerbates cascading risks (*high confidence)* (Section 6.2.6).

[END BOX 6.1 HERE]

Adaptation and related concepts of urban climate resilience are also concerns for the broader agenda of sustainable development (Wachsmuth, Cohen and Angelo, 2016). Urban areas can play a positive role in advancing sustainability, but the pace and scale of urban development can also undermine progress in SDGs (Barnett and Parnell, 2016; Maes et al., 2019; Anarfi, Hill and Shiel, 2020) (*high confidence*). With careful planning, urbanization can be a transformative force, enhancing equity and wellbeing through co-benefits and synergies between climate change adaptation, equitable urban development and mitigation (*medium evidence, medium agreement*) (Parnell, 2016a; Solecki et al., 2015; Sharifi, 2020). Cities can be effective change agents when supported by networked local and national institutions including professional bodies (*high confidence*) (Andonova, Hale and Roger, 2017; Brandtner and Suárez, 2021; Heidrich et al., 2016; Kern, 2019; Farzaneh and Wang, 2020). Low Emission Development Strategies (LEDS) have developed effective science-policy interaction to support energy system, environmental, and economic development planning strategies in the city of Shanghai, China (Farzaneh and Wang, 2020). New literature is emerging about how adaptive changes at the urban level could integrate both far reaching rapid emission reduction and community protection in transformative ways (Wamsler and Raggers, 2018; Rosenzweig and Solecki, 2018; UN-Habitat, 2020; Ziervogel, 2019a). There is an increasing consensus about the need for integrated governance of urban areas within and across regions, so that urban risk management and adaptation happen hand in hand with more general processes of transition towards more sustainable urban regions (Simon, 2016; UN-Habitat, 2020).

Since AR5 there has also been increasing recognition of the contribution of diverse knowledges including local and Indigenous knowledge in contributing to the development and interpretation of urban relevant climate change data and policy for effective action (Klenk et al., 2017; Hosen, Nakamura and Hamzah, 2020; Makondo and Thomas, 2018). Indigenous and local knowledge inform coping strategies in urban adaptation planning and new directions for action (Nakashima, Krupnik and Rubis, 2018; Abudu Kasei, Dalitso Kalanda-Joshua and Tutu Benefor, 2019). Indigenous and local knowledge is also found to shape perceptions about urban climate risk awareness, its acceptable limits, causation and preferences for adaptation (see also Pyhälä et al., 2016 for a review; see Jaakkola, Juntunen and Näkkäläjärvi, 2018 for impacts on Indigenous peoples in the EU; Saboohi et al., 2019). Local perceptions about climate change in turn influence adaptation behaviours in settlements and urban communities (Lee et al., 2015; Larcom, She and van Gevelt, 2019). Engagement with Indigenous and local knowledge is an enabling condition for planning community-appropriate climate adaptation responses (Fernández-Llamazares et al., 2015). Urban decision-making that includes Indigenous and local knowledge has co-benefits for addressing Indigenous dispossession, historical inequities and marginalization of Indigenous values that occurred (Parsons et al., 2019; Carter, 2019; Maldonado et al., 2016; Orlove et al., 2014; Pearce et al., 2015). Indigenous and local knowledge can help deliver culturally appropriate strategies and local choices for urban risk management through, for example community-based observation networks (Alessa et al., 2016), integrating ecosystem-based adaptation strategies in institutional structures (Nalau et al., 2018), using Multiple Evidence-Based Approaches (Tengö et al., 2014), and adopting forms of governance that centre Indigenous peoples in urban adaptation and decision making (Horn, 2018; Parsons, Fisher and Nalau, 2016).

6.1.5 Changes in the Global Enabling Environment

This section reports on changes in global enabling environment – the architecture of international agreements available to inform policy for national governments and others on urbanization and climate adaptation, since the AR5.

Six new international agreements and initiatives have been achieved, each of which has far-reaching implications for the management of rapid urbanization and climate change: the Paris Climate Agreement (United Nations, 2015b); the 2030 Agenda for Sustainable Development including the Sustainable Development Goals (United Nations, 2015c); the Sendai Framework for Disaster Risk Reduction (UNISDR, 2015); the New Urban Agenda (United Nations, 2016a); Addis Ababa Action Agenda (July 2015) and the World Humanitarian Summit (May 2016). Table 6.2 summarises these.

Table 6.2: International policy agreements with implications for urbanization and climate adaptation

Agreement (date of agreement)	Scope of agreement	Relevance for cities, settlements and infrastructure	Relevance for addressing climate change risk
Sendai Framework for Disaster Risk Reduction (March 2015)	Global agreement for reducing disaster risks in all countries and at all levels. Highlights urbanization as a key driver of risk and resilience.	Identifies rapid urbanization as a key underlying risk factor for disasters and driver of resilience. Promotes shift from disaster response to disaster risk management & reduction through cooperation between national and local governments. Limited focus on the role of civil society.	Highlights the need to respond to systemic risk, including compound and cascading risks and impacts from natural, technological and biological hazards. Includes focus on chronic stressors and sudden shocks through governance, planning, disaster response, post-event recovery.
Addis Ababa Action Agenda (July 2015)	Global agreement arising from the International Conference on Financing for Development (United Nations, 2015a) emphasized the need for adequate financing at all levels of government, especially sub-national and local, to support sustainable development, infrastructure and climate mitigation (UN-Habitat, 2016b).	Includes general comments on the importance of local actors and recognises the need for strengthening capacities of municipal and local governments. Commits to "support" local governments to "mobilise revenues as appropriate". Offers little on how to get finance to support local governments addressing these commitments.	Financing a critical element of risk reduction in cities and settlements (see section 6.4). Underlying variability of institutional arrangements inhibits development of universal framework.
Transforming our world: the 2030 Agenda for Sustainable Development (September 2015)	Global agreement adopted by 193 governments that includes the 17 Sustainable Development Goals (SDGs)	SDG11 speaks explicitly to making cities "inclusive, safe, resilient and sustainable". Extensive reference to universal provision of basic services in other SDGs which will require substantial efforts in cities; equality and governance are also stressed. Focuses on national goals and national monitoring with insufficient recognition of key roles of local and regional governments and urban civil society in addressing most of the SDGs.	SDG13 on climate action requires action in cities and settlements. Integrated approach can address underlying drivers of risk.
The Paris Agreement (December 2015)	Global agreement under UN Framework Convention on Climate Change: signed by 194 and ratified by 189 member states (05/01/21)	References the role of the local or sub-national levels of government and cities as non-state actors.	Encourages cities to develop specific agendas for climate action (mitigation and adaptation).

The World Humanitarian Summit (May 2016)	Not an agreement, but a summit of 180 member states generating over 3,500 commitments to action & addressing the role of non-state actors in reducing risk of climate change related forced-displacement of people	Includes five agreed 'core responsibilities' with relevance for urban areas, and commitments were made by professional associations, non-governmental organizations and networks of local authorities to address these in towns and cities.	Climate change likely to shape flows of refugees and migrants who are likely to live in highly exposed areas, particularly in low-income cities. However "meagre funding for collaboration, poor data collection and sharing" (Acuto, 2016) limits commitment effectiveness (Speckhard, 2016).
The New Urban Agenda (October 2016)	Global agenda adopted at UN Conference on Housing and Sustainable Urban Development (Habitat III) Envisioned national urban policies and adaptation plans as a central device to inform subnational governments addressing sustainable development.	Intended as the global guideline for sustainable urban development for 20 years, seeking to provide coherence with other agreements. Focus on national policy and action. Limited recognition of urban governments or civil society as initiators and drivers of change. .	Clearly frames roles for cities within national and international systems in contributing to sustainability (including low-carbon development) and resilience (including adaptation). Frames the role for cities within national and international systems, including an ongoing assessment of their contribution to sustainability and resilience (Kaika, 2017; Valencia et al., 2019)

Alongside new international agreements are a series of new landmark global stocktake reports: three IPCC special reports including the IPCC 1.5 report (Pörtner et al., 2019; Shukla et al., 2019; Hoegh-Guldberg et al., 2018), the UN Environment GEO6 (UN Environment, 2019), IPBES 2019 (Brondizio et al., 2019), and UNDRR 2019 (UNDRR, 2019), each have argued for urgent action on climate mitigation and to invest in inclusive strategies for adaptation if the Sustainable Development Goals are to be met. These findings are comprehensively evidenced and do not need to be revisited here. Our starting point then is to assess the science on how inclusive, sustainable development can be delivered through enhanced adaptation to climate change risks.

As a blueprint for advancing human dignity, the Sustainable Development Goals emphasize the need to consider how to achieve a better and more sustainable future while 'leaving no one behind.' In doing so, they highlight an agenda focused on wellbeing, equality and justice. The objective for SDG11 is defined as: "Make cities and human settlements inclusive, safe, resilient and sustainable" with ten associated targets including ensuring access for all to adequate, safe and affordable housing and basic services; participatory planning; safeguarding heritage features; reducing disasters particularly water related disasters and economic impacts on the poor; and promoting resource efficiency, mitigation and adaptation to climate change, resilience to disasters, and develop and implement plans, in line with the Sendai Framework for Disaster Risk Reduction. Similarly SDG9 aims to build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation, with associated targets. The IPCC 1.5 special report emphasized that there are often cobenefits in pursuit of SDGs and adaptation strategies where "well-designed mitigation and adaptation responses can support poverty alleviation, food security, healthy ecosystems, equality and other dimensions of sustainable development" (Masson-Delmotte et al., 2018 FAQ 5.1). However there may also be negative trade-offs for example between pursuit of growth and reducing climate change risk (International Council for Science, 2017; Masson-Delmotte et al., 2018 Executive Summary; Roy et al., 2018).

The Paris Agreement also envisioned a significantly more active role for cities and other non-state actors in facilitating policy change (Hale, 2016) including through participation in Nationally Determined Contributions (NDCs), although there is little systematic review of the contributions made by cities to NDCs (Hsu et al., 2020; Bäckstrand and Kuyper, 2017). Over two-thirds – 113 out of 164 – of initial Intended Nationally Determined Contributions, prior to ratification, had referenced urban responses in the context of sustainable development, climate mitigation and adaptation (UN-Habitat, 2016a). Analysis of those INDCs revealed 58 focused on urban climate adaptation, 17 focused on both adaptation and mitigation, and 4 focused on mitigation (UN-Habitat, 2017). Simultaneously, multiple efforts have emerged to align the actions of nation states with those of other actors, including the UNFCC 2014 Global Climate Action Portal (Hsu, Weinfurter and Xu, 2017). While significant optimism has been gathered around the possibility to intervene at subnational level, the most difficult challenge has been to establish a coherent view of the overall contribution that cities and settlements are making (Hale, 2016; Chan et al., 2015b). Although meeting the Paris goals will require staying within a 'carbon budget', supporting rapidly developing urban areas in the Global South to the same infrastructure level as developed cities, may consume significant proportions of that budget (Bai et al., 2018).

There is increasing international effort amongst non-Party stakeholders to the Paris Climate Agreement to collaborate to meet the Paris Climate goals (Data Driven Yale New Climate Institute PBL, 2018; Chan et al., 2015a). A review of contributions by non-state actors in 2019 by the EU Covenant of Mayors identified 10427 cities with climate commitments, while the Global Covenant of Mayors included 10543 cities representing a population of 969 million citizens (Palermo et al., 2020; Peduzzi et al., 2020). International efforts also include the United Nations Framework Convention on Climate Change (UNFCCC) Non-State Actor Zone for Climate Action (Data Driven Yale New Climate Institute PBL, 2018). There is also a proliferation of new non-governmental and public-private actors that address both adaptation and mitigation in cities and settlements, including: the C40 Cities Climate Leadership Group, 100 Resilient Cities; the Global Resilient Cities Network, We Mean Business, and We Are Still In (Ireland and Clausen, 2019) and the Global Alliance for Buildings and Construction (Dean et al., 2016). However, there is as yet limited research into the effectiveness of these initiatives in enhancing medium and small city adaptation and limited documentation of climate adaptation actions by non-traditional agents, particularly in the Global South (Lamb et al., 2019).

New urban activists and stakeholders including youth, and Indigenous and minority communities and Non-Governmental Organizations alongside business groups have also been visible in the global urban climate debate, pressing for faster, more far reaching change (Frantzeskaki et al., 2016; O'Brien, Selboe and Hayward, 2018; Alves, Campos and Penha-Lopes, 2019; Smith and Patterson, 2018; Crnogorcevic, 2019; Campos et al., 2016; Hayward, 2021). Emergent urban social movements for climate justice often build on established international networks including local activists such as Shack and Slum Dwellers International while others are inspired by indigenous movements and are focused on human rights, indigenous sovereignty and land claims, and access to water, intergenerational justice, and gender and youth movements coordinated on social media (Agyeman et al., 2016; Cohen, 2018; Ulloa, 2017; Hayward, 2021; Prendergast et al., 2021). The emergence of climate justice movements in urban communities has the potential to reframe policy discussion in cities in ways that also bring inequality and climate justice to the fore (Sheller and Urry, 2016) underscoring growing public calls for more far-reaching, transformative changes towards socially just urban transformations (Akbulut et al., 2019; Foran, 2019; Vandepitte, Vandermoere and Hustinx, 2019; Smith and Patterson, 2018).

This section demonstrates the consistency with which urban processes and places have been rising to the top of international agreements and agendas in the last 10 years (Bulkeley, 2015; van der Heijden et al., 2018; Knieling, 2016). However, many cities, particularly smaller cities and informal settlements in the Global South where development is rapid, need greater support for local governance, more information, and more diverse sources of finance to meet the vision of global climate agreements (Greenwalt, Raasakka and Alverson, 2018; Cohen, 2019). Moreover, the response of many cities to climate change is often constrained by wider political, social and economic structures, development path dependences and high carbon lock-in (Princeti, 2016; Johnson, 2018; Jordan et al., 2015).

6.2 Impacts and Risks

This section assesses the impacts of hazards associated with climate change that will affect cities, settlements and key infrastructure, particularly how climate systems and urban systems interact to produce patterns of risk and loss. The conclusions of the IPCC Special Report on Global Warming of 1.5°C noted that "Global warming of 2°C is expected to pose greater risks to urban areas than global warming of 1.5°C (*medium confidence*)."

This section commences with a review of scenarios and pathways linking urban and infrastructural development with climate change; then assesses the key risks (with a focus on those for which there is a greater degree of evidence or confidence since AR5) and how these risks are created in urban settings. It then assesses evidence on the differentiated nature of human vulnerability and the risks affecting key infrastructure. Finally, this discussion reviews compound and cascading risks, and risks created by adaptation actions.

6.2.1 Risk Creation in cities, settlements, and infrastructure

In addition to direct climate impacts, interactions between changing urban form, exposure and vulnerability can create climate change-induced risks and losses for cities and settlements. Climate change already interacts with on-going global trends in urbanization to create regionally specific impacts and risk profiles. Through demographic change and encroachment into natural and agricultural lands and coastal zones, rapidly expanding urban settlements can place new physical assets and people in locations with high exposure (Tessler et al., 2015; Arnell and Gosling, 2016; Kundzewicz et al., 2014). Increasing rates of global urbanization will pose additional challenges to areas that have high levels of poverty, unemployment, informality, and housing and service backlogs (Jiang and O'Neill, 2017; Williams et al., 2019). There is some evidence to suggest that climate change impacts themselves are increasing urbanization rates generating a challenging feedback loop. In Sub-Saharan Africa, for example, manufacturing towns have experienced growth due to population movement following droughts in agricultural hinterlands (Henderson, Storeygard and Deichmann, 2017). The rapid rate of urbanization therefore presents a time-limited opportunity to work towards risk reduction and transformational adaptation in towns and cities. The following sections explore these dynamic interactions between urban systems and climate change, and how these shape risk for people and for key infrastructures.

Examining projected climate change impacts and resulting risks in cities, settlements and key infrastructures requires the prerequisite development of scenarios which are plausible descriptions of how the future may develop based on a coherent and internally consistent set of assumptions about key driving forces, (e.g., rate of technological change, prices and relationships) and pathways or the temporal evolution of natural and/or human systems, such as demographic and urban land cover change, towards a future state or states ((Gao and O'Neill, 2020; Gao and O'Neill, 2019); see also 6.1.5).

Climate change research creates scenarios integrating emissions and development pathways dimensions (Ebi et al., 2014; van Vuuren et al., 2017b; van Vuuren et al., 2017a) and Representative Concentration Pathways (RCPs) (Riahi et al., 2017). For risk reduction at regional scales, scenarios require urban-relevant climate projections e.g. downscaling from global and regional climate models of variables such as temperature, precipitation, air pollutants, and sea level rise that are analyzed usually for mid- or end-21st Century timeframes (e.g. Mika et al., 2018; Kusaka et al., 2016; Masson et al., 2014b). These data are needed to ascertain likely ranges of climate change impacts within city and settlement boundaries, and to quantify physical exposure when developing pathways for risk reduction. Consideration of current and projected future growth pathways of multiple urban sectors and key infrastructure e.g. transport, energy, and buildings, are also needed to estimate probabilities of risk outcomes and damages within and across urban systems (O'Neill et al., 2015)(WGIII AR6 Chapter 8).

The challenges of managing these risks are amplified by the complex interactions between climate and urban scenarios, due to the smaller spatial-temporal scales of urban areas in climate change modelling relative to Global Climate Models (GCM) and Shared Socioeconomic Pathways (SSP); geographical or geomorphological variations in city location; uncertainties arising from incomplete assumptions about socio-economic pathways at urban scales affecting urban demographics e.g. fertility rates and life expectancies, or increased rural-urban migration; and challenges in modelling the urban climate and in developing urban climate observational networks in cities (WGI Box 10.3; (Kamei, Hanaki and Kurisu, 2016; Yu, Jiang and Zhai, 2016; Jiang and O'Neill, 2017; Baklanov et al., 2018). Additionally, carbon-intensive economic growth, increasing inequalities, global pandemics, and uncontrolled or unmanaged urbanization will exacerbate the exposure and vulnerability of urban systems modelled in existing climate scenarios and pathways *(high confidence*) (Phillips et al., 2020a; Jackson, 2021; Raworth, 2017; Moraci et al., 2020). Mitigating these outcomes requires new forms of urban governance for climate adaptation, disaster risk reduction, and building resilience (see Section 6.4).

Strong connections exist between climate change scenarios and urban climate-related risks. In some cases, the linkage is direct as climate change is associated with more frequent and more intense extreme weather and climate events as assessed in Section 6.2.3. In other contexts, the connection is mediated by urban developmental pathways arising from local-scale environmental stresses and degradation, and access to adaptation options as reviewed in Section 6.2.4.

6.2.2 Dynamic Interaction of Urban Systems with Climate

Urban systems interact with climate systems in multiple, dynamic and complex ways (Section 6.1.1, WG1 Box 10.3). Climate change can have direct impacts on the functioning of urban systems, while the nature of those systems plays a substantial role in modifying the effects of climate change (*high confidence*) (Frank, Delano and Caniglia, 2017; Smid and Costa, 2018). An example of this urban system-climate nexus is the urban heat island effect (discussed in in section 6.2.3.1) (Susca and Pomponi, 2020). Assessing the inter-relationships between multiple systems and a range of hazards is particularly important, as many cities are presently exposed to multiple climate-related hazards: more than 100 cities analyzed as part of a 571 city study in Europe were deemed vulnerable to two or more climate impacts (Guerreiro et al., 2018). Rapid expansion of urban areas increases the exposure of urban populations to various hazards independent of global climate change. Huang et al. (2019) project that urban land areas will expand by 0.6–1.3 million km^2 between 2015 and 2050, an increase of 78%–171% over the urban footprint in 2015. Specifically in relation to floods and droughts, Güneralp et al (2015a) calculate that even without accounting for climate change, the extent of urban areas exposed to flood hazards will increase 2.7 times between 2000 and 2030, the extent exposed to drought hazards will approximately double during this period, and urban land exposed to both floods and droughts will increase more than 2.5 times.

This section assesses observed and expected impacts from the main hazards identified for cities, settlements and infrastructure – temperature extremes (and the urban heat island), flooding (including sea-level rise), water scarcity and security – as well as other hazards that are either less well-studied and/or likely to affect only a limited number of locations. The data assessed in this section are limited by uneven coverage. Despite improvements since AR5, data continue to be more complete for extreme events than for chronic hazards and everyday risks - which may have high aggregate impacts and disproportionately erode the wellbeing of urban poor households, especially for the most vulnerable, including women, children the aged, disabled and homeless (van Wesenbeeck, Sonneveld and Voortman, 2016; Kinay et al., 2019; Connelly et al., 2018). Data coverage is also less comprehensive for smaller settlements in poorer countries – the locations where urban growth is often high and adaptive capacities are often low (e.g. Rufat et al., 2015). Thus, data gaps frequently coincide with highly vulnerable populations (Rufat et al., 2015; Satterthwaite and Bartlett, 2017). Here, even small changes in livelihoods, health, or representation and voice can rapidly bring households into positions of risk, even when hazard conditions are relatively stable (Ziervogel et al., 2017). These structural limits in available data are discussed also in chapters 7 (Health, wellbeing and the changing structure of communities) and 8 (Poverty, livelihoods and sustainable development), and WGI Box 10.3. There are implications also for Adaptation (Section 6.3) where the greater availability of evidence on exposure driven risk can limit resilience building interventions that focus on the reduction of vulnerability.

6.2.2.1 Temperatures and the Urban Heat Island

Higher temperatures associated with climate change, through warmer global average temperatures and regional heat wave episodes, will interact with urban systems in a variety of ways (WG1 Box 10.3). Future urbanization will amplify projected local air temperature increase, particularly by strong influence on minimum temperatures, which is approximately comparable in magnitude to global warming (*high confidence*) (WG1 Box TS14). Within cities exposure to heat island effects is uneven with some populations disproportionately exposed to risk including low income communities, children, the elderly, disabled, and ethnic minorities ((Quintana-Talvac et al., 2021; Sabrin et al., 2020; Chambers, 2020) and see later in this section).

The risks to cities, settlements and infrastructure from heat waves will worsen (*high confidence*) (Leal Filho et al., 2021) see also 6.2.5; 6.3.3.1, WG1 Box TS14). Depending on the RCP, between half (RCP2.6) to three-quarters (RCP8.5) of human population could be exposed to periods of life-threatening climatic conditions arising from coupled impacts of extreme heat and humidity by 2100 (Figure 6.3; (Mora et al., 2017b; Zhao et al., 2021)). Cities in mid-latitudes are potentially subject to twice the levels of heat stress compared to their rural surroundings under all RCP scenarios by 2050 e.g. Belgian cities (Wouters et al., 2017). A disproportionate level of exposure exists in subtropical cities subject to year-round warm temperatures and higher humidity, requiring less warming to exceed "dangerous" thresholds e.g. Nairobi (Scott et al., 2017) and São Paulo (Diniz, Gonçalves and Sheridan, 2020). It is expected that more than 90% of the 300 million people who will exposed to super- and ultra-extreme heatwaves in the Middle East and North Africa will live in urban centres (Zittis et al., 2021), while the major driver for increased heat exposure is the combination of global warming and population growth in already-warm cities in regions including Africa, India and the Middle East (Klein and Anderegg, 2021).

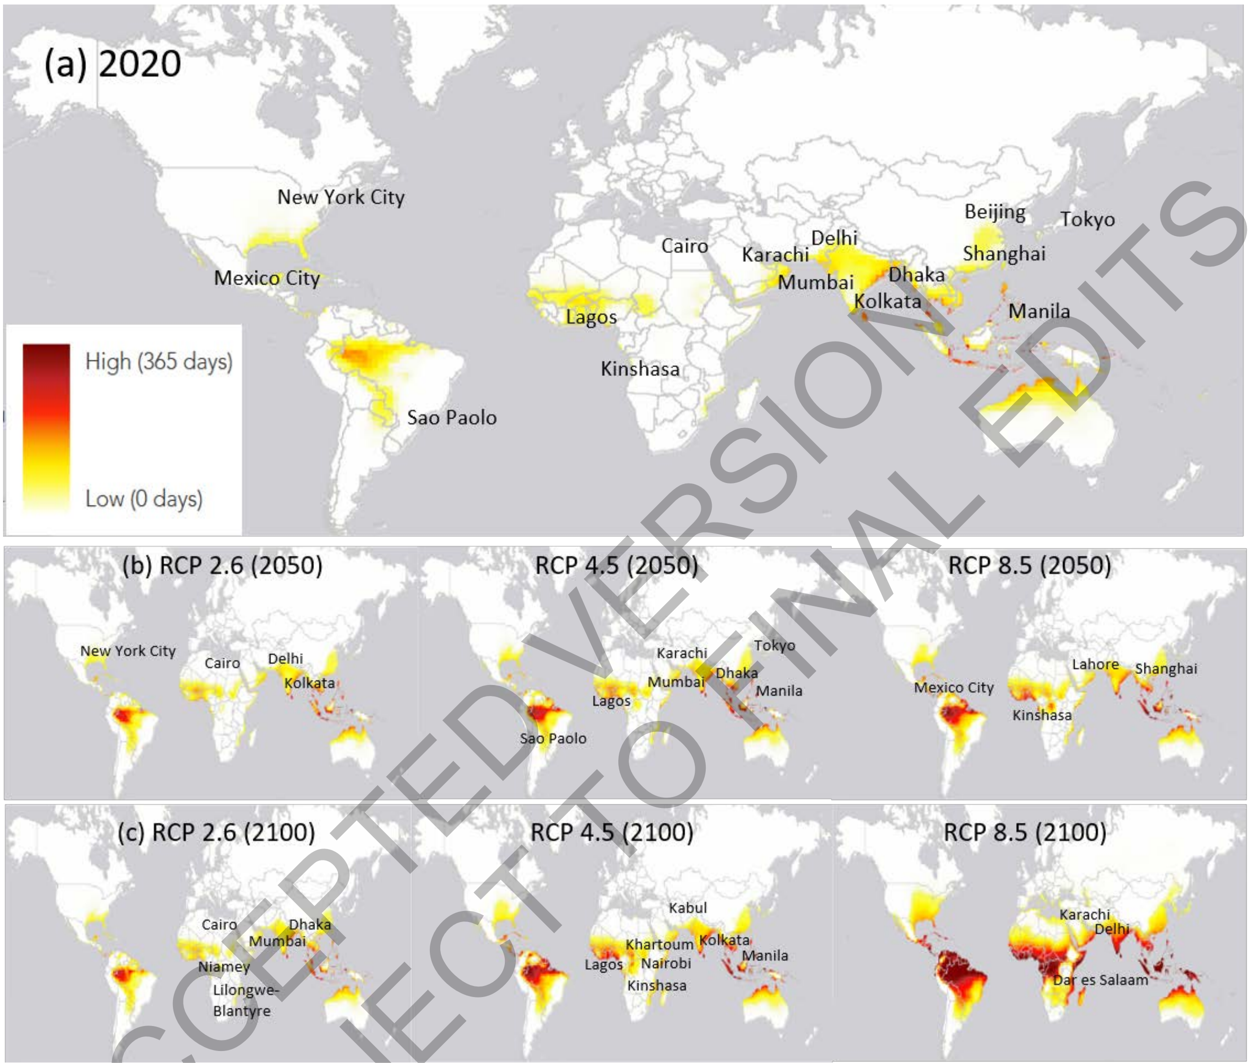

Figure 6.3 Global distribution of population exposed to hyperthermia from extreme heat for the present (a), and projections from selected Representative Concentration Pathways in (b.) mid-21st Century, and (c.) end 21st Century. Shading indicates projected number of days in a year in which conditions of air temperature and humidity surpass a common threshold beyond which climate conditions turned deadly and pose a risk of death (Mora et al., 2017b). Named cities are top fifteen urban areas by population size during 2020, 2050, and 2100 respectively as projected by Hoornweg and Pope (2017)

Locally, the urban heat island also elevates temperatures within cities relative to their surroundings. It is caused by physical changes to the surface energy balance of the pre-urban site from urbanization, resulting from the thermal characteristics and spatial arrangement of the built environment, and anthropogenic heat release ((Oke et al., 2017; Chow et al., 2014; Susca and Pomponi, 2020); WGI FAQ10.1). A considerable body of evidence exists on how the multi-scale impacts and consequent risks arise when local elevated temperatures within settlements are enhanced by climate change, with specific elements of this affecting megacities (Darmanto et al., 2019). The urban heat island itself is amplified during heat waves (Founda and Santamouris, 2017), but the extent to which varies regionally and by time of day (Ward et al., 2016a; Zhao et al., 2018b; Eunice Lo et al., 2020). When combined with warming induced by urban growth, extreme heat risks are expected to affect half of the future urban population, with a particular impact in the tropical Global South and in coastal cities and settlements ((Huang et al., 2019); CCP2.2.2; Table CCP2.A.1).

Heat risk is associated with a range of health issues for urban residents, with the consequences of higher urban temperatures being unevenly distributed across urban populations (*high confidence*). Clear evidence exists of increased health risks to elderly populations in settlements, especially higher levels of mortality in elderly populations from urban heat island during heat wave events (Fernandez Milan and Creutzig, 2015; Taylor et al., 2015; Ward et al., 2016a; Heaviside, Macintyre and Vardoulakis, 2017; Gough et al., 2019; Xu et al., 2020a), while health and fitness variables are also major determinants of the effects of heat stress (Schuster et al., 2017) (see also Table 7.2). Heat stress and dehydration are also related to behavioural and learning concerns, with dehydration impairing concentration and cognition for both adults and children (Merhej, 2019). Literature on pediatric heat exposure is associated with increases in emergency department visits for heat-related illnesses, electrolyte imbalances, fever, renal disease, and respiratory disease in young children (Winquist et al., 2016), with less severe outcomes such as lethargy, headaches, rashes, cramps, and exhaustion negatively affecting children in school and play environments (Vanos, 2015; Hyndman, 2017). Young children in cities are particularly sensitive to heatwaves, and may have little experience or capacity to cope with heat extremes (Norwegian Red Cross, 2019). Such vulnerability of young children to heat is compounded with projected urbanization rates and poor infrastructure, particularly in South Asian and in African cities (Smith, 2019). There is evidence that socioeconomically disadvantaged populations are more likely to live in hotter parts of cities associated with higher-density residential land-use in dwellings with less effective insulation built with poorer or older construction materials (Inostroza, Palme and de la Barrera, 2016; Tomlinson et al., 2011). Specific emerging risks for occupational and related heat illnesses are found in urban tropical or subtropical low-income and middle-income countries (Andrews et al., 2018; Green et al., 2019).

There is an emerging risk of diminished indoor thermal comfort due to climate change, evidenced by research into negatively affected thermal comfort indices and/or increased number of overheating hours under future emissions scenarios (*medium confidence)* (e.g. Liu and Coley, 2015; van Hooff et al., 2014; Vardoulakis et al., 2015; Dodoo and Gustavsson, 2016; Invidiata and Ghisi, 2016; Makantasi and Mavrogianni, 2016; Mulville and Stravoravdis, 2016; Taylor et al., 2016; Hamdy et al., 2017; Pérez-Andreu et al., 2018; Salthammer et al., 2018; Dino and Meral Akgül, 2019; Osman and Sevinc, 2019; Roshan, Oji and Attia, 2019). Decreases in thermal comfort and increases in overheating risks depends on building characteristics, such as thermal resistance, presence of solar shading, thermal mass, ventilation, orientation and geographical location (e.g. Liu and Coley, 2015; van Hooff et al., 2014; Vardoulakis et al., 2015; Dodoo and Gustavsson, 2016; Invidiata and Ghisi, 2016; Makantasi and Mavrogianni, 2016; Mulville and Stravoravdis, 2016; Taylor et al., 2016; Hamdy et al., 2017; Pérez-Andreu et al., 2018; Salthammer et al., 2018; Dino and Meral Akgül, 2019; Osman and Sevinc, 2019; Roshan, Oji and Attia, 2019; Alves, Gonçalves and Duarte, 2021). Most of these studies employed numerical simulations in which different climate scenarios were used to construct future climate data. In hot climates, energy-efficient buildings with high insulation values and high airtightness, which have insufficient protection from solar heat gains and/or limited ventilation capabilities, are generally more vulnerable to overheating than older buildings with lower insulation levels ((e.g. van Hooff et al., 2014; Vardoulakis et al., 2015; Makantasi and Mavrogianni, 2016; Mulville and Stravoravdis, 2016; Salthammer et al., 2018; Fisk, 2015; Hamdy et al., 2017; Fosas et al., 2018; Ozarisoy and Elsharkawy, 2019); see also WGIII 9.7 for building heat mitigation/adaptation links).

Higher urban temperatures result in lower labour productivity levels and economic outputs (*medium confidence*) ((Graff Zivin and Neidell, 2014; Yi and Chan, 2017; Houser et al., 2015; Stevens, 2017); see Section 8.2.1). Globally, urban heat stress is projected to reduce labour capacity by 20% in hot months by 2050 compared to a current 10% reduction (Dunne, Stouffer and John, 2013). Burke et al. (2015) demonstrate a non-linear relationship between temperature and global economic productivity, with potential global losses of 23% by 2100 due to climate change alone. In specific cases, Zander et al. (2015) estimate heat-related reductions in urban labour productivity in Australia to cost USD 3.6 to USD 5.1 billion per year, based on self-reported performance reduction and absenteeism amongst 1,726 workers in 2013–14[2]; while the high-temperature subsidies given in China at outdoor air temperatures above 35°C are projected to

[2] Paper provides figures in Australian dollars: $5.2–7.3 billion Australian dollars. Exchange rate correct July 2020.

increase to USD 35.7 billion per year after 2030 (compared to 5.5 billion USD per year for 1979–2005) (Zhao et al., 2016) [3].

Higher urban temperatures place unequal economic stresses on residents and households through higher utilities demand during warm periods, e.g. electricity in regions where air conditioning is predicted to become more prevalent, and due to medical costs associated with care for heat illnesses and related health effects, missed work, and other related impacts (*medium confidence*) (Jovanović et al., 2015; Liu et al., 2019; Schmeltz, Petkova and Gamble, 2016; Soebarto and Bennetts, 2014; Zander and Mathew, 2019; Zander et al., 2015). Such stresses are projected to increase in many regions associated with continuing global-scale climate change and urbanization (e.g. Véliz et al., 2017; Ang, Wang and Ma, 2017; Bezerra et al., 2021), although some of these effects in cold-climate cities are offset by reduced stresses in winter associated with urban heat island or rising temperatures more generally (see Section 6.2.2.4).

Thermal inequity can also be seen as a distributive justice risk (Mitchell and Chakraborty, 2018). There are often disproportionate increases of risk for individuals of lower socioeconomic status, especially migrants, from exposure to urban heat. These arise from inadequate housing, less access to air-conditioning, and occupations, such as manual labour and waste-picking, that exacerbate heat exposure (Chu and Michael, 2018; Santha et al., 2016). Research from South Africa has shown that housing occupied by poor communities regularly experience indoor temperature fluctuations that are between 4 and 5 °C warmer compared to outdoor temperatures (Naicker et al., 2017); while evidence from the United States indicates that historical housing policies – particularly the 'redlining' of neighbourhoods based on racially motivated perceptions – are associated with areas that are exposed to elevated land surface temperatures (Hoffman, Shandas and Pendleton, 2020).

Social surveys from temperate and tropical cities highlight the risk of reduced quality of life during heat events, including increased incidence of personal discomfort in indoor and outdoor settings, elevated anxiety, depression, and other indicators of adverse psychological health, and reductions in physical activity, social interactions, work attendance, tourism, and recreation (*high confidence*) (Chow et al., 2016; Elnabawi, Hamza and Dudek, 2016; Obradovich and Fowler, 2017; Wang et al., 2017; Wong et al., 2017; Lam, Loughnan and Tapper, 2018; Alves, Duarte and Gonçalves, 2016). Extreme heat may also have a cultural impact, for example affecting major sporting events, with negative impacts on the athletic performance (Brocherie, Girard and Millet, 2015; Casa et al., 2015) and the experience and health of spectators (Hosokawa, Grundstein and Casa, 2018; Kosaka et al., 2018; Matzarakis et al., 2018; Vanos et al., 2019).

6.2.2.2 Urban Flooding

Flood risks in settlements arise from hydrometeorological events interacting with the urban system, which exposes settlements to river (fluvial) floods, flash floods, pluvial (precipitation-driven) floods, sewer floods, coastal floods, and glacial lake outburst floods (Field et al., 2012). Sea level increase and increases in tropical cyclone storm surge and rainfall intensity will increase the probability of coastal city flooding (*high confidence*) (WG1 Box TS14). Globally, the increase in frequencies and intensities of extreme precipitation from global warming will *likely*[4] expand the global land area affected by flood hazards (*medium confidence)* ((Alfieri et al., 2018; Alfieri et al., 2017; Hoegh-Guldberg et al., 2018); Chapter 4.2.4.2). Mishra et al. (2015) noted that out of 241 urban areas, only 17% of cities experienced statistically significant increases in frequencies of extreme precipitation events from 1973-2012. In the future, there is some evidence that changes in high intensity short duration (sub-daily) rainfall in urban areas will increase *(limited evidence, medium agreement)* (Kendon et al., 2014; Ban, Schmidli and Schär, 2015; Abiodun et al., 2017).

[3] Paper provides figures in yuan: 250 billion yuan per year after 2030 (compared to 38.6 billion yuan per year for 1979–2005). Exchange rate correct July 2020.

[4] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

Flooding associated with sea level rise is addressed in more detail in CCP2, with detailed regional examples from Africa discussed in chapter 9.3. Coastal flooding associated with sea-level rise is exacerbated due to the significant number of people living in subsiding areas. As a result of this, the average coastal resident is experiencing (over the last two decades) rates of relative sea-level rise three to four times higher than typical estimates due to climate-induced changes (Nicholls et al., 2021). This process can also result in release of coastal waste into urban areas (Beaven et al., 2020).

Urban flooding risks are also increased by urban expansion, and land use and land cover change, which enlarges impermeable surface areas through soil sealing, impacting drainage of floodwaters with consequent sewer overflows (*high confidence*) (Arnbjerg-Nielsen et al., 2013; Ziervogel et al., 2016; Aroua, 2016; Kundzewicz et al., 2014). These risks are also driven by increasing societal complexity, urban developmental policy on flood control, and long-term economic growth (Berndtsson et al., 2019), including in mega-cities (Januriyadi et al., 2018). The increase in flood risk from urban development can be considerable; based on modelling of two RCP (4.5 and 8.5) scenarios, Kaspersen et al. (2017) noted flooding in four European cities could increase by up to 10% for every 1% increase in impervious surface area. Risks are also compounded by the location of settlements, with greater risks within cities located in low elevation coastal zones subject to sea level rise, potential land subsidence, and exposure to tropical cyclones (((Koop and van Leeuwen, 2017; Hoegh-Guldberg et al., 2018); see also CCP 2.2) and within informal settlements, where generally little investment in drainage solutions exists and flooding regularly disrupts livelihoods and disproportionately undermines local food safety and security for the urban poor ((Dodman, Colenbrander and Archer, 2017; Dodman et al., 2017; Kundzewicz et al., 2014); Chapter 5.4 and 5.8).

Future risks of urban flooding is increasing in conjunction with continued increases in global surface temperature (*high confidence*) (Pörtner et al., 2019; Winsemius et al., 2015; Kulp and Strauss, 2019; Hoegh-Guldberg et al., 2018). In particular, Asian cities are highly exposed to future flood risks arising from urbanization processes. Between 2000 and 2030, rapid urbanization in Indonesia will elevate flood risks by 76-120% for river and coastal floods, while sea level rise will further increase the exposure by 19-37% (Muis et al., 2015). In Can Tho, Vietnam, current urban development patterns put new assets and infrastructure at risk due to sea level rise and river flooding in the Mekong Delta (Chinh et al., 2017; Chinh et al., 2016). Flooding in urban areas is exacerbated both by encroachment of urban areas into areas that retain water, and by the lack of infrastructure such as embankments and flood walls, as is the case for large areas of Dhaka East (Haque, Bithell and Richards, 2020). Zhou et al. (2019) have also shown that for the city of Hohhot, China, the increase in impervious surfaces contributes between 2-4 times more to modelled annual flood risk compared to risk induced by climate change.

Global trends in surface water flooding are increasing, which poses risks to vulnerable urban systems depending on current adaptation measures to manage flooding impacts e.g. stormwater management, green infrastructure, and sustainable urban drainage systems (Molenaar et al., 2015). The economic risks associated with future surface water flooding in towns and cities are considerable. For example in the UK, expected annual damages from surface water flooding may increase by £60-200 million for projected 2-4°C warming scenarios; enhanced adaptation actions could manage flooding up to a 2°C scenario but will be insufficient beyond that (Sayers et al., 2015). Analyses conducted in South Korea suggests that future flood levels could exceed current flood protection design standards by as much as 70% by 2100, considerably increasing urban flood risk (Kang et al., 2016). Modelling of urban flood damage to in the Kelani River Basin in Sri Lanka showed increased frequency of flooding by 2030 could increase potential urban property damage by up to 10.2%" (Komolafe Akinola, Herath and Avtar, 2018). Urban flood impacts may also exacerbate health burdens (including disease outbreaks of malaria, typhoid and cholera), which are compounded by damage to medical facilities (e.g. damage to hospitals, and disruption of medicinal supply chains), as observed in urban areas of Ghana (Gough et al., 2019). In addition emerging research shows the cascading consequences of hazard events – in this case urban flooding - on other risks to wellbeing in ways that are particularly severe for the urban poor, including mental ill-health, incidents of domestic violence impacting children and women, chronic diseases, and salinity of drinking water ((Matsuyama, Khan and Khalequzzaman, 2020); Chapter 4.2.4.5; Chapter 6.2.4.2; Box 7.2; Chapter 8.4.5.2).

6.2.2.3 Urban water scarcity and security

Urban water scarcity occurs when gaps exist between supply and demand of available freshwater resources (Zhang et al., 2019). Urban water security requires a sustainable quantity and quality of water to meet community and ecosystem needs in a changing climate (Romero-Lankao and Gnatz, 2019; Allan, Kenway and Head, 2018; Huang, Xu and Yin, 2015; Chen and Shi, 2016). Risks arising from urban water scarcity worldwide are *very likely* increasing due to climate drivers (e.g. warmer temperatures and droughts) and urbanization processes (e.g. land use changes, migration to cities, and changing patterns of water use including over extraction of surface and groundwater resources) affecting supply and demand (*high confidence*) ((Allan, Kenway and Head, 2018; Crausbay et al., 2020; Haddeland et al., 2014; Pickard et al., 2017; De Stefano et al., 2015; Sun et al., 2019; Van Loon et al., 2016; Zhang et al., 2019); Chapter 4.2.4.4; See Box 8.6 for case study on 2018 Cape Town drought). Flörke et al. (2018) estimates that nearly a third of all major cities worldwide may exhaust their current water resources by 2050. Globally, projections suggest that 350 million (± 158.8 million) more people living in urban areas will be exposed to water scarcity from severe droughts at 1.5°C warming, and 410.7 million (± 213.5) at 2°C warming (Liu et al., 2018).

Decreased regional precipitation and associated changes in runoff and storage from droughts is exacerbating urban scarcity by impairing the quality of water available for its resource management in cities (*high confidence*). For example, less runoff to freshwater rivers can increase salinity, concentrate pathogens and pollutants that increases risks of urban water scarcity (Hellwig, Stahl and Lange, 2017; Jones and van Vliet, 2018; Leddin and Macrae, 2020; Lorenzo and Kinzig, 2020; Ma et al., 2020; Mosley, 2015; Zhang et al., 2019; van Vliet, Flörke and Wada, 2017) ; See also Box 6.2). Drought also changes the dynamics of groundwater pollution leading to increased environmental health risks when those sources are used for urban water supplies (Kubicz et al., 2021; Moreira et al., 2020; Pincetl et al., 2019). Changes in the nature of droughts e.g. hotter droughts (Herrera and Ault, 2017), snow droughts (Cooper, Nolin and Safeeq, 2016; Mote et al., 2016), or 'flash' droughts (Otkin et al., 2016; Otkin et al., 2018; Pendergrass et al., 2020) can exacerbate urban water scarcity exposing the limitations of engineered water infrastructure, designed to accommodate historical patterns of supply and demand (Gober et al., 2016; Ulibarri and Scott, 2019; Zhao et al., 2018a).

Risks of urban water scarcity and security are compounded by vulnerabilities such as service availability and quality of infrastructure to supply water for increased urban demand from in-migration to cities (*medium confidence*) (Ahmadalipour et al., 2019; Dong et al., 2020; Reynolds et al., 2019; Thomas et al., 2017; Mullin, 2020). Risks to local water security in cities are also exacerbated by drivers such as dependence on imported water resources from distant locales that may be exposed to additional drought risks (*high confidence)* (Ahams et al., 2017; Li et al., 2019b; Marston et al., 2015; Zhao et al., 2020; Zhang et al., 2020); from considerable projected urban expansion in drought-stressed areas e.g. across drylands of Western Asia and North Africa (Güneralp et al., (2015b); and by export of virtual water (i.e. export of water embedded in food and energy) from local sources to distant trading partners (Djehdian et al., 2019; D'Odorico et al., 2018; Fulton and Cooley, 2015; Rushforth and Ruddell, 2016; Verdon-Kidd et al., 2017; Vora et al., 2017).

Droughts interact and manifest in complex ways in interconnected urban areas that *likely* increase risks of urban water scarcity (Tapia et al., 2017; Rushforth and Ruddell, 2015). Urban interdependencies mean droughts in one region can limit water resources availability in another (e.g., Macao and Zhuhai, Hong Kong, Shenzhen in China, Singapore and Johor, and in cities in Pakistan and India, in the west and southwest USA) (Chuah, Ho and Chow, 2018; Gober et al., 2016; Srinivasan, Konar and Sivapalan, 2017; Zhang et al., 2019; Zhao et al., 2020). Likewise, physical and social teleconnections mean decisions made about water resources in one region or location may impact another in unexpected ways (Moser and Hart, 2015; Liu et al., 2015).

Urban water security risks are confounded by inequities in economic opportunity, risk exposure, and human well-being (*medium evidence*)((Sena et al., 2017; Stanke et al., 2013); Chapter 4.2.4.5). Water scarcity is felt more acutely among low-income compared to high-income populations (Nerkar et al., 2016), and scarcity on top of inequities and political instability can lead to security issues e.g. conflict between different water users (Cosic et al., 2019; von Uexkull et al., 2016; Ahmadalipour et al., 2019; Döring, 2020; Ide et al., 2021), particularly when road infrastructures and access to water are limited (Detges, 2016; Sena et al., 2017). Scarcity risks may also be exacerbated by human and ecosystem needs in water short years (Srinivasan, Konar and Sivapalan, 2017). Finally, growing populations along with migration into water scarce regions can exacerbate water security issues (Akhtar and Shah, 2020; Singh and Sharma, 2019).

6.2.2.4 Other dynamic interactions

A range of other dynamic climate interactions are relevant for cities, settlements, and infrastructure: cold spells, landslides, wind, fire, and air pollution.

Cold spells. Although frequencies and intensities of cold spells/cold waves are *virtually certain* to have decreased globally, and are projected to consistently decrease for most warming levels (*high confidence*); WGI Table 11.2), cold weather events can periodically occur and impact urban areas and their connected infrastructures. For cities in eastern Canada, the intra-annual distribution of freezing rain events may become more frequent from December-February, and less frequent in other months by 2100 (Cheng, Li and Auld, 2011). Freezing rain is also a risk to urban populations and infrastructure. In general, higher population mortality rates *likely* occur during the winter season, while more temperature-attributable deaths are caused by cold than by heat in cities located in temperate climates (Gasparrini et al., 2015; Chen et al., 2017; Ryti, Guo and Jaakkola, 2016). Winter mortality is unlikely to significantly decrease due to warming trends, partly because a range of other medical factors (e.g. influenza seasons, and elevations in cardiac risk factors) also drive this winter-excess mortality (Kinney et al., 2015). However, the evidence is unclear whether mortality related to cold waves will decrease in coming decades in European (Smid et al., 2019), or United States cities (Wang et al., 2016). While projected global cold extremes are expected to decrease in frequency and intensity, the higher regional variability of future climates means that cold waves may remain locally important threats, including in milder regions where there are larger temperature differences between 'normal' winter days and extreme cold events, and where there is less capacity to adapt (Ma, Chen and Kan, 2014; Ho et al., 2019). This will be accentuated in many cities, particularly in Europe, by anticipated demographic changes that result in a more elderly population susceptible to cold wave health risks (Smid et al., 2019).

The effects of cold waves on the energy sector include breakdowns in power plants and reduced oil and gas production (Jendritzky, 1999), and failures in overhead power lines and towers leading to outages in Moscow and Bucharest (Panteli and Mancarella, 2015; Andrei et al., 2019). Six major power outages associated with cold shocks and ice storms have been recorded since 2010, the majority recorded from large cities the US (Añel et al., 2017). Cold waves can also significantly increase energy demand. A cold wave that affected the Iberian Peninsula in January 2017 caused electricity prices to peak at a mean price of 112.8 €/MWh, the highest ever recorded in Spain (AEMET, 2017).

Landslides. While geomorphological events (e.g. land subsidence from permafrost thaw at high latitudes or from groundwater extraction), and factors associated with the built environment (e.g. settlement location adjacent to steep slopes, and zonation laws for building construction) are major factors determining urban landslide risk, these can also be influenced by a range of climatic variables, namely precipitation (frequency, intensity and duration), snow melt and temperature change. Some 48 million people are exposed to landslide risk in Europe alone, with the majority in smaller urban centres (Mateos et al., 2020). Travassos et al. (2020) also documented all landslide deaths in the São Paulo Macro Metropolis Region from 2016-2019 occurred from extreme rainfall events in vulnerable areas prone to landslides. An increase in the number of people exposed to urban landslide risks is projected for landslide-prone settlements lying within regions projected to experience corresponding increase in extreme rainfall (Gariano and Guzzetti, 2016). In addition, human factors such as expansion of towns onto unstable land and land use changes within settlements (e.g., road building, deforestation) are increasing human exposure to landslides, and the likelihood of landslides occurring (Kirschbaum, Stanley and Zhou, 2015). Rainfall triggered landslides kill at least 5000 people per year, and at least 11.7% of these landslides occurred on road networks (Froude and Petley, 2018). Although the spatial footprint of an individual landslide might be small (i.e., <1km^2), the 'vulnerability shadow' cast over an area in terms of regional transport network disruptions can be a significant proportion of a region, and cascade to other infrastructures (Winter et al., 2016).

Landslides tend to occur on moderate to steep slopes, and are thus particularly prevalent in mountainous regions which are also characterised by low infrastructure redundancy (i.e., few alternative routes) and increased impacts from climate change (Schlögl et al., 2019). More robust forecasts of landslides driven by climate risk requires (a) more complete long-term records of previous landslides and (b) baseline studies of the Global South which are currently missing from the literature (Gariano et al., 2017).

Wind. Urban morphology alters wind conditions at multiple spatial scales; generally, increased surface roughness in settlements have resulted in declining trends in both measured wind speed and frequency of extremely windy days ((Mishra et al., 2015; Peng et al., 2018; Ahmed and Bharat, 2014); WGI Box 10.3). Urban wind risks can also be affected by city location adjacent to mountains, lakes, or coasts with localised wind systems (WGI 10.3.3.4.2; WGI 10.3.3.4.3). In large cities with significant urban heat island, an urban-driven thermal circulation can enhance pollution dispersion under calm conditions (Fan, Li and Yin, 2018) or advect heat to areas downwind of the city (Bassett et al., 2016). Microscale wind conditions within urban canyons also strongly affect ventilation of air pollution dispersion and thermal comfort at pedestrian level, especially in cities located in warm climates (Rajagopalan, Lim and Jamei, 2014; Middel et al., 2014; Lin and Ho, 2016).

In cities, wind risks from climate change hazards can arise from increased exposure from the expanding built environment. Very high wind speeds associated with severe weather systems e.g. tropical cyclones or derechos can cause significant structural damage to buildings and key infrastructure with insufficient wind load, as well as causing human injury through flying debris (Burgess et al., 2014). In particular, there is evidence from North American cities that tornado damage are *likely* fundamentally driven by growing built-environment exposure (*medium confidence*) (Ashley et al., 2014; Rosencrants and Ashley, 2015; Ashley and Strader, 2016).

Extreme winds in urban areas can have particularly damaging effects on poorly constructed buildings, including low-income houses in African cities (Okunola, 2019), as well as on urban trees that may be uprooted by strong wind gusts from downbursts (Ordóñez and Duinker, 2015; Pita and de Schwarzkopf, 2016; Brandt et al., 2016), and on disrupting transportation along urban road and railway networks (Koks et al., 2019; Pregnolato et al., 2016).

Fire. Hotter and drier climates in several regions e.g. Australia, the Western United States, the Mediterranean, and Russia (Masson-Delmotte and Waterfield, 2018), *likely* enable weather conditions driving fire events impacting cities within these regions (Chapter 2.4.4.2, 2.5.5.2). These include wildfires along the margins where cities are adjacent to wildlands i.e. the wildland-urban interface (WUI) (Bento-Gonçalves and Vieira, 2020; Radeloff et al., 2018), or fires in cities with a high degree of informal settlements having greater vulnerability to fire hazards ((Kahanji, Walls and Cicione, 2019; Walls and Zweig, 2017); Chapter 8.3.3.2). This vulnerability is considerable; over 95% of urban fire related deaths and injuries occur within informal settlements in in low- and middle-income countries (Rush et al., 2020).

For wildfires at the WUI, anthropogenic climate change, natural weather variability, expansion of human settlement and a legacy of fire suppression are key factors in determining fire risk (Abatzoglou and Williams, 2016; Knorr, Arneth and Jiang, 2016; van Oldenborgh et al., 2020). Recent wildfires in Australia and in California both occurred under hot and dry weather conditions exacerbated by climate change, and resulted in substantial property damage along the WUI, ecosystem destruction, and lives lost (Brown et al., 2020; Lewis et al., 2020; Yu et al., 2020). Future climate risk of fires at the WUI are *likely* (*medium confidence*), and are compounded by projected urban development along WUI within several regions, such as in the Western United States (Syphard et al., 2019), Australia (Dowdy et al., 2019) and the Bolivian Chiquitania (Devisscher et al., 2016).

Air Pollution. Despite recent observed improvements in air quality arising from COVID-19 restrictions (Krecl et al., 2020); WGI Cross-Chapter Box 6.1), significant risks to human health in cities leading to premature mortality *very likely* arise from exposure to decreased outdoor air quality from a combination of biogenic (e.g. wildfires at the WUI that advect into the urban atmosphere; (Reddington et al., 2014); WGI Chapter 12 Box 12.1), and anthropogenic sources that are influenced by climate change (e.g. fine particulate matter such as $PM_{2.5}$, tropospheric ozone, oxides of nitrogen, and volatile organic compounds)((Burnett et al., 2018; Knight et al., 2016; Turner et al., 2016; West et al., 2016; Chang et al., 2019b; Li et al., 2019a; Alexader, Luisa and Molina, 2016); WGI Chapter 6.7.1.1, 6.7.1.2). Risks of premature mortality from indoor air pollution in cities, arising from biomass burning for heating in winter or cooking, indoor pesticide use, or exposure to volatile organic compounds from poor thermal insulation in buildings, are also *likely* to occur ((Leung, 2015; Peduzzi et al., 2020); Cross-Chapter Box HEALTH in Chapter 7).

The mortality risk for several pollutants, e.g. $PM_{2.5}$, is considerable (*high confidence*). Current estimates indicate that 95% of global population live in areas where ambient $PM_{2.5}$ exceeds the WHO guideline of annual average exposure of 10 µg m^{-3} (Shaddick et al., 2018a; Shaddick et al., 2018b; Chang et al., 2019b). Among the 250 most populous urban areas, estimated $PM_{2.5}$ concentrations are generally highest in cities in Africa, South Asia, the Middle East, and East Asia; $PM_{2.5}$ in many cities in North Africa and the Middle East is *likely* due mainly to windblown dust, whereas that in South Asia and East Asia are mainly anthropogenic in origin (Anenberg et al., 2019). However, data on $PM_{2.5}$ concentrations are unavailable in many cities in low- and middle-income countries due to a lack of measurements (Martin et al., 2019).

For some air pollutants e.g. concentrations of $PM_{2.5}$ in several United States, Western European, and Chinese cities have recently decreased as a result of clean air regulations that have controlled emissions from sources such as motor vehicles, fossil fuel power plants, and major industries (Zheng et al., 2018a; Fleming et al., 2018). These decreases have brought substantial improvements in public health in settlements within these regions (Ciarelli et al., 2019; Zhang et al., 2018). In South Asia, Southeast Asia, and Africa, however, concentrations of other air pollutants e.g. tropospheric ozone, oxides of nitrogen, and volatile organic compounds are *likely* to continue to grow and peak by mid-century before they subside due global urbanization assumptions embedded in the SSPs (WGI Chapter 6.2.1; 6.7.1). Broadly, future air pollutant emissions are projected to decline globally by 2050 as societies become wealthier and more willing to invest in air pollution controls, but the trajectories vary among pollutants, world regions, and scenarios (Silva et al., 2016b; Rao et al., 2017; Silva et al., 2016c). Whereas cities in East Asia and South Asia currently have large exposure to anthropogenic air pollution, African cities may emerge by 2050 as the most polluted because of growing populations and demand for energy, increased urbanization, and relatively weak regulations to control emissions (Liousse et al., 2014).

Studies modelling climate change impacts on air quality find that the spatiotemporal patterns of concentration changes vary strongly at urban scales, and that often those patterns differ among the different years modelled due to internal variability (Saari et al., 2019), and different models used (Weaver et al., 2009). Changes in $PM_{2.5}$ due to climate change are less clear than for ozone, and may be relatively smaller (Westervelt et al., 2019), as climate change can affect $PM_{2.5}$ species differently (Fiore, Naik and Leibensperger, 2015). For Beijing, climate change is expected to cause a 50% increase in the frequency of meteorological conditions conducive to high $PM_{2.5}$ concentrations (Cai et al., 2017). The impacts of future climate change on air quality and consequent risks on human health have been studied at urban (Knowlton et al., 2004; Physick, Cope and Lee, 2014) and national scales (Fann et al., 2015; Orru et al., 2013; Doherty, Heal and O'Connor, 2017); globally, these studies have found a *likely* net increased risk of climate change on air pollution-related health (*low confidence*). They have focused mainly on the US and Europe with few studies elsewhere (Orru, Ebi and Forsberg, 2017), although the relationship between climate and air quality in megacities is particularly complex (Baklanov, Luisa and Molina, 2016). Silva et al. (2017) found that global premature mortality attributable to climate change (and not from urbanisation) from ozone and $PM_{2.5}$ will increase by about 260,000 deaths per year in 2100 under RCP8.5 , but substantial variance in results exists between individual models.

6.2.3 Differentiated Human Vulnerability

Evidence from urban and rural settlements is unambiguous; climate impacts are felt unevenly, with differentiated human vulnerability leading to uneven social, spatial and temporal loss, risk and experiences of resilience - including capacity for transformation (high confidence) (Woroniecki et al., 2019; Tan, Xuchun and Graeme, 2015; Simon and Leck, 2015; Long and Rice, 2019; Chu, Anguelovski and Roberts, 2017; Borie et al., 2019). The evidence is also clear that for those with fewest resources and already constrained life chances, losses from climate change associated events reduce wellbeing and exacerbate vulnerability (high confidence) (van den Berg and Keenan, 2019; Kashem, Wilson and Van Zandt, 2016; Michael, Deshpande and Ziervogel, 2018). Human vulnerability is influenced by the adaptive capacity of physical (built) structures, social processes (economic, wellbeing and health) and institutional structures (organisations, laws, cultural and political systems/norms) (see 6.4). This section should be read in conjunction with Chapter 8 (Poverty, livelihoods and sustainable development) and will emphasise urban processes that lead to the creation of differential vulnerability, risks and impacts.

6.2.3.1 Urban Poverty and Vulnerability

In both developed and less-developed regions, poverty in urban areas is frequently associated with higher levels of vulnerability (Huq et al., 2020b). This is evident in both rural and urban settlements in a wide range of contexts, including the Philippines (Porio et al., 2019; Valenzuela, Esteban and Onuki, 2020), Bangladesh (Matsuyama, Khan and Khalequzzaman, 2020), Brazil (Lemos et al., 2016), Santiago, Chile (Inostroza, Palme and de la Barrera, 2016) and New York City (Madrigano et al., 2015).

For individuals in urban communities, new literature highlights how differences in vulnerability established by social and economic processes are further differentiated by household and individual variability and intersectionality (Kaijser and Kronsell, 2014; Kuran et al., 2020).This includes differences in wealth and capacity (Romero-Lankao, Gnatz and Sperling, 2016); gender and non-binary gender (Michael and Vakulabharanam, 2016; Sauer and Stieß, 2021; Mersha and van Laerhoven, 2018); education, health, political power and social capital (Lemos et al., 2016); age, including young and elderly, low physical fitness, pre-existing disability, length of residence and social and ethnic marginalization (Inostroza, Palme and de la Barrera, 2016; Schuster et al., 2017; Malakar and Mishra, 2017). An increasing proportion of refugees and displaced people now live in urban centres, and their characteristics also make them vulnerable to a range of shocks and stresses (Earle, 2016). While some individuals, including children may be able to exercise agency to reduce their risk (Treichel, 2020) and some indicators are culturally specific, overall, poor, marginalized, socially isolated and informal urban households are particularly at risk (*high confidence*) (Brown and McGranahan, 2016; Kim et al., 2020b; Huq et al., 2020a; Huq et al., 2020b).

6.2.3.2 Informality, planning, and vulnerability

Particularly in Low- and Middle-Income Countries, much urban building occurs outside formal parameters and entails a high degree of urban informality. According to the United Nations statistics, the proportion of urban populations living in slums and informal settlements increased from 23% in 2014 to 23.5% in 2018 (United Nations, 2018). Informality is one pathway through which urbanization generates differentiated vulnerability tending to increase exposure and susceptibility of physical structures and their occupants to climate-related risks (Dodman et al., 2017; Dobson, 2017) in contexts including Guadalajara, Mexico (Gran Castro and Ramos De Robles, 2019), Kampala, Uganda (Richmond, Myers and Namuli, 2018), Bengaluru, India (Kumar, Geneletti and Nagendra, 2016), and Dar es Salaam, Tanzania (Yahia et al., 2018). In addition to facing emerging water- and heat-related risks, such areas are also more vulnerable to the health impacts of climate change (Scovronick, Lloyd and Kovats, 2015).

Even where formal planning is the norm, this has often remained oriented toward enabling value adding construction or the protection of existing high value physical assets, e.g., infrastructure and built cultural heritage; private residential) rather than enabling disaster risk reduction for all (Long and Rice, 2019). This tendency has been widely documented, including from cases in Australia, Thailand and Indonesia (King et al., 2016), Canada (Stevens and Senbel, 2017), Amman, Moscow, and Delhi (Jabareen, 2015), and South Africa (Arfvidsson et al., 2017). Such inconsistencies between the delivery of land-use planning and the aims of the Sustainable Development Goals combine with other social structures, economic pathways, and governance systems to shape city risk profiles (Dodman et al., 2017).

6.2.3.3 Migration and differentiated vulnerability

Migration, displacement, and resettlement each play a foundational role in differentiated vulnerability (see Cross-Chapter Box MIGRATE in Chapter 7). The relationship between migration and vulnerability is complex (*robust evidence, high agreement*), and is the first of the three components discussed within this section. Climate change, as a push factor, is only one among multiple drivers (political, economic, and social) related to environmental migration (Heslin et al., 2019; Plänitz, 2019; Luetz and Merson, 2019). There is consensus that it is difficult to pin climate change as the sole driver of internal (within national boundaries) rural to urban migration decisions due to, among other factors, the disconnect between national and international policies (Wilkinson et al., 2016), the lack of unifying theoretical frameworks, and the complex interactions between climatic and other drivers (social, demographic, economic, and political) at multiple scales (Cattaneo et al., 2019; Borderon et al., 2019). Environmental migration – including rural to urban migration – triggered by climate change may ensue from either slow or rapid onset climatic events and could be either temporary, cyclical, or permanent movement that occurs within or beyond national boundaries (Heslin et al., 2019; Silja, 2017).

A range of specific studies highlight specific elements of vulnerability and migration, including the ways in which slow-onset events affect precarious, resource dependent livelihoods (such as farming and fisheries) (Cai et al., 2016). In small town Pakistan and in small town Colombia, heat stress increases long-term migration of men, driven by a negative effect on farm income (Mueller, Gray and Kosec, 2014; Tovar-Restrepo and Irazábal, 2013). A study from Mexico reveals that an increase in drought months led to increased rural to urban migration, while increased heat (temperature) led to a "non-linear" pattern of rural to urban migration that occurred only after extended periods of heat (nearly 34 months) (Nawrotzki et al., 2017). This aligns with other findings that a consistent increase in temperature between 2-4ºC in some parts of the world render involuntary, forced migration inevitable (Otto et al., 2017).

The complexity of migration drivers (as push or as pull factors) explains why there is little agreement around quantitative estimates on migration (especially international) triggered by climate change (Silja, 2017; Otto et al., 2017), and why estimates of future displacement attributed to climate change and other environmental causes vary between 25 million and 1 billion in 2050 (Heslin et al., 2019). Many authors are critical of existing perspectives on climate-related migration, and argue for more nuanced research on the topic (Boas et al., 2019; Kaczan and Orgill-Meyer, 2020; Silja, 2017; Sakdapolrak et al., 2016; Singh and Basu, 2020; Luetz and Havea, 2018).

Climate-induced migration is not necessarily higher among poorer households whose mobility is more likely to be limited due to the poverty trap (i.e., lack of financial resources) (*high confidence*) (Cattaneo et al., 2019; Kaczan and Orgill-Meyer, 2020; Silja, 2017). For example, in Bangladesh, vulnerability of rural populations is increasing, so many of the poorest employ migration as a strategy of last resort (Paprocki, 2018; Penning-Rowsell, Sultana and Thompson, 2013; Adri and Simon, 2018) that occurs as soil salinity (as opposed to inundation alone) increases and is paralleled by economic diversification (i.e., aquaculture) (Chen and Mueller, 2018). There is robust evidence and high agreement that rapid-onset climatic events trigger involuntary migration and short-term, short-distance mobilities (Cattaneo et al., 2019). There is also robust evidence and high agreement that slow-onset climatic events (such as droughts and sea-level rise) lead to long-distance internal displacement more so than local or international migration (Kaczan and Orgill-Meyer, 2020; Silja, 2017); while sea level rise is expected to lead to the displacement of communities along coastal zones, such as in Florida in the USA (Hauer, 2017; Butler, Deyle and Mutnansky, 2016).

Migration, including rural-urban migration, is also recognized as an adaptation strategy in some circumstances, whether this is voluntary or planned (Jamero et al., 2019; Esteban et al., 2020a; Bettini, 2014). Voluntary migration can be an element of household strategies to diversify risk, depending on the nature of the climatic stress and interacts with household composition, individual characteristics, social networks, and historical, political, and economic contexts (Hunter, Luna and Norton, 2015; Carmin et al., 2015; Hayward et al., 2020). For example, in Colombia, rural to urban migration is differentiated across gender depending on the climatic stress whereby men migrate due to droughts, while women migrate due to excessive rain triggers (Tovar-Restrepo and Irazábal, 2013). Especially in Pacific small island developing states, migration can be a strategy for urban settlements or tribal communities to relocate in customary areas, as in the case of Vunidogoloa in Fiji (McMichael, Katonivualiku and Powell, 2019; Hayward et al., 2020); it can be a livelihood strategy as shown in the Cataret Islands in Papua New Guinea (Connell, 2016); or it can be used to enhance education and international networks (i.e., voluntary "migration with dignity") as is the case in Kiribati (Heslin et al., 2019; Voigt-Graf and Kagan, 2017).

The second component, displacement, also plays a crucial role in differentiated vulnerability. The lack of resources and capacities to support mobility limits the effectiveness of migration as an adaptation strategy, therefore leading to both displacement and trapped populations in the future (Adger et al., 2015; Faist, 2018). For example, studies from Colombia (Tovar-Restrepo and Irazábal, 2013), India (Singh and Basu, 2020), Mekong Delta in Vietnam (Miller, 2019), and Pakistan (Islam and Khan, 2018) showed that migration as an adaptation strategy can be constrained due to resource barriers and low mobility potential, and also, to high-levels of place attachment such as, in the Peruvian Highlands (Adams, 2016), Vanuatu (Perumal, 2018), and the Tulun and Nissan Atolls of Bougainville, Papua New Guinea (Luetz and Havea, 2018). Migration can also be maladaptive for the receiving contexts whether due to the pressure on and/or conflict over land

and/or the urban resources (*high confidence*) (Faist, 2018; Singh and Basu, 2020; Luetz and Havea, 2018). Other views maintain that migration as adaptation overlooks the agency of people and their resilience –i.e., the nuances of 'translocal social resilience' (Kelman, 2018; Silja, 2017; Sakdapolrak et al., 2016). For example, the ni-Vanuatu prioritize in-situ adaptation measures and leave migration as a last resort (Perumal, 2018).

Regardless of the reasons and the initiators for migration, community control over resettlement both at the original and destination leads to more positive outcomes for both the communities being resettled and the receiving communities (*high confidence*) (Perumal, 2018; Ferris, 2015; Price, 2019; Mortreux and Adams, 2015; Tadgell, Doberstein and Mortsch, 2018; Luetz and Havea, 2018). The protection of livelihoods contributes to ensuring the wellbeing (physical and mental) and the protection of the rights of communities *(high confidence*) (Ferris, 2015; Price, 2019). There is *limited evidence but high agreement* that the outcomes of resettlement initiatives are complex and multi-faceted (Ferris, 2015). For example, in Shangnan County, northwest China, the Massive Southern Shaanxi Migration Program, based on voluntary participation, reduced risk exposure and improved the quality of life in general, but also disproportionately increased the vulnerability of disadvantaged groups (the poor, migrants, and those left behind) (Lei et al., 2017). Similarly, vulnerability increased due to the loss of connection to place and community bonds in Mekong Delta, Vietnam (Miller, 2019) and due to unsafe construction, poor infrastructure, institutional incapacity, and general neglect in resettlement initiatives in Malawi, sub-Saharan Africa (Kita, 2017).

6.2.4 Risks to Key Infrastructures

Projected climatic changes – such as changing precipitation patterns, temperatures, and sea levels – contribute to pressures on human wellbeing and the functioning of infrastructure systems (high confidence). Furthermore, risks evolve due to macro-scale drivers of change such as urbanization, economic development, land use changes and other emergent factors (Adger, Brown and Surminski, 2018). Infrastructure networks are rapidly growing around the world (see Table 6.3). Since the quality and accessibility of infrastructure services are varied, it is important to understand how climate change poses different kinds of risk on them. Infrastructure can be broadly understood to include social infrastructure (housing, health, education, livelihoods and social safety nets, security, cultural heritage/institutions, disaster risk management and urban planning), ecological infrastructure (clean air, flood protection, urban agriculture, temperature, green corridors, watercourses and riverways) and physical infrastructure (energy, transport, communications (including digital), built form, water and sanitation and solid waste management) (Thacker et al., 2019). This section focuses especially on physical infrastructure where the literature provides discrete risk and impact assessments. Physical infrastructure systems are often immobile, indivisible, involve high fixed costs, and have longer lifecycles. Social and ecological infrastructure elements are rarely assessed alone and instead tend to be included in wider assessments of event impacts.

Table 6.3 Selected indicators of global proliferation of infrastructure networks and their annual usage.

Infrastructure	Scale	Usage on annual basis	Coverage / Equity of access	References
Electricity networks	>20M km power lines in Europe and USA.	25,721 TWh (2017)	Global: 3130kWh/person Haiti: 39kWh/person Iceland: 53,832kWh/person	(IEA, 2019) (World Bank, 2019) (ETSAP, 2014)
Gas and LPG pipelines	Worldwide: >2.5M km w	40,531 TWh (2017)	Global 4.96 MWh/person (2015) South Africa 0.96 MWh/person (2015) Saudi Arabia: 34.65 MWh/person (2015)	(CIA, 2015) (OWID, 2020)

Railways	2.69M km	3,835 billion passenger km (2019) 9,279.81 billion tonne km (2019)	Switzerland: 0.7m/person; 141m/km^2 Canada: 2.2m/person; 8.6m/km^2 India: 0.06m/person; 23m/km^2	(Koks et al., 2019) (Statista, 2020)
Roads	63.46M km	12,148 billion passenger km private vehicles (2015) 5,713 billion passenger km public vehicles e.g. buses (2015) 302.5 billion passenger km active modes e.g. walking and bicycles (2015)	Belgium: 15m/person; 5km/km^2 Malawi: 1m/person; 164m/km^2 Canada: 31m/person; 115m/km^2	(Koks et al., 2019) (WorldByMap, 2017) (ITF, 2019)
Information and Communication Technology	Worldwide: 91M mobile phones in 1995; 8.2BN in 2018 worldwide	Worldwide: 43,000 PB in 2014 242,000 PB in 2018 (*1PB = 1 million GB)	Europe: 85% population are unique mobile subscribers Asia Pacific: 66% SSA: 45%	(ITU, 2019) (Vodafone, 2019) (GSMA, 2019)
Water	3.3M km^2 land equipped for irrigation The Global Reservoir and Dam Database (conservatively records) at least 7100 dams	This irrigated land accounts for about 70% of total water withdrawals These dams can retain over 7,800km^3 water.	Sub-Saharan Africa: 24% coverage of safely managed drinking water services, 28% safely managed sanitation services Europe & North America: 94%, 78%	(Grigg, 2019) (Lehner et al., 2011) (Lehner et al., 2019) (UN Water, 2018)

Current climate variability is already causing impacts on infrastructure systems around the world (*high confidence*). For global physical infrastructure with a present value of US$143 trillion The Economist Intelligence Unit (2015) estimates present value losses of $4.2 trillion by 2100 under a 2oC scenario. This estimation rises to $13.8 trillion under a 6oC scenario. Extreme events are associated with disruption or complete loss of these infrastructure services, whilst gradual changes in mean conditions are altering physical infrastructure performance. Physical infrastructure is usually costly to repair and also have significant impacts on people's health and wellbeing.

This section synthesises and assesses the emerging literature on climate change risks to key physical infrastructure domains as listed in Table 6.3: energy/electricity infrastructure, transportation infrastructure, and information and communication technology (ICT) (water infrastructure is discussed in Section 6.2.2). It draws on evidence from around the world, but the specific risks to infrastructure in different contexts are explained in more detail in the regional chapters (especially 9.8.4.1 for Africa, 10.4.6.3.8 for Asia, and 13.6.1 for Europe). For cities and settlements such risks are of particular concern due to a lack of adaptive capacity across many economically important sectors and low levels of resource and capacity support to enhance adaptive capacity. Recent literature also illustrates the interconnected and interdependent nature of infrastructure systems (see Box 6.2), which lead to uncertainties over how risks in one sector lead to cascading, compounding, or knock-on effects across other sectors (Zscheischler and Seneviratne, 2017) (see Section 6.2.6 for elaboration). Therefore, adaptation options should address climate risks to infrastructure in an integrated and co-beneficial manner (*medium evidence, high confidence*) (see Section 6.3 and Section 6.4).

[START BOX 6.2 HERE]

Box 6.2: Infrastructure Interdependencies

Infrastructure networks are increasingly dependent on each other —for power, control (via ICT) and access for deliveries or servicing (see Figure 6.2). Moreover, a range of other mechanisms can create interdependencies that impact upon climate risks by creating pathways for cascading failure (Undorf et al., 2020; Barabási, 2013). In the UK, for example, all infrastructures utilities identify failure of components in another utility as a risk to their systems (Dawson et al., 2018).

Key interdependencies include:

i. The use of ICT for data transfer, remote control of other systems, and clock synchronization. Pant et al. (2016) show that ICT is crucial for the successful operation of the UK's rail infrastructure. The study shows that flooding of the ICT assets in the 1-in-200-year floodplain would disrupt 46% of passenger journeys across the whole network.
ii. Water to generate hydroelectricity and for cooling thermal power stations. Reductions in usable capacity for 61–74% of the hydropower plants and 81–86% of the thermoelectric power plants worldwide for 2040–2069 (Van Vliet et al., 2016), with some power generation technologies, including carbon capture and storage, requiring far higher volumes of water for cooling (Byers et al., 2016);
iii. Energy to power other infrastructure systems. Failure of urban energy supply disrupts other infrastructure services, with disproportionate impacts on the urban poor (Silver, 2015);
iv. Transport systems that ensure access for resources such as fuel, personnel and emergency response. Pregnolato et al. (2017) show disruption across the city from a 1-in-10 year storm event could increase by 43% by the 2080s.
v. Green infrastructure can provide multiple services, creating interdependencies between multiple physical infrastructure systems. For example, green space can support sustainable urban drainage, in-situ wastewater treatment, and urban cooling (Demuzere et al., 2014).
vi. Geographical proximity of assets leads to multiple infrastructures being simultaneously exposed to the same climate hazard. Disruption is disproportionately larger for interconnected networks (Fu et al., 2014).

There is usually limited information on the risks between infrastructure sectors. Without frameworks for collaboration and coupled with commercial and security sensitivities this remains a barrier to routine sharing and cooperation between operators. Despite this, methods to tackle interdependence in climate risk analysis are emerging (Dawson, 2015). For example, Thacker et al. (2017) analysed the criticality of the UK's infrastructure networks by integrating data on infrastructure location, connectivity, interdependence, and usage. The analysis showed that criticality hotspots are typically located around the periphery of urban areas where there are large facilities upon which many users depend or where several critical infrastructures are concentrated in one location. As infrastructure systems become increasingly interconnected, associated risks from climate change will increase and require a cross-sectoral approach to adaptation (Dawson et al., 2018).

[END BOX 6.2 HERE]

6.2.4.1 Energy infrastructure

Energy infrastructure underpins modern economies and quality of life. Disruption to power or fuel supplies impacts upon all other infrastructure sectors, and affects businesses, industry, healthcare, and other critical services both within an across jurisdictional boundaries (Groundstroem and Juhola, 2019). The economic impacts of climate change risks are significant, for example in the EU the expected annual damages to energy infrastructure, currently €0.5 billion per year, are projected to increase 1612% by the 2080s (Forzieri et al., 2018). In China, 33.9% of the population are vulnerable to electricity supply disruptions from a flood or drought (Hu et al., 2016), whilst in the USA, higher temperatures are projected to increase power system costs by about $50 billion by the year 2050 (Jaglom et al., 2014). In a study of 11 Central and Eastern Europe countries, researchers found that energy poverty is exacerbated by existing infrastructure deficits, an energy efficient building stock, as well as income inequality, which can lead to reduced economic productivity (Karpinska and Śmiech, 2020). Climate change is expected to alter energy demand (Viguié et al., 2021), for example heatwaves increase spot market prices (Pechan and Eisenack, 2014) with a disproportionate impact on the poorest and most vulnerable populations. Energy infrastructure are susceptible to a range of climate risks (Cronin, Anandarajah and Dessens, 2018), whilst issues pertaining to energy demand are considered by Working Group III.

Climate change can, for example, influence energy consumption patterns by changing how household and industrial consumers respond to short-term weather shocks as well as how they adapt to long-term changes (Auffhammer and Mansur, 2014). Recent studies from Stockholm, Sweden, show that future heating demand will decrease while cooling demand will increase (Nik and Sasic Kalagasidis, 2013). A study from the USA showed that climate change will impacts buildings by affecting peak and annual building energy consumption (Fri and Savitz, 2014). From an infrastructure standpoint, the vulnerability of current hydropower and thermo-electric power generation systems may change due to changes in climate and water systems and projected reduction of usable capacities (Van Vliet et al., 2016; Byers et al., 2016). These examples show how energy infrastructure planning under climate change must take into account a greater number of scenarios and investigate impacts on particular energy segments (Sharifi and Yamagata, 2016).

Electricity generation. Electricity generation infrastructure can be directly damaged by floods, storm and other severe weather events. Furthermore, the performance of renewables (solar, hydro-electric, wind) is affected by changes in climate.

Most thermoelectric plants require water for cooling, many are therefore situated near rivers and coasts and therefore vulnerable to flooding. Increases in water temperature or restrictions on cooling water availability affect hydro-electric and thermoelectric plants. A 1°C increase in the temperature of water used as coolant yields a decrease of 0.12-0.7% in power output (Mima and Criqui, 2015; Ibrahim, Ibrahim and Attia, 2014). Excess biological growth, accelerated by warmer water, increases risk of clogging water intakes (Cruz and Krausmann, 2013). While some regions are expected to experience increased capacity under climate change (namely India and Russia), global annual thermal power plant capacity is likely to be reduced by between 7% in a mid-century RCP2.6 scenario and 12% in a mid-century RCP8.5 scenario (Van Vliet et al., 2016). Worldwide, hydro-electric capacity reductions are projected 0.4-6.1% (Van Vliet et al., 2016). Analysis of the UK's water for energy generation abstractions showed that an energy mix of high nuclear or carbon capture technologies could require as much as six times the current cooling water demands (Byers, Hall and Amezaga, 2014; Byers et al., 2016).

Increasing temperatures improve the efficiency of solar heating, but decrease the efficiency of photovoltaic panels, and deposition and abrasive effects of wind-blown sand and dust on solar energy plants can further reduce power output, and the need for cleaning (Patt, Pfenninger and Lilliestam, 2013). Projected changes in wind and solar potential are uncertain, the trends vary by region and season (Burnett, Barbour and Harrison, 2014; Cradden et al., 2015; Fant, Schlosser and Strzepek, 2016). In an RCP8.5 scenario, Wild et al. (2015) conservatively calculate a global reduction of 1% per decade between 2005-2049 for future solar power production changes due to changing solar resources as a result of global warming and decreasing all-sky radiation over the coming decades. However, positive trends are projected in large parts of Europe, South-East of North America and the South-East of China.

Electricity transmission and distribution. Electricity transmission and distribution networks span large distances, with overhead power lines often traversing exposed areas. Power lines and other assets, such as substations, are often located near population centres, including those in floodplains. Structural damage to overhead distribution lines will increase in areas projected to see more ice or freezing rain (e.g. most of Canada), snowfall (e.g. Japan) or wildfires (e.g. California, USA) (Bompard et al., 2013; Mitchell, 2013; Sathaye et al., 2013; Jeong et al., 2018; Ohba and Sugimoto, 2020). Electricity outages maybe last for prolonged periods of time and across vast areas, in addition to potentially disproportionately affecting poorer or more vulnerable communities. Increases in windstorm frequency and intensity increase the risk of direct damage to overhead lines and pylons, in many locations this is limited but Tyusov et al. (2017) calculate an increase as high as 30% in parts of Russia. Where the mode of failure is recorded, transmission pylons are seen to be more susceptible to wind damage, whilst distribution pylons are more likely to be affected by treefall and debris (Karagiannis et al., 2019). Increased temperatures can lead to the de-rating (lower performance) of power lines whose resistance increases with temperature with efficiency reductions of 2-14% being projected by 2100 (Cradden and Harrison, 2013; Bartos et al., 2016).

Fuels extraction and distribution. Non-electric energy infrastructure is susceptible to many of the same impacts as the electric infrastructure. Extreme weather events impact extraction (onshore and offshore) and refining operations of petroleum, oil, coal, gas and biofuels. Disruption of road, rail and shipping routes (see Section 6.2.5.2) interrupts fuel supply chains. However, there are a number of risks that are specific to these sectors. Heat can lead to expansion in oil and gas pipes, increasing the risk of rupture (Sieber, 2013). Whilst heatwaves and droughts can reduce the availability of biofuel (Moiseyev et al., 2011; Schaeffer et al., 2012). Subsidence and shrinkage of soils damages underground assets such as pipes intakes (Cruz and Krausmann, 2013), while additional human activity such as extractive drilling may induce earthquakes, as observed in the northern Dutch province of Groningen (Van der Voort and Vanclay, 2015). In Alaska, USA, the thaw of permafrost and subsequent ground instability is estimated to lead to $33M damages to fuel pipelines in an end-of-century RCP8.5 scenario (Melvin et al., 2017), with low lying coastal deltas particularly vulnerable (Schmidt, 2015).

6.2.4.2 Transport

Since AR5, research has highlighted the implications for disruption to global supply chains (Becker et al., 2018; Shughrue and Seto, 2018; Pató, 2015), and has made advancements in quantifying costs of climate risks to transportation infrastructure. Climate risks to transport infrastructure (from heat- and cold waves, droughts, wildfires, river and coastal floods and windstorms) in Europe could rise from €0.5 billion to over €10 billion by 2080s (Forzieri et al., 2018). Across the Arctic, nearly four million people and 70% of all current infrastructure, including resource extraction and transportation routes, will be at risk by 2050 (Hjort et al., 2018), although the design of specific infrastructure may also affect the degree of infrastructure damage depending local geological and ecological conditions. Globally, Koks et al. (2019) calculated that approximately 7.5% of road and railway assets are exposed to a 1/100 year flood event, and total global expected annual damages (EAD) of US$3.1-22 billion (mean $14.6 billion) due to direct damage from cyclone winds, surface and river flooding, and coastal flooding. The majority of this is caused by surface water and fluvial flooding (mean $10.7 billion). Although twice as much infrastructure is exposed to cyclone winds compared to flooding, a mean EAD of $0.5 billion is significantly less that for coastal flooding ($2.3 billion) as cyclone damages are largely limited to bridge damage and the cost of removing trees fallen on road carriageways and railway tracks. This is small relative to global GDP (~0.02%). However, in some countries EAD equates to 0.5-1% of GDP, which is the same order of magnitude as typical national transport infrastructure budgets, but especially significant for countries like Fiji that already spend 30% of their government budget on transport (World Bank Group, 2017). Koks et al. (2019) did not assess future climate change impacts, but comparable studies calculating changes in EAD from flooding based upon land use show increases of 170%--1370% depending on global greenhouse gas emissions levels (Alfieri et al., 2017; Winsemius et al., 2015). Moreover, Schweikert et al., (2014) report that climate risks to transport infrastructure could cost as much as 5% of annual road infrastructure budgets by 2100, with disproportionate impacts in some low and lower middle-income countries.

Changes in rainfall and temperature patterns are expected to increase geotechnical failures of embankments and earthworks (Briggs, Loveridge and Glendinning, 2017; Tang et al., 2018; Powrie and Smethurst, 2018) from landslides, subsidence, sinkholes, desiccation and freeze-thaw action. For instance, Pk et al. (2018) show this could lead to a 30% reduction in the engineering factor of safety of earth embankments in Southern Ontario (Canada). Increased river flows in many catchments will also increase failures from bridge scours (Forzieri et al., 2018). HR Wallingford (2014) calculate that the projected 8% increase in scouring from high river flows in the UK will lead to 1 in 20 bridges being at high risk of failure by the 2080s, whilst in the USA the 129,000 bridges currently deficient could increase by 100,000 (Wright et al., 2012). With respect to temperature, analysis by Forzieri et al. (2018) concludes that heatwaves will be the most significant risk to EU transport infrastructure in the 2080s as a result of buckling of roads and railways due to thermal expansion, melting of road asphalt and softening of pavement material. In the USA, over 50% more roads will require rehabilitation (Mallick et al., 2018), whilst $596m will be required through 2050 to maintain and repair roads in Malawi, Mozambique, and Zambia (Chinowsky, Price and Neumann, 2013).

In addition to direct damages from flooding and heatwaves, disruption caused by road blockages will be increased by more frequent flood events. For example in the city of Newcastle upon Tyne (UK), road travel disruption across the city from a 1-in-50 year surface water flood event could increase by 66% by the 2080s

(Pregnolato et al., 2017) whilst heatwaves could treble railway speed restrictions in parts of the UK (Palin et al., 2013). Knott et al. (2017) highlighted risks to coastal infrastructure where ~30cm sea level rise sea level rise would also push up groundwater and reduce design life by 5-17% in New Hampshire (USA). Heavy rain and flooding can also inundate underground transport systems (Forero-Ortiz, Martínez-Gomariz and Canas Porcuna, 2020).

Many airports, and by their nature ports, are in the low elevation coastal zone making them especially vulnerable to flooding and sea level rise. Under a 2ºC scenario the number of airports at risk of storm surge flooding increases from 269 to 338 or as many as 572 in an RCP8.5 scenario; these airports are disproportionately busy and account for up to 20% of the world's passenger routes (Yesudian and Dawson, 2021). Airport and port operations could be disrupted by icing of aircraft wings, vessels, decks, riggings, and docks (Doll, Klug and Enei, 2014; Chhetri et al., 2015). Warming will increase microbiological corrosion of steel marine structures (Chaves et al., 2016). Fog, high winds and waves can disrupt port and airport activity but changes are uncertain and with regional variation (Mosvold Larsen, 2015; Izaguirre et al., 2021; Becker, 2020; León-Mateos et al., 2021; Taszarek, Kendzierski and Pilguj, 2020; Danielson, Zhang and Perrie, 2020; Kawai et al., 2016).

Waterways are still important transport routes for goods in many parts of the world, although they are mostly expected to benefit from reduced closure from ice (Jonkeren et al., 2014; Schweighofer, 2014), low flows will likely lead to reduced navigability and increased closures, van Slobbe et al. (2016) estimate the Rhine may reach a turning point for waterway transportation between 2070-2095. Obstruction due to debris and fallen vegetation of roads and rails and to inland and marine shipping from high winds are expected to increase (Koks et al., 2019; Kawai et al., 2018; Karagiannis et al., 2019)..

6.2.4.3 Information and Communication Technology

Information and Communication Technology (ICT) comprises the integrated networks, systems and components enabling the transmission, receipt, capture, storage and manipulation of information by users on and across electronic devices (Fu, Horrocks and Winne, 2016). ICT infrastructure faces a number of climate risks. Increased frequency of coastal, fluvial or pluvial flooding will damage key ICT assets such as cables, masts, pylons, data centres, telephone exchanges, base stations or switching centres (Fu, Horrocks and Winne, 2016). This leads to loss of voice communications, inability to process financial transactions and interruption to control and clock synchronization signals. Insufficient information about the location and nature of many ICT assets limits detailed quantitative assessment of climate change risks.

Fixed line ICT networks that sprawl over large areas are especially susceptible to increases in the frequency or intensity of storms would increase the risk of wind, ice and snow damage to overhead cables and damage from wind-blown debris. More intense or longer droughts and heatwaves can cause ground shrinkage and damage underground ICT infrastructure (Fu, Horrocks and Winne, 2016). In mountain and northern permafrost regions, communications and other infrastructure networks are subject to subsidence because of warming of ice-rich permafrost (Shiklomanov et al., 2017; Li et al., 2016; Melvin et al., 2017).

6.2.4.4 Housing

For the urban housing sector, climate impacts such as flooding, heat, fire, and wind assessed in Section 6.2.3 will *likely* have detrimental effects on housing stock (including physical damage and loss of property value) as well as on residents exposed to climate risks (robust evidence*, high agreement*)

In the USA, for example, 15.4 million housing units fall within a 1-in-100-year floodplain (Wing et al., 2018). Assessment of the Miami-Dade area in Florida noted that coastal inundation caused by tidal flooding (and to a lesser extent sea level rise) resulted in over $465 million in lost real-estate market value between 2005 and 2016 (McAlpine and Porter, 2018), although property values have increased from high-end housing construction and climate adaptation measures (Kim, 2020). Emergent risk reflecting novel research include aggravated moisture problems in buildings from wind driven rain (Nik et al., 2015). Future risks from future sea level rise are elaborated in CCP2.2.1. Housing infrastructure are also susceptible to extreme heat and wind events (Stewart et al., 2018). These risks are further elaborated on in Section 6.2.3, although it is important to note that heat risks, in particular, tend to be concentrated within communities with higher proportion of social housing (Mavrogianni et al., 2015; Sameni et al., 2015) or low-cost government-built houses and informal settlements.

6.2.4.5 Water and Sanitation

Apart from land subsidence from urbanization (e.g. Case Study 6.2), substantial climate risks to urban sanitation arise from droughts, flooding and storm surges. Low flows from drought can lead to sedimentation, increase pollutant concentration and block sewer infrastructure networks (Campos and Darch, 2015). Flooding poses a greater risk for urban sanitation in low and middle income settings (Burgin et al., 2019) where onsite systems are more common. Floodwater may wash out pits and tanks, mobilising faecal sludges and other hazardous materials leading to both direct and indirect exposure via food and contaminated objects and surfaces and pollute streams and waterbodies (Howard et al., 2016; Braks and de Roda Husman, 2013; Bornemann et al., 2019). Floods also damage infrastructure; toilets, pits, tanks and treatment systems are all vulnerable (Sherpa et al., 2014; UNICEF and WHO 2019).

Sanitation systems coupled with floodwater management are at risk of damage and capacity exceedance from high rainfall (Thakali, Kalra and Ahmad, 2016; Kirshen et al., 2015; Dong, Guo and Zeng, 2017). In England, the number of water and wastewater treatment plants at risk of flooding is projected to increase by 33% under a 4°C scenario (Sayers et al., 2015), but risks are generally increasing for both formal and informal urban sanitation systems (Howard et al., 2016).

6.2.4.6 Natural and Ecological Infrastructure

Urban ecological infrastructure includes green (i.e., vegetated), blue (i.e., water-based), and grey (i.e., non-living) components of urban ecosystems (Li et al., 2017). While land cover change from urbanization directly reduces the extent of natural and ecological infrastructure (e.g. Lin, Meyers and Barnett, 2015), notable risks arise from climate drivers. Recent research particularly highlights future climate impacts on coastal natural infrastructure – including beaches, wetlands, and mangroves – which cause significant economic losses from property damage, decreasing tourism income, as well as loss of natural capital and ecosystem services. Research on climate risks to urban trees and forests is comparatively limited. Instead, urban vegetation and green infrastructure are most often cast as adaptation strategies to reduce urban heat, mitigate drought, and provide other ecosystem benefits (see 6.3.2).

Coastal natural infrastructure is exposed to sea level rise, wave action, and inundation from increasing storm events (See also CCP 2.2.1). Beaches, in particular, are highly exposed to climate-induced coastal erosion ((Toimil et al., 2018); CCP2). Research from settlements across coastal Southern California, USA, show that 67% of all beaches may completely erode by 2100 (Vitousek, Barnard and Limber, 2017). Coastal zones across Cancún, Mexico, are exposed to a combination of sea level rise and tropical hurricanes, further exacerbated by urban development patterns blocking natural sediment replenishment to beaches (Escudero-Castillo et al., 2018). In another case, beach erosion along the heavily urbanized Valparaíso Bay, Chile, is heightened by El Niño Southern Oscillation (ENSO) events, which in the past have caused an additional 15-20cm in mean sea level rise (Martínez et al., 2018).

Wetlands, mangroves, and estuaries – which tend to be heavily urbanized areas – are highly at risk from sea level rise and changing precipitation (Green et al., 2017; Feller et al., 2017; Alongi, 2015; Osland et al., 2017; Chow, 2018; Godoy and Lacerda, 2015). Sea level rise is a concern for wetlands and mangroves across coastal urban Asia, the Mississippi Delta (USA), and low lying small island states (Ward et al., 2016b). Research on the highly urbanized Yangtze River estuary in China shows that soil submersion and erosion from sea level rise, compounded by land conversation to agriculture and urban development, will cause all tidal flats to disappear by 2100 (Wu, Zhou and Tian, 2017). In another example, sea level rise and high rates of tidal inundation have increased overall salinity in the San Francisco Bay-Delta estuary, threatening the ecosystem's ability to support biodiversity (Parker and Boyer, 2019).

Research on climate risks to urban trees and forests highlight direct impacts from extreme temperatures, precipitation, wind events, and sea level rise, as well as exposure to other hazards such as air pollution, fires, invasive species, and disease (Ordóñez and Duinker, 2014). Since the 1960s, climate change has enabled growth of urban trees, supported by longer growing seasons, higher atmospheric CO2 concentrations, reduced diurnal temperature range (Pretzsch et al., 2017), as well as increased fertilization through urban-enhanced nitrogen deposition (Decina, Hutyra and Templer, 2020). However, these trends may change in the future as further warming and decreasing water supply may depress tree fitness, thus enabling more pests (Dale and Frank, 2017).

Climate risks to urban natural and ecosystem infrastructure entail significant economic costs. For example, in 2012, Hurricane Sandy led to total losses of up to US$6.5 million to the New York City region's low-lying salt marshes and beaches (Meixler, 2017). Research from coastal settlements across Catalonia, Spain, shows significant levels of tourism loss (which contribute to 11.1% of the region's GDP), infrastructure damage, and natural capital loss attributed to inundation and erosion of beaches, which are projected to retreat by -0.7 meters per year given current sea level rise projections of 0.53 to 1.75 meters by 2100 (Jiménez et al., 2017).

6.2.4.7 Health systems infrastructure

Healthcare facilities (hospitals, clinics, residential homes) will suffer increasing shocks and stresses related to climate variability and change (Corvalan et al., 2020). Some may be sudden shocks from extreme weather events, which both threaten the facility, staff and patients and increase the number of people seeking health care. There are extensive reports of health facilities being damaged after major floods and windstorms (e.g. 2010 floods in Pakistan, Hurricane Sandy in the US) which can be further exacerbated by power and water supply failures (Powell, Hanfling and Gostin, 2012). Disruption to services may persist for many months due to damage to buildings, loss of drugs and equipment, and damaged transport infrastructure significantly increasing travel time for patients (Hierink et al., 2020). The impacts of climate change on the health of residents of 'slum' settlements will also compound the existing health burdens faced by these individuals, including infectious disease and other environmental public health concerns (Lilford et al., 2016; Mberu et al., 2016).

6.2.5 Compound and Cascading Risks in Urban Areas

Compound events can be initiated via hazards such as single extreme events, or multiple coincident events overlapping and interacting with exposed urban systems or sectors as compound climate risks (Leonard et al., 2014; Pörtner et al., 2019; Piontek et al., 2014). Hydrometeorological hazards - such as extreme precipitation from tropical cyclones, fronts, and thunderstorms - often combine with storm surges and freshwater discharge leading to high compound risks at exposed settlements (Zheng, Westra and Sisson, 2013; Chen and Liu, 2014; Ourbak and Magnan, 2018; Dowdy and Catto, 2017). The compounding effect between these hydrometeorological hazards suggest that the combined impact of these events are greater than each of these variables on its own, and can amplify risks in affected settlements (Kew et al., 2013; Vitousek et al., 2017). These risks are concentrated in coastal cities exposed to sea level rise and severe storms (van den Hurk et al., 2015; Wahl et al., 2015; Paprotny et al., 2018b; Lagmay et al., 2015), or in settlements located in valleys prone to slope failure, such as the 2013 Uttarakhand floods and landslides arising from extreme precipitation and glacial lake outbursts along the Mandakini river in India (Ziegler et al., 2016; Barata et al., 2018).

Cascading climate events occur when an extreme event triggers a sequence of secondary events within natural and human systems that causes additional physical, natural, social or economic disruption. The resulting impact can be significantly larger than the initial hazard (Pörtner et al., 2019). Each step in a risk cascade can generate direct (immediate impacts) and secondary (consequential impacts) losses. Risks from these cascading impacts are complex and multidimensional (Hao, Singh and Hao, 2018; Zscheischler and Seneviratne, 2017). For instance, combined droughts and heat waves increases risks of urban water scarcity (Miralles et al., 2019; Gillner, Bräuning and Roloff, 2014; Gill et al., 2013), as well as increasing wildfire extent and lowering snowpack conditions that affected peri-urban settlements adjacent to forested areas as observed in California during the 2014 drought (AghaKouchak et al., 2014). Similarly, heat waves can increase the risk of mortality associated with air pollution (see 7.2.2.5).

Urban areas and their infrastructure are susceptible to both compounding and cascading risks arising from interactions between severe weather from climate change and increasing urbanization (*medium evidence, high agreement*) (Moretti and Loprencipe, 2018; Markolf et al., 2019). Risks are complex and multidimensional, and can significantly amplify the impact of single events across space, scale, and time.

Impacts are determined by the magnitude of urban vulnerability and/or the interdependence of urban critical infrastructure (Pescaroli and Alexander, 2018; Zuccaro, De Gregorio and Leone, 2018). Poorer and wealthier settlements and cities are then both at risk from compound and cascading risks though potentially through contrasting mechanisms. For richer and poorer cities, managing climate risk as part of compound and cascading risks that can also include technological, biological, and political risks places renewed emphasis on investment in generic capabilities that reduce vulnerability and on risk monitoring capability to track and respond to impacts across infrastructures and places (*low evidence, high agreement*). Considering climate risk and managing such risk as part of complex, compounding and/or cascading risks is in its infancy but rapidly being accepted as necessary especially when considering the wider poverty and justice implications of climate change arising from differentiated vulnerability in cities.

Compound risks to key infrastructure in cities have increased from extreme weather (*medium evidence, high agreement*), such as from urban flooding from extreme precipitation and storm surges disrupting transport infrastructure and networks, e.g. (Mehrotra et al., 2018); See also San Juan case study in this chapter), ICT networks e.g. underground cables or transmission towers (Schwarze et al., 2018), and energy generation from power plants (Marcotullio et al., 2018).

The increased risk arises not just from greater exposure from climate events impacting cities, but is also magnified by low adaptive capacity that can arise from intra-urban variations in infrastructure quality. For instance, infrastructure within expanding informal settlements are associated with deficiency in materials, structural safety, and a lack of accessibility. These areas are often located in the most risk-prone urban areas in developing nations that are vulnerable to compound hazards (Dawson et al., 2018). Further these risks can be exacerbated from complications arising from local vs. national governance and/or regulations related to hazard management (Garschagen, 2016; Castán Broto, 2017).

Projected global compound risks will increase in the future, with significant risks across energy, food, and water sectors that likely overlap spatially and temporally while affecting increasing numbers of people and regions particularly in Africa and Asia (*high confidence*) (Hoegh-Guldberg et al., 2018). In cities, the prevalence of compounding risks therefore necessitates methodologies accounting for nonstationary risk factors.

Secondary impacts occurring sequentially after an extreme hazard can severely affect disaster management especially in complex urban systems (*robust evidence, high agreement*). Over time, relatively small perturbations can cascade outward from a primary failure, triggering further failures in other dependent parts of the network some distance away from the primary failure (Penny et al., 2018). In some cities, such as those prone to compound flood hazards, these dependent network parts can be dams, levees, or other critical flood protection infrastructure that are essential for managing these cascading risks (Serre and Heinzlef, 2018; Fekete, 2019). Failure of these infrastructure systems can result in sequential failures in urban transport (Zaidi, 2018), energy networks (Sharifi and Yamagata, 2016), urban biodiversity (Solecki and Marcotullio, 2013) and so-called na-tech disasters - when natural hazards trigger technological disasters (Girgin, Necci and Krausmann, 2019). This risk cascade can propagate more widely by stopping flows of people, goods, and services, with economic consequences beyond urban areas (Wilbanks and Fernandez, 2014).

Compound and cascading climate risks require a different way of accounting for cumulative hazard impacts in urban areas (*medium evidence, high agreement*). There is emerging literature calling for analysis on interactions between individual and interrelated climate extremes with complex urban systems, so as to ascertain how urban and key infrastructural vulnerabilities can be identified and managed in a warming world (Butler, Deyle and Mutnansky, 2016; Gallina et al., 2016; Moftakhari et al., 2017; Zscheischler et al., 2018; Baldwin et al., 2019; Pescaroli and Alexander, 2018; Yin et al., 2017; AghaKouchak et al., 2020), as well as in managing adaptation for present and future pandemics e.g. COVID-19 (Pelling et al., 2021; Phillips et al., 2020b).

In term of policy, case studies from London's resilience planning process stressed the need for intermodal coordination, hazard risk and infrastructure mapping, clarifying tipping points and acceptable levels of risk, training citizens, strengthening emergency preparedness, identifying relevant data sources, and developing scenarios and contingency plans (Pescaroli, 2018). Others also note the utility of a systems approach to analyzing risks and benefits, including considerations of potential cascading ecological effects, full life cycle environmental impacts, and unintended consequences, as well as possible co-benefits of responses (Ingwersen et al., 2014). Lowering these risks requires urban stakeholders to reduce urban vulnerability by going beyond linear approaches to risk management (*medium evidence, high agreement*).

6.2.6 Impacts and Risks of Urban Adaptation Actions

Planning and implementing climate adaptation in cities and settlements can be hampered by incomplete scientific knowledge, a lack of awareness of cascading impacts (and residual risks), mismanagement of actions, human capacity and financing deficits, as well as opportunities for eroding long-term sustainable development priorities (Juhola et al., 2016). These tensions can become acute in fragile and conflict affected states (see Box 6.3). It is important to differentiate between the climatic drivers of risk and social drivers that may compound risk exposures and experiences (Brown, 2014; Nightingale et al., 2020), especially since technically- and scientifically-informed adaptation actions can be redirected depending on socioeconomic, political, or cultural conditions on the ground (Eriksen, Nightingale and Eakin, 2015). The implementation of adaptation – whether by government, private sector, or civil society actors – can therefore lead to unanticipated and unintended amplification of political, economic and ecological risks (Swatuk et al., 2020). Many cities are still in the phase of piloting or testing out appropriate adaptation actions, although there is emerging consensus that adaptation plans and projects should acknowledge trade-offs, intentionally avoid past development mistakes, not lock-in detrimental impacts or further risks arising from implementation, and explicitly anticipate the risks of maladaptation in decision-making (Magnan et al., 2016; Gajjar, Singh and Deshpande, 2019). Maladaptation describes actions that lead to increased vulnerability or risk to climate impacts or diminish welfare. Urban examples include green gentrification which offers nature based solutions to the few, social safety nets that promote risk inducing subsidies. Whether an action is maladapted can depend on context, e.g. air conditioning can reduce risk for the individual but is maladaptive at a societal level (see 6.3.4.2). It is informed by process – corruption can distort processes and generate maladaptation (see 6.4.5.2). Climate Resilient Development raises the ambition for adaptation actions so that it is also possible to describe actions that do not also enhance climate mitigation and sustainable development outcomes as maladaptive (see 6.4.3.1). This section assesses three broad categories of risk arising from downstream adaptation actions, including interventions that transfer vulnerability across space and time, plans that yield socioeconomically exclusionary outcomes, and actions that undermine long-term sustainable and resilient development priorities.

[START BOX 6.3 HERE]

Box 6.3: Climate Change Adaptation for Cities in Fragile and Conflict Affected States

Larger cities may be the most stable administrative entities in states affected by conflict. Even here ability to plan and deliver adaptation can be hampered. Extending into urban areas within stable states, alienation and loss of trust between local populations and the state can be exacerbated by top-down adaptation planning and delivery; socially and spatially uneven adaptation investment., and in the economic and administrative limits of government that can lead to some places being excluded from formal planned investment (*high confidence*) (see 6.3 and 6.4). These pathways for exclusion can combine amongst already marginalized and low-income populations where trust in government agencies may already be low (Rodrigues, 2021).

Climate change can be a threat multiplier in cities and urban regions, exacerbating existing human security tension (*limited evidence, medium agreement*) (Froese and Schilling, 2019; Flörke, Schneider and McDonald, 2018; Rajsekhar and Gorelick, 2017). Where conflict or administrative tensions extend beyond cities, adapting regional infrastructure systems that underpin urban life is challenging for example where elements of networked infrastructure are under the control of conflicting political interests. This has been noted for the water sector (Tänzler, Maas and Carius, 2010). Coordinating political processes is a major challenge even for industrialized countries with adequate administrative capacity. In post-conflict societies , the difficulties of coordination for urban planning are disproportionately greater (Sovacool, Tan-Mullins and Abrahamse, 2018).

In planning adaptation measures in cities, conflict-sensitive approaches to ensure participatory methods (Bobylev et al., 2021) can avoid adaptation being a polarising activity (Tänzler, Maas and Carius, 2010; Tänzler, 2017). Adaptation can provide a common goal reaching across political differences and be a part of building political trust and local cooperation between alienated communities (Tänzler, Maas and Carius, 2010). Peacebuilding programmes led by government or civil society are typically concerned with the short-term and framed by socioeconomic policy, integrating the longer-term view and engineering-technical expertise for adaptation is a challenge (*limited evidence, medium agreement*) (Ishiwatari, 2021).

[END BOX 6.3 HERE]

Downstream impacts occur because adaptive capacity is often unequally distributed across sectors and communities (Matin, Forrester and Ensor, 2018; Makondo and Thomas, 2018). In cities and settlements, adaptation interventions can displace ecological impacts to more vulnerable areas or directly lead to socioeconomically exclusionary outcomes (Anguelovski et al., 2016), particularly when adaptation plans and actions are primarily assessed through the prism of economic and/or financial viability (Shi et al., 2016; Klein, Juhola and Landauer, 2017). As a result, adaptation actions make only minimal contributions to the reduction of vulnerability – as the increased vulnerability of excluded communities more than offsets the decreased vulnerability of more well-off communities. Numerous examples ranging from the mega coastal planning in Jakarta, Indonesia (Salim, Bettinger and Fisher, 2019; Goh, 2019), fragmentation of urban infrastructure intended to promote climate resilience in Manila, Philippines (Meerow, 2017), exclusionary modes of flood control in São Paulo, Brazil (Henrique and Tschakert, 2019), strategies to reduce risks in the event of mudslides in Sarno, Italy (D'Alisa and Kallis, 2016), involuntary community relocations in Vietnam (Lindegaard, 2019) and Mozambique (Arnall, 2019) all point to how an economic logic to adaptation can lead to exclusion of lower income, informal, or minority communities in adaptation.

A specific form of maladaptation is so called green gentrification, this privileges wealthy urban residents in urban greening projects (Rice et al., 2020; Shokry, Connolly and Anguelovski, 2020; Anguelovski, Irazábal-Zurita and Connolly, 2019; Blok, 2020). For example, in Miami-Dade County, Florida, United States, researchers found that adaptation functionality had a positive effect on property values (Keenan, Hill and Gumber, 2018). In New York City and Atlanta, Georgia, United States, research has shown that adaptation investments can increase property values and lead to neighborhood change (Immergluck and Balan, 2018; Gould and Lewis, 2018). In Gold Coast and Sunshine Coast, South East Queensland, Australia, where local communities have a strong preference for waterfront living, local governments are pressured by property developers to protect these coastal zones (Torabi, Dedekorkut-Howes and Howes, 2018). In Lagos, Nigeria, efforts to achieve climate resilience and sustainability through future city practices risk perpetuating the enclosure and commodification of land (Ajibade, 2017). The exclusionary outcomes of some adaptation interventions can therefore further heighten the risk to communities that are socioeconomically more vulnerable. See Section 6.3 for further discussion of equity and justice considerations in local climate adaptation.

Human behaviour can exacerbate climate impacts – for example in the emergence of 'last chance tourism'(Lemieux et al., 2018) focused on built cultural heritage at risk from climate change associated events including from decay or even total loss generated by increased flooding and sea-level rise (Camuffo, Bertolin and Schenal, 2017) and water infiltration from post-flood standing water (Camuffo, 2019). Last chance tourism can lead to increased touristic interest over a short time horizon and to precarious economic conditions, which can lead to further accelerated degradation cultural heritage sites already at-risk from climate change.

Finally, some adaptation policies or actions can erode the preconditions for sustainable and resilient development by indirectly increasing society's vulnerability (Neset et al., 2019; Juhola et al., 2016). Mandates to mainstream adaptation into existing development logics and structures perpetuates development-as-usual, reinforcing technocratic forms of local governance and locking-in structural causes of marginalization and differential vulnerability (Scoville-Simonds, Jamali and Hufty, 2020). Adaptation policy examples include: Australia's adaptation policy focus on financial strategies, preference for business-as-usual scenarios and incremental change will not contribute to transformative change (Granberg and Glover, 2014); Surat, India, where a focus on adapting industries and economically important assets in the city can divert policy attention away from general social equity and urban sustainability priorities (Chu, 2016; Blok, 2020); Cambodia where conflict between adaptation practitioners and local communities and non-compliance with regulatory safeguards led to conflict and potential for maladaptation (Work et al., 2018). Finally, although insurance has the potential to incentivize practices to reduce risks – including through measures to reduce premiums (see Section 6.4.5 for additional details) – researchers of insurance-led adaptation actions have argued that since insurance regimes privilege normality, they tend to structurally embed risky behavior and inhibit change (O'Hare, White and Connelly, 2016). All of these examples illustrate how incremental strategies that rely on business-as-usual actions can further entrench unequal and unsustainable development patterns in the long-term. There are also significant limits to urban adaptation (see Section 6.4) with consequential impacts on human wellbeing.

Table 6.4 lists a selection of key risks (broadly defined as have severe outcomes common to a majority of cities) identified in our assessment of urban impacts and risks in this section. It provides a description of the consequences of the risk that would constitute a severe outcome, as well as the hazard, exposure and vulnerability conditions contributing to its severity. It also provides adaptation options identified and elaborated on in Section 6.3 as having the highest potential for reducing the risk, and an assessment of the confidence in the judgement that this risk could become severe. This table is also reflected in Chapter 16.5.1, and the methodology is described in Table SM16.5.1.

Table 6.4 Key Risks to Cities, Settlements and Infrastructure

Synthesis of key risks for cities, settlements, and key infrastructure								
Key risk	Geographic region	Consequence that would be considered severe, and to whom	Hazard conditions that would contribute to this risk being severe	Exposure conditions that would contribute to this risk being severe	Vulnerability conditions that would contribute to this risk being severe	Adaptation options with highest potential for reducing risk	Confidence in key risk identification	Chapter & section
Risk to population from increased heat	Global but higher risk in temperate and tropical cities (6.2.3.1)	Increased heat stress, mortality and morbidity events from urbanization and climate change. Increased health risks and mortality in elderly population; vulnerability of the young to heat, (6.2.3.1)	Substantial increase in frequency and duration of extreme heat events, exacerbated by urban heat island effects. (6.2.3.1) Concentration of a mixture of extreme heat and humidity (6.2.3.1)	Large increases in exposure, particularly in urban areas, (6.2.3) driven by population growth, changing demographics, and projected urbanization patterns. Urbanization increases annual mean surface air temperature by more than 1°C Correlation between rising temperatures and	Changing demographics from aging populations, potential for persistent poverty, slow penetration and increasing cost of air conditioning, and inadequate improvements in public health systems. (6.2.3.1) Inadequate housing and occupations with	Nature-based solutions e.g. urban greenery at multiple spatial scales; vegetation; shading; lower energy costs; green roofs; community gardens (6.3.3.1) enhanced space conditioning in buildings; broader access to public health systems for most vulnerable populations.	High confidence, high evidence & agreement	6.2, 6.3

				increased heat capacity of urban structures, anthropogenic heat release and reduced urban evaporation (6.2.3.1)	exposure to heat (6.2.3.1)	Less economic stress on residents through utilities, especially electricity (6.2.3.1) Tree planting in communities that lack urban greening (6.3.3.1)		
Urban infrastructure at risk of damage from flooding and severe storms	Global, but higher risk in coastal cities	Damage to key urban infrastructure (e.g. buildings, transport networks, and power plants) and services from flood events, particularly high risk within coastal cities, especially those located in low elevation coastal zones (6.2.3.2)	Substantial increase in frequency and intensity of extreme precipitation (6.2.3.2) from severe weather events and tropical cyclones contributing to pluvial and fluvial floods, which are exacerbated by long-term sea level rise and potential land subsidence (6.2.3.2)	Large increases in exposure, particularly in urban areas, driven by population growth, changing demographics, and projected urbanization patterns with a geographical focus in coastal regions. Flooding is exacerbated both by encroachment of urban areas into areas that retain water, and lack of infrastructure such as embankments and flood walls (6.2.3.2)	Costly maintenance of protective infrastructure, downstream levee effects, and increased concentrations of coastal urban population. Little investment in drainage solutions (6.2.3.2)	Early warning systems, Adaptive Social Protection (ASP) to reduce vulnerable populations, nature-based solutions e.g. in sponge cities to enhance flood protection and regulate storm- and floodwaters- this can be improved through reduced risk unto vulnerable urban systems such as stormwater management, sustainable urban drainage system, etc. (6.2.3.2) Green infrastructure can be more flexible and cost effective for providing flood risk	High confidence, high evidence & agreement	6.2, 6.3, CCP2

						reduction (6.3.3)		
Population at risk from exposure to urban droughts	Cities located in regions with high drought exposure, (e.g., Europe, South Africa, Australia,)	Water shortages in urban areas, and restricted access to water resources to vulnerable populations and low-income settlements. People living in urban areas will be exposed to water scarcity from severe droughts (6.2.3.3). Increased environmental health risks when using polluted groundwater (6.2.3.3)	Projections of more frequent and prolonged drought events potentially compounded with heat wave hazards, and land subsidence from coastal cities that extract groundwater. Climate drivers (warmer temperatures and droughts) along with urbanization processes (land use changes, migration to cities, and changing patterns of water use) contribute to additional risks (6.2.3.3)	Large increases in exposure, particularly in urban areas, driven by population growth, changing demographics, and projected urbanization patterns. Limitations of engineered water infrastructure is also exposed by flash droughts (6.2.3.3). Settlements are increasingly dependent on imported water resources by locales that may also be exposed to drought risk (6.2.3.3)	Greater water demand from urban populations from in-migration and key economic sectors, and inefficient or ineffective water resource management. (6.2.3.3)	Demand and supply side management strategies that include incorporation of indigenous/local knowledge and practices, equitable access to water. Better water resource management will increase quality of water available. More beneficial physical and social teleconnections to bring mutual benefit of water resources between regions (6.2.3.3)	High confidence, high evidence & agreement	6.2, 6.3
Health risks from air pollution exposure in cities	Global, in cities located in Africa, South Asia, the Middle East and East Asia	Increased mortality and morbidity events from respiratory-related illnesses and co-morbidities towards vulnerable urban populations, arising from	Increased emissions of pollutants from anthropogenic (e.g. transportation, electric power generation, large industries, indoor burning of fuel, and commercial	Large increases in exposure, particularly in urban areas, driven by population growth, changing demographics, projected urbanization patterns, and demand for energy combined	High proportion of young or aging populations vulnerable to respiratory illness, potential for persistent poverty, advection of pollutants	Enhanced monitoring of air quality in rapidly developing cities, investment in air pollution controls e.g. stricter emissions regulations, and increased GHG emissions	High confidence, medium evidence & agreement	6.2, 6.3

		PM2.5 and tropospheric ozone exposure	and residential sources) and biogenic (e.g. forests, windblown dust, and biomass burning) emissions Potential for severe compound risks arising from droughts and wildfire. Projections for frequency of meteorological conditions are expected to severe PM2.5 concentrations (6.2.3.4)	with weak regulations for emissions control (6.2.3.4)	from upwind, ex-urban areas, and stay in shelter policies from COVID-19 (Box 6.4; 6.2.5)	controls resulting in co-benefits with air quality improvements. Increase in trees or vegetated barriers with low VOC emissions, low allergen emissions, and high pollutant deposition potential to reduce particulate matter and maximize adaptation benefits (6.3.3.2)		
Health risks from water pollution exposure and sanitation in cities	Cities located in regions with high drought exposure resulting in polluted water	Increased environmental health risks when using polluted groundwater (6.2.3.3) Vulnerability of users such as women; children; the elderly; ill or disabled (6.3.4.6)	Decreased regional precipitation and changes in runoff and storage from droughts impairs the quality of water available. Less runoff to freshwater rivers can increase salinity, concentrate pathogens, and pollutants (6.2.3.3)	Large increases in exposure, particularly in urban areas, driven by population growth, changing demographics, and projected urbanization patterns. Low flows from drought can lead to sedimentation, increase pollutant concentration and	Costly maintenance of protective infrastructure. Sanitation systems coupled with flood water management are at risk of damage and capacity exceedance from high rainfall (6.2.5.8)	Investment in well-regulated water sections; wastewater treatment plants; pumping stations. Reducing impacts of floods on sanitation infrastructure through active management such as reducing blockage in sewer infrastructure (6.3.4.6)	High confidence, medium evidence & agreement	6.2, 6.3

				blocking of sewer infrastructure networks (6.2.5.8).		Adaptive planning; integration of measures of climate resilience; improved accounting and management of water resources (6.3.4.6)		

Table Notes:
Following Chapter 16, the severity of a risk or impact is a subjective judgment based on a number of criteria. Key Risks are 'potentially' severe because, while some could already be severe now, more typically they may become so over time due to changes in the nature of the climate-related hazards and/or of the exposure and/or vulnerability of societies or ecosystems to those hazards. They also may become severe due to the adverse consequences of adaptation or mitigation responses to the risk.

6.3 Adaptation Pathways

6.3.1 Introduction

Adaptation pathways are composed of sequences of adaptation actions connected through collaborative learning with the possibility of enabling transformations in urban and infrastructure systems (Werners et al., 2021). Individual adaptation actions co-evolve with risks (see Section 6.2) and development processes (Section 6.4) to compose more or less planned adaptation pathways, that can include a range of unanticipated outcomes. This section engages with this complexity by approaching adaptation through the notion of infrastructure. The adaptation options for individual infrastructure systems are reviewed, and in Section 6.4 brought together through assessment of cross-cutting enabling conditions. Interpreted broadly, infrastructure includes the social systems, ecological systems and grey/physical systems that underpin safe, satisfying and productive life in the city and beyond (Grimm et al., 2016). Social infrastructure includes housing, health, education, livelihoods and social safety nets, cultural heritage/institutions, disaster risk management and security and urban planning. Ecological infrastructure includes nature-based services: temperature regulation, flood protection and urban agriculture. Grey, or physical infrastructure includes energy, transport, water and sanitation, communications (digital), built form and solid waste management. Framing infrastructure in this way enables an assessment of adaptation that is not constrained to the administrative boundaries of urban settlements, but also includes the flows of material, people and money between urban, peri-urban and more rural places and can include adaptation actions deployed by government, individuals and the private sector. Recognising the complexity of adaptation and the research literature that reaches beyond individual infrastructural domains, the section also reviews urban adaptation through the cross-cutting lenses of equity and mitigation. Section 6.4 assesses the enabling environment (political will, governance, knowledge, finance and social context) that shapes specific adaptation contexts and futures.

6.3.2 The Adaptation Gap in Cities and Settlements

The adaptation gap is difference between the ability to manage risk and loss and experienced risk and loss (Chen et al., 2016; UNEP, 2021). It describes both levels of capacity and residual risk. Figure 6.4 presents an analysis by IPCC World Region for urban populations and current levels for risk and loss. The analysis seeks to draw out equity considerations by comparing the poorest and wealthiest quintiles for each region and for adaptation to the direct impacts of flooding and heatwave but also impacts felt in cities that include climate change impacts on supply chains – water and food security. Figure 6.4 should not be used to compare regions but can be used to contrast adaptation gaps by hazard type within regions.

The key finding from Figure 6.4 is that for all urban populations both *currently deployed* and *currently planned* adaptations are not able to meet current levels of risk associated with climate change. Even if *all conceivabl*e adaptation was to be deployed the majority of risks faced by the urban rich and poor today would not be fully resolved. This emphasizes clearly the fundamental importance of climate change mitigation to avoid urban risk and loss.

The urban adaptation gap is also found to be unequal. The poorest quintile has a larger adaptation gap than the richest quintile. Reported inequality in the application of urban adaptation is greatest in North, East and Southeast Asia reflecting rapid urbanization in this region. Reported inequality is lowest in Europe and Australasia. Observed inequalities indicate that the markets, government actions and civil society investments available to reduce vulnerability and risk amongst the poor have not been observed to offset inequalities based on individual and household capacities.

There is some catch-up as analysis moves through *actually deployed* to *planned* and *all conceivable* deployment – particularly for water and food security - but even here inequality in risk is not fully resolved. Africa and South and Central Asia in particular show considerable disparity in adaptation to urban food security even with *all conceivable adaptation*. This means that even if all available adaptation was to be deployed inequality in ability to adapt to climate change would remain. This highlights the significance of addressing underlying inequalities in development that shape differential vulnerability (see 6.2.3.1, 6.2.3.3, 6.3.5.1, 6.4) as part of vision and action on reducing risk to climate change so that no one is left behind.

Some hazard types and regions show strong capacity to close the adaptation gap if *all planned* adaptation was to be deployed: for example, Europe for heatwave and Europe and Central and South America for riverine and coastal flooding (particularly for wealthier populations). This reveals capacity within the current approaches to climate risk management, but also highlights the importance of resolving challenges that prevent planned adaptation from being deployed and deployed equitably.

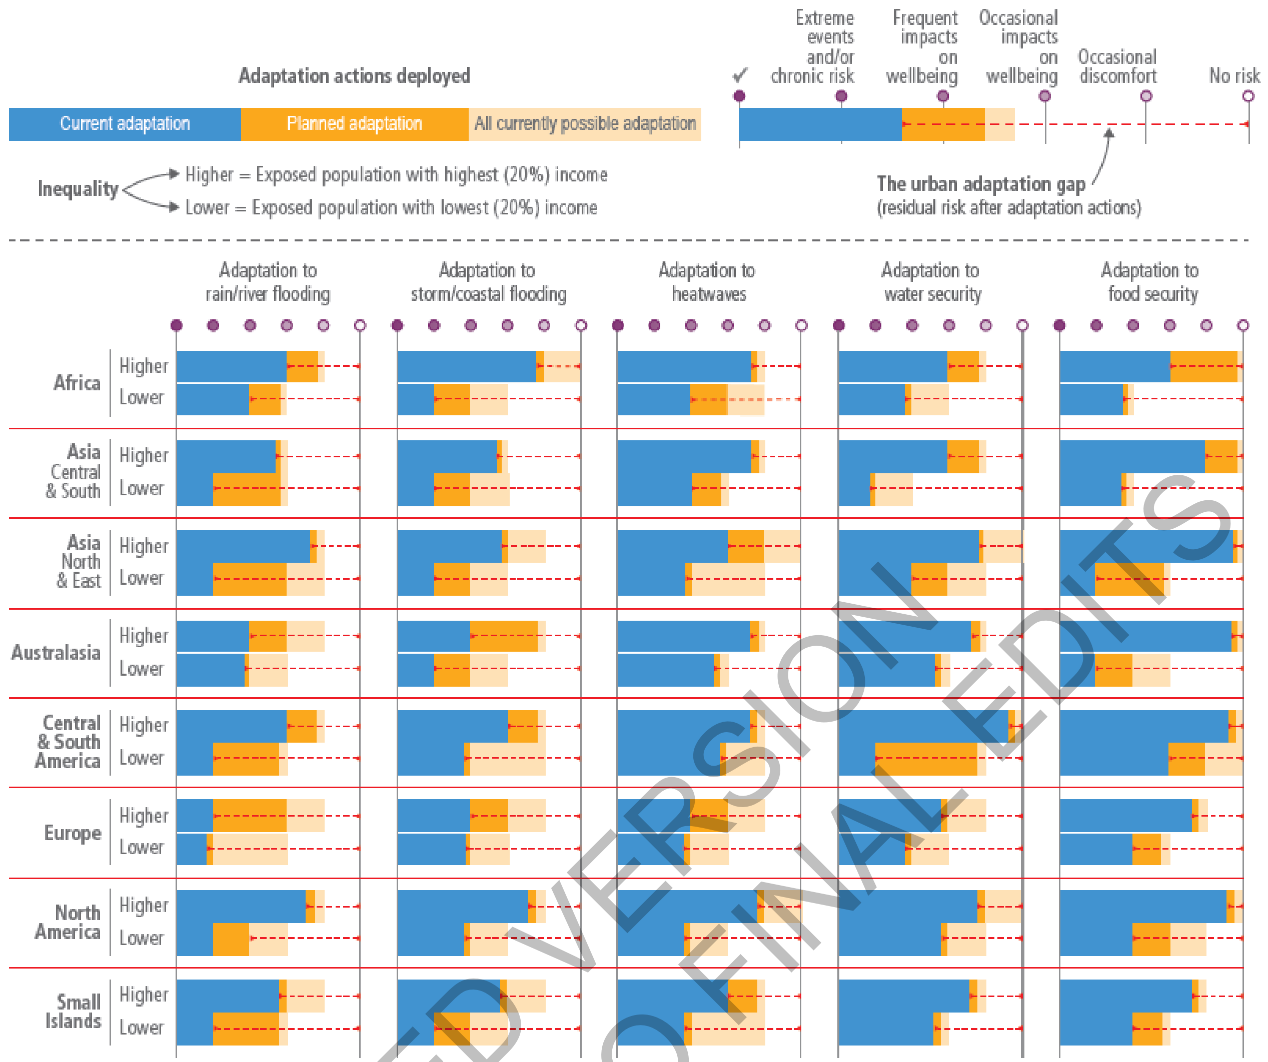

Figure 6.4: The Urban Adaptation Gap. Notes: This is a qualitative assessment presenting individual, non-comparative data for world regions from 25 AR6 CLAs and LAs, the majority from regional chapters. Respondents were asked to make expert summary statements based on the data included within their chapters and across the AR6 report augmented by their expert knowledge. Multiple iterations allowed opportunity for individual and group judgement. Urban populations and risks are very diverse within regions making the presented results indicative only. Variability in data coverage leads to the overall analysis having *medium agreement – medium evidence*. Major trends identified in 6.3.1 at least meet this level of confidence. Analysis is presented for current observed climate change associated hazards and for three adaptation scenarios: (1) current adaptation (based on current levels of risk management and climate adaptation), (2) planned adaptation (assessing the level of adaptation that could be realised if all national, city and neighbourhood plans and policies were fully enacted), (3) transformative adaptation (if all possible adaptation measures were to be enacted). Assessments were made for the lowest and highest quintile by income. Residual risk levels achieved for each income class under each adaptation scenario are indicated by five adaptation levels: no risk, occasional discomfort, occasional impacts on wellbeing, frequent impacts on wellbeing, extreme events and/or chronic risk. The urban adaptation gap is revealed when levels of achieved adaptation fall short of delivering 'no risk'. The graphic uses IPCC Regions, and has split Asia into two regions: North and East Asia, and Central and South Asia. Technical support is acknowledged from Greg Dodds and Sophie Wang

6.3.3 *Adaptation Through Social Infrastructure*

Social infrastructure refers to social, cultural and financial activities and institutions as well as associated property, buildings and artefacts that can be deployed to reduce risk and recover from loss. This section examines land use planning, livelihoods and social protection, emergency and disaster risk management, health systems, education and communication, and cultural heritage.

6.3.3.1 Land Use Planning

Land use planning plays a major role in the siting of settlements and infrastructure. In relation to climate change, it affects whether development takes place in locations that are exposed to hazards; similarly, it shapes the potential effects that the built environment can have on natural systems. Despite this, generally speaking, there is limited implementation of zoning and land use measures for climate adaptation from cities across diverse contexts (*robust evidence, high agreement*), see for example Maputo (Castán Broto, 2014), sub-Saharan cities (Dodman et al., 2017) and Amman, Moscow and Delhi (Jabareen, 2015). Certain countries, such as South Korea, have, however, recently begun to address disaster risk reduction within their land use planning systems (Han et al., 2019).

Conventional zoning regulations (in which only one kind of use is permitted in a given area) and land use planning range in scale from the regional to the local and can be deployed to minimize risks through protection, accommodation, or retreat. Protection entails, in addition to allocating zones for protective urban infrastructure (like seawalls, levees and dykes, and slope revetments), avoidance measures that restrict or prevent urban development (e.g., through growth containment and/or no-build zones). Accommodation involves land use modifications and/or conversions while retreat requires either compulsory or voluntary relocations and may entail buy outs (Butler, Deyle and Mutnansky, 2016; León and March, 2016; Lyles, Berke and Overstreet, 2018). Risk eliminating retreat measures are less widely adopted than other risk reducing zoning and land use measures (Anguelovski et al., 2016; Butler, Deyle and Mutnansky, 2016; Lyles, Berke and Overstreet, 2018). This is attributed to the controversies of relocation and to the complexities of buyouts (Butler, Deyle and Mutnansky, 2016; King et al., 2016).

Evidence from both richer countries and the Global South reveals that conventional zoning is more effective when governance systems facilitate the implementation of land use policies for climate adaptation that preclude negative human-nature interactions and that curb spatial inequity – both of which can trigger climate gentrification and increase the vulnerability of economically disadvantaged groups to climate-related risk (*high confidence*) (Marks, 2015; Liotta et al., 2020; Keenan, Hill and Gumber, 2018).. Cascading benefits of zoning and land use planning for climate adaptation are associated with the use of soft land cover, green infrastructure and improvement of livability through better conditions for walkability and cycling. This decreases auto-dependency and contributes to health and economic development (by attracting businesses and retail that stimulate economic prosperity and increase property values) (Larsen, 2015; Carter et al., 2015). Such increases in property values have also been observed in zones and areas protected from risks (such as flooding), where it may trigger spatial inequity leading to climate gentrification (Marks, 2015; Votsis, 2017; Votsis and Perrels, 2016; Keenan, Hill and Gumber, 2018).

Adaptation actions through zoning and land use are more effective when combined with other planning measures (*high confidence*), for example with ecosystem-based adaptations (e.g., for flood management and curbing the urban heat island effect) (Larsen, 2015; Nalau and Becken, 2018; Perera and Emmanuel, 2018; Anguelovski et al., 2016; Carter et al., 2015; Tsuda and Duarte, 2018; Nolon, 2016); with community-based adaptations (trade-offs and valuations, i.e., which land uses are valued more) (Larsen, 2015; Nalau and Becken, 2018; Perera and Emmanuel, 2018; Anguelovski et al., 2016; Carter et al., 2015; McPhearson et al., 2018; Nolon, 2016); and with built form regulations and codes (León and March, 2016; Yiannakou and Salata, 2017; Perera and Emmanuel, 2018; Straka and Sodoudi, 2019; Larsen, 2015; Nolon, 2016). The imposition of planning-based tools such as scenario planning, flexible zoning, and development incentivisation (among others) has the capacity to influence and encourage these adaptations (United States Environmental Protection Agency, 2017). Local risk-reduction inputs can inform land use adaptation policies (accommodation and/or avoidance, specifically growth containment and no-build zones) that are better integrated within larger urban plans (Lyles, Berke and Overstreet, 2018; Nalau and Becken, 2018; Tsuda and Duarte, 2018) (*limited evidence, high agreement*).

Implementation of zoning and land use measures for climate adaptation from cities across diverse contexts remains limited (*high agreement, robust evidence*) due to a range of challenges. A range of evidence from multiple locations indicates the challenges of mainstreaming land use planning for climate adaptation, including in Bangkok, Thailand (Marks, 2015), Legazpi City and Camalig Municipality in the Philippines (Cuevas et al., 2016; Cuevas, 2016), the United States (Cuevas et al., 2016; Cuevas, 2016), British Columbia, Canada (Stevens and Senbel, 2017), and Australia (Serrao-Neumann et al., 2017). Mainstreaming is hindered by a lack of clarity of implementation strategies for climate adaptation, insufficient funding, competing priorities (especially, among professional planners and politicians), institutional challenges (see

Jabareen's (2015) study of 20 cities globally) and the need to fill data gaps and continuously update weather statistics (Oberlack and Eisenack, 2018) (*medium evidence, high agreement*). At the same time, however, limited evidence from cities around the world such as: the urban Regions of Stuttgart and Berlin in Germany (Larsen, 2015), Greater Manchester in the UK (Carter et al., 2015), and Colombo in Sri Lanka (Perera and Emmanuel, 2018) reveals that risk reduction through zoning and land use can effectively protect and expand green infrastructure and soft land cover to alleviate pluvial flooding and decrease the urban heat island effect. This evidence points that one of the primary roles of land-use planning is to guide the development of the urban form. As such, it underpins and establishes the basis for other infrastructure systems such as physical infrastructure and nature-based solutions (Morrissey, Moloney and Moore, 2018).

6.3.3.2 Livelihoods and Social Protection

Understanding how livelihoods, particularly of the urban poor, are both impacted by climate risk and how they might be strengthened is central to understanding climate adaptation in cities and settlements (Dobson et al. 2015). Rapid urbanization and expanding physical infrastructure do not have a clear relationship with improved outcomes for urban livelihoods of low-income residents (Soltesova et al., 2014). Municipal and national efforts need to be closely aligned with building adaptive capacity of residents themselves, often through community-based adaptation (Soltesova et al., 2014; Dobson, Nyamweru and Dodman, 2015). Social safety nets protect individuals or households from falling below a defined standard of living by providing cash, in kind and other social transfers to fight vulnerabilities (Islam and Hasan, 2019) including those associated with climate change impacts including food shocks. Strengthening the financial and social infrastructure of poor households is a critical component of adaptive and transformative capacity (Haque, Dodman and Hossain, 2014; Ziervogel, Cowen and Ziniades, 2016). Social safety nets are one mechanism for strengthening this capacity.

Social protection, or social security, is defined as the set of policies and programmes designed to reduce and prevent poverty and vulnerability throughout the life cycle (ILO, 2017). Safety nets are intended to protect vulnerable households from impacts of economic shocks, natural hazards and disasters, and other crises. The UN policy frameworks for sustainable development, including the Sendai Framework for Disaster Risk Reduction 2015-2030, the new Strategic Framework 2018-2030 of the United Nations Convention to Combat Desertification (UNCCD) and UNFCCC, highlight the essential role of social protection in promoting comprehensive risk management (Aleksandrova, 2019). Since the term Adaptive Social Protection was introduced by the World Bank (2015) and the IPCC (2014), Adaptive Social Protection has been an emerging strategic tool to integrate poverty reduction, disaster risk reduction and humanitarian-development into adaptation to climate change (Béné, Cornelius and Howland, 2018; Aleksandrova, 2019; Watson et al., 2016).

Adaptive Social Protection (ASP) is defined as a resilience-building approach by combining elements of social protection, disaster risk reduction and climate change adaptation, so as to break the cycle of poverty and vulnerability of household by investing in their capacity to prepare for, cope with, and adapt to all types of shocks especially under climate change and other global challenges (Bowen et al., 2020; Ivaschenko et al., 2018). Adaptive Social Protection has been justified as an effective instrument to build household and community resilience to climate extremes and slow-onset climate events like sea level rise and environmental degradation (Schwan and Yu, 2018; Aleksandrova, 2019). In contexts of extreme poverty or climatic extremes, international development organizations, national provisions and market charities are complementary where family and kinship networks are weak and inadequate. To deal with short-term vulnerability to climate shocks, Adaptive Social Protection can act as a crucial complement to risk management tools provided by communities and markets, tools which tend to be insufficient in the face of large or systemic shocks, by providing predictable transfers, developing human capital and diversifying livelihoods (Hallegatte et al., 2016). Adaptive Social Protection can also facilitate long-term change and adaptation by improving education and health levels, as well as providing a proactive approach to managing climate-induced migration in both rural and urban areas (Schwan and Yu, 2018; Adger et al., 2014).

Many national Adaptive Social Protection programmes are established to cover both rural and urban areas, however, only a small number of researchers pay attention to urban cases (Aleksandrova, 2019). Adaptive Social Protection instruments can be classified into four major types as shown in Table 6.5 (Ivaschenko et al., 2018; ILO, 2017). Adaptive Social Protection can contribute to both incremental and transformative interventions both at the system level (short-term and long-term coping strategies from communities) and at the beneficiaries' level (vulnerable populations) (Béné, Cornelius and Howland, 2018; World Bank, 2015; Aleksandrova, 2019; Ivaschenko et al., 2018).

Table 6.5 Four categories and examples of adaptive social protection.

Category	Example	Urban cases	Function
Social safety nets (or social assistance)	Conditional and unconditional cash transfers, including non-contributory pensions and disability, birth and death allowances; Food stamps, rations, emergency food distribution, school feeding and subsidies; Cash or food for work programmes; Free or subsidized health services; Housing and utility subsidies; Scholarships and fee waivers, etc.	-A targeted asset transfer project for urban extreme poor in Dhaka city (Hossain and Rahman, 2018) - Emergency food stockpiling in Japan; safety net food stocks in India, Indonesia and Malaysia (Lassa et al., 2019) - Household cash transfer programme in contingency planning in Mexico (Ivaschenko et al., 2018) - Governmental transfer to hurricane affected households in United States (Bowen et al., 2020) - Non-contributory disability cash benefits (ILO, 2017)	Incremental adaptation; protective measures
Social insurance	Old age, survivor, and disability contributory pensions; Occupational injury benefit, sick or maternity leave; Health insurance, etc.	Old-age social pensions (Ivaschenko et al., 2018)	Incremental adaptation and ex-ante prevention
Labour market policies	Unemployment, severance, and early retirement compensation; Training, job sharing, and labor market services; Wage subsidizes and other employment incentives, including for disabled people, etc.	Public works and employment protection in Africa, Asia cases (World Bank, 2015; ILO, 2017; Ivaschenko et al., 2018)	Ex-post protection and ex-ante prevention measures, Incremental adaptation
Livelihood development measures	Income diversification, employment support, weather-index insurance, housing subsidies, post disaster construction, relocation planning, livelihood shift strategies, etc.	Multiple programs for differing household needs in Philippines (Bowen et al., 2020) Weather-index insurance in Chinese coastal cities (Rao and Li, 2019); Early warning forecast system and public meteorological service information in Beijing (Song, Zheng and Lin, 2021)	Promotive and anticipatory measures; transformational adaptation

Adaptive Social Protection (ASP) may be very good at reducing extreme poverty by helping to meet individual or household needs but not collective needs to mitigate long-term climate shocks. For example, few programmes consider risk assessment and climate-proof infrastructures as anticipatory measures to foster early action and preparedness (Aleksandrova, 2019; Costella et al., 2017). They therefore need to enable the adoption of forward-looking strategies for long-lasting adaptation (Tenzing, 2020). Some examples from China show social protection can improve adaptive capacity of urban communities with social medical insurance, housing subsidies, weather-index insurance, post disaster construction, relocation planning, livelihood shift strategies, and so on (Pan et al., 2015; Zheng et al., 2018b; Rao and Li, 2019; Song, Zheng and Lin, 2021). However, social protection may lead to maladaptation in urban policy when social security, or similar tools (for example insurance) compensate for exposure deincentivise risk reduction (Grove, 2021). In many developing countries, high concentration of poor and vulnerable groups living in disaster-prone zones of urban centres, new urban dwellers and informal residents are often excluded from community-based networks and social services (Aleksandrova, 2019). Risk transfer tools (like insurance) and risk retention measures (like social safety nets) can avoid and minimise the burden of loss and damage and limit secondary and indirect effects (Aleksandrova, 2019; Roberts and Pelling, 2018).

Inclusive, targeted, responsive and equitable social protection can support long-term transition toward more sustainable, adaptive and resilient societies (Hallegatte et al., 2016; Shi et al., 2018; Béné, Cornelius and Howland, 2018; Carter and Janzen, 2018; Adger et al., 2014). Adaptive Social Protection systems can be cost-effective and equitable when targeting accuracy, timely risk sharing (disaster assistance) and improved policy coherence. Carter & Janzen (2018) find that the long-term level and depth of poverty can be improved by incorporating vulnerability-targeted social protection into a conventional social protection system. Countries at all income levels can set up Adaptive Social Protection systems that increase resilience to natural hazards, but the systems need to identify cost-benefits, be scalable and flexible to adjust to future, increasing climate risk. Bastagli (2014) suggested a new design for effective social protection including: (i) increasing the amount or value of transfer; (ii) extending the coverage of beneficiaries; and (iii) introducing payments or new program of social protections. For social protection programmes to contribute more effectively to adaptation, they need to be better coordinated across a range of agencies; better integrated with climate data to anticipate times of need for vulnerable groups; and better aligned with other risk management instruments such as insurance (Agrawal et al., 2019).

6.3.3.3 Emergency and Disaster Risk Management

There is growing evidence of the benefits of early warning systems for urban preparedness decision-making and action for climate and weather-related hazards such as cyclones, hurricanes and floods (*medium evidence; high agreement*) (Lumbroso, Brown and Ranger, 2016; Zia and Wagner, 2015; Marchezini et al., 2017). Climate forecasting is constantly evolving and becoming increasingly accurate. Global organizations such as the World Meteorological Organizations are increasingly focusing on new and emerging technologies such as crowdsourced data collection to support integrated city services and early warning systems (Baklanov et al., 2018). However, while climate forecasting is an increasingly central tool for risk management agencies, a focus on urban areas or key infrastructure is still considerably rare (Lourenço et al., 2015; Nissan et al., 2019; Harvey et al., 2019). The significant rise in urban risks poses significant challenges to humanitarian agencies. Humanitarian responses and local emergency management are vital for disaster risk reduction yet are compromised in urban contexts where it is difficult to confirm property ownership and where renters and informal dwellers are often excluded from decision making and planning (Parker and Maynard, 2015; Maynard et al., 2017). Disaster survivors and growing urban refugee populations are often displaced across the city thereby complicating efforts to track and provide support (Maynard et al., 2017).

Existing early warning systems remain insufficient and the complexity of urban landforms makes accurate and detailed early warning difficult (*medium evidence; high agreement*) (Jones et al., 2015)This is particularly the case in low- and middle-income countries (LMICs) where urban centres are often characterized by rapid expansion of interlinked formal and informal human settlements and land use zones. In such contexts, early warning services vary in effectiveness within the same urban centre (Allen et al., 2020c; Rangwala et al., 2018). Often, forecast-based action follows linear structures where forecast information is applied mainly for responding to negative impacts rather than anticipatory decision making and preparation to avoid such impacts (Marchezini et al., 2017). Early warning systems are effective for warning of threshold breaching events including cyclonic activity and riverine flooding but less able to provide localised warning, though capability is rapidly increasing. Probabilistic risk forecasting and forecast based early action are only beginning to be applied to urban contexts and often those that are most vulnerable do not receive warnings regarding hazardous events (Nissan et al., 2019). There is less capacity for early warning systems in LMICs with key challenges linked to a lack of well-established risk baseline information; accessibility, communication and understanding of forecast information, as well as political and institutional barriers and limited resources and capacities to act on such information (Jones et al., 2015; Mustafa et al., 2015; Zia and Wagner, 2015; Marchezini et al., 2017; Gotgelf, Roggero and Eisenack, 2020). Political and institutional barriers to the incorporation of climate information to decision making are not limited to LMICs (Harvey et al., 2019). For example, comprehensive studies on sectoral use of climate information in Europe revealed that despite climate services becoming increasingly accessible and well resourced, there is limited organizational uptake of seasonal climate forecasts across key sectors (e.g. energy, transport, water and infrastructure) in informing their decision-making processes (Soares and Dessai, 2016; Soares, Alexander and Dessai, 2018). This is due both to technical and non-technical barriers such as lack of awareness and knowledge of climate information and forecasting (Soares and Dessai, 2016; Soares, Alexander and Dessai, 2018).

Globally, a considerable diversity of tools and frameworks for urban resilience assessments being developed at multiple scales (Arup and Rockefeller, 2015; Elias-Trostmann et al., 2018). These include hybrids such as Ecosystem based Disaster Risk Reduction (Eco-DRR) (Begum et al., 2014).While important advances have been made in assessing urban resilience, much debate remains around such tools and assessment approaches regarding issues such as validation, dynamics in exposure and vulnerability and appropriateness of generic methods in high density urban settlements (Leitner et al., 2018; Cardoso et al., 2020; Rufat et al., 2019). Disaster impact and recovery time are strongly influenced by the behaviour and actions of individuals, communities, businesses, and government organizations (Meriläinen, 2020; Räsänen et al., 2020). For example, Aaerts et al's (2018) review shows how the limitations of existing flood risk assessment methods (which tend to account for human behaviour in limited terms) can be addressed through innovative flood-risk assessments that integrate behavioural adaptation dynamics. Moghadas et al's (2019) study highlights the importance of hybrid multi-criteria approaches for assessing urban flood resilience in Tehran, Iran. A growing literature shows how multidisciplinary and inclusive approaches that include local knowledges can achieve greater accuracy in risk characterization and support lasting impact of investments into more robust climate services (Aerts et al., 2018; Lourenço et al., 2015; Sword-Daniels et al., 2018; Singh et al., 2018; Nissan et al., 2019; Harvey et al., 2019; Simon and Palmer, 2020). This literature highlights the need for innovative approaches in urban contexts that transcend traditional approaches of local knowledge inclusion widely applied in rural contexts, such as participatory rural appraisal.

The inclusion of local knowledge and Indigenous knowledge in urban vulnerability and risk assessments can strongly enhance local resilience but its effectiveness is constrained by wider decision-making and policy contexts dominated by top-down approaches (*medium evidence; high agreement*) (Jones et al., 2015; Sword-Daniels et al., 2018; Nissan et al., 2019). Established non-state actors such as Shack and Slum Dwellers International are particularly effective at implementing inclusive approaches for local knowledge incorporation into urban decision making. Climate change and disaster risk exacerbate existing problems of economic development, yet macro-economic planning seldom incorporates adaptation. Recent evidence also confirms the role of Indigenous knowledge and local knowledge in management practices to reduce climate risks through early warning preparedness and response (see also section 6.3.2.3). These practices are particularly important where alternative early warning methods are absent. For instance, Kasei et al (2019) show that Indigenous knowledge gathered through observations on changes in natural indicators (such as links between rainfall patterns, certain flora and fauna, and temperature changes) could be applied to develop early warning of climate hazards (floods and droughts) in informal urban settlements in African countries like Ghana. Similarly, Hiwaski et al (2015) show that observations of changes in the environment and celestial bodies are used to predict climate-related hazards in Indonesia, the Philippines and Timor-Leste where communities in turn use local materials and methods, and customary practices to respond to the impacts of climate change.

Insurance is a risk transfer mechanism for middle and high-income countries, yet is less widely available in LMICs (Surminski and Thieken, 2017). Additionally, where insurance options do exist in LMICs, these are not usually available to large populations living or operating in the informal sector. Flood insurance is widely available in many Organisation for Economic Co-operation and Development (OECD) countries but the demand and uptake differ significantly across countries (Hanger et al., 2018). This financial tool is subject to increasing pressure under the changing climate with growing concerns around affordability and availability. More integrative approaches are required, such as where changes in the insurance industry are closely linked to adaptation strategies, building standards and land-use planning and their application (Cremades et al., 2018). This is particularly important in LMICs and of central concern for all insurance schemes is ensuring access, fairness and affordability for the most poor and vulnerable. However, there are some notable examples of low-income communities setting up their own disaster insurance mechanisms. For example, the Community Development Funds for the Baan Mankong upgrading programme in Thailand include disaster funds as insurance against housing damage (Archer, 2012). Such approaches also need to be more closely linked to existing urban risk management planning approaches where urban livelihoods are seldom integrated and informed by more dynamic risk reduction frameworks that consider adaptive cycles and how resilience changes over time (Beringer and Kaewsuk, 2018; Cremades et al., 2018).

Disaster risk management systems face increasing challenges in adapting to evolving risk profiles, shaped by expanding urban areas and changing environmental conditions associated with climate change. In addition to flooding, risk monitoring and management systems have recently shown considerable shortfalls in planning for and responding to increased fire risk such as the devastating Californian wildfires in October 2019 (Morley, 2020) and Australia's unprecedented and catastrophic 2019-2020 wildfire season. Risk management has also been challenged by new risk experiences including wild/bush fires encroaching on expanding urban areas and fire outbreaks in densely populated informal settlements pose increasing threats to livelihoods, human health and habitats globally (see also Sections 2.4.4.2 and 2.5.5.2).

6.3.3.4 Climate Resilient Health Systems

Climate resilient health systems are a vital part of adaptation to protect the most vulnerable from climate change (WHO, 2020). Cardiovascular fitness for example is a root cause of morbidity and mortality form heat stress (Schuster et al., 2017). The World Health Organization has developed a framework of climate-resilient health systems that addresses both mitigation and adaptation goals (WHO, 2015). Universal Health Coverage (UHC) is an essential component of climate resilient health systems. In most countries, access to health services is better in urban than in rural areas. However, there remain large urban populations with insufficient coverage of health services (WHO and WB, 2015) and UHC tracking needs to take better account of inequalities in coverage, including differences in access within cities and further disaggregation of urban populations by income. Thus, health sector investment is an important tool in adaptive action and capacity. Analyses of health survey data shows that, globally, access to health care is increasing towards UHC targets (Lozano et al., 2020). Financing for global health has increased steadily in the last two decades and modelling shows this trend is likely to continue to 2050, but at a slower pace of growth and the current disparities in per-capita health spending persist between high and low/middle income countries, leading to insufficient health service coverage for the poorest populations (Chang et al., 2019a). Out-of-pocket spending is projected to remain substantial in LMIC and will remain the only means to access health care for many poor urban populations.

The WHO Operational Framework highlights the components that can be strengthened to adapt to extreme weather (e.g., health care workforce, information systems etc.). The evidence is greatest for impacts on larger health facilities (such as hospitals) and there is less evidence regarding impacts on health service delivery outside these settings (smaller health facilities, pharmacies, first responders, public health inspectors etc.). Improved building design and spatial urban planning (where facilities are located) are essential to increase resilience for higher temperature and flood risk (*medium evidence; high agreement*) (WHO, 2021; Codjoe et al., 2020; Korah and Cobbinah, 2017). Public health systems rely on information systems (including disease and vector surveillance and monitoring) to identify new and emergent public health risks. Improvements to health surveillance will increase resilience, particularly for populations in informal settlements that are absent from health and vital registration systems.

City-level and local government adaptation planning is facilitated by information on health impacts (Reckien et al., 2015), highlighting the need for monitoring and surveillance and the need for local evidence based risk assessments. Adaptation in the health sector can be limited by lack of collaboration between health and other sectors, although this is often easier to facilitate at the local level (Woodhall, Landeg and Kovats, 2021).

6.3.3.5 Education and Communication

Since AR5 there has been significant growth in research about climate education and activism (Simpson, Napawan and Snyder, 2019; O'Brien, Selboe and Hayward, 2018; Hayward, 2021). Access to knowledge is an important determinant of wellbeing, inclusivity and livelihood mobility and of driving human behaviour. Knowledge systems include formal educational provision (capital assets, syllabus and human capital), informal learning based in social interaction and customary institutions (including through social media) and public communication (news media, government and other information systems including commercial messaging). There is a growing body of literature addressing the role of information and communication technology in shaping behaviour in disaster response and recovery and climate action with particular focus on social media use and serious gaming (Houston et al., 2015; Carson et al., 2018) (see Section 6.3.4.3)

Given the amount of time that children spend in school settings, adapting educational infrastructure and programs to climate change is highly important. This includes not only making physical structures safe but also providing students with the knowledge and confidence to support individual and family-based adaptation. Several UN agencies (e.g. UNICEF and UNDRR) and international non-governmental agencies (e.g. Plan International) have prioritised safer schools and child centred risk management that often focus on schools as places that should be prioritised for retrofitting and safe construction but also as focal points for knowledge dissemination and community organising where impacts can extend beyond the school to reduce risk amongst students' families. Universities, think tanks, as well as the third and private sector are key support mechanisms, particularly at the local level and when working in collaboration with local government and communities. They can support the development of critical educational resources and innovative communication methods, as well as facilitate the design and implementation of climate policies and related action plans.

Youth, adult communities, the social media and commercial media can have a significant impact on advancing climate awareness and the legitimacy of adaptive action, particularly in large urban areas (*medium evidence; high agreement*). Climate change education has increasingly focused in urban settlements on enhancing children and young people's political agency in schools, universities, and in formal and informal media settings (Cutter-Mackenzie and Rousell, 2019). However, an ambiguous framing of climate impacts and adaptation, for example around the science of urban heat islands by media can also exacerbate local community confusion and uncertainty (Iping et al., 2019) and further training and capacity building opportunities such as for vocational qualifications is still required across diverse settings (Simmons, 2021). Communication strategies deployed in formal education and social media can be highly influential in exchanging information and establishing narratives and viewpoints that frame what adaptive action is legitimate, especially in large cities (Simpson, Napawan and Snyder, 2019). However, the effectiveness of communication strategies for change for example from Mayoral offices, can also be influenced by wider political and structural drivers including community literacy or political partisanship (Boussalis, Coan and Holman, 2019). Recent research (e.g. Macintyre et al., 2018) highlights the need for new, learning approaches to climate education from school age to adult education. Emphasis is on inclusivity in learning and recognising diverse perspectives across multiple levels and settings, from formal and informal education to wider social learning. Informal learning that takes place outside of school settings such as in libraries and botanical gardens in everyday life is increasingly recognised as a key arena for climate education, life-long learning and nurturing environmental citizenship and activism (Paraskeva-Hadjichambi et al., 2020).

6.3.3.6 Cultural heritage/institutions

The integration of culture into urban policy and planning is increasingly recognised as critical to developing sustainable and resilient cities and features in international agreements such as the SDGs (*limited evidence; high agreement*) (Sitas, 2020). However, urban cultural policies are still limited, for example, Cape Town is the only African city to have developed a city level cultural policy (Sitas, 2020). Cultural heritage refers to both tangible (e.g. historic buildings and sites) and intangible (e.g. oral traditions and social practices) resources inherited from the past (Fatorić and Egberts, 2020; Jackson, Dugmore and Riede, 2018). Learning about past societal and environment changes through heritage offers opportunity for reflection, transfer of knowledge and skills. This takes place in multiple contexts such as museums and cultural landscapes, and in everyday life (Fatorić and Egberts, 2020; Jackson, Dugmore and Riede, 2018). Cultural heritage is primarily associated with identity and is closely intertwined with the complexities of history, politics, economics and memory. Climate change adds another layer of complexity to cultural heritage and resource management (Fatorić and Seekamp, 2017). Changing climatic conditions are already negatively impacting World Heritage Sites such as the Cordilleras' Rice Terraces of the Philippines and earthen architecture sites - for example the Djenné mosque in Mali are particularly vulnerable to changes in temperature and water interactions (UNESCO, 2021). Climate change impacts intangible cultural heritage across diverse settings such as in the Caribbean and Pacific SIDS where traditional ways of life and related aspects such as oral traditions and performing arts are under threat from extreme weather events (UNESCO, 2021).

The climate change adaptation options for built cultural heritage fall into seven categories (Rockman et al., 2016; Fatorić and Seekamp, 2017). Financial constraints are the primary barriers that underpin the first four adaptation options: no action at all, merely monitoring and/or documenting, or annual maintenance (Xiao et al., 2019; Sesana et al., 2019; Fatoric and Seekamp, 2017; Fatorić and Seekamp, 2017; Fatorić and Seekamp, 2018). Core and shell preservation, the fifth and sixth categories, are cost effective when they improve the condition of built cultural heritage (BCH) (Bertolin and Loli, 2018; Loli and Bertolin, 2018a; Loli and Bertolin, 2018b), while elevation and/or relocation, the final adaptation options, are extremely costly and might jeopardize the historic value (Xiao et al., 2019). To date, however, evidence indicates that adaptation actions prioritize archaeological sites (Carmichael et al., 2017; Fatorić and Seekamp, 2018; Pollard et al., 2014; Dawson, 2013). The efficacy of adaptation of historic buildings can be increased through increased and stable funding, incentives, stakeholder engagement, and legal and political frameworks (Dutra et al., 2017; Fatorić and Seekamp, 2018; Fatorić and Seekamp, 2017; Fatoric and Seekamp, 2017; Leijonhufvud, 2016; Phillips, 2015; Sesana et al., 2019; Sesana et al., 2018; Sitas, 2020).

Other barriers to implementation include harnessing expert and local knowledge (of individuals and organizations) to identify both quantitative and qualitative methods and indicators that connect cultural significance and local values vis-à-vis climatic change over time and that move beyond the prevalent high risk- or high vulnerability-centred approaches (Carmichael et al., 2017; Fatorić and Seekamp, 2018; Haugen et al., 2018; Leijonhufvud, 2016; Pollard et al., 2014; Puente-Rodríguez et al., 2016; Richards et al., 2018; Dawson, 2013; Filipe, Renedo and Marston, 2017; Kotova et al., 2019). This is particularly important given that the significance of cultural heritage is often intangible, and its value cannot be determined solely through quantitative indicators. Accessing local resources (craftsmanship and materials compatible with the originals) can also improve built cultural heritage's adaptation capacity (Phillips, 2015).

Effective decision making and practice for adapting built and intangible cultural heritage requires open dialogue and exchange of cultural, historical and technical information between diverse stakeholders and decision-makers (Fatorić and Seekamp, 2017; Benson, Lorenzoni and Cook, 2016). As noted in Section 6.2.6, human behaviour can be a driving force for adaptation impacts on built cultural heritage at risk. Despite challenges associated with intangibility, socio-cultural heritage such as Indigenous knowledge (e.g. food security and water management practices) presents important opportunities for climate adaptation and resilience building. More research is needed across diverse contexts to understand feasible climate adaptation measures and barriers and opportunities for building the resilience of both built and intangible cultural heritage, as well as to increase awareness of cultural heritage benefits among climate change policymakers (Fatorić and Egberts, 2020).

6.3.4 Adaptation Through Nature-Based Solutions

Well-functioning ecosystems can play a significant role in buffering cities, settlements and infrastructure from climate hazards at multiple scales *(robust evidence, high agreement)*. Nature-based solutions (NBS) are actions to protect, sustainably manage and restore natural or modified ecosystems that address societal challenges effectively and adaptively, simultaneously providing human well-being and biodiversity benefits (Cohen-Shacham et al., 2016). Widely recognized as low-regret measures for disaster risk reduction and climate change adaptation, green and blue infrastructure investments and natural area conservation in cities can provide NBS at across scales to reduce temperature shocks and provide natural flood defences among other adaptation and resilience benefits (McPhearson et al., 2018; Andersson et al., 2019; Frantzeskaki et al., 2019). Blue infrastructure for example provides ecological and hydrological functions (e.g. evaporation, transpiration, drainage, infiltration, detention) critical to sustainable urban water management (Iojă et al., 2021). Public parks, urban forests, street trees and green roofs as well as lakes, ponds and streams are widely documented for providing local cooling, grass and riparian buffers and forested watersheds can enhance flood and drought protection for cities and settlements, and mangrove stands and wetlands in coastal areas can reduce storm surges. Despite increasing knowledge about NBS (here encompassing literature on ecosystem services for climate change adaptation and resilience, ecosystem-based adaptation, and benefits of green and blue infrastructure for adaptation), recent studies indicate that nature-based approaches to adaptation and resilience are still under-recognised and under-invested in urban planning and development (Matthews, Lo and Byrne, 2015; Geneletti and Zardo, 2016; Frantzeskaki et al., 2019), despite the potential scale of benefits – for example, a recent study covering 70 cities in Latin America calculated that 96 million people would benefit from improving main watersheds with green infrastructure (Tellman et al., 2018).

Grey infrastructure often damages or eliminates biophysical processes (e.g. through soil sealing, stream burial, or altered hydrology) necessary to sustain ecosystems and habitats, and livelihoods, where urban ecological infrastructure (Childers et al., 2019) can be more flexible and cost effective for providing flood risk reduction and other benefits (Palmer et al., 2015). Hybrid approaches are emerging that integrate ecological and grey (engineered) infrastructure in adaptation planning and hazard protection (Grimm et al., 2016; Depietri and McPhearson, 2017). Explicit policy uptake by city authorities is increasing (Hansen et al., 2015; Hölscher et al., 2019) such as in New York where in 2010 the city committed to a hybrid infrastructure plan for storm water management, investing US$ 5.3 billion over 20 years, of which US$2.4 billion was targeted for green infrastructure investments (NYC, 2010). A subset of services from urban ecosystems are being increasingly invested in as NBS for climate adaptation pathways (Keeler et al., 2019; Kabisch et al., 2016) and included as regulatory drivers through flood management, hazard mitigation, and air pollution regulations that encourage or enforce the implementation of green infrastructure practices (Davis et al., 2020).

Development and climate mitigation co-benefits of NBS is an additional reason that NBS are being increasingly taken up by cities including for improving health and livelihoods, particularly for poor, marginalized groups (Poulsen et al., 2015; Poulsen, Neff and Winch, 2017; Maughan, Laycock Pedersen and Pitt, 2018; Simon-Rojo, 2019; Cederlöf, 2016). Co-benefits include a wide range of social and environmental benefits (Brink et al., 2016; Alves et al., 2019) for human physical and mental health (Kabisch, van den Bosch and Lafortezza, 2017; Sarkar, Webster and Gallacher, 2018; Engemann et al., 2019; Rojas-Rueda et al., 2019), climate mitigation (De la Sota et al., 2019) and as habitat for local biodiversity (Ziter, 2016; Knapp, Schmauck and Zehnsdorf, 2019). At the same time concerns about the unintended consequences of investing in green infrastructure for NBS such as how it may contribute to gentrification (Turkelboom et al., 2018; Anguelovski et al., 2018; Haase et al., 2017b), create more public use, increase water demand (Nouri, Borujeni and Hoekstra, 2019), or contribute to criminal activity (Cilliers and Cilliers, 2015) underlines the challenges of investing in adaptation in complex urban systems (See Section 6.2.6). Additionally, more place-based analysis of the efficacy of nature-based solutions for reducing climate impacts across varying urban contexts and future climate scenarios is needed to better understand the cost effectiveness of investing in NBS to provide disaster risk reduction and deliver critical co-benefits for human well-being. Cooperation between scientists, decision makers and indigenous knowledge-holders can supplement current efforts as well as to ensure that investments in nature-based solutions do not negatively impact indigenous communities (Ban et al., 2018; Seddon et al., 2021; Townsend, Moola and Craig, 2020).

6.3.4.1 Temperature Regulation

Nature-based strategies – including street trees, green roofs, green walls, and other urban vegetation – can reduce heat and extreme heat by cooling private and public spaces (*robust evidence, high agreement*). Shading and evapotranspiration are the primary mechanisms for vegetation induced urban cooling (Coutts et al., 2016). Shading reduces mean radiant temperature, which is the dominant influence on outdoor human thermal comfort under warm, sunny conditions (Thorsson et al., 2014; Viguié et al., 2020). Outdoor green space and parks may also slightly reduce indoor heat hazard (Viguié et al., 2020). Apart from lowering temperature, nature-based solutions may also contribute to lower energy costs by reducing extra demand for conventional sources of cooling (e.g. air conditioning) (Viguié et al., 2020; Foustalieraki et al., 2017), especially during peak demand periods. Homes with shade trees that are located in cities where air conditioning systems are common can save over 30% of residential peak cooling demand (Zardo et al., 2017; Wang et al., 2015). Green roofs have been shown to significantly lower surface temperatures on buildings (Bevilacqua et al., 2017) and modelling suggests that green roofs, if employed widely throughout urban areas, have the potential to impact the regional heat profile of cities (Bevilacqua et al., 2017; Rosenzweig, Gaffin and Parshall, 2006). Community or allotment gardens, backyard greening, and other types of low vegetation, as well as lakes, ponds, rivers, and streams, can also provide local cooling benefits to nearby residents (Gunawardena, Wells and Kershaw, 2017; Larondelle et al., 2014; Santamouris, 2020).

Urban climate models show that increased vegetation cover results in reducing both mean air temperatures and extreme temperatures during heat waves (Heaviside, Cai and Vardoulakis, 2015; Ferreira and Duarte, 2019; Schubert and Grossman-Clarke, 2013). Greater density and more canopy coverage relative to other built and paved surfaces increases shade provision and evapotranspiration (Hamstead et al., 2016; Grilo et al., 2020; Herath, Halwatura and Jayasinghe, 2018; Knight et al., 2021). However, local cooling by vegetation depends on regional climate context, geographic setting of the city, urban form, the density and placement of the trees, in addition to a variety of other ecological, technical, and social factors, such as local stewardship (Salmond et al., 2016). Green spaces less than 0.5-2.0 ha may have negligible cooling effects at regional scales, but impacts of shading can have microscale cooling benefits (Gunawardena, Wells and Kershaw, 2017; Zardo et al., 2017). Vegetation impacts on day versus night-time cooling varies (Imran et al., 2019) as does cooling potential in temperate versus tropical climates. The supply of cooler air from surrounding peri-urban and rural areas can impact cooling in the urban core suggesting that regional adaptation planning for NBS is important to maintain or extend ventilation paths from the urban fringe into the city centre (Schau-Noppel, Kossmann and Buchholz, 2020).

To maximize the adaptation benefits of NBS for regulating urban heat, it can be helpful to prioritize tree planting and other urban greening investments in areas where heat vulnerability and risk are the highest, especially communities that lack urban tree canopy or accessibility to parks to cool off during hot days or heat waves (Ziter et al., 2019). Planting trees closely together or in partly permeable vegetated barriers along streets can improve local cooling benefits. Additionally, choosing tree species with leaves that have the greatest leaf area index or the largest leaves can improve cooling performance, as those trees have the greatest shading and evapotranspiration benefits that, in turn, provide the greatest cooling effects (Keeler et al., 2019). Drought resistant trees, often native trees, are ideal to avoid high watering costs, though dry or water scarce areas may limit adoption of urban vegetation as an NBS strategy (Coutts et al., 2013). Native trees and permaculture can provide additional benefits for local biodiversity as shown in study in Melbourne, Australia which found that increasing vegetation from 10 to 30 percent increased occupancy of bats, birds, bees, beetles and bugs by up to 130% (Threlfall et al., 2017), with particularly high impact on native species.. Additionally, planting fruit or nut trees can provide co-benefits for local food production, and yet choice of species and placement is important to consider with respect to local cultural needs and norms (Adegun, 2018; Adegun, 2017).

6.3.4.2 Air Quality Regulation

Nature-based solutions in cities can help regulate air quality by absorbing air pollutants (*medium evidence, medium agreement*). For example, planting trees or vegetated barriers along streets or in urban forests can reduce particulate matter, the ambient air pollutant with the largest global health burden (Janhäll, 2015; Tiwary, Reff and Colls, 2008; Matos et al., 2019; McDonald et al., 2016). However, findings show that trees can also positively affect ground-level ozone (Calfapietra et al., 2013; Kroeger et al., 2014), airborne pollen concentrations (Willis and Petrokofsky, 2017), and indirectly affect air quality through reduced emissions from energy production offset by shade provision (Keeler et al., 2019). Certain tree species however can also be detrimental to urban ozone formation by emitting significant amounts of reactive biogenic volatile organic compounds (VOCs). Decreasing urban emissions of VOCs is an increasingly important ozone mitigation strategy in urban areas (Fitzky et al., 2019).

Trees can also have negative effects by increasing pedestrian exposure to pollution if trees are introduced in heavily travelled street canyons where air pollutants can be trapped (Vos et al., 2013; Gromke and Blocken, 2015). To maximize the adaptation benefits of NBS for improving air quality planners and managers can target tree selection for species with low VOC emissions, low allergen emissions, and high pollutant deposition potential (Keeler et al., 2019) and combine with low pollution transportation policies. Studies suggest sensitive planting of roadside tree canopies can have positive effects on air pollutants (Beckett, Freer Smith and Taylor, 2000; Yang, Chang and Yan, 2015). For example, Xue et al (2021) found that the PM2.5 reduction between 2013 and 2017 in China was associated with a saving of approximately USD 111 billion per year nationally. Tree planting near schools, nursing homes, and hospitals can ensure that benefits provided by trees are delivered to the local populations that stand to benefit the most from improved air quality, but species need to be adapted to regional climate to provide benefits over time (Donovan, 2017; Nowak et al., 2018).

6.3.4.3 Stormwater Regulation and Sanitation

Urban parks and open spaces, forests, wetlands, green roofs and engineered stormwater treatment devices help manage stormwater and wastewater by reducing the volume of stormwater runoff, reducing surface flooding, and reducing contamination of runoff by pollutants (*robust evidence, high agreement*). Engineered devices include bioswales, rain gardens, and detention and retention ponds, and are becoming common and standard approaches to mitigate the negative effects of impervious surfaces on stormwater quality and surface flooding in cities (Zhou, 2014; McPhillips et al., 2020). Allotment gardens, street trees, green roofs and urban forests may also help reduce runoff and provide a stormwater retention service (Pennino, McDonald and Jaffe, 2016; Berland et al., 2017; Gittleman et al., 2017). Modelling and empirical studies show that nature-based solutions at small spatial scales lead to improvements in water quality and reduction of peak flows (Moore et al., 2016; Keeler et al., 2019; Webber et al., 2020). Peak flow reductions are greatest for small rain events. For example, D-Ville et al. (2018) observed 30-70% reduction in peak flow for the 1 in 30 year storm, but performance reduces for more intense rainfall or if saturated (Garofalo et al., 2016). Employing NBS to reduce flooding on roads can be an important adaptation mechanism for reducing the impact of flooding events on traffic flows (Pregnolato et al., 2016).

During periods with intense precipitation, low-lying urban parks and open space, engineered devices, and wetlands can play an important role in reducing stormwater runoff volumes, by providing places for water to be stored and infiltrate during heavy storms (Moore et al., 2016). However, the magnitude of the runoff reduction service will depend on the total area of green infrastructure, vegetation type, and its position on the landscape. There is less evidence of the effectiveness of nature-based solutions at larger temporal and spatial scales (Pregnolato et al., 2017; Jefferson et al., 2017). The performance of NBS depends on the degree to which their extent and spatial configuration in the city are optimized to capture runoff (Fry and Maxwell, 2017). Investing in a diversity of NBS types may be important to maximize stormwater management and flood regulation as different types of engineered NBS have different strengths and weaknesses.

Overall, NBS are attractive adaptation options for stormwater management and to reduce impacts of pluvial and fluvial flooding in cities (Rosenzweig et al., 2018a) compared to, and in combination with, grey infrastructure. Cities with combined sewer infrastructure are likely to see benefits from NBS due to reductions in stormwater quantity and reduced sewage overflows. Cities where a large proportion of residents lack access to piped infrastructure and drink surface water may see large benefits, especially to human health, from NBS investments (Keeler et al., 2019). Where future large-scale upgrades or installation of grey infrastructure will be necessary, new and growing cities may have more opportunity to realize large net benefits from investments in NBS. Older cities, and new, rapidly urbanizing areas that lack large scale water infrastructure may see the greatest benefits from enhanced NBS, relative to cities where heavy investments infrastructure upgrades have already been made. Cities facing climate changes that including more frequent or extreme precipitation may also see large water quality benefits from investment in NBS (Keeler et al., 2019). Overall, there is increasing evidence that NBS for addressing stormwater is cost-effective (Bixler et al., 2020; Kozak et al., 2020; Mguni, Herslund and Jensen, 2016), especially in cities facing a need to update current infrastructures.

6.3.4.4 Coastal Flood Protection

Coastal ecosystems including coral and oyster reefs, coastal forests including mangroves and other tree species, salt marshes and other types of wetland habitat, seagrass, dunes, and barrier islands can reduce impacts of coastal flooding and storms (*robust evidence, high agreement*) (Zhao, Roberts and Ludy, 2014; Boutwell and Westra, 2016; Narayan et al., 2017; Yang, Kerger and Nepf, 2015; Bridges et al., 2015; World Bank, 2016) (see also CCP2 Cities and Settlements by the Sea). Recent literature highlights the value of nature-based approaches for coastal protection in terms of avoided damages and human well- being (Narayan et al., 2017; Silva et al., 2016a). Nature-based solutions (NBS) can protect coasts from flooding through reducing the wave energy by drag friction, reducing wave overtopping by eliminating vertical barriers, and absorbing floodwaters in soil (Arkema, Scyphers and Shepard, 2017; Dasgupta et al., 2019; Zhu et al., 2020). For example, coastal and marine vegetation and reefs can dissipate wave energy, attenuate wave heights and nearshore currents, decrease the extent of wave runup on beaches, and trap sediments (Ferrario et al., 2014; Bridges et al., 2015). These effects result in lower water levels and reduce shoreline erosion, which in turn has potential to save lives and prevent expensive property damages (Narayan et al., 2017).

Researchers, practitioners, and policy-makers are increasingly calling for the use of nature-based approaches to protect urban shorelines from coastal hazards (Cunniff and Schwartz, 2015; Bilkovic et al., 2017). The expectation is that coastal ecosystems can help stabilize shorelines, protect communities against storm surge, and from tidal influenced flooding while providing other co-benefits for people and ecosystems. However, vegetation along protected coastlines, with higher frequency, lower intensity coastal hazards (National Research Council, 2014) may be more effective for stabilizing shorelines and reducing risk to coastal communities and properties and benefits will depend on local hydrology of the coastal region. Narayan et al. (2017) estimate that coastal wetlands alone reduced direct flood damages by US$625 million during Hurricane Sandy in the United States in 2012. Similarly, researchers found that villages with wider mangroves between them and the coast experienced significantly fewer deaths than villages with narrow or no mangroves during a 1999 cyclone in India (World Bank, 2016). Recently, Arkema et al. (2017) noted that the number of people, poor families, elderly and total value of residential property most exposed to hazards along the entire coast of the USA can be reduced by half if existing coastal habitats remain fully intact.

Coastal habitats also have limitations in their ability to protect coasts from extreme events. Some studies suggest reduced effectiveness of vegetation and reefs for coastal protection from large storm waves and surge (Möller et al., 2014; Guannel et al., 2016) and there is active debate in the literature about the ability of ecosystems to mitigate the impact of tsunamis (Gillis et al., 2017). Further research is needed to understand and quantify coastal protection services provided by these hybrid green-grey solutions, especially in urban areas (Bilkovic et al., 2017). Additionally, in some coastlines water may be too deep or waves too high for some species such as mangroves to grow, thrive and provided needed NBS.

Maximizing the adaptation benefits of NBS for improving coastal flood protection research requires that cities seek to restore and conserve the vegetation and reef types that are appropriate for the exposure setting and in sufficient abundance to be effective. In particular planners and managers can use vegetation in protected bays as alternatives to hard infrastructure for shoreline stabilization. However, the influence of ecosystems on flooding and erosion is variable and depends on a suite of social, ecological, and infrastructural factors that vary within and among urban areas (Narayan et al., 2017; Ruckelshaus et al., 2016; Bridges et al., 2015). Additionally, long-term planning to restore or ensure resilience of individual species and ecosystems that may themselves be damaged or destroyed during extreme events is needed in order for urban green and blue infrastructure to continue providing NBS over the longer term.

6.3.4.5 Riverine Flood Impact Reduction

Nature-based solutions reduce both the volume of floodwater and the impact of floods (*medium evidence, medium agreement*). NBS reduce the volume of runoff by increasing infiltration and water storage (Shuster et al., 2005; Salvadore, Bronders and Batelaan, 2015), and affect the production and impact of flood waters through reducing river energy and flow speed through physical blockage, stabilizing riverbanks during flood events, creating space for floodwaters to expand, and combating land subsidence (Palmer, Filoso and Fanelli, 2014; Ahilan et al., 2018). Installing nature-based solutions to increase infiltration on low slopes and high-permeability soils can reduce the impacts of potential increases in urban flooding driven by climate change, especially for small to medium-scale flood events (lower than 20% mean annual flood) (Moftakhari et al., 2018).

Source reduction strategies include creating permeable areas such as parks and open spaces as well as engineered devices like raingardens, bioswales, and retention ponds that help retain stormwater runoff from impervious areas. River restoration can reduce flood peak flow and provide space for floodwaters to expand. Planting and maintaining vegetation along riverbanks, often in the form of parks or river restoration, maintains structural integrity during flood events. Wetland construction and improved connectivity to floodplains also reduces flood peaks. Efforts to restore floodplains are important to create space for floodwaters and reduce exposure by moving people out of the hazard zone. Floodplain restoration also provides access to the river that has multiple benefits including recreation, access to water for domestic use, and other cultural ecosystem services. A key adaptation strategy is to reduce streambank erosion (a result of high peak flow) using riparian vegetation to stabilize riverbanks during flood events.

Cities manage flood risk using different types of adaptation and regulatory mechanisms (Naturally Resilient Communities, 2017). Built flood-control infrastructure, such as levees and stream channelization, reduces the demand for nature-based flood impact reduction. Cities facing flood risk that do not currently have extensive grey flood-mitigation infrastructure may find nature-based solutions to be an appealing, lower cost solution (Keeler et al., 2019). In cities where flood-control grey infrastructure already exists there is less demand for nature-based solutions of flood protection, but nature-based solutions may provide important back-up, especially in a changing climate that may increase flood hazards (City of Los Angeles, 2017; Elmqvist et al., 2019). Overall, city and basin wide NBS for riverine flood impact reduction can reduce the generation of new hazards by making space for water which can reduce the potential for a false sense of security provided by traditional flood management approaches (Ruangpan et al., 2020; Turkelboom et al., 2021).

6.3.4.6 Water Provisioning and Management

The role of nature-based solutions has been increasingly recognized for improving urban water management emphasizing it contribution for climate adapted development and sustainable urbanization (*robust evidence, high agreement)* (Wong and Brown, 2009). Nature-based solutions that protect or restore the natural infiltration capacity of a watershed can increase the water supply service to various extents, improving drought protection, and provide resilient water supply (Drosou et al., 2019; Krauze and Wagner, 2019), although different forms of NBS (e.g. street trees, parks and open space, community gardens, and engineered devices such as rain gardens, bioswales or retention ponds) contribute in different ways to increasing stormwater infiltration. Additional sources of water may be available to replace the water supplied by nature-based solutions, such as rainwater harvesting, inter-basin transfers, or desalination plants. Reliance on naturally sourced, locally available surface water and groundwater is more energy-efficient and economical than desalination or water reuse for potable use (Boelee et al., 2017), while rainwater harvesting is even more economical. Increasing the amount of green space in urban areas can secure and regulate water supplies, improving water security (Liu and Jensen, 2018; Bichai and Cabrera Flamini, 2018). However, Bhaskar et al (2016) reviewed the effect of urbanization and nature-based solutions on baseflow and suggest that the confounded effects of infiltration and evapotranspiration losses, combined with the subsurface infrastructure (sewer systems) and geology, makes it difficult to predict the magnitude of baseflow enhancement resulting from the implementation of nature-based solutions in cities.

To maximize the adaptation benefits of NBS for urban water supply research suggests that managers and planners consider nature-based solutions as alternatives to traditional stormwater management techniques, where possible, since these solutions can promote groundwater recharge. As green infrastructure is increasingly being used for stormwater absorption in cities (McPhillips et al., 2020), rain gardens, wetlands, or engineered infiltration ponds and bioswales are the nature-based solutions most likely to promote recharge, reduce evapotranspiration, and contribute to water provisioning.

6.3.4.7 Food Production and Security

Urban agriculture can serve as a NBS for food security (*medium evidence, medium agreement*) across a range of urban contexts (Lwasa and Dubbeling, 2015; Nogeire-McRae et al., 2018; Pourias, Aubry and Duchemin, 2016) by contributing to food provisioning as well as providing co-benefits including for recreation, place-making, and mental health (Petrovic et al., 2019; Soga, Gaston and Yamaura, 2017; Goldstein et al., 2016b).

Urban agriculture among poorer communities in lower income areas is already an important source of food supply for those communities contributing to food security and health (Orsini et al., 2013). However, potential for expanding open air urban food production may be practically constrained by land availability (Badami and Ramankutty, 2015; Martellozzo et al., 2014). This is particularly true in some lower-income countries where rapid urbanization is occurring, which compounds existing food insecurity (Satterthwaite, McGranahan and Tacoli, 2010; Vermeiren et al., 2013). Land availability and suitability for gardens can be further constrained by land-use history, including past industrial uses that can contaminate soils with pollutants such as lead.

At the same time, investments in vertical agriculture continue to expand, such as in Singapore where private investment in food production is occurring in high rise buildings (Wong, Wood and Paturi, 2020). Not all cities can benefit similarly from vertical agriculture since higher heating costs to produce vegetables indoors during northern winters consumes considerable amounts of energy and may generate fossil fuel emissions depending on the energy source (Goldstein et al., 2016a; Mohareb et al., 2017). Some regions can benefit from more traditional outdoor urban farming such as in South and Southeast Asia which can support multiple growing cycles per year for some crops, particularly in tropical areas where irrigation is available. Light availability, soil health, and water available will impact food production in urban areas. For example, a study conducted in Vancouver, Canada, demonstrated that light attenuation from buildings and trees can both reduce crop yield and reduce water demand for crop growth (Johnson et al., 2015).

Climate change may have important impacts on urban food production and food security. While urban agriculture may provide benefits in terms of stability of food access in low-income households in some regions of the Global South where the climate is warmer, the shorter growing seasons in colder climates will reduce the role of outdoor urban agriculture in year-round food supply and diets. Though urban agriculture constitutes a small fraction of total food consumption in some urban areas, several studies have attempted to estimate the extent to which urban agriculture could theoretically meet urban total food or vegetable demand (Badami and Ramankutty, 2015; McClintock, 2014; Hara et al., 2018). Maximizing the adaptation and resilience benefits of NBS for food production and security suggests the need to embrace the multi-functionality of urban agriculture rather than viewing it as solely concerning food production (Barthel, Parker and Ernstson, 2015).

6.3.5 Adaptation Through Grey/Physical Infrastructure

Globally it is estimated that as much as US$94tn of investment is required between 2016 and 2040 to replace, upgrade and extend the world's physical infrastructure (Oxford Economics, 2017), much of which is ageing and will require replacement. Given the typical lifespan of infrastructure this is both an opportunity and an imperative to ensure this investment is low carbon and resilient to climate change risks (Grafakos et al., 2020). 'Grey' or physical infrastructure is a priority for adaptation because its performance is sensitive to climate (particularly extreme events) and decisions on design and renovation have long-lasting implications and are hard to reverse (Ürge-Vorsatz et al., 2018). Avoiding longer-term impacts on society, the economy, and environment, will require future investment, and retrofit of existing infrastructure, to be undertaken in the context of the risks of climate change (Dawson et al., 2018; Rosenzweig et al., 2018b). However, evidence from Africa shows that the benefits of pro-active adaptation measures and policies for infrastructure can result in net savings depending on the country context (Section 9.8.5).

Engineered measures for hazard mitigation such as seawalls, slope revetments, river levees, as well as air conditioning are increasingly implemented in urban centres but many engineering interventions are less affordable and accessible in low and middle-income countries due to high construction and maintenance costs. These adaptive measures can also counter mitigation objectives due to reliance on climate polluting energy sources. Despite this, engineering measures such as seawalls for tsunami protection and cooling areas in cities provide critical hazard reduction functions in urban contexts (Depietri and McPhearson, 2017). As Pelling et al (2018a) highlight, sustainable risk reduction can be better achieved where these engineering measures include the at-risk poor majority and inclusive planning to support pro-poor risk reduction. Inclusive design and management of physical infrastructure can enhance contributions to Climate Resilient Development (Table 6.6 and Supplementary Material). This section covers urban morphology and built form, building design, information and communication technology, energy, transport, water and sanitation, and coastal management. All these domains of physical infrastructure will require adaptation to cope with a changing climate, many of them can also contribute to broader adaptation for cities and settlements.

6.3.5.1 Urban Morphology and Built Form

Urban morphology describes the overall status of cities as physical, environmental and cultural entities. Cities interact with surrounding environmental processes – for example as documented in Section 6.2 by influencing urban temperature, but also precipitation and through coastal and riverine development fluvial and coastal sedimentary regimes of erosion and deposition that impact on flood risk. Rapid, increased urbanization has contributed to observed flood risks in recent decades (see Chapter 5 4.2.4 (Tramblay et al., 2019)). The design process for physical infrastructure projects and significant construction (e.g. residential or industrial estates and large industrial development) typically includes risk assessments and social and environmental impact assessments that consider neighbouring land uses and connected infrastructure. Land use planning can consider diverse land-uses and their interactions at the neighbourhood level (Section 6.3.2.1). Resilience planning aims to bring together integrated, systemic views and enable joined-up planning at the city level (as well as lower scales) (Section 6.3.2.1). There is however a lack of long-term studies that assess the climate change impacts on urban form, including informal settlements (Bai et al., 2018; Ramyar, Zarghami and Bryant, 2019), leading to impact assessments that often overlook urban form (Ramyar, Zarghami and Bryant, 2019). Additionally, context-specific spatial tools and community-based approaches lack a precise connection to urban morphology. For example, there is a need for further studies that connect solar radiation, urban morphology (e.g., aspect and plot ratio), and the urban heat island spatio-temporal variability (Giridharan and Emmanuel, 2018; Li et al., 2019c).

Several tools and models have emerged in response to recommendations from AR5, including models that assess the impacts of urban heat island (Ramyar, Zarghami and Bryant, 2019), climatic uncertainty (Dhar and Khirfan, 2017), flood vulnerability (Abebe, Kabir and Tesfamariam, 2018), and inundation (Barau et al., 2015; Ford et al., 2019). For example, findings from Kano, Nigeria reveal that a lack of distribution of certain urban morphological features, including open spaces and streets (both pervious and impervious), roof and building materials (e.g., concrete and metallic), and urban ecological features (e.g., urban ponds and ecological basin) exacerbates inundations and their associated impacts (Barau et al., 2015). Also, findings about the urban forms of coastal settlements, particularly in small islands, reveal that they often experience severe beach erosion due to wave action, sea-level rise and storm surge that leads to landward retreat of coastline which threatens their social and economic activities (Dhar and Khirfan, 2016; Lane et al., 2015; Khirfan and El-Shayeb, 2019). Despite these examples very limited research is available to offer assessments of different urban scale morphologies and urban scale adaptation planning, including planning adaptation across supply chains and networked relationships with distant urban and rural places connected through trade and resource (financial, human and material) or waste flows.

Interventions in the morphology and built form of cities can contribute to the reduction of the urban heat island effect and reduce the consequences of urban heat waves. These can include installing air conditioning, establishing public cooling centers (i.e., for use during heat waves), pavement-watering (Parison et al., 2020a), and increasing surface albedo through "cool roofs" (i.e., with high-reflectance materials) and walls. Air conditioning can significantly increase the local urban heat island (Salamanca et al., 2014; Wang et al., 2019a) and the choice of refrigerant has a significant impact on global warming potential (McLinden et al., 2017). The relative efficiency of cool roofs compared to green roofs is variable, because while white roofs have similar potential to reduce the urban heat island (Li, Bou-Zeid and Oppenheimer, 2014), they can quickly turn grey due to dust and air pollution, losing their effectiveness (Gunawardena, Wells and Kershaw, 2017) although these effects are now well studied and newer performance standards should account for ageing and soiling effects on reflectivity (Paolini et al., 2014). Ageing of "cool pavements" is more complex which makes their long term performance less reliable to predict (Lontorfos, Efthymiou and Santamouris, 2018). The cooling performance of green roofs is highly variable and depends on the actual water content of the green roof substrate, with dry vegetation performing poorly in terms of cooling (Parison et al., 2020b). This holds true for regular vegetation and Nature-Based Solutions in general (Daniel, Lemonsu and Viguie, 2018). For all built environment adaptations, changes are locked-in for a long time and are likely to be expensive so that care is needed to avoid potential negative impacts on social equity (Cabrera and Najarian, 2015; Romero-Lankao et al., 2018; Fried et al., 2020; Rode et al., 2017) and carbon-intensive construction (Bai et al., 2018; Seto et al., 2016).

6.3.5.2 Building Design and Construction

Architectural and urban design regulations at the single building scale (building codes and guidelines) facilitate climate responsive buildings that adapt to a changing climate and have the potential to collectively change user behaviour during extreme weather events (Osman and Sevinc, 2019). They include buildings that are adaptive to ensure user comfort during extremes of hot and cold, and to floods (e.g., building on stilts and amphibian architecture). Changes to design standards can scale quickly and widely, but retrofit of existing buildings is expensive so care must be taken to avoid potential negative impacts on social equity (Schünemann et al., 2020; Matopoulos, Kovács and Hayes, 2014; Ajibade and McBean, 2014; Bastidas-Arteaga and Stewart, 2019). Buildings can be adapted to the negative consequences of climate change by altering their characteristics, for example increasing the insulation values (e.g. van Hooff et al., 2014; Makantasi and Mavrogianni, 2016; Fisk, 2015; Fosas et al., 2018; Barbosa, Vicente and Santos, 2015; Invidiata and Ghisi, 2016; Pérez-Andreu et al., 2018; Taylor et al., 2018; Triana, Lamberts and Sassi, 2018), adding solar shading (e.g. van Hooff et al., 2014; Makantasi and Mavrogianni, 2016; Barbosa, Vicente and Santos, 2015; Invidiata and Ghisi, 2016; Pérez-Andreu et al., 2018; Taylor et al., 2018; Triana, Lamberts and Sassi, 2018; Dodoo and Gustavsson, 2016; Osman and Sevinc, 2019), increasing natural ventilation, preferably during the night (e.g. van Hooff et al., 2014; Makantasi and Mavrogianni, 2016; Pérez-Andreu et al., 2018; Triana, Lamberts and Sassi, 2018; Dodoo and Gustavsson, 2016; Osman and Sevinc, 2019; Mulville and Stravoravdis, 2016; Cellura et al., 2017; Fosas et al., 2018; Dino and Meral Akgül, 2019), solar orientation of bedroom windows (Schuster et al., 2017), applying high-albedo materials for the building envelope (van Hooff et al., 2014; Invidiata and Ghisi, 2016; Baniassadi et al., 2018; Triana, Lamberts and Sassi, 2018), altering the thermal mass (van Hooff et al., 2014; Mulville and Stravoravdis, 2016; Din and Brotas, 2017), adding green roofs/facades to poorly insulated buildings (Geneletti and Zardo, 2016;

Skelhorn, Lindley and Levermore, 2014; van Hooff et al., 2014; de Munck et al., 2018; Feitosa and Wilkinson, 2018) and for water harvesting (Sepehri et al., 2018).

In general, the most promising adaptation measures are a combination of solar shading with increased levels of insulation and ample possibilities to apply natural ventilation to cool down a building (e.g. van Hooff et al., 2014; Makantasi and Mavrogianni, 2016; Fosas et al., 2018; Barbosa, Vicente and Santos, 2015; Taylor et al., 2018; Triana, Lamberts and Sassi, 2018; Dodoo and Gustavsson, 2016). However, it must be noted that the cooling potential of natural ventilation will decrease in the future due to increasing outdoor air temperatures (Gilani and O'Brien, 2020). Increased insulation (including through green solutions) without shading and ventilation can also lead to adverse impacts through the lowering of night-time cooling (Reder et al., 2018). Similarly, air conditioning performance also decreases with increasing outdoor temperatures, in addition to being maladaptive where use increases anthropogenic heat emissions into the urban area, and global greenhouse gas emissions if powered by carbon intensive energy systems (Wang et al., 2018c).

Passive cooling is a design-based, widely used strategy to create naturally ventilated buildings, making it an important alternative to address the urban heat island for residential and commercial buildings (Al-Obaidi, Ismail and Rahman, 2014). Generally, passive cooling is achieved by controlling the interactions between the building envelope and the natural elements. Façade fixes such as overhangs, louvres, and insulated walls are effective at shading buildings from solar radiation while complex ones such as texture walls, diode roofs, and roof ponds are effective at minimizing heat gains from solar radiation and ambient heat (Oropeza-Perez and Østergaard, 2018). Passive cooling is inspired also by traditional design forms, for example from Mediterranean, Islamic and Mughal architecture in the Indian sub-continent (Di Turi and Ruggiero, 2017; Izadpanahi, Farahani and Nikpey, 2021).

In addition, wind towers, solar chimneys, and air vents are features that facilitate cool air circulation within buildings while dissipating heat (Bhamare, Rathod and Banerjee, 2019). These features may be arranged to address hotspots or highly frequented spaces within buildings. Similar to nature-based solutions, the effectiveness of passive cooling to ameliorate the urban heat island varies widely depending on the location of the sun, wind direction, and the type of strategy used. For instance, natural ventilation strategies (e.g. wind towers, solar chimneys, etc.) have shown temperature reductions of up to 14°C (Bhamare, Rathod and Banerjee, 2019; Calautit and Hughes, 2016; Rabani et al., 2014). Shading strategies alone can reduce indoor temperatures by 3°C, while heat sinks (in which heat is directed at a medium such as water) may result in indoor temperatures up to 6 °C lower than the outdoor temperature (Oropeza-Perez and Østergaard, 2018). More systemic interventions, such as altering urban form through urban planning can mitigate the urban heat island across suburbs and cities (Lee and Levermore, 2019; Takkanon and Chantarangul, 2019; Yin et al., 2018; Liang and Keener, 2015; Emmanuel and Steemers, 2018). Experience in Kano (Nigeria) has shown that incorporating Indigenous knowledge into building design and urban planning can increase resilience to heat and flood risks (Barau et al., 2015). A review by Lemi (2019) suggests that traditional ecological knowledge can provide wider climate change adaptation benefits.

Limits on housing and building adaptation include failure of regulatory systems so that formal design standards are not followed even when legally required (Arku et al., 2016; Durst and Wegmann, 2017; Pan and Garmston, 2012; Awuah and Hammond, 2014). This can be a result of pressures from clients for cheaper structures, developers illegally cutting costs or regulators lacking capacity for enforcement. Technological innovation can also be slow to embed itself in building norms and standards. Innovation also lies outside the formal sector and can include artisanal building techniques that may have adaptive value. Examples from Latin America demonstrate how initiatives in informal settlement improvement associated with housing policy, guaranteeing access to land and decent housing, show the opportunity for overarching policies encompassing development, poverty reduction, disaster-risk reduction, climate-change adaptation, and climate-change mitigation (See 12.5.5).

6.3.5.3 Information and Communication Technology

Information and Communication Technologies (ICTs) are deeply intertwined with the functioning of urban and infrastructure systems, and are at the core of the 'smart city' concept (Angelidou, 2015). ICT is more flexible than other physical infrastructure, although as other sectors are increasingly reliant on ICT it is creating new climate-related failure mechanisms (Norman, 2018; Maki et al., 2019). ICT assets and networks in urban, national and international communications systems will need to be strengthened to enable ICT infrastructure to better cope with climate change, and to enable ICT infrastructure to support the resilience of cities, settlements, and other infrastructure. The increased pervasiveness of ICT, in smart cities, smart infrastructure and day to day living, will evidently have long term implications for exposure to climate change risks and how cities manage those risks (Norman, 2018; Maki et al., 2019). For example, even if the ICT network is resilient to heatwaves, it is dependent on the electricity network to power it. Conversely, other networks are dependent upon ICT for control systems, e.g., Smart Grids for energy. There is limited information on how these interdependencies, and associated risks, will evolve.

Although networked like many other infrastructure systems, ICT components have some distinctive properties. They are relatively cheap, and the advent of wireless communications has enabled ICT to have the widest reach of all infrastructures. Components can be rapidly deployed or repaired, and generally ICT networks are therefore built with inherent redundancy and flexibility (Sakano et al., 2016). Components have a wide range of expected lifetimes which leads to faster cycles of innovation. There is therefore greater potential to accelerate uptake of climate resilience in this infrastructure sector, but conversely this can increase waste and (energy intensive) resource consumption. For example, mobile phones and computers may last as little as a year, cables and switching units may be moved and upgraded to improve bandwidth every few years, poles and masts are typically designed to last several decades, whilst exchanges and other critical nodes can be in use for over half a century.

ICTs are playing an increasing role in resilience building and enabling climate change adaptation. They are enabling access to information needed for decision-making, facilitating learning and coordination among stakeholders and building social capital, as well as helping to monitor, visualize and disseminate current and future climate impacts (Eakin et al., 2015; Heeks and Ospina, 2019; Haworth et al., 2018; Imam, Hossain and Saha, 2017). Advocacy and awareness raising through ICTs such social media applications can influence behaviours and attitudes in support of adaptive pathways (Laspidou, 2014).

ICTs play a role in adaptive responses to both short-term shocks and long-term trends associated with climate change. Timely access to information (e.g. early warning, temperature and rainfall, agricultural advice) through ICTs (e.g. mobile devices, SMS, radio, social media) can be crucial to respond and mitigate the impact of emergencies such as floods and drought, for identifying pest and disease prevalence, and for informing livelihood options, key in adaptation pathways of vulnerable (Devkota and Phuyal, 2018; Panda et al., 2019).

In addition to contributing to the robustness and stability of the critical infrastructure in the event of disasters, ICTs can strengthen other attributes of resilient urban systems by enabling learning and community self-organization, cross-scale networks and flexibility, helping vulnerable stakeholders, in particular, to adjust to change and uncertainty (Heeks and Ospina, 2015; Heeks and Ospina, 2019). Big data is being used to inform responses to humanitarian emergencies (Pham et al., 2014; Ali et al., 2016), as well as to generate new forms of citizen engagement and reporting (e.g. community-based maps of flood-prone areas) that can help to inform coping and adaptive responses (Ogie et al., 2019).

The selection and use of ICTs for adaptation needs to be fairly grounded in the broader socio-cultural, economic, political and institutional context, to ensure that these tools effectively help address existing, emerging and future adaptive needs. Typically, ICT is inadequate on its own to make a significant difference (Toya and Skidmore, 2015). The role of ICTs in adaptive pathways is influenced by; the availability of locally relevant information (e.g. weather-based advisory messages, local market prices), the accessibility of information by all members of the community (e.g. using various text, audio and visual content, local languages, addressing gender-related exclusion, cost and digital competencies), and the applicability of information at the appropriate scale (local, regional or national), including data quality and verification (Namukombo, 2016; Haworth et al., 2018).

Information privacy and security, as well as the unintended impacts of ICTs on inequality, spread of misinformation, and on widening existing gaps (e.g. due to poverty, gender and power differentials), can also constrain the contribution of ICTs to urban adaptation (Haworth et al., 2018; Coletta and Kitchin, 2017; Leszczynski, 2016) and are among the key challenges that need to be addressed in order to fully realize their potential.

6.3.5.4 Energy

A number of measures are available to adapt existing energy infrastructure to climate change. These typically involve changing engineering design codes and upgrading facilities to cope with new climatic conditions, building redundancy and robustness into systems, and preparation to ensure continued operation following extreme events. Adapting low carbon energy infrastructure improves its climate resilience whilst simultaneously delivering mitigation goals (Kemp, 2017; Feldpausch-Parker et al., 2018), benefitting all other sectors (Dawson et al., 2018; Pescaroli and Alexander, 2018; Kong, Simonovic and Zhang, 2019).

Hall et al. (2019) identified 4223GW of global power generation at risk of flooding. If these assets were protected by 0.5m flood protection, ~700GW would be at risk from the 1 in 100-year flood. Many assets can be strengthened, relocated, or replaced with new equipment built to higher standards. An example of this is in the UK where a total of £172 million is being invested in between 2011-2023 to raise flood protection of substations to be resilient to the 1 in 1000 year flood (ENA, 2015). Electricity cables can be upgraded in anticipation of reduced efficiency in a warmer climate, although in many locations this may be achieved autonomously to meet growth in electricity demand (Fu et al., 2017).

Fuels, including oil, natural gas, hydrogen, biomass, and CO_2 prior to sequestration are delivered and distributed by pipeline or transportation by road, rail and shipping. In addition to engineering improvements, adaptation measures also include planning and preparation for service disruption by changing transport patterns, increasing local storage capacities, and identifying and prioritising protection of critical transport nodes (Wang et al., 2019b; Panahi, Ng and Pang, 2020).

Several options are available to reduce the impacts of reduced cooling water for thermoelectric power generation, increases in water temperature, and lower flows for hydropower generation. These include (i) switching from freshwater to seawater (if available) or air cooling; (ii) replacing once through cooling systems with recirculation systems; (iii) replacing fuel sources for thermoelectric power generation; (iv) increasing the efficiency of hydro and thermoelectric power plants; (v) relaxing discharge temperature rules to allow warmer water to enter rivers; (vi) installation of screens to stop algae or jellyfish blooms clogging intakes (vii) reducing power production and managing demand; and, (viii) changing reservoir operation rules (where available). Shreshta et al. (2021) show that changing reservoir operation rules can offset reduced water availability under RCP8.5 until 2050, but is insufficient by the 2080s. Van Vliet et al., (2016) showed that a 10% increase in hydroelectric generation efficiency can compensate for reduced water availability in most regions. Higher efficiency thermoelectric plans offset impacts under lower climate change scenarios but are shown to be inadequate under RCP8.5 by the 2080s; whereas a switch to seawater and dry (air) cooling provides a net increase under this scenario. However, these technologies can increase costs. Increasing the temperature of water discharged from the power station can have negative environmental impacts (Thome et al., 2016; Yang et al., 2015).

Longer term systemic strategies could include a combination of increased network redundancy and decentralization of generation locations (Fu et al., 2017), or the use of 'defensive islanding' which involves splitting the network into stable islands in order to isolate components susceptible to failure and subsequently trigger a cascading event (Panteli et al., 2016). Smart grids are being increasingly deployed within municipalities to provide more efficient management of supply and demand and mitigate greenhouse gas emissions, however, there is limited understanding of their performance and reliability during floods and other extreme weather events (Vasenev, Montoya and Ceccarelli, 2016; Feldpausch-Parker et al., 2018).

Adaptation and preparedness at the household level can minimize impacts during power outages, but neighbourhood level assistance may be more appropriate to ensure support for vulnerable households, and coordination of action and information (Ghanem, Mander and Gough, 2016). More generally, it is important for responder organisations integrate energy needs in disaster preparedness and response plans. Whilst over the longer term, reducing household and industrial demand for energy supply will reduce the need for capital investments and upgrades (Fu et al., 2017).

Providing a reliable and resilient power supply is crucial to economic and social development (Fankhauser and Stern, 2016). Furthermore, there are co-benefits from the use of low carbon energy systems (Chapter 8, WGIII AR6). For example, solar-charged street lamps and household lighting provides reliable nighttime lighting providing safety, security and resilience to disruption of network power supplies (Burgess et al., 2017). At larger scales, deploying solar power on building roofs, reduces energy demand for cooling by 12% and lowers the urban heat island and thereby has health benefits (Masson et al., 2014a). In the USA, construction of solar panels over 200millin parking spaces would generate a quarter of the country's electricity supply (Erickson and Jennings, 2017).

As shown in Table 6.3 access to energy supply varies considerably. In particular, many African countries require substantial energy infrastructure to support their economic development. The combination of smart technologies with solar and other renewable generation provides a huge opportunity (Anderson et al., 2017; Kolokotsa, 2017). However, care must be taken in rapidly developing cities as failure to ensure energy access during urbanization can reduce resilience (Ürge-Vorsatz et al., 2018).

6.3.5.5 Transport

A wide range of adaptation options are available for transport infrastructure and most provide a good benefit cost ratio (Doll, Klug and Enei, 2014; Forzieri et al., 2018). Options include upgrading infrastructure (which can often be achieved autonomously as part of standard repair and replacement schedules), strengthening, or relocating (critical) assets. Adaptation of road and rail networks in Australasia includes re-routing, coastal protection, improved drainage, and upgrading of rails (Table 11.7. In areas with substantial infrastructure deficits, such as much of Africa, investments in public transport and transit-oriented development are highlighted as desired mitigation-adaptation interventions within cities of South Africa, Ethiopia, and Burkina Faso (Section 9.8.5.3). Adapting low carbon transport infrastructure will be crucial to ensure resilience to climate change impacts whilst simultaneously delivering mitigation goals (Shaheen, Martin and Hoffman-Stapleton, 2019; Costa et al., 2018).

Wright et al. (2012) calculated that strengthening bridges in the USA would cost \$140-\$250bn by 2090 (or several billion dollars a year), but costs are reduced by 30% if interventions are made proactively. Koks et al. (2019) calculate a benefit cost ratio of greater than one for over 60% of the world's roads exposed to flooding. The greatest benefits from adaptation of the global road network are in low- and middle-income countries where reductions in flood risk are typically between 40-80%. Pregnolato et al. (2017) showed that in the city of Newcastle upon Tyne (UK) two carefully targeted interventions at key locations to manage surface water flooding reduced the impacts of the 1 in 50-year event in 2050 by 32%. In permafrost regions geo-reinforcement, foundation and piles can be strengthened (Trofimenko, Evgenev and Shashina, 2017), whilst passive cooling methods, including high-albedo surfacing, sun-sheds, and heat drains can cool infrastructure (Doré, Niu and Brooks, 2016).

Hanson and Nicholls (2020) calculate the total global investment costs for port adaptation to sea-level rise and provision of new areas US\$223-768bn by 2050. However, adaptation of existing ports is only 6% of this. Yesudian and Dawson (2021) estimate the cost of maintaining present levels of flood risk in 2100 for the global air network will cost up to \$57bn (Monioudi et al., 2018; Esteban et al., 2020b).

New technologies and design innovations can improve the resilience of cars, trains, boats and other vehicles to cope with more extreme weather. Mobility transitions have the potential to improve mobility and accessibility, to influence urban form and to reduce vehicular use (and thereby infrastructure degradation), vehicle miles travelled and vehicle-based emissions (Sperling, Pike and Chase, 2018). For example, use of electric vehicles, hydrogen vehicles, and greater uptake of public transport and other vehicles that reduce exhaust head emissions reduces the urban heat island (Kolbe, 2019) Carsharing can reduce carbon emissions by over 50% (Shaheen, Martin and Hoffman-Stapleton, 2019). Ride-hailing - matching nonprofessional drivers of private vehicles with paying passengers - positively impacts low-income, low car ownership households in Los Angeles (Brown, 2018), and fills market gaps in cities where public transit infrastructure is inadequate, unreliable or unsafe (Suatmadi, Creutzig and Otto, 2019; Vanderschuren and Baufeldt, 2018), but can also create a precarious and insecure job market that impacts wellbeing (Fleming, 2017). Whether the resulting impacts are positive or negative, largely depends on local, national and international policy and practices.

Safe and convenient walking and cycling (and public transport) infrastructure in cities reduces carbon emissions and urban heat island intensity, but also improve cardiovascular capacity which reduces heat stress (Schuster et al., 2017). In some regions warmer weather may bring opportunities for increased uptake of cycling and walking, though precipitation or thermal discomfort caused by high temperature and humidity can reduce the use of active travel modes for commuting and recreation (Chapman, 2015). Shaded pavements and lanes, and measures to mitigate the urban heat island can reduce risks to disruption of active travel thereby also enhancing mitigation (Wong et al., 2017).

Full system re-design may enable the greatest resilience but it does not usually have a good benefit cost ratio (Doll, Klug and Enei, 2014). Moreover, Caparros-Midwood et al. (2019) show that transport infrastructure planners will not always be able to resolve trade-offs between managing climate risks and mitigating greenhouse gases without tackling other sectors. However, infrastructure planners should continually seek opportunities for positive infrastructure lock-in where available (Ürge-Vorsatz et al., 2018).

6.3.5.6 Water and Sanitation

Adaptation to water scarcity can be through measures to increase supply (e.g. water storage, rainwater harvesting, desalination, river basin transfers, increased abstraction, reduce pollution of water sources), or manage demand (e.g. reduce leakage lower consumption, use of water efficiency devices, greywater reuse, behaviour change). A combination of these measures is usually required (e.g. Ives, Simpson and Hall, 2018; Dirwai et al., 2021; Wang et al., 2018a). Reliable, well adapted, water and sanitation services support economic growth, public health, reduced marginalisation and poverty, can lower energy use and improve water quality (Campos and Darch, 2015; Miller and Hutchins, 2017; Jeppesen et al., 2015; Hamiche, Stambouli and Flazi, 2016).

Globally, water sector adaptation costs are estimated to be $20 billion per year by 2050 (Fletcher, Lickley and Strzepek, 2019). Globally, the budget required by 2030 for water infrastructure (new and refurbishment) is more than half of the budget required for all infrastructure (Koop and van Leeuwen, 2017). For OECD countries water adaptation increases costs by 2%, but this proportion is far higher for developing nations (Olmstead, 2014).

A number of adaptation actions are available to reduce the impacts of floods on water and sanitation infrastructure. Active management reduces blockages in water infrastructure, and protect related services such as roads and culverts which are essential to ensure the operation of onsite sanitation infrastructure (Capone et al., 2020). The impact of floods for onsite or sewerage systems can be lowered by reducing or eliminating excreta from the environment through regular maintenance, cleaning, and clearing of blockages (O'Donnell and Thorne, 2020; Borges Pedro et al., 2020).

Infrastructure to protect key assets such as water and wastewater treatment plants or pumping stations has a high cost but benefits all connected households and reduces pollution from flood events. In well-regulated water sectors, there has been an increasing focus on such investments (Campos and Darch, 2015). Whereas more diffused cheaper interventions can reduce flood water ingress to domestic toilets (Irwin et al., 2018). Luh et al. (2017) found that protected dug wells were one of the least resilient technologies, whereas piped, treated, utility managed surface water systems had higher resilience.

Protecting water sources from pollution is even more important in a warmer climate that increases the frequency of algal blooms. Individual assets such as water intake pipes can be protected using screens (Kim et al., 2020a), whereas basin scale land management is required to reduce nutrient load from runoff (Me et al., 2018), whilst injecting water or installing barriers can protect coastal aquifers from salinization (Siegel, 2020).

More radical structural interventions may be needed in the longer term, but would need to be planned and delivered in coordination with investments in other sectors, particularly housing (Lüthi, Willetts and Hoffmann, 2020). As an interim measure, sanitation services with a lower reliance on fixed infrastructure, or container based sanitation could be appropriate in many urban areas that are badly affected by flooding (Mills et al., 2020).

Other actions include use of adaptive planning (Evans, Rowell and Semazzi, 2020), integration of measures of climate resilience into water safety plans (Prats et al., 2017), as well as improved accounting and management of water resources (Lasage et al., 2015). Policy prescriptions on technologies for service delivery, and changes in management models offer potential to reduce risks, particularly in low-income settings (Howard et al., 2016). Where formal sewerage provision is lacking, community based adaptation that incorporates both the function of the sanitation system as well as the vulnerability of users (e.g., women, children, elderly, ill or disabled) into the design is essential (Duncker, 2019).

6.3.5.7 Flood management

Cities are deploying a broad range of strategies to adapt infrastructure to flooding, with hard engineering approaches (e.g. dikes and seawalls) increasingly complementing soft approaches, including planning and use of nature based solutions, that emphasize natural and social capital (Jongman, 2018; Sovacool, 2011). The infrastructure can alter downstream risks and lead to increased residual risk by encouraging more floodplain construction (Miller, Gabe and Sklarz, 2019; Ludy and Kondolf, 2012). Physical infrastructure is highly cost effective for large settlements, but not always for small settlements (Tiggeloven et al., 2020) and can be inaccessible to poorer communities (Sayers, Penning-Rowsell and Horritt, 2018; Van Bavel, Curtis and Soens, 2018). It is often inflexible once installed but new designs and adaptive pathways are emerging (Anvarifar et al., 2016; Kapetas and Fenner, 2020).

As urban areas have expanded, so too have the number of vulnerable assets, and efforts may now emphasize reducing construction in high risk regions (Paprotny et al., 2018a). The National Flood and Coastal Erosion Risk Management Strategy for England, for example, calls for reductions in inappropriate developments in floodplains (Kuklicke and Demeritt, 2016; UK Environment Agency, 2020). Because climate change increases the flood risk profile of certain regions, reconsideration of design criteria has become more common (Ayyub, 2018). New York City now requires the sewer system currently designed for hydraulic capacity in 5-year design life should be designed for 50-year design life taking into account climate changes over that period (NYC, 2019).

Adaptation strategies are diverse and often involve hybrid physical and nature-based solutions, and increasingly integrated management plans that consider both flood prevention and designing infrastructure and supporting people to cope with floods when they occur. Adaptation typically focuses on (i) increasing the standard of protection to compensate for the increased magnitude of extreme events; (ii) increased maintenance to cope with increased frequency of extremes and changes in ambient conditions; (iii) changed maintenance regimes from narrower maintenance windows e.g. as assets are used more frequently (Sayers, Walsh and Dawson, 2015); (iv) land use planning and management to reduce exposure and manage hydrological flows, and (v) raising awareness, preparedness, and incident management. In high population areas, hard interventions such as dikes and levees are generally cost effective (Jongman, 2018; Ward et al., 2017).

Prevention or attenuation solutions include: rooftop detention, reservoirs, bioretention, permeable paving, infiltration techniques, open drainage, floating structures, wet-proofing, raised structures, coastal defences, barriers, and levees, and have been deployed in diverse configurations, and environments, around the world (Matos Silva and Costa, 2016). Barcelona (Spain) by the 1980s reached 90% impermeable surface cover, and has recently begun implementing artificial detention, underground reservoir, and permeable pavement technologies (Favaro and Chelleri, 2018; Matos Silva and Costa, 2016). Florida Power and Light (USA) which provides service to approximately 10 million people, is investing $3b in flood protection and the hardening of assets (for example, upgrading wooden polls to steel and concrete) (Brody, Rogers and Siccardo, 2019). The City of Seattle recommends increasing preventative maintenance activities, the regular review of appropriate pavement technologies, and modifications to subgrades and drainage facilities for high risk areas (City of Seattle, 2017), whilst also providing benefits to transport disruption (Arrighi et al., 2019). Adaptation in African cities is often dominated by informal responses (Owusu-Daaku and Diko, 2018). In the absence of centralized responses, low-income residents in Nairobi (Kenya) dig trenches and construct temporary dikes to protect homes, and in Accra (Ghana) the community has developed a range of social responses including communal drains and local evacuation teams, to help protect people and critical valuables, although these innovations require connection to city-wide infrastructure to effectively reduce widespread risk (Amoako, 2018).

More recent developments include sensor arrays to catalogue a river's reach and how changing hydraulics interact with roadways (Forbes et al., 2019). Kuala Lumpur's (Malaysia) Stormwater Management and Road Tunnel (SMART) during extreme rain events transitions the motorway to a stormwater conduit, an example of multifunctionality enabling agility (Isah, 2016; Markolf et al., 2019). Smart stormwater control systems are starting to use real time control to dynamically manage the retention and movement of water during storms, though uptake at large scales which provide the greatest improvements in performance have been limited (Xu et al., 2020b).

In contrast to a "fail-safe" approach to design which emphasises strengthening infrastructure against more intense environmental conditions, "safe-to-fail" flood strategies allow infrastructure to fail in its ability to carry out its primary function but control the consequences of the failure. Examples include the use of a bioretention basin in Scottsdale (Arizona, USA) to accommodate excess runoff and help drain the city; a subsidy for affected farmers for lost crop production as part of the Netherlands' Room for the River program; targeted destruction of a levee to control flooding in the Mississippi River Valley in 2011 (Kim et al., 2019). Water Sensitive Urban Design, Low Impact Development, Sponge Cities, Sustainable Urban Drainage, and Natural Flood Management, involve deployment of systems and practices that use or mimic natural processes that result in the infiltration, evapotranspiration or use of stormwater to protect water quality and associated aquatic habitat. These are being designed and implemented at increasingly ambitious scales. For example, China's Sponge City initiative sets a goal of 80% or urban land able to absorb or reuse 70% of stormwater through underground storage tanks and tunnels, and use of pervious pavements, in addition to nature-based solutions (Chan et al., 2018; Muggah, 2019). Similarly, several thousand Water Sensitive Urban Design interventions have been implemented across the city of Melbourne (Kuller et al., 2018).

6.3.5.8 Coastal Management

Physical coastal management infrastructure has significant benefits in reducing flood and erosion losses and damage from storms. Physical infrastructure includes seawalls, dikes, breakwaters, revetments, groynes, or tidal barriers. Adapted infrastructure can alter risks in morphologically connected areas, and lead to increased residual risk by encouraging more construction in the coastal zone (Miller, Gabe and Sklarz, 2019; Ludy and Kondolf, 2012). The infrastructure is highly cost effective for large settlements, but not always for small settlements (Tiggeloven et al., 2020) and can be inaccessible to poorer communities (Fletcher et al., 2016; Pelling and Garschagen, 2019).

Anticipated costs for this vary widely. For example, Hinkel et al. (2014) calculate that adaptation costs to maintain current global levels of coastal flood protection would be 1.2–9.3% of Gross World Product but protect assets in human settlements of $US21-210bn; Tiggeloven et al. (2020) calculate the cost of adaptation to be US$176bn (although this would provide a Benefit to Cost Ratio of 106 under RCP8.5); while Nicholls et al (2019) estimate that global coastal protection would cost substantially more, up to $18.3 trillion between 2015 to 2100 for RCP8.5 (this includes ranges of unit costs and maintenance costs which have often been ignored).

Coastal protection infrastructure such as dikes and sluice gates can inhibit salinity intrusion through careful management of water levels, this can provide co-benefits for flood risk reduction and agricultural productivity but can also have negative impact on ecosystems (Renaud et al., 2015). Managed aquifer recharge can be effective if the objective is to secure freshwater drinking supply (Hossain, Ludwig and Leemans, 2018).

Physical infrastructure can provide substantial benefits, can be constructed quickly, and has enabled coastal cities and settlements around the world to flourish and grow. Multifunctional physical infrastructure can also provide economic and social co-benefits. These include integration of transport, recreation, agriculture e.g. cattle pasture, founding for wind turbines, housing, office or industry into the coastal management infrastructure (Anvarifar et al., 2017; Kothuis and Kok, 2017). However, physical infrastructures can also disrupt natural processes, often leading to undesirable impacts such as pollution, degradation of ecosystems, and displacement of erosion and flood risk to other locations (Wang et al., 2018b; Dawson, 2015; Nicholls, Dawson and Day, 2015). Coastal management strategies that take a hybrid approach, integrating physical and natural infrastructure, provide the best opportunities for managing risk and achieving wider socio-economic and environmental benefits (Depietri and McPhearson, 2017; Morris et al., 2018; Schoonees et al., 2019; Powell et al., 2019).

6.3.6 Cross-Cutting Themes

This section builds on 6.3.4 to offer two entry points for assessing urban adaptation that extend beyond individual infrastructure types and that demonstrate the interdependent and dynamic natures of urban systems.

6.3.6.1 Equity and Justice

Questions of equity and justice influence adaptation pathways for cities, settlements and infrastructure (see also Chapter 8). Although infrastructure, ranging from social to ecological and physical to digital, can help to reduce the impacts of climate change (Stewart and Deng, 2014; Baró Porras et al., 2021), there is limited evidence of how infrastructures, implemented to reduce climate risk also reduce inequality. Rather, there is more evidence to suggest that both adaptation plans and associated infrastructure implementation pathways are increasing inequality in cities and settlements (Chu, Anguelovski and Carmin, 2016; Anguelovski et al., 2016; Romero-Lankao and Gnatz, 2019). Social, economic and cultural structures that marginalize people by race, class, ethnicity and gender all contribute in complex ways to climate injustices and need to be urgently surfaced in order for adaptation options to shift to benefit those most vulnerable rather than mainly benefitting the already privileged and maintaining the status quo (Thomas et al., 2019; Porter et al., 2020; Ranganathan and Bratman, 2019). Innovation and imagination are needed in adaptation responses to ensure that cities and settlements shift from perpetuating structural domination and inequality to fairer cities (Porter et al., 2020; Henrique and Tschakert, 2019; Parnell, 2016b). To support these possibilities, this section explores adaptation through the lens of distributive and procedural justice. Although not expanded on here, spatial and recognition injustices are equally important (Fisher, 2015; Chu and Michael, 2018; Campello Torres et al., 2020). Recognition can be supported through a capabilities approach that helps to bring attention to past cultural domination and enable citizens to develop the functioning life they choose (Schlosberg, Collins and Niemeyer, 2017). This brings a focus on local action emphasizing the relevance to vulnerability reduction and resilience building of individual and local/community capacities and supporting structures. This blurs the distinction between climate change adaptation and community development with the former firmly embedded in the latter. Struggles for recognition are deeply political and central to adaptation responses, which requires increased focus on power to support more equitable and just adaptation (Nightingale, 2017). Justice question are not static, Box 6.4 overviews the implications of COVID-19 for urban justice and vulnerability.

[START BOX 6.4 HERE]

Box 6.4: Adapting to Concurrent Risk: COVID-19 and Urban Climate Change

COVID-19 impacts have highlighted the depth and unevenness of systemic social vulnerability and the compounding characteristics of contemporary development models with direct relevance to climate change risk accumulation and its reduction (Patel et al., 2020b; Manzanedo and Manning, 2020; Bahadur and Dodman, 2020). This is plain at the global level: of the estimated 119 to 124 additional people induced into poverty by COVID-19 in 2020, South Asia and sub-Saharan Africa each contribute two-fifths (Lakner et al., 2021). These are rapidly urbanizing and highly climate hazard exposed world regions indicating COVID-19 impacts may further concentrate risk in these regions. Within cities, COVID-19 and climate change risk and loss is concurrent by gender, race and income or livelihood. For example, when vulnerable elderly populations are simultaneously exposed to COVID-19 and heatwave risk. Globally, in 2020, about 431.7 million vulnerable people were exposed to extreme heat during the COVID-19 pandemic, including about 75.5 million during a July and August 2020 European heatwave with an excess mortality of over 9,000 people arising from heat exposure (Walton and van Aalst, 2020).

The pandemic has demonstrated the multiple, often reinforcing ways in which specific drivers of vulnerability interact both in generating urban risk and shaping who is more or less able to recover (Phillips et al., 2020b; Honey-Rosés et al., 2020) (see Section 6.2). Again, this is not a new lesson for urban climate change adaptation, but it is a lesson that has not yet been seen to enter into routine practice for urban adaptation. Two key challenges for climate change adaptation are the associations between COVID-19 risk and urban connectivity and overcrowding. Connectivity has been presented in urban adaptation policy as a virtue, a means to share risk and diversity inputs (Ge et al., 2019; Kim and Bostwick, 2020), COVID-19 has surfaced the unevenness with which people and places are connected and also the need to balance connectivity against risk transfer – through the failure of food supply chains or remittance flows as well as by the direct transfer of disease (Challinor et al., 2018). High density living has advantages for urban resource efficiency including benefiting climate change mitigation. When high density living is not supported by adequate access to critical infrastructure (sufficient internal living space, access to potable water and sanitation, access to open green space) this exacerbates overcrowding and generates vulnerability to multiple risks – including climate change hazards and communicable disease (Bamweyana et al., 2020; Hamidi, Sabouri and Ewing, 2020; Peters, 2020; Satterthwaite et al., 2020). Where overcrowding coincides with precarious livelihoods, for example in informal settlements, risk is further elevated (Wilkinson, 2020). Neighbourhood associations (a benefit of high density living) have been an important source of resilience through providing trusted information, access to food and water for washing during the pandemic, serving populations unable to access government or market provision (Pelling et al., 2021). Here local organising has not only met gaps in service provision but opened dialogue to vision and organise for alternative development futures. These distinctly urban challenges should be read as a sub-set of wider cross-cutting lessons for recovery from COVID-19 (see Cross-Chapter Box COVID in Chapter 7).

Where responses to COVID-19 include addressing inequities in social infrastructure this opens a considerable and potentially society-wide opportunity to reduce social vulnerability to climate change risks. (see Cross-Chapter Box COVID in Chapter 7).

[END BOX 6.4 HERE]

Distributive justice calls attention to unequal access to urban services, land, capital and technology. Related to this, exposure to health, flooding and drought risks of people living in low-income and informal settlements is a growing concern, as is disaster preparedness and the ability to support the needs of vulnerable groups such as the elderly, children and disabled, where data is often lacking (Lilford et al., 2016; Castro et al., 2017). There are also differences in who benefits from infrastructures, as they are inherently political, embedded in social contexts, politics and cultural norms (McFarlane and Silver, 2017) and often tend to benefit those already privileged (Henrique and Tschakert, 2019). As an example, fixing water leaks can depend as much on the politics of who is involved and whose knowledge is prioritised, as on the technical aspects (Anand, 2015).

The quality and maintenance of infrastructure is often unequal across cities benefiting some and increasing vulnerability of others. Some property is seen as dangerous and of lower value if highly exposed to risk (Wamsley et al., 2015). Similarly, areas suffering from disinvestment in infrastructure, might have a high risk of flooding (Haddock and Edwards, 2013). Zoning and land use trade-offs have been seen to be unequally skewed in favour of prime real estate and economically valuable assets (e.g., protecting factories and refineries from flooding) (Anguelovski et al., 2016; Carter et al., 2015). Urban planning reforms are therefore central to building a fairer urban adaptation response (Parnell, 2016b).

Infrastructure is often not adequately implemented in low-income urban areas and not equally accessible to all (Meller et al., 2017). For example, low-income neighbourhoods often have less green space and therefore less associated cooling benefits. Even in high-income areas, there is often unequal access to services. For example, an assessment of sustainable urban mobility plans in Portugal showed that some areas have considered equity in their plans and increased access for disadvantaged users including the elderly and disabled, but in other cities this is lacking (Arsenio, Martens and Di Ciommo, 2016). Understanding who has access to what infrastructure can help to redress the drivers of social vulnerability, that are central to just urban adaptation (Michael, Deshpande and Ziervogel, 2018; Shi et al., 2016).

Changing land use and increasing green spaces to reduce climate risks and attract investments and job opportunities has increased real estate values, triggered climate gentrification in some areas (Keenan, Hill and Gumber, 2018) and decreased access to affordable housing in other areas (Larsen, 2015; Carter et al., 2015). Displacement through evictions and relocations linked to land use conversion and resettlement in the name of adaptation has also increased people's vulnerability (Anguelovski et al., 2016; Henrique and Tschakert, 2019).

Understanding social and economic elites and their investment in infrastructure has implications for distributive justice, particularly when there is secession from public infrastructure services that has financial implications for viability (Romero-Lankao, Gnatz and Sperling, 2016). In the case of the 2015-17 Cape Town drought, wealthy households secured their water needs through off-grid technologies such as rainwater tanks and boreholes. Although this resulted in more water being available in the dams, it also led to less revenue being collected for municipal water and less ability to cross-subsidize water for poor households (Ziervogel, 2019b; Simpson, 2019; Bigger and Millington, 2019). More attention needs to be paid to how shifts in infrastructure are serving the interests of urban elites, often driving by the state, and failing to adequately consider the needs of the disadvantaged (Bulkeley, Castán Broto and Edwards, 2014; Ajibade, 2017; Shi et al., 2016). Equally, more risk-reducing infrastructure is needed across all urban areas (Reckien et al., 2018a).

Procedural justice, which focuses on the institutional processes by which adaptation decisions are made, brings attention to the lack of opportunity for engaging in political decision-making and limited representation of diverse voices in cities and settlements, and in relation to investment in infrastructure (Coates and Nygren, 2020; Henrique and Tschakert, 2019). Even when inclusive adaptation processes are run, they seldom produce procedurally just outcome (Malloy and Ashcraft, 2020). Understanding who is excluded and included is important (Sara, Pfeffer and Baud, 2017). One example, are the increasing numbers of migrants who are confronted with lack of access to citizenship rights and housing tenure (Romero-Lankao and Norton, 2018). Often, migrants are not allowed to formally claim public provisions in health, finance, and shelter (Chu and Michael, 2018). Further, migrants and their settlements are likely unrecognized in spatial or infrastructure development plans. In this context, social infrastructure, zoning and land use planning for climate adaptation has triggered inequity through omission, as some planning process have been racialized and excluded groups such as migrants and ethnic minorities (Anguelovski et al., 2016). Urban adaptation policy-making processes that explicitly integrate multiple stakeholder interests can help to balance top-down solutions (Reckien et al., 2018a).

Identifying who is least able to adapt to climate risks sufficiently is important (Thomas et al., 2019). Some people may have few opportunities to relocate away from flooded areas in the long-term or to evacuate in the short term. It is also harder for many from low-income areas to rebuild after an extreme event. Lack of housing tenure and sub-standard housing has been shown to limit the ability of residents to improve and manage their landscapes and therefore it is hard for them to enhance energy efficiency (Dempsey et al., 2011). Access to information is critical for adapting to climate risk and reducing vulnerability to hazards, yet access to this information is often not equally available (Ma et al., 2014). For example, low literacy can hamper ability to respond to early warning information (Dugan et al., 2011). In other instances, racial violence has surfaced during disasters, with black victims' lives being seen as less important than others (Anderson et al., 2020).

When looking at justice issues in urban adaptation it is important to recognise that the adaptation of one individual or household may lead to maladaptation and negative impacts elsewhere (Holland, 2017; Limthongsakul, Nitivattananon and Arifwidodo, 2017; Atteridge and Remling, 2018). For example, the case of an area of peri-urban Bangkok experiencing localized flooding due to unregulated private sector development saw households take both individual action (building flood walls around homes, digging temporary drainage swales in the carriageway) and collective action (petitioning authorities, pumping water into vacant land). These actions, to a certain extent, merely displaced the flood water to other areas, or created new problems by damaging the carriageway, creating negative impacts on other households and the wider community. However, ultimately it was the actions of improperly-regulated private sector developers driving the need for this autonomous adaptation (Limthongsakul, Nitivattananon and Arifwidodo, 2017).

One of the tensions that emerge when addressing injustice is that the global provision of modern infrastructure is increasingly seen as unfeasible. It is unfeasible, both in terms of the current high emissions associated with infrastructure (World Bank, 2017) as well as the centralized, high standard ideal (Lawhon, Nilsson and Silver, 2018; Coutard and Rutherford, 2015). Decentralisation is increasingly needed, which the urban poor already engage in through their use of 'informal' infrastructure technologies, given their limited access to infrastructure networks. Transformative adaptation pathways that reduce climate risk whilst reducing inequity require an approach that sees infrastructure as inherently social and political.

6.3.6.2 Mitigation and Adaptation

As analytical concepts, mitigation and adaptation have helped, over the years, to structure thinking and action around climate change. However, since AR5 there has been a growing debate about the adequacy of a neat separation between adaptation and mitigation (Castán Broto, 2017).

The delivery of climate change action has revealed numerous co-benefits between adaptation and mitigation, around diverse areas such as implementing nature-based solutions and delivering health and development benefits (Ürge-Vorsatz et al., 2014; Suckall, Stringer and Tompkins, 2015; Puppim de Oliveira and Doll, 2016; Spencer et al., 2017). There has been a strong interest in delivering development benefits alongside climate mitigation, thus benefiting the overall infrastructure base (Suckall, Stringer and Tompkins, 2015). Some of these co-benefits have also emerged in experiences of urban planning, pointing towards the dilemma of separating adaptation and mitigation in a context in which integration, rather than an analytical differentiation, was seen as being required to transcend work in silos (Aylett, 2015). Because urban planning needs to carefully consider long timescales, the neat separation between mitigation and adaptation runs counter to integrated forms of planning that can consider scales (time and space) carefully and that are aimed to deliver the sustainable city as a whole (Solecki et al., 2015; Grafakos et al., 2020).

For example, the ideas of climate resilient development and climate compatible development help planners to consider the simultaneous wins that emerge between adaptation, mitigation, and development, requiring institutional building and partnerships to deliver triple win solutions (Stringer et al., 2014; Seo, Jaber and Srinivasan, 2017; Mitchell and Maxwell, 2010). While the evidence base for the actual possibility of achieving such triple wins remains scarce (Tompkins et al., 2013; Sharifi, 2020), emerging examples show important developments. For example, establishing safe and convenient walking and cycling infrastructure can lead to improvements in population health, thereby highlighting the close interaction between urban land-use, infrastructure and population health (Schuster et al., 2017); while clean cooking has the potential to deliver positive health outcomes alongside improvements in air quality and emissions reductions and through reducing pressure on woodland as a fuel source for expanding urban populations (Msoffe, 2017). Furthermore, active transport infrastructure reduces air pollution and related health risk, and helps to mitigate further climate change (Schuster et al., 2017). These are supported by city networks such as the C40 Clean Air Cities Declaration and the Clean Air Coalition that complements WHO guidelines and standards for example through the Breathe Life Campaign. In conclusion, in both urban environments and infrastructural sectors, triple wins are only realizable through broader perspectives that link climate compatible development to institutional change or the achievements of wider welfare objectives such as those enshrined in the United Nations 2030 Agenda of Development (Castán Broto et al., 2015; England et al., 2018) (*medium evidence, high agreement*).

The aspiration to deliver climate change action within a broader agenda of transformative change, introduced in the SREX report, received renewed attention after the publication of IPCC Special Report on Global Warming of 1.5°C, which argues for a focus on urban transformations and highlighted that informal settlements were vital for understanding the delivery of these transformations. Deep decarbonization has emerged as a new idea that regards the development of low or zero carbon pathways as a condition for good adaptation in the long term. Decarbonization becomes urgent in the face of growing impacts attributable to climate change (Ribera et al., 2015; Bataille et al., 2016; Wesseling et al., 2017). Urbanization opens opportunities for deep mitigation in low impact developments, and hence, it is imperative to understand the implications of those opportunities for climate action (Mulugetta and Broto, 2018). These gains are not limited to urban areas. The reliance on connected urban-rural systems for water, food and fuel has led to city government and urban based businesses supporting landscape adaptations in rural hinterlands with strong potential for mitigation and rural development cobenefits. Water Funds bring downstream urban public and private finance to support upstream, rural residents to make land-use and agricultural management decisins to avoid damaging run-off, soil erosion and downstream sedimentation with reduction in water quality and increased flood risk. There are more than 30 Water Funds in Latin America and sub-Saharan Africa. These operate at landscape scale, the Upper Tana-Nairobi Water Fund, Kenya (Vogl et al., 2017) planned for a US$10 million investment in water fund-led conservation interventions with a projected return of US$21.5 million in economic benefits over a 30-year timeframe (Apse and Bryant, 2015). However, these investments do not occur where communities lack funding or the institutions to direct funding from downstream beneficiaries to upstream residents (Brauman et al., 2019).

6.3.7 Climate Resilient Development Pathways

Table 6.6 represents the contribution of 21 adaptation measures identified in this chapter to 17 components of Climate Resilient Development (CRD). Climate Resilient Development brings together the aims of climate adaptation, climate mitigation, sustainable development and social justice (Singh and Chudasama, 2021). This provides a first assessment of the viability of adaptation to cities, settlements and key infrastructure as a part of global transition to sustainability (see also Cross-Chapter Box FEASIB in Chapter 18).

Two overarching messages and one key consequence for planning arise from Figure 6.4. First, urban adaptation measures can offer a considerable contribution to Climate Resilient Development. Second, this potential is realised by adaptations that extend predominant physical infrastructure approaches to also deploy nature based solutions and social interventions. The consequence for planning is support for comprehensive monitoring and joined-up evaluation across the multiple components of Climate Resilient Development as well as between the sectors that contribute to adaptation.

Table 6.6 shows adapting key grey/physical infrastructure (built form and design, ICT, energy, transport, water and sanitation) is fundamental to Climate Resilient Development. This provides resilience to a range of hazards, with benefits to livelihoods, social capital and health and provides benefits for the adaptation of other, connected infrastructure systems. Challenges to the contributions of grey/physical infrastructure, where adaptation through nature based solutions and social policy offer alternatives are: a lack of flexibility post-deployment constraining ability to flex as climate and vulnerability change; risk transferred to other people/places, not resolved; negative ecological consequences; and, limited evidence of targeting marginality and inequality.

The significance of a Climate Resilient Development lens for the evaluation of adaptation strategy can be seen in approaches to riverine and coastal flooding. This viewpoint brings physical (e.g. embankments and defenses), nature based (e.g. mangrove stands) and social policy (livelihood and social protection) options together. The benefits of physical infrastructure interventions for strengthening existing livelihoods and protecting health, for being deployable at scale and supporting other infrastructures to adapt are recognised and set these against challenges including hazard generation and risk transfer, limited flexibility, ecological harm, carbon costs and an undermining of social inclusion and accountability. Final evaluations will be determined by individual contexts raising the importance of comprehensive monitoring of existing urban systems adaptation interventions and their association with ongoing development processes and outcomes (see Section 6.4).

The most consistent limit for all urban systems infrastructure types is in risk transfer. Current adaptation approaches in cities, settlements and key infrastructure have a tendency to move risk form one sector or place to others. With the exception of social infrastructure the observed contribution of adaptation to social transformation is also limited. There are consequences for equity and sustainability as the impacts of climate change increase, and implications for evaluation and planning to work across adaptation interventions and connect with social and environmental policy and practice.

Table 6.6 Urban Climate Resilient Development

Inf. Systems	Adaptation Measure	Risk coverage				Benefits to Human			Benefits to ecosystem services	Potential effectiveness				Contribution to GHG emission reduction	Equity benefits		Transformation towards sustainable development (human systems fundamental change + impact on wider system)

Table Notes:

Overall confidence: *Medium agreement - medium evidence.* Supplementary Material provides a detailed analysis including definitions for each component of Climate Resilient Development and for each of the 357 entries an underlying explanatory statement linked to key evidence. Analysis was by Chapter 6 Lead and Contributing Authors.

6.4 Enabling Conditions for Adaptation Action in Urban Areas, Settlements, and Infrastructure

This section assesses the effectiveness of efforts to create enabling conditions for adaptation. New policy innovations like National Urban Policies are emerging to address the multi-level governance demands of climate change (UN-Habitat, 2020; Kinyanjui, 2020). There is no one-size-fits-all approach to deliver adaptation that will fit every case because the local conditions of implementation bear a strong influence on adaptation's feasibility and impacts (Archer et al., 2014). Ways to foster adequate enabling conditions for adaptation are well-documented (Masson-Delmotte and Waterfield, 2018 Ch.4). These often include integrated planning, multi-agency working and multi-scale and sector action. Existing techniques can be shared as well as new innovations taken-up (Maxwell et al., 2018).

Adaptation in urban areas and settlements can be *incremental* (when it addresses the causes of problems but without fundamentally changing the social and political structures that drive it, for example through planning or new regulations), *reformist* (when it changes the features that cause problems but without fundamentally changing the structures), or *transformative* (when it addresses fundamental systems attributes and outcomes such as reducing inequality, in political and socio-economic structures or enhancing wellbeing (Mendizabal et al., 2018; Rosenzweig and Solecki, 2018) which change the situation completely) (Heikkinen, Ylä-Anttila and Juhola, 2019; Roberts and Pelling, 2020; O'Brien, Selboe and Hayward, 2018). In the context of the Sustainable Development Goals mission to leave-no-one behind, transformative adaptation addresses fundamental systems' functions to enable enhanced social justice and socio-ecological wellbeing. Incremental adaptation actions seeks to maintain the essence and integrity of a system or process at a given scale (see glossary). Adaptation that seeks only to defend existing development status will not contribute to enhanced wellbeing and is not transformative, even if fundamental infrastructure engineering or legislative systems are changed to maintain the status quo in the face of increasing risk (Mendizabal et al., 2018).

City populations, and non-state actors together with local and regional governments can play an essential role in creating enabling conditions for action, including for example civil society mobilizing concerns of marginalized voices and future generations- as indicated in the worldwide student mobilizations against climate change (Wood, 2019; Maor, Tosun and Jordan, 2017; Cloutier, Papin and Bizier, 2018; Prendergast et al., 2021), which may then be prioritised by local and regional governments. National governments also play a crucial role for example in facilitating resources and finance for urban adaptation actions, alongside financial organizations and the business sector (see 6.4.5). The section starts assessing adaptation experiences in cities, settlements, and infrastructures since the AR5, before reviewing evidence of how to foster enabling conditions for adaptation through institutionalization, governance capacity, finance, evaluation, and social learning.

6.4.1 Adaptation Experiences in Cities, Settlements and Infrastructures

Since AR5, there is increasing evidence that successful adaptation to climate change is context-specific and responsive to the particular needs of urban locations. This section assesses the contributions of key urban actors – local government, civil society and the local private sector – in enabling adaptation. Wider influences from national government cross-cut this and discussed on international agencies, including through finance is assessed in Section 6.4.5.

The literature on the governance of adaptation has grown since the AR5, though with few cases from cities and settlements in the Middle East, North Africa, Central Asia, and former USSR countries. Potential reasons for the continued lack of studies in these areas include the centralized character of decision-making systems in countries in these regions and the early stage of adaptation planning in these urban areas (Clar, 2019; Mitchell and Laycock, 2019; Olazabal et al., 2019a).

Flexible institutions that allow for both top-down and bottom-up action can bring capacities together from across levels of government and actors within a settlement (Sharifi and Yamagata, 2017). Predominant planning and capacity-building strategies, however, lack the flexibility to address the needs of a rapidly changing environment (Carter et al., 2015; Dhar and Khirfan, 2017b; Juhola, 2016). Efforts to adapt to new challenges may have to speed up. This is especially in urban areas and settlements with lower levels of development and experiencing rapid urbanization, growing inequality and exposure to multiple hazards (Dulal, 2019; Grafakos et al., 2019; Solecki et al., 2018). Even within cities that share similar characteristics there are considerable differences in the level of investment in adaptation (Georgeson et al., 2016). There is also a danger that uncoordinated actions for climate change mitigation and adaptation may constrain future adaptation opportunities or create maladaptation (Juhola et al., 2016). The evidence emerging since the AR5 suggests that institutional change can be accelerated by closer collaboration between the diverse actors and deployment of the diverse approaches that can deliver adaptation.

6.4.1.1 Experiences of adaptation action in sub-national governments

The assessment of cases of local adaptation demonstrates that most urban adaptation is led by local governments (although the local government is also a heterogeneous category and local governance arrangements may vary across administrative and political contexts) (*high confidence*) (Amundsen et al., 2018; Lesnikowski et al., 2021). Local government reform at different levels can improve local adaptation, whether this is by strengthening specific teams or building cross-departmental linkages (*high confidence*) (Paterson et al., 2017; Shi, 2019; Wamsler and Raggers, 2018). Adaptation success often depends on having political champions driving the adaptation agenda alongside measures such as access to a knowledge base, resources at hand, political stability, and the presence of dense social networks that can be supported through local government reform (Pasquini et al., 2015). Aligning adaptation objectives with other potential benefits of sustainable development also supports adaptation. Specifically, policies and plans that link adaptation to the objectives of Agenda 2030 supports action at the local level (UN-Habitat, 2016b). Showing the economic benefits of adaptation is a strategy for local institutions to gain support for adaptation action. For example, local governments in Surat, Indore, and Bhubaneswar in India linked adaptation to local development needs in experiments that facilitated accessing human and finance resources, at the local, national and international levels (Chu, 2016b). However, linking adaptation to co-benefits may also divide efforts and reduce the effectiveness of adaptation actions. For example, urban land use planning and management in Ambo town, Ethiopia resulted in the implementation of urban greening projects, but these projects did not directly address the climate-related disaster risks affecting the settlement, including urban flooding, water stress, and water shortages, increased urban heat, wind and dust storms (Ogato et al., 2017).

Multi-level governance measures that support local governments can foster robust adaptation approaches and address risks and vulnerabilities across scales (*high confidence*) (Westman, Broto and Huang, 2019; Hardoy et al., 2014; Romero-Lankao and Hardoy, 2015). Effective action by local government requires national government's support (*medium confidence*). For example, Araos et al (2017) documents the case of Dhaka, Bangladesh where a national plan prioritizes measures for protecting coasts and agricultural production. In this context, the local government has minimal access to human and financial resources. Without national support, the local government struggles to coordinate action amongst different stakeholders. National urban adaptation directives can influence municipal governments' action and planning but evidence suggests that national policy alone is not sufficient to deliver action on the ground without understanding local conditions (*high confidence)* (Archer et al., 2014; Lehmann et al., 2015).

There are barriers for municipal adaptation plans to deliver effective adaptation outcomes and implemented actions often diverge from plans (see 6.4.6). For example, a comparison of adaptation plans and budget expenditures of six metropolitan cities in South Korea between 2012–2016 showed that the implementation of adaptation programs diverged substantially from the original plans, both in terms of total spending and sector-specific spending (Lee and Kim, 2018). Often, a focus on institutional change and reform limits attention to more practical aspects of adaptation that improve communities' resilience (Castán Broto and Westman, 2020). Adaptation actions, even where financed effectively, do not always deliver positive outcomes (*high confidence*) (Reckien et al., 2015; Woodruff and Stults, 2016; Uittenbroek, 2016; Aguiar et al., 2018; Reckien et al., 2018a; Olazabal et al., 2019b; Campello Torres et al., 2021) (see also 6.4.7).

6.4.1.2 The role of non-state actors in local adaptation

There are multiple actors, other than local governments that can deliver adaptation action including businesses, not for profit organizations and trade unions (*high confidence)* (Giordano et al., 2020; Eakin et al., 2021). Empirical evidence since the AR5 highlights the role of communities, universities, the private sector, and transnational networks in adaptation (Hunter et al., 2020; Bäckstrand et al., 2017). Non-state actors are particularly important in enabling adaptation by linking government agencies with low-income and marginalised communities including those living in informal settlements (Kuyper, Linnér and Schroeder, 2018; Khosla and Bhardwaj, 2019).

Since AR5 civil society and private actors have emerged as core knowledge holders and drivers of experimentation, even succeeding in changing public policy in the process (Klein, Juhola and Landauer, 2017; McKnight and Linnenluecke, 2016; Mees, 2017). Previous IPCC Assessment Reports noted that civil society actors enable local risk awareness, sensitization, adaptive capacity and generate locally-based innovation (e.g., through community-based adaptation programs).

Community-based adaptation includes a range of initiatives that put communities at the centre of planning for adaptation, often led by communities themselves (Reid, 2016). Community-based adaptation is a comprehensive and effective strategy to deliver resilience at a human scale (Trogal et al., 2018; Greenwalt et al., 2020). Many community-based responses to climate impacts represent coping strategies developed within households with a small effect on adaptation capacities beyond incremental improvements. Residents adopt private coping strategies to reduce exposure to and the impacts of heat, floods, flash floods, landslides, storms, and diseases on their lives (Hambati and Yengoh, 2018). These coping strategies include the construction of physical protection against flooding, through reforestation, the construction of terraces, flood diversion measures, and interventions to protect houses (such as raised doorsteps or use of sandbags and adoption of building techniques for making homes resilient to storms and landslides), ventilation of houses, urban agriculture, and redefinition of daily practices and livelihoods (Navarro et al., 2020; Malabayabas and Baconguis, 2017; Apreda, 2016; de Andrade and Szlafsztein, 2020; Sahay, 2018; Bausch, Eakin and Lerner, 2018).

Individual coping strategies are generally ineffective in reducing extreme risks and they rarely address the underlying structural causes of vulnerability (*high confidence*) (Sahay, 2018; Rözer et al., 2016; Jay et al., 2021). Expending resources on private coping strategies in some cases may divert resources and capacity for wider community adaptation efforts (de Andrade and Szlafsztein, 2020). However, individual coping strategies can provide foundations for the implementation of collaborative action in communities building on people's experiences, in ways which may have a longer-term, durable impact on developing resilience (*high confidence*) (McEwen et al., 2018). Community-based adaptation can be effective at different scales, whether this is to manage transboundary issues (Limthongsakul, Nitivattananon and Arifwidodo, 2017), support the replication of local solutions (Danière et al., 2016), increase the uptake of adaptation measures (Liang et al., 2017), or inform the design of more effective policies for resilience (Berquist, Daniere and Drummond, 2015; Odemerho, 2015). Community action may be mediated by NGOs or third sector organizations who play a coordinating or enabling role, particularly where other local government mechanisms are absent.

6.4.1.3 The role of the private sector in local adaptation

There is weak evidence of private sector involvement in urban adaptation (Pauw, 2015; Heurkens, 2016). The absence of private sector investment in adaptation is particularly visible in rapidly urbanizing countries (Nagendra et al., 2018). Business continuity describing private sector preparedness notes firms underestimate the impacts of climate risks on their business models (Goldstein et al., 2019; Forino and von Meding, 2021; Korber and McNaughton, 2017; Crick et al., 2018b). There is little research on how businesses can play a leading role in urban adaptation (Klein et al., 2018). A global assessment of the private sector's role in urban adaptation using data from 402 cities shows that most adaptation projects focus on the public sector and do not address private sector concerns or local people's participation (Klein et al., 2018). Recorded private sector action is recognized through partnerships and participation (Peterson and Hughes, 2017; Hughes and Peterson, 2018). There are a few examples of studies of private sector-led adaptation action which adopts a national focus (Crick et al., 2018a; Crick et al., 2018b). This lack of evidence contrasts with a well-developed body of literature on private sector-led mitigation (Averchenkova et al., 2016).

Businesses have an essential role in urban adaptation actions, through the collective formulation of adaptation strategies, through the provision of critical adaptive interventions, and through collaboration in partnerships. Businesses in the property sector, such as real estate developers, are on the frontline of climate change impacts but display differing attitudes towards climate adaptation. A study of property businesses in cities in Australia (Taylor et al., 2012) showed that speeding up planning approval processes facilitated adaptation actions, and joint private-public decision making was the preferred mode of governance for responding to climate concerns. Property businesses in cities in Sweden had a limited and reactive engagement in climate issues and resisted regulation (Storbjörk et al, 2018). Corporate, private sector interventions in urban risk reduction more broadly remain limited with a mix of public and private responsibility for planning, implementing, and maintaining adaptations in the built environment and yet, limited engagement of private sector actors in providing healthcare measures for heat prevention (medium confidence) (Mees, 2017).

There is little published literature documenting the heterogeneity of business and the private sector's responses to climate impacts (Linnenluecke, Birt and Griffiths, 2015; Doh, Tashman and Benischke, 2019). Firms have varying abilities to introduce climate adaptation measures related to staff availability, levels of awareness, perceptions of responsibility, and duration of contracts (short-term projects implies less interest in adaptation outcomes) (Shearer et al., 2016). The impact of COVID-19 has serious but uncertain implications for both access to finances for sustainable development by low and middle income countries and sub-national governments, and the possibility of stimulating mal-adaptive infrastructure and policy responses (OECD, 2020; Sovacool, Del Rio and Griffiths, 2020). The response of businesses to disasters influences the resilience in the communities in which they operate (McKnight and Linnenluecke, 2016; Linnenluecke and McKnight, 2017). However, at the same time there is a growing literature that warns against the conflict interests that businesses may have in their adaptation strategies. For example, real estate responses to flooding have led to processes of climate gentrification, whereby lower income populations are displaced towards higher risk areas which stablishes racialized and class-based patterns of inequality of exposure to risk, with hard evidence rapidly growing specially in US cities (Keenan, Hill and Gumber, 2018a; Shokry, Connolly and Anguelovski, 2020; De Koning and Filatova, 2020; Aune, Gesch and Smith, 2020). Private-sector participation in adaptation solutions depend on having mechanisms to enable transparency and open reporting on the nature of support and the solutions proposed. For example, businesses adopting 'community-centric' disaster management strategies can assist local recovery efforts by protecting employment, provision of emergency supplies, and participation in reparations (McKnight and Linnenluecke, 2016). Private sector actors engaged in community climate responses can play a role in funding and managing programs that address public health and education concerns. The potential of ecopreneurship, social enterprises, cooperatives and other sustainability-oriented business models (Schaltegger, Hansen and Lüdeke-Freund, 2016; Lopes et al., 2020; Battaglia, Gragnani and Annesi, 2020) for urban adaptation remains under-explored in the literature on urban climate governance.

The private sector also constitutes a key stakeholder group involved in collaborative processes to develop adaptation strategies. The inclusion of private sector actors in deliberative policy-making processes in urban adaptation can lead to higher procedural legitimacy levels, as witnessed in Rotterdam's case (Mees, Driessen and Runhaar, 2014). Rotterdam has created an institutional environment that favours eco-innovation (Huang-Lachmann and Lovett, 2016). The municipal government works directly with the private sector to enhance protection against flooding constructing a marketing strategy around a 'floating city' concept. A 'floating housing' market has expanded, with benefits for the local real estate and construction industries and knowledge-exporting businesses that provide consultation expertise, delta technologies, and architectural models. Nevertheless, these new trends raise new governance challenges to deliver adaptation.

There are obstacles associated with reconciling private sector interests with public priorities and justice agendas in local climate programs. The involvement of the private sector in adaptation actions may lead to the appropriation of land and natural resources, and to the exclusion of vulnerable populations (Anguelovski et al., 2016; Rumbach, 2017; Scoppetta, 2016) (see also section 6.4.4.2). Navigating the inclusion of businesses in urban planning processes requires local authorities to engage in ongoing negotiations, to reflect on constantly shifting power balances, and to move delicately between the role of regulator and facilitator in the process of defining and maintaining long-term objectives (Storbjörk, Hjerpe and Glaas, 2019b; Storbjörk, Hjerpe and Glaas, 2019a).

6.4.1.4 Partnerships for adaptation

Multi-level governance remains an influential paradigm that recognizes government institutions' influence at different scales and the diversification of actors intervening in public issues from the private sector and civil society (robust evidence, high agreement). Establishing linkages between multiple organizations can help deliver coordinated action. Multi-level governance includes mechanisms for multiple actors to engage in local adaptation strategies through collaborative processes of planning, learning, experimentation, capacity building, construction of coalitions, and communication channel (Barton, 2013; Jaglin, 2013; Reed et al., 2015; Restemeyer, van den Brink and Woltjer, 2017; Melica et al., 2018). Many of these studies directly focus on institutional arrangements that facilitate interaction between communities and civil society, experts, government representatives, firms, and international organizations. Box 6.5 demonstrates the decisive role that community activists can play in building resilience over long periods.

Institutional fragmentation reduces the capacity to deliver adaptation (Den Uyl and Russel, 2018) Multi-level governance shows a commitment to tackling fragmented and complex policy issues through collaboration between national governments and non-state actors, as explained in the 2030 Development Agenda, especially SDG17 ("Revitalize the global partnership for sustainable development"). Multi-level governance is particularly important to deliver adaptation at the metropolitan scale, that require coordinating actions across different institutions in inter-municipal institutions (Lundqvist, 2016). Gaps in knowledge remain regarding the effectiveness of multi-level governance actions in different contexts and the extent to which multi-level governance strategies transfer the brunt of responsibility for adaptation action to less-resourced local governments (Hale et al., 2021).

Public-private partnerships are increasingly relevant for collaborative development of urban adaptation (Klein et al., 2018). Partnerships can deliver infrastructure, coordinate policy, and support learning. The main limitation of partnerships is scale, as partnership action is usually limited to discrete projects or objectives. Partnerships tend to be linked to reactive (rather than proactive) adaptation projects and the deviation of objectives away from adaptation concerns (Harman, Taylor and Lane, 2015). Partnerships can support capacity building in public and private organizations and facilitate networking efforts that extend beyond the private sector to communities and NGOs (Bauer and Steurer, 2014; Castán Broto et al., 2015b). Public actors can benefit from the private sector's innovation and implementation capacity, and businesses can de-risk investments. Still, partnerships can also strengthen the ideologies of growth and managerialism within the operations of the local government (Taylor et al., 2012). Reconciling divergent norms and routines within public and private organizations remains one of the challenges to establishing successful public-private partnerships for adaptation (Lund, 2018). Administrative and political culture influences the nature of interactions between public and private sector actors in urban adaptation agendas (Bauer and Steurer, 2014) with negative consequences such as the imposition of vertical chains of commands on horizontal collaborations, and the need to formalize contractual relations (Klein and Juhola, 2018).

Local authorities are an important enabling actor that can guide the private sector and communities to take responsibility for creating policy and regulatory environments that encourage private sector participation aligned with the Sustainable Development Goals' equity and ecological sustainability principles (*high confidence*). For example Frantzeskaki et al (2014) report a port relocation project in the Netherlands where sustainability principles drove private sector participation. Klein et al (2017) cite examples from two cities - Helsinki and Copenhagen - where local authorities have shifted adaptation responsibilities to private actors through regulation and public problem ownership. In Mombasa, private companies provide green infrastructure to match local government requirements, in what has frequently been cited as an example of nature-based solutions (Kithiia and Dowling, 2010; Kitha and Lyth, 2011).

[START BOX 6.5 HERE]

Box 6.5: Building Water Resilience in Urban Areas through Community Action and Activism

In Bengaluru, India, communities have traditionally managed a network of water tanks of immense ecological importance. However, in the last half-century, urban development has increasingly threatened this blue network (Unnikrishnan and Nagendra, 2015). Today's Bengaluru depends on long-distance water transfers that create political conflict and a dense network of private boreholes that are depleting the city's water resources. The restoration of the existing community-managed water tanks network offers a more sustainable and socially just alternative for managing water resources.

Unnikrishnan et al (2018) have documented how the colonial and postcolonial history of water management in Bengaluru shapes the water infrastructure and provision systems today. Water access inequalities can be traced to the patterns of spatial development developed by colonial policies. Records from the 6th century onwards show how city rulers invested in an interconnected, community-managed network of tanks and open wells, regularly recharged through harvested rainwater. The water system was changed at the end of the 18th century, as first the colonial state, then the post-independence government of Karnataka took responsibility for water management. Ideas of modernist planning influenced the development of new water infrastructure and piped networks, including the first piped infrastructure, bringing water from sources 30km away, including the Hesaraghatta and then the TG Halli reservoirs. The old network of tanks gradually deteriorated as tanks became disused, polluted, or built over. More prolonged and costly water transfers took place in the post-colonial period, delivering water from the Cauvery river in a massive engineering project with a high energetic cost and enmeshed in inter-state conflicts over water use (Castán Broto and Sudhira, 2019). Scarcity is still a problem in Bengaluru. The citizen response has been an activist movement to reclaim the city's tanks, accompanied by a plea to reconsider current water uses within the city, including actions to protect and rejuvenate water wells (Nagendra, 2016). Unnikrishnan et al (2018) document different actions led by citizen-led collectives, including projects for lake rejuvenation, filtering technologies to treat sewage, recovering the value of lakes through a share of photos and art projects, and involvement of local knowledge in-tank restoration. Those efforts suggest an untapped potential to deliver adaptive green spaces through the recovery of Bengaluru's tanks.

[END BOX 6.5 HERE].

6.4.1.5 Trans-national municipal networks

Since the late 1990s, transnational municipal networks (TMNs) have increased awareness of climate change and served as a bridge for cities to access critical financial resources from private and philanthropic sources (Rashidi and Patt, 2018; Fünfgeld, 2015). Recently, transnational municipal networks have taken on more programmatic functions, working with cities to strategize, plan, and incrementally improve their organization functions in the face of climate change. For example, the Rockefeller Foundation's 100 Resilient Cities program (2014-2019) provided a two-year salary for a Chief Resilience Officer (CRO) to be situated in a municipal authority to bridge silos, incentivize change, and develop development strategies for resilience (Bellinson and Chu, 2019; Spaans and Waterhout, 2017). In these cases, external actors have enabled broad organization change, resource mobilization pathways, and alternative forms of agenda-setting in cities (Chu, 2018a; Hakelberg, 2014) (see also case study 6.2, Semarang).

A range of transnational municipal networks (TMNs) also support and encourage cities and settlements to plan and implement adaptation actions. ICLEI-Local Governments for Sustainability has developed protocols and implemented projects for member cities. The C40 Climate Leadership Group has facilitated the coordination of both local governments and business actors at a global scale (Gordon, 2020). Policy coordination has been central to the signatories of the Covenant of Mayors (Domorenok et al., 2020). Such networks can encourage: the sharing of information about appropriate practices between urban areas; contribute to goal-setting; support experimentation and development of new policy instruments; enhance stakeholder engagement; institutionalize climate agendas; and encourage policy integration across governance levels and sectors (Bellinson and Chu, 2019; Busch, Bendlin and Fenton, 2018; Fünfgeld, 2015; Busch, 2015; Papin, 2019; Rashidi and Patt, 2018). However, participation in TMNs is biased towards cities in the global North (Bansard, Pattberg and Widerberg, 2017; Haupt and Coppola, 2019). A recent comparative study of 337 cities found out that cities that participation in TNMs are more likely to take adaptation action and that being part of multiple networks leads to higher levels of adaptation planning (Heikkinen et al., 2020).

6.4.2 Institutional change to Deliver Adaptation in Cities, Settlements, and Infrastructure

The main barriers to urban climate adaptation, and strategies to address them, relate to institutional change (*high confidence*) (see Table 6.7). Institutions include legislative and policy frameworks and guidelines intended to direct the action of government, civil society and private sector organisations and extend into informal and customary practices that shape individual behaviour. Many of the barriers that inhibit institutions acting in ways that can support action for inclusive and sustainable adaptation have historical roots, grounded in complex political and social relations and can be reinforcing (Table 6.7). Overcoming these barriers requires coordinating the activities of multiple actors who can facilitate institutional and political change (Eisenack et al., 2014).

Table 6.7 Barriers to climate adaptation

Examples of barriers to climate adaptation	Institutional changes to overcome those barriers	Examples	Evidence
Lack of financial resources	Strategic combination of municipal, regional and national level funds Access to multiple financing mechanisms	In European countries, large cities tend to fund their own adaptation, while smaller settlements depend on regional or national funding	(Aguiar et al., 2018) (Moser et al., 2019)
Lack of human resources and capacities	Development of formal and informal partnerships, cooperative agreements and inter-agency arrangements	International cooperation programmes for adaptation in urban areas in the Global South are most likely to succeed if they can align their objectives with local priorities and capacities	(UN-Habitat, 2016b)
Political commitment and willingness to act	Use of policy windows and extreme events to generate interest and create lasting responses	In Germany, responses to flooding were strongly shaped by public perceptions of safety during the electoral cycle, leading to inadequate responses	(Gawel et al., 2018; Di Giulio et al., 2018)
Uncertainty about future impacts and dynamic interactions	Develop institutional arrangements that acknowledge and reduce uncertainty Facilitate the development of bottom-up initiatives that relate directly to the context of action	Power plant operators and the federal state of Baden-Württemberg negotiated the minimum power plant concept (“Mindestkraftwerkskonzept”, MPP), a contract to establish more predictable and workable procedures for curtailment in the event of severe heat waves	(Eisenack, 2016) (Thaler et al., 2019)
Institutional fragmentation and unclear responsibilities	Evaluation of existing institutions to diagnose miscoordination Creation of policy networks that address emerging interdependences	In settlements in Languedoc, France, decentralisation adds complexity to the ongoing challenges of population growth and climate change	(Therville et al., 2019)
Legal issues and regulations	Address the legal hurdles to create frameworks that allow for experimental action	Policy makers in the San Francisco Bay Area, US reported that minor changes could have a definitive influence in delivering regulatory changes to support adaptation action In The Netherlands, a lack of climate change adaptation policy for cultural heritage hamper adaptation of cultural heritage to current and projected climate risks	(Ekstrom and Moser, 2014) (Fatorić and Biesbroek, 2020)
Competition of adaptation with other policy agendas and polarisation	Prioritization and development of synergies across sectors Mainstreaming adaptation into other sectors	In European cities, for example, urban planning is strongly correlated with water management strategies	(Aguiar et al., 2018) (Sieber, Biesbroek and de Block, 2018)
Lack of data, knowledge generation capacity, and knowledge exchange	Mobilise multiple strategies for the use of climate information in local decision-making	In Scotland, Hungary and Portugal local decision makers use HECC scenarios, but most often as background data	(Lourenço et al., 2019) (Herrmann and Guenther, 2017)

	Involve a wide range of stakeholders- with different values and knowledge- in decision making	Sharing knowledge alongside the supply chain favours adaptation for both multinationals and SMEs	(Gotgelf, Roggero and Eisenack, 2020) (Wamsler, 2017)

Institutional change, is needed to open new options for inclusive and sustainable adaptation and to integrate adaptation and mitigation (*robust evidence, high agreement*) (see also Section 6.3.5).

Institutional change refers to processes that aim to shift existing norms and practices within organizations to deliver more effective action for adaptation. Institutional change at the local level can be achieved with diverse strategies (Patterson, de Voogt and Sapiains, 2019). Table 6.7 illustrates various instruments that enable the institutionalisation of climate adaptation concerns into policy and planning. As Table 6.7 shows, institutional change is often used as synonymous with mainstreaming. Both terms refer to the integration of climate adaptation concerns into other areas of work and as part of practical routines and arguments (Chu, Anguelovski and Carmin, 2016; Storbjörk and Uggla, 2015; Runhaar et al., 2018; Uittenbroek et al., 2014). Early assessments understood mainstreaming as activities that integrate climate adaptation into long-range and sectoral plans (Anguelovski and Carmin, 2011; Aylett, 2015). Since then, efforts to mainstream climate adaptation have grown into agendas around the community and economic development (Ayers et al., 2014), climate mitigation (Göpfert, Wamsler and Lang, 2019), spatial and infrastructure planning (Anguelovski, Chu and Carmin, 2014), urban finance (Musah-Surugu et al., 2018; Keenan, Chu and Peterson, 2019), public health (Araos et al., 2015), environmental management (Wamsler, 2015; Kabisch et al., 2016), and multi-level decision-making (Ojea, 2015; Visseren-Hamakers, 2015). Such efforts require various degrees of regulatory or programmatic action to integrate adaptation with other concerns (Wamsler and Pauleit, 2016). However, institutional change has a broader remit than mainstreaming adaptation, as it may include, for example, changing the organizations already dealing with climate adaptation and make them more effective including changes in inputs, procedures, and options (Patterson, de Voogt and Sapiains, 2019).

6.4.2.1 Input-driven institutional change

Input-driven institutional change creates incentives to deliver adaptation action. An input view focuses on the intrinsic capacities of a given organization. Input indicators are often referred to as political capital (Rosenzweig and Solecki, 2018; Diederichs and Roberts, 2016), existing or endogenous resources (Moloney and Fünfgeld, 2015; Wamsler and Brink, 2014), or local drivers for adaptation (Dilling et al., 2017). Research conducted across two municipalities in Western Cape, South Africa, showed the importance of a dedicated environmental champion, access to a knowledge base, the availability of resources, political stability, and the presence of dense social networks (Pasquini et al., 2015). Research from In São Paulo, Brazil, showed how intrinsic political capacities and contextual factors – such as the political ideology of elected officials –shaped opportunities for embedding adaptation into ongoing urban agendas (Di Giulio et al., 2018).

Networks, interactions, and actor coalitions shape options for institutional change. Aylett (2015) noted the importance of internal networks between municipal departments, including informal communication channels, cultivating personal contacts and trust between the person or team responsible for climate planning and staff within other local government agencies. Internal networks can facilitate the commitment of local elected officials (Hughes, 2015), support higher municipal expenditures per capita, and foster perceptions that climate adaptation is needed (Shi, Chu and Debats, 2015). Collective decision making can integrate multiple types of information with moral concerns and provide key rationales that enable adaptation action (Carlson and McCormick, 2015). In urban areas in Africa, research on internal networks has also investigated how informal arrangements shape action possibilities (Satterthwaite et al., 2020). For example, in Zimbabwe, informal, traditional, and civil society institutions are core arenas for issue discussion due to lower public sector capacities (Mubaya and Mafongoya, 2017). In Durban, South Africa, local governments rely considerably on shadow systems and informal spaces of information and knowledge exchange across their operations to introduce and sustain new ideas (Leck and Roberts, 2015). In the Metropolitan Area of Styria, Austria, informal cooperation has supported the development of rural-urban partnerships for the formulation of common goals (Oedl-Wieser et al., 2020). In Arkansas, US, informal governance structures support planning to manage wildfires (Miller, Vos and Lindquist, 2017).

Cities can leverage input driven institutional change even without national support for climate change adaptation or mitigation. For example, where cities have defined policy making and budget raising powers, city level political leadership can support adaptation action going beyond national policy (Hamin, Gurran and Emlinger, 2014; Shi, Chu and Debats, 2015; Carlson and McCormick, 2015). Examples include the Surat Climate Change Trust in Surat, India (Chu, 2016a) and Initiative for Urban Climate Change and Environment in Semarang, Indonesia (Taylor and Lassa, 2015). In Saint Louis, Senegal, support from national and state-level actors enabled local institutional change (Vedeld et al., 2016). Processual levers may be also mobilized in situations of political instability (which disrupts patterns in champions and networks), clientelism (which can cause environmental projects to be discontinued) (Pasquini et al., 2015), or in contexts where there are high political and socioeconomic inequalities (Harris, Chu and Ziervogel, 2018; Chu, Anguelovski and Carmin, 2016).

6.4.2.2 Output-driven institutional change

Output-driven institutional change is shaped by organisational products such as strategies, plans, policies, and evaluative metrics (Patterson and Huitema, 2019; Bellinson and Chu, 2019) (See table 6.8). There are numerous examples of institutional change through planning outcomes. For example, Manizales, Colombia has included climate adaptation into long-established environmental policy (Biomanizales) and a local environmental action plan (Bioplan), which follows on from a long coherent trajectory of climate change policy (Hardoy and Velásquez Barrero, 2014). A significant number of North American cities have integrated adaptation into long-range plans, while fewer cities integrate adaptation in sustainable development plans or sectoral plans (Aylett, 2015). Canadian cities are more likely to have a plan specifically focused on adaptation than having adaptation integrated into municipal long-range planning (Aylett, 2015). In the European Union, adaptation plans depended on national climate legislation or, in fewer cases, the influence of an international climate network (Reckien et al., 2018b). A comparative report from the Covenant of Mayors, however, suggests that the adaptation pillar needs development to demonstrate the effectiveness of adaptation responses and their integration with mitigation goals (Bertoldi et al., 2020). Municipalities in Sweden have been called ‘pre-reactive’ because adequate strategic guidelines are in place to frame the accessibility, aesthetics, and adaptability of waterfront developments (Storbjörk and Uggla, 2015). Some Asian cities also report high output effectiveness, where they are more likely to indicate senior local government officials' performance management contracts, the budgeting procedures of local government agencies, and the procedures that local government agencies use for budgeting infrastructure spending (Aylett, 2015). Despite this evidence, there is a gap in understanding the general trends of planning and institutional change in Africa, Asia, East Europe and the Middle East.

Table 6.8 Examples of institutional and policy instruments to enable adaptation

Objective	Type of instrument	Description	Examples	Assessment
Policy	Information Instruments	A diverse range of activities such as training, research and development, awareness campaigns to produce and share information	Urban-LEDS II Capacity Building Workshop for cities in Laos arranged for local government by ICLEI Southeast Asia Secretariat and UN-Habitat (UN-Habitat, 2019)	Information instruments tend to be low-cost and low-risk options, but their impact is unpredictable and the effects may be uneven (Henstra, 2016). In the example of the workshops in Laos (UN-Habitat, 2019), the result was to map vulnerable sectors and build capacity for mainstreaming
	Voluntary Instruments	Practices such as codes, labeling, management standards or audits, voluntarily, that can	PUB, Singapore's National Water Agency's Voluntary Water Efficiency Labelling Scheme (Voluntary WELS)	A problem with voluntary instruments is that implementation varies. Uptake is likely to be more common among organizations self-identifying as ‘champions’ and less effective among other actors to

		provide incentives for adaptation	(Tortajada and Joshi, 2013)	bring about far-reaching change (Haug et al., 2010)
	Economic Instruments	Taxes or subsidies can be used to promote adaptive activities	US Office for Coastal Management NOAA Coastal Resilience Grants Program (NOAA, 2019)	Economic incentives can be effective as they "engage local stakeholders and provide price signals that stimulate individual adaptation" (Filatova, 2014). However, uptake of incentives may be low (Sadink, 2013; Henstra, 2016) and resource intensiveness and potential regressive effects (equity impacts) must be considered (Henstra, 2016).
	Regulatory Instruments	These include a range of mandatory requirements through controls, bans, quotas, licensing, standards often applied when a specific outcome is required	Building codes to enhance structural stability for storm resilience in Moore, Oklahoma (US) (Ramseyer, Holliday and Floyd, 2016)	Regulatory instruments can be effective in changing and institutionalizing adaptation behaviours (Nilsson, Gerger Swartling and Eckerberg, 2012; Henstra, 2016), but outcomes depend on the strength of implementation (e.g. monitoring, transparency, mechanisms for accountability)
Process	Visioning	Events that bring together different stakeholders to produce a city vision	Rotterdam Resilient City participatory processes to create resilience strategies (Resilient Rotterdam, 2016)	There may be challenges in translating complex climate science into understandable and meaningful forms (Sheppard et al., 2011) and creating inclusive processes that allow for co-creation of visions, for example, by involving new digital platforms (Baibarac and Petrescu, 2019)
	Baseline studies	Focus on understanding the current conditions in a neighbourhood or city from an interdisciplinary perspective	*Flood Risks, Climate Change Impacts and Adaptation Benefits in Mumbai,* an OECD assessment study (Hallegatte, Ranger and Bhattacharya, 2010)	Baseline studies can be mobilized to track the progress of adaptation actions in multiple sectors over time. In the example of the study in Mumbai (Hallegatte, Ranger and Bhattacharya, 2010), the analysis includes different climate scenarios and quantification of how adaptation could reduce economic loss
	Development priorities	Specific methods to ensure an open definition of multiple priorities and contrasting values that will inform the planning process	Participatory housing upgrading through the Baan Mankong Program in Bangkok (Thailand) (Berquist, Daniere and Drummond, 2015)	Participatory planning can help navigate which action to take to build resilience and, at the same time address prioritized social concerns (Cloutier et al., 2015). As with all participatory processes, issues of recognition, access/inclusion, and potential capture of the process by actors in power must be considered
Planning	Profiles	Develop a common understanding of how different sectors interact with adaptation and the governance capacity	New York City Panel on Climate Change 2019 Report (Nycpcc, 2019)	As with baseline studies, the development of profiles can inform plans for adaptation action, which considers social priorities and synergies across various sectors. Multiple forms of knowledge should be considered in the development of profiles (Codjoe, Owusu and Burkett, 2014)

	Risk assessment	This includes a range of instruments to evaluate the impact of risk	Climate risk assessment for Buenos Aires, conducted by the World Bank (Mehrota et al., 2009)	Risk assessments can be a useful starting point for adaptation. However, assessments do not directly prescribe adaptation options but must be seen as the basis for debate (Yuen, Jovicich and Preston, 2013). A common challenge is a lack of data at the city level (Maragno, Dalla Fontana and Musco, 2020; Cloutier et al., 2015)
	Impact assessment tools	Tools such as Strategic Impact Assessment or Sustainability Assessment provide a means to assess the impact of specific policies and programmes concerning adaptive capacity	Economic Impact Assessment of Climate Change in Key Sectors in Nepal (Government of Nepal, 2014)	Embedding climate risks into impact assessment tools (either mandatory or voluntary) builds resilience by integrating climate objectives into plans and specific projects (Richardson and Otero, 2012), and they are seen as a legitimate tool in many contexts (Runhaar, 2016)
	Monitoring systems and indicators	Systems to take measurements at regular intervals to specify progress against objectives and revise the planning process	Climate Change Adaptation Indicators for London (London climate change partnership, 2018)	Monitoring systems are essential to make sure that formal objectives are met. However, many urban climate adaptations do not have monitoring and evaluation components (Woodruff and Stults, 2016) and there is no standard set of indicators to monitor adaptation or resilience (Brown, Shaker and Das, 2018; Ford and Berrang-Ford, 2016)
Management	Budgets and audits	Methods for the periodic revision of adaptation plans and policies	Helsinki Metropolitan area climate change adaptation monitoring strategy (HSY, 2018)	As with monitoring, budgets and audits can be incorporated into the adaptation planning process to ensure reflexivity and accountability. Low levels of implementation and monitoring of adaptation plans suggest that the uptake may be low (although the evidence is limited)

Institutional change processes are complex, contested, and sporadic (Patterson, de Voogt and Sapiains, 2019). Such processes are often inhibited by unclear planning mandates, conflicting development priorities, lack of leadership, and resource and capacity shortfalls (Anguelovski et al 2014). There is no one size fits all approach to institutional change, which works in situ, and benefits from clearly defined plans and an incremental approach to revising new elements and addressing gaps or failures (Beunen et al, 2017). A longitudinal view of institutional change allows for assessing actors and dynamics involved in integrating adaptation into the sectoral agendas or governance arrangements mentioned above. (Patterson and Huitema, 2019).

6.4.3 Solution spaces to address the 'policy action gap'

A policy action gap arises when administrative, communication, financial and other organisational blockages and inertia interrupt implementation of policy, the intent of political leadership and delivery of adaptation interventions on the ground (Ampaire et al., 2017; Bell, 2018; Shi, 2019). Political and policy confidence are key enabling conditions for adaptation decision-making. As the AR5 already acknowledged, political inaction can arise where there is low confidence that adaptation actions can deliver a safer future for all (Chan et al., 2015a). For example, in some administrative jurisdictions (most of them local governments), calls by social movements for the adoption of Climate Emergency Declarations were addressed, however, practical outcomes in terms of adaptation have been limited, and may have foreclosed other future local actions (Nissen et al., 2020; Ruiz Campillo, Castan Broto and Westman, 2020), and raised concerns about maladaptation (Long and Rice, 2019). Political inaction for climate justice is particularly visible in contexts of informality (Ziervogel, 2020). Studies of city and local authority decision making in South America (Di Giulio et al., 2019), Asia (Araos et al., 2017) and Europe (Lesnikowski et al., 2021) indicate where there is insufficient political will (that is lack of prioritization of the issue, and inadequate allocation of resources including staffing and finance) and lack of inclusive, coordinated leadership, it can be difficult to overcome inaction, generating a policy action gap.

Multiple actors contribute to deliver climate change adaptation (Chan et al., 2015a; Bäckstrand et al., 2017). There are also multiple scales of action, from the provision of local services to large infrastructures of national or even international significance. Figure 6.5 provides an insight into the challenges that shape the policy action gap and a range of strategies that can help bridge policy action gaps. Effective adaptation governance will depend on the compound impact of the actions of multiple agents operating at different scales (*medium confidence, medium agreement*) (Di Giulio et al., 2019; Hale et al., 2021; Zwierzchowska et al., 2019).

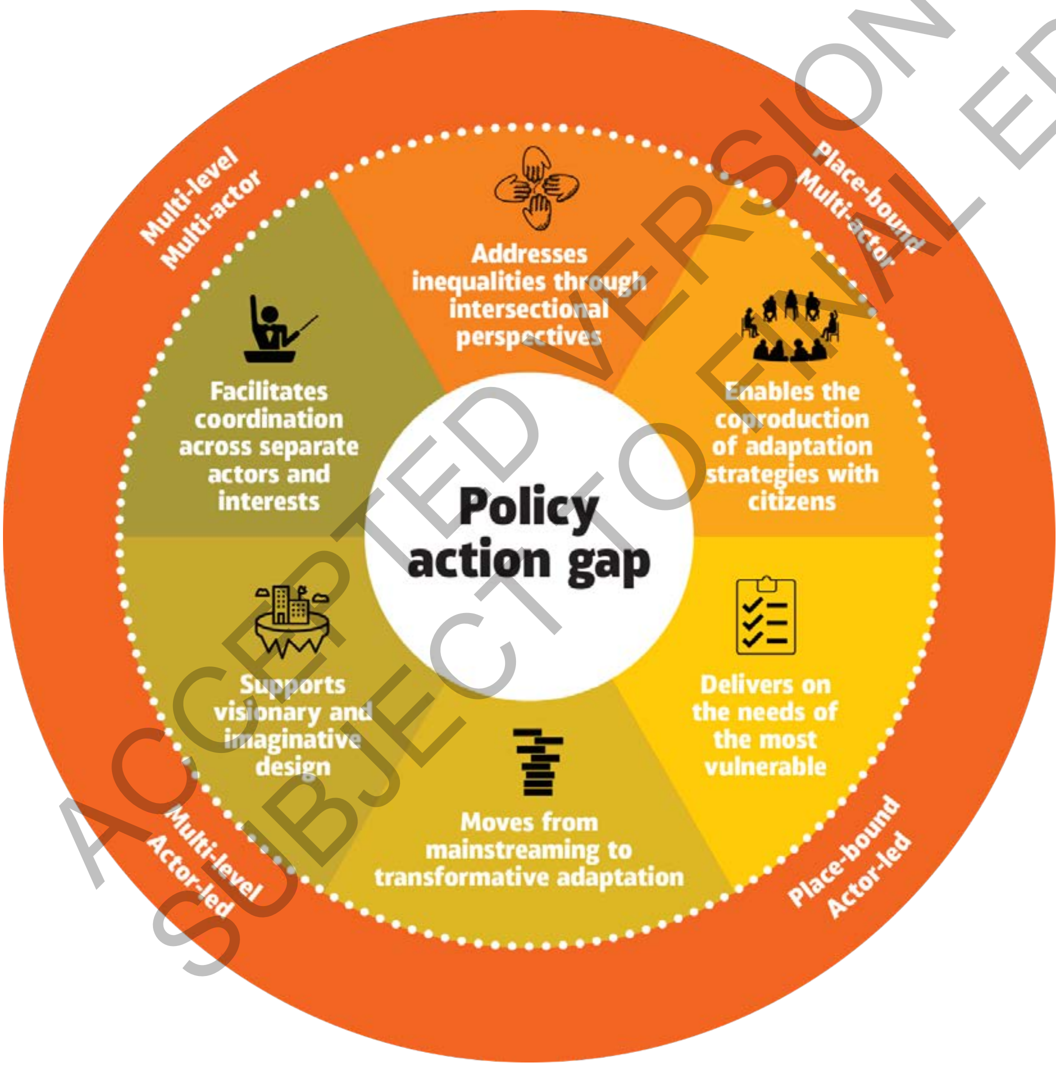

Figure 6.5 Solution spaces for the policy action gap. The categories in the outer circle represent the tension that shape the policy action gap. On the one hand, there is a tension between the need to deliver action at scale (Multi-level) and the need to mobilise the capacities in a given place (Place-bound). On the other hand, there is a tension between the need to facilitate collaborations among multiple actors (Multi-actor) and the fundamental impact that leadership can have in actor-led initiatives (Actor-led). These two tensions interact creating different possibilities for transformative adaptation. The inner ring represents different areas of intervention that configure the solution space to tackle the policy action gap, and that bridge these two tensions.

6.4.3.1 Delivers on the needs of the most vulnerable

Success in urban adaptation is most often understood as requiring measurable outcomes and evaluation (see also section 6.4.6). However, many adaptation outcomes are not measurable (*medium evidence , medium agreement*) (Béné et al., 2018). Adaptation action solely focused on action tends to ignore areas of action in the city for which there is no existing data even though they may play an essential role in shaping resilience and its limits. Informal settlements and informal economies which are integral in managing urban resources for effective climate adaptation are not routinely included in formal urban and national monitoring, including through tax receipts —are (Guibrunet and Castán Broto, 2016). The resulting understanding and monitoring of city needs, capacities and actions that feed into policy is incomplete. The innovation as well as particular concerns and capacities of the informal sector, which is often highly gendered are not always measured (Brown and McGranahan, 2016). An emphasis on measurable adaptation outcomes may lead to prioritizing techno-economic measures to adaptation at the local level. Technocratic approaches to environmental policy continue to shape local sustainability politics (Bulkeley, 2015a). The deployment of such technocratic approaches at the local scale is detrimental for democratic and collaborative practices (Metzger and Lindblad, 2020). For example, China has received praise in terms of delivering urban policies that put climate change at its core, thus suggesting its role providing leadership in climate change debates (Liu et al., 2014; Wang and He, 2015; Fu and Zhang, 2017). However, a detailed analysis of case studies of sustainable development in China's cities demonstrates that processes of planning only take into account certain groups and interests (Westman and Broto, 2018). Urban sustainability policy may, as a result, fail to deliver collaborative social and environmental objectives, and this is maladaptive in the terms of Climate Resilient Development.

6.4.3.2 Moves from mainstreaming to transformative adaptation

Two forms of mainstreaming are usually found in urban policy: incorporating climate adaptation into different sectors or incorporating climate adaptation in holistic sustainability or resilience plans, linking climate adaptation objectives with other social and development objectives (Reckien et al., 2019; Fainstein, 2018). The integration of climate adaptation in local policies in cities and settlements has often been seen as maintaining business-as-usual and not always aligned with transformative efforts to address structural drivers of vulnerability (*high confidence*). For example, mainstream actions that seek to advance other development objectives, as explained above, may reduce adaptation to 'low-hanging fruits,' which may maintain business-as-usual practices without any fundamental transformation of the social, institutional and economic systems that drive vulnerabilities (Aylett, 2014). However, as explained above, mainstreaming can also generate wider processes of institutional change (section 6.4.2). Mainstream strategies may help to demonstrate how policy and frameworks can produce practical outcomes on the ground (Biesbroek and Delaney, 2020). However, previous experiences in other sectors, such as gender mainstreaming, have shown the limitations of the mainstreaming approach, particularly in terms of addressing the structural drivers of inequality and vulnerability, and in achieving justice for those who suffer most (Moser, 2017). Local governments, in particular, can link mainstreaming efforts with specific strategies that support justice in adaptation, including redistribution efforts to address vulnerabilities (see section 6.3.2), representation in local institution and deliberative processes, and recognition of the conditions for self-realization, including personal and collective safety (Agyeman et al., 2016; Castán Broto and Westman, 2017; Castán Broto and Westman, 2019; Hess and McKane, 2021).

6.4.3.3 Facilitates coordination across separate actors and interests

Coordination of adaptation policy goals cuts across cities to integrate cities into international processes of climate policy formulation; coordination in cities produces effective collective outcomes, cementation of common standards and methodologies for climate action (e.g., emission inventories) (*high agreement, medium evidence*) (Gordon and Johnson, 2017; Hsu and Rauber, 2021). A collective global response has become a significant concern in international climate policy (Chan et al., 2015a). The UNFCCC has adopted a role as an orchestrator including providing framework for city governments (Bäckstrand and Kuyper, 2017). Within cities, coordination can arise from active programming; for example, in Rotterdam and New York City local authorities adopted long-term objectives and conditions for action, bringing together a multiplicity of actors across sectors to orient contributions, share knowledge, and coordinate actions (Hölscher et al., 2019). Where national politics is supportive, coordination between city and national government is an asset (Chan and Amling, 2019; Inch, 2019). The use of social media and digital mechanisms for coordination with public interest is ambiguous: in China, Weibo has facilitated an expansion of public engagement, although it remains top down and dominated by a few individuals (Yang and Stoddart, 2021). The pilot project #OurChangingClimate is one example of engaging youth with an understanding of their communities and their resilience or vulnerability to climate change (Napawan, Simpson and Snyder, 2017).

6.4.3.4 Enables the coproduction of adaptation strategies with citizens

Co-production can advance urban sustainability and social justice in cities and settlements to provide infrastructure adapted to the human scale, and advancing SDGs (*medium confidence*) (McGranahan, 2015; McGranahan and Mitlin, 2016; Chowdhury, Jahan and Rahman, 2017; Moretto and Ranzato, 2017; Nastiti et al., 2017). Co-production involves the active involvement of citizens and citizens' organization in iterative public service planning and delivery and has become increasingly central in climate change responses alongside other bottom-up, community-led strategies (Bremer et al., 2019; Vasconcelos, Santos and Pacheco, 2013).

Coproduction builds on public participation that brings together diverse sets of citizen interests, values, and ideas to inform change and solve problems relating to a collective adaptation challenge (Archer et al., 2014; Bisaro, Roggero and Villamayor-Tomas, 2018; Sarzynski, 2015) and is increasingly important in environmental policy more widely (McGranahan, 2015; Moretto and Ranzato, 2017). For example, in three cities across the Czech Republic, stakeholder participation exercises were used to prioritize climate change risks, provide impetus and opportunity for knowledge co-production, and support adaptation planning (Krkoška Lorencová et al., 2018). In municipalities in Malaysia, stakeholders and citizens are active in the adaptation policy cycle (Palermo and Hernandez, 2020). In Quebec, Canada, citizens collaborated with the municipal authority to bring together climate science and 'ordinary' urban management and design solutions (Cloutier et al., 2015). Service coproduction enables integrating multiple actors in the management and delivery of public services (Pestoff and Brandsen, 2013; Pestoff, Brandsen and Verschuere, 2013). Civil society-driven, co-productive approaches can pioneer new forms of institutional relations and practices filling gaps where the public sector is absent or retreating (Frantzeskaki et al., 2016).

A coproduction approach to climate change governance addresses the increasing public interest on climate change (Davies, Broto and Hügel, 2021). Youth movements such as Forum for Future have joined forces with other environmental and Indigenous organisations to lobby governments and institutions to action (Kenis, 2021; Fisher and Nasrin, 2021; Davies and Hügel, 2021; Hayward, 2021). These movements have built momentum moving local governments and other institutions to declare a climate emergency and have supported the creation of new forums where climate change can be addressed collectively, such as citizens' assemblies. In the UK, for example, initial scepticism has led to the proliferation of citizen-centric Climate Assemblies at the local level (Sandover, Moseley and Devine-Wright, 2021).

Cooperative governance models provide insights for designing forms of participatory and collaborative planning through which communities and state actors can identify concrete actions and resources to improve services and mitigate structural vulnerabilities to disasters (Castán Broto et al., 2015b). Experiences of co-production of sanitation services show how co-production may improve outcomes while at the same time opening up avenues for grassroots organizations to claim political influence (McGranahan and Mitlin, 2016). Coproduction may change institutions in response to external interventions (Das, 2016). Although there are drawbacks in terms of the extent to which coproduction can be used to legitimize unfair interventions within a given context, coproduction may also be a tool for improving the accountability of dominant groups to vulnerable sectors of the population (Nastiti et al., 2017). There are limitations to coproduction. The city of Barcelona, Spain used coproduction methodologies to develop the Barcelona Climate Plan. However, policy makers and civil servants were reluctant to use lay knowledge from participants and political deadlines constrained the time dedicated to deliberation (Satorras et al., 2020).

6.4.3.5 Addresses inequalities through intersectional perspectives

Inclusive and sustainable adaptation can address the causes of systemic vulnerability (medium evidence, high agreement). This points to the fundamental requirements of adaptation action in line with the Universal

Declaration of Human Rights. Climate justice theories draw on the environmental justice movement experiences at the local level (Bickerstaff, 2012; Bickerstaff, Walker and Bulkeley, 2013; Perez et al., 2015; Hall, Hards and Bulkeley, 2013). Slogans such as 'leave no one behind' embedded in international policy for cities and settlements recognize the connection between systems of oppression and exclusion that reproduce and perpetuate urban inequality and the delivery of urban services and security (Kabeer, 2016; Stuart and Woodroffe, 2016).

Intersectional strategies of action seek to consider the multiple forms of structural oppression experienced at the local level (Grunenfelder and Schurr, 2015) and, in the context of adaptation, explain how they produce or exacerbate vulnerabilities. For example, intersectionality ties with the idea of how multiple deprivations shape access to services (from sanitation to health and education) and the exposition to environmental risks (Sicotte, 2014; Lau and Scales, 2016; Van Aelst and Holvoet, 2016; Lievanos and Horne, 2017; Raza, 2017; Yon and Nadimpalli, 2017; European Environment Agency, 2020) (see Box 6.6 on the participation of women in local decision making bodies). For example, fisherwomen in the western coast of India rely on a complex arrangement of relationships around categories of class, caste, and gender that shapes their possibilities to draw political resources to maintain their livelihoods, and hence, influence the dynamics of transformation (Thara, 2016). Intersectionality is central to build resilience across communities, rather than in particular areas (Khosla and Masaud, 2010; Reckien et al., 2017). Including intersectionality deliberately in partnerships with communities can empower socially excluded groups and highlight justice issues while aligning agendas with local development priorities (Castán Broto et al., 2015a). Despite the high confidence on the growing importance of intersectionality concerns in the delivery of just environmental policies, there is limited evidence of its explicit inclusion in adaptation policies.

[START BOX 6.6 HERE]

Box 6.6: Invisible Women: Lack of Women's Participation in Urban Authorities

Women are under-represented internationally in governance structures (Prihatini, 2019; Gonzalez-Eiras and Sanz, 2018; Rashkova and Zankina, 2017; Koyuncu and Sumbas). This situation is reflected in urban authorities where participation by those who identify as women is low (Williams, Devika and Aandahl, 2015; Kivoi, 2014). Das (2014) reports deep-rooted economic inequalities are barriers for women's participation in Indore, India, and that women's collective empowerment could increase their bargaining power within households as well as in the community and state. Kivoi (2014) draws a similar conclusion presenting experience from Kenya. The big question is how to make women more visible in the urban governance process?

What are the barriers women face and how do we increase their participation so that urban governance become more inclusive? Escalante and Valdivia (2015) show the participatory tools that can be used at different stages of planning for women's empowerment using bottom up planning models. Using these tools makes planning process more inclusive. Araujo & Tejedo-Romero (2016) show from Spanish local councils that women's political representation in municipalities has a positive influence on the level of transparency, increasing information transparency and reducing information asymmetry. In Myanmar (Minoletti, 2014) increased levels of women's participation in urban authorities helped to improve the quality of governance such as reducing corruption and conflicts and improving service delivery.

[END BOX 6.6 HERE]

People traditionally excluded from climate change governance, such as children, are also more likely to have their needs and priorities considered in urban planning for adaptation where there are national advocacy bodies, for example, Commissions for Future, or Children's commissions (Nordström and Wales, 2019; Watts et al., 2019; Hayward, 2021). An emphasis on procedural justice in decision making has potential to produce transformational outcomes where these are defined as significantly reducing inequality (Holland, 2017). In this light emerging evidence suggests transformative adaptation is more likely to occur if people have the agency to influence decisions and enact change (Archer and Dodman, 2015). Cities are also more likely to build and develop infrastructure that serves the needs of disadvantaged groups, when urban climate governance encourages wider community participation and inclusion (Ziervogel, 2019a; Hölscher et al., 2019; Anguelovski et al., 2016). This can help to stimulate innovation, shift power relations and address diverse needs (Martel and Sutherland, 2019; Chu, Schenk and Patterson, 2018). Experiments in including marginalized groups in adaptation planning are starting to emerge in places such as Quito (Ecuador), Lima (Peru), Manizales (Colombia) and Surat (India), where disadvantaged youth, informal settlers, and other vulnerable communities are included in discussions of short-/long-term adaptation needs and fair distribution of adaptation resources (Chu, Anguelovski and Carmin, 2016; Sara, Pfeffer and Baud, 2017; Hardoy and Velásquez Barrero, 2014). These processes can also support citizens to manage risks as they encounter them in their everyday life (Ziervogel et al., 2017).

In order to respond to urban injustices, attention needs to be paid to both the local level and to broader system-wide governance issues (that are unpacked further in section 6.4). At the local level it is important to understand who is most vulnerable to climate risk, which is likely to be related to class, race, gender, ability and age (Wilby and Keenan, 2012; Ranganathan and Bratman, 2019; Thomas, Cretney and Hayward, 2019). Factors such as age and levels of ability, as well as those pursuing outdoor livelihoods, have a direct link to higher vulnerability to heat stress (Conry et al., 2015). In least developed countries, less than 60% of the urban population have access to piped water which impacts on health and well-being, and emphasizes the importance of alternative resources for these households (World Health Organization, Nations and Fund, 2017).

6.4.3.6 Supports visionary and imaginative design

The failure to deliver inclusive and sustainable adaptation contributes to a collective inability to mobilize the power of creative community vision (*medium evidence, high agreement*). Urban design plays a central role to support creative adaptation strategies (Box 6.7). Much adaptation action repeats previous experiences. However, the potential for building resilience to deliver adaptation- especially transformative adaptation- requires an articulation of collective visions of the future and the imagination of new or alternative urban futures (Glaas et al., 2018) including through design and deliberate engagement with cultural artefacts, technologies, and performances (Jordan, 2020). Social movements can be powerful sources of such alternative visions of the future, as exemplified by recent Youth Climate Strikes and Extinction Rebellion (limited evidence, medium agreement). Community protest including Youth Climate Strikes have influenced urban climate policy agendas including the declaration of climate emergency in municipalities worldwide, fostering a new debate on climate change, although their impact on local policy is ambiguous (Davidson et al., 2020; Thomas, Cretney and Hayward, 2019; Prendergast et al., 2021; Ruiz Campillo, Castan Broto and Westman, 2020). Social movements on climate mitigation, such as the Transition Movement and Transition Towns (Feola and Nunes, 2014), and School strikes may serve as an example for mobilizations more specifically about climate adaptation and the way new, networked, grassroots citizen activism and community organizations can encourage urban institutional change (Gunningham, 2019; Jordan et al., 2018; Wahlström et al., 2019). Other strategies such as cultural production and exhibitions may also have an impact (Stripple, Nikoleris and Hildingsson, 2021).

[START BOX 6.7 HERE]

Box 6.7: The Role of Urban Design in Local Adaptation

Since AR5 there has been a growing literature about the role of urban design, creating new opportunities for both incremental and transformative adaptive responses to climate change (*medium evidence, high agreement*). For example some of these creative design approaches compliment and extend regulatory and land use planning approaches such as form-based codes and established certifications like LEED-ND (Leadership in Energy and Environmental Design – Neighbourhood Design) (Garde, 2018; Garde and Hoff, 2017) and the USA's Sustainable Sites Initiative (SITES) (Valente, 2014). Emphasis on sufficiency has also influenced urban design, for example, with the mobilization of 'doughnut' economics that emphasize both a social foundation and an environmental ceiling, for example Amsterdam (Raworth, 2017). However, such cases are rare, substantial public investment is often required (high confidence, high agreement) (see also section 6.4.7 on finance and insurance). Other approaches underscore innovation and creativity, at the essence of which are context-specific interventions that draw on a compendium of urban design principles such as: indeterminacy (to accommodate climate uncertainty), polyvalency and diversity, and harmony with nature (Dhar and Khirfan, 2017a). Creative interventions include the daylighting of buried streams to create climate adaptive public realms (Khirfan et al., 2020; Khirfan, Mohtat and Peck, 2020). For example, the demolition of a major expressway and the restoration of the Cheonggyecheon stream reorganised downtown Seoul, South Korea and significantly contributed to climate change adaptation through stormwater management and reducing the urban heat island effect (Kim and Jung, 2019). Biomimicry and ecological infrastructure are design features that governance bodies can use to reshape space and contribute to place making (Santos Nouri and Costa, 2017; Prior et al., 2018). For example, urban metabolism and local ecological knowledge has constituted the essence of urban design interventions in the Island of Tobago in ways that capitalize on the contiguous relationship between ecosystems (e.g., the mangrove forest) and human actions (rainwater harvesting and grey water management) (Khirfan and Zhang, 2016). While lack of funding, or design capacity, restrictive planning regulations, inequality and competing urban agendas can create barriers for the implementation of creative design solutions, transition architecture movements are also driving local urban adaptation experiments and exploring ways local learning can be scaled up (Tubridy, 2020; Irwin, 2019).

[END BOX 6.7 HERE]

6.4.4 Limits of Adaptation Capacity at the Institutional Level

In delivering adaptation in cities, settlements, and infrastructure, however, there is a need to understand and measure the adaptive capacity and limits to manage future risks in communities, institutions, and organizations (Filho et al., 2019). However efforts to track urban adaptation lack consistent methods, metrics and data gathering (Olazabal et al., 2019b). The scale of complex, cascading challenges, limited finance and governance capacity combined with the impacts of growing social inequality and sustainable development priorities can result in both soft and hard limits on cities government's capacity to adapt to climate change (Chanza, 2018; Sanchez Rodriguez, Ürge-Vorsatz and Barau, 2018; Lehmann et al., 2015; Di Giulio et al., 2018). Hard limits to adaptation are identified when it is unfeasible to avoid severe risks while soft limits exist when technological and socioeconomic options are not immediately deployable (Pachauri, Meyer and Barros, 2014). In urban contexts soft limits may become hard limits when large numbers of people are unable to avoid severe climate related risks of loss and damage (Mechler et al., 2020). Climate change-related loss and damage that are intangible also require more caution in assessment processes (Roberts and Pelling, 2018; Andrei et al., 2015; Barnett et al., 2016; Thomas and Benjamin, 2018). Incorporating Indigenous knowledge can identify people-oriented and place-specific scenarios leading to developing urban adaptation policies that foster identity, dignity, self-determination, and better collective decision-making/capacity to act (McShane, 2017; Preston, 2017) and are sensitive to the local context and limits of community adaptation (Makondo and Thomas, 2018).

Urban transformations represent forms of adaptation that challenge the principles in which a society is established (Pelling, O'Brien and Matyas, 2015) and can be deployed to go beyond the existing limits of development justice and climate change adaptation capacity. While not all adaptation will be transformative, transformative capacities support both ongoing adaptation efforts and the broader systemic change processes that align adaptation efforts with decarbonization requirements and the SDGs' delivery. 'Urban transformative capacity' focuses on understanding what elements of a system to respond to external changing conditions in a manner that transforms the system towards a more sustainable state (Ziervogel, Cowen and Ziniades, 2016). The capacities required to deliver adaptation action in cities and settlements are 'transformative capacities,' because they move away from thinking of adaptation as an adjustment to a changing external environment to think instead of adaptation as a reconfiguration of infrastructures and institutions to build resilience in the surrounding environment (Pelling, 2010; Matyas and Pelling, 2015). Reflective and iterative learning is integral to fostering transformative capacity (c.f. Luederitz et al., 2017). Transformative capacity extends across multiple agency levels or geographical locations, as well as various domains (Wilson et al., 2013; Olsson, Bodin and Folke, 2010; Keeler et al., 2019b). The components of transformative capacity in cities and settlements can be grouped into three categories (see Table 6.9): (1) agency and forms of interaction, (2) development processes, and (3) relational dimensions (Wolfram, 2016). Alongside different forms of technical expertise, there is a need to broaden the interventions of disadvantaged populations in urban sustainability (Wolfram, Borgström and Farrelly, 2019).

Table 6.9 presents a defined framework of ideas that local institutions- mostly local governments- can put into practice to improve their adaptive capacity. Enabling transformative capacity requires novel governance arrangements based on broad participation, a diversity of actor-networks, socially embedded leadership, and empowerment of communities, alongside an understanding of the system dynamics, which refers to system awareness, collective visions, practical experimentation, reflexivity, capacity building, and institutional mainstreaming, and the multiple levels of agency or scales (Ziervogel, Cowen and Ziniades, 2016; Ziervogel, 2019a; Wolfram, 2019; Hölscher and Frantzeskaki, 2020; Castán Broto et al., 2018). Many of the transformative capacity components are already visible in local adaptation actions, but many efforts emphasize one element at others' expense, without delivering a systemic perspective. In particular, measures to facilitate the empowerment of communities, reflexivity, and social learning are rare but often point towards heightened capacities for transformative, alongside incremental, adaptation (Castán Broto et al., 2018). Transformative capacity frameworks may foster inclusive governance to deliver risk management that works for the poor in countries such as South Africa (Ziervogel, 2019a).

Table 6.9 Components of urban transformative capacity with broader relevance for multiple forms of adaptation (Wolfram, 2016).

Component		Manifests in…
Agency and interaction	**Inclusive, multiform urban governance (C1)** Participation / inclusiveness (C1.1)	Citizens and/or civil society organizations participating directly in planning and/or decision-making processes.
	Diverse governance modes / Networks (C1.2)	Different and various stakeholders working together and building connections between sectors in different manners.
	Sustained intermediaries and hybridization (C1.3)	An intermediary positioned between the stakeholders of a project.
	Transformative leadership (C2)	Leadership acting as a collaborative driving force in an initiative.
	Empowered communities (C3) **Social needs (C3.1)**	Either analysing or addressing social needs.
	Autonomous communities (C3.2)	Integrating into the design of the project different aspects of community empowerment.
Development processes	**System awareness (C4)** Baseline analysis and system(s) awareness (C4.1)	Agendas aiming to tackle sustainability challenges after deliberate analysis of urban systems.
	Recognition of path dependencies (C4.2)	Explicitly tackling systemic barriers to change.
	Foresight (C5) Co-production of knowledge (C5.1)	Involvement of various and multiple stakeholders in knowledge production processes.
	A collective vision for change (C5.2)	An explicit future vision shared among stakeholders as a means for motivating partners and fostering commitments.
	Alternative scenarios, future pathways (C5.3)	Comparative scenarios that evaluate the mutual shaping of social, ecological, economic and technological dimensions.
	Experimentation with disruptive solutions (C6)	The deliberate use of experiments or ideas that seek to challenge the existing landscape of established policies, technologies or social practices.
	Innovation embedding (C7) Resources for capacity development (C7.1)	Project stakeholders sharing resources for capacity development outside the project to disseminate and multiply results.
	Mainstreaming transformative action (C7.2)	Attempts to generalise the project operation or results beyond the initial context of an application.
	Regulatory frameworks (C7.3)	A new regulation was established as a result of the project or as part of the project activities.

Relational dimensions	**Reflexivity and social learning (C8)**	Stakeholders reflecting on learning and capacity building processes.
	Working across human agency levels (C9)	Project activities contributing to capacity development across human agency levels.
	Working across levels and scales (C10)	Project activities contributing to building capacity across geographical or political-administrative levels.

6.4.5 Financing Adaptation in Cities, Settlements and Infrastructures

The amount invested in urban adaptation is limited. The Cities Climate Finance Leadership Alliance tracked USD 3.7 billion of investments in adaptation projects in 2017-2018, of which only 3-5% had an urban component (Richmond et al., 2021). Cities and settlements frequently face barriers of inadequate financing for climate adaptation and mitigation (Cook and Chu, 2018).Finance barriers interact with economic barriers and socio-economic conflicts and need to be considered within an integrated perspective (Hinkel et al., 2018).

Many early leaders in climate adaptation are, therefore, perhaps unsurprisingly, political capitals or financial centers in the global North with much larger resource envelopes and well-developed fiscal and financing capacities (Westerhoff, Keskitalo and Juhola, 2011; Shi, Chu and Debats, 2015).

The funding required to deliver climate change adaptation will depend on choices made about climate mitigation (Masson-Delmotte and Waterfield, 2018). Still, the cost of adapting to a global temperature increase of 1.5°C will be a fraction of the cost of adapting to a global temperature increase exceeding 3°C (Pörtner et al., 2019; Shukla et al., 2019; Hoegh-Guldberg et al., 2018). It will also depend on selected adaptation options, as they have different capital requirements, operating costs, and returns on investment (See 6.3). Finally, costs depend on financing sources and mechanisms selected.

Broadly, there are two options for adaptation investment: funding – direct expenditure in preparation for or response to climate change impacts – and financing – the deployment of market-based instruments to attract third-party resources to an adaptation action (Keenan, 2018; Banhalmi-Zakar et al., 2016). Using funding can be a lower-cost strategy, as there is no third party expecting a return on investment. However, using financing can expand the total resources available for adaptation (White and Wahba, 2019).

The choice of funding and financing mechanism is often based on implicit economic world views (Keenan, Chu and Peterson, 2019) or on the technical support available to subnational governments, such as preparing municipal bonds or contracting for public-private partnerships (Bisaro and Hinkel, 2018). The urban finance literature has long called for critical interrogation of these choices, as adaptation finance has profound justice implications (Khan et al., 2020). However, the literature on adaptation investments is limited (Harman, Taylor and Lane, 2015; Keenan, Chu and Peterson, 2019). The use of municipal debt such as green bonds, for example, intensify the financial and environmental risks borne primarily by the poor, the working class, or people discriminate against because of race, sexual orientation, or ability (Bigger and Millington, 2019).

The climate imperative has not yet fundamentally changed urban infrastructure investment (White and Wahba, 2019). Mobilizing adaptation investment in urban areas continues to depend on strengthening public finance capacities (particularly evaluating and integrating climate risk into economic decisions) and meeting private investors and lenders' expectations. Climate change creates new investment risks and physical risks (Martimort and Straub, 2016), and highlights the limitations of current models to account for risk and uncertainty when pricing investments (Keenan, 2018). Private investors and lenders do not seem ready to provide adaptation finance on significantly easier or cheaper terms than conventional finance (White and Wahba, 2019). However, a variety of means for financing climate change adaptation in urban areas exist (Table 6.10).

Table 6.10 Finance instruments to deliver adaptation in urban areas (source: adapted from (Richmond et al., 2021) and (UN-Habitat, 2016b)).

Type of finance	Finance source	Instruments	Examples of specific instruments in urban settings
Public	Municipal government	Local revenue generation	Utility fees Open space funds/land value capture General obligation bonds Local property, income, and sales taxes
	State/Provincial government National government	Grants, incentives, technical assistance funds	Insurance Tax advantages Low-cost project debt Infrastructure investment funds Shared taxes Intergovernmental funding transfers/revenue sharing
Public finance	National DFIs Bilateral DFIs Multilateral DFIs	Grants, project debt (low-cost market rate), technical assistance, risk instruments	Risk mitigation support of PPP Project level debt Project preparation facilities and other technical advisory Insurance
	Climate funds	Grants, debt, equity, guarantees	Dedicated climate fund
Private	Commercial FIs	Project debt and equity (market-rate), guarantees	Internal climate risk mitigation PPP Financing Climate loans
	PE/Infrastructure funds	Project equity (market rate)	Direct urban infrastructure investments Corporate equity investment
	Institutional investors	Project debt and equity (market-rate)	Direct urban infrastructure investment Corporate debt and equity investments
	Private insurance	Insurance	Public and private risk mitigation Catastrophe bonds Parametric insurance
	Corporate actors	Balance sheet financing and project equity (market rate)	Internal risk mitigation Leasing PPP
	Household	Balance sheet financing	Internal climate risk mitigation
	Non-profits, philanthropies and foundations	Grants, technical assistance, donations	Microfinance Impact investment
	Communities	Grants and collective support	Risk sharing Upgrading funds Community development funds Crowdfunding

6.4.5.1 Urban adaptation financing gap

Cities and settlements in higher-income countries typically have access to funding that could be used to enhance resilience and build adaptive capacity; this includes both the private resources of individual households and firms (which varies significantly within and among cities) and public budgets of different government tiers (see Table 6.10).

Depending on fiscal devolution levels within a country, public revenues may be collected and managed primarily at the national, state, metropolitan, or local level. In federal countries, subnational governments collect an average of 49.4% of public revenues compared to only 20.7% in unitary countries (OECD/UCLG, 2019). For example, subnational revenues represent over a quarter of total public revenues in Belgium, Canada, and Denmark, but less than 5% in Greece, Ireland, and New Zealand (OECD/UCLG, 2019). The share of the national revenue transferred to subnational governments also varies significantly among countries: grants and subsidies account for over three-quarters of subnational government revenue in Malta, but less than a quarter of subnational revenue in Iceland (OECD/UCLG, 2019). A local government's capacity to collect revenues is further mediated by incomes within a city (which dictates the prospective tax base) and the capacity of civil servants to administer taxes, fees, and charges. The result is that metropolitan and local governments' budgets vary dramatically, across and within countries. For example, per capita municipal budgets vary from $1,114 in Saskatoon and $2,682 in Peterborough (Canada), $2,635 in Leipzig and $3,638 in Freiburg (Germany), to $4,907 in Bristol and $5,612 in Aberdeen (the United Kingdom) (Löffler, 2016).

Revenue streams are often insufficient relative to the scale of adaptation requirements. For example, Kano, Nigeria, is a large urban area that urgently needs investment in human development and climate resilience, but where a fragmented local government has little capacity to finance their climate plans (Mohammed, Hassan and Badamasi, 2019). Many local governments are unable to mobilise funds for adaptation as they face competing priorities, meaning that resources for resilience must be allocated by higher levels of government (Hughes, 2015) – which also perceive opportunity costs to adaptation investments. Funding from non-state actors is, therefore, proving important. For example, in the U.S., private foundations and non-profit organizations account for 17% and 16% of adaptation support in urban areas (Carmin, Nadkarni and Rhie, 2012). However, tapping into these funding sources raises complex questions about accountability and ownership of urban adaptation (Chu, 2018a). Land reclamation may foster real estate markets and mobilize finance for adaptation, as shown in Germany, the Netherlands, and the Maldives (Bisaro et al., 2019).

City governments need to anticipate climate shocks and stresses and design their operating models and investment plans accordingly to ensure financial resilience (Clarvis et al, 2015). Climate risks threaten fiscal models, for example, a drought may disrupt water revenues by reducing total water consumption and incentivizing households and firms to invest in independent water storage or supply infrastructure (Simpson et al., 2019). Storm surges and sea-level rise may threaten sunk investments in revenue-generating infrastructures, such as toll roads or electricity generation and transmission systems. .

6.4.5.2 Barriers to adaptation investments

Common sources of adaptation finance might include donor agencies including the Green Climate Fund; sovereign funds (e.g. the Bangladesh Climate Change Resilience Fund) and private finance from commercial banks, investment companies, pension funds and insurance companies (Floater et al., 2017). These capital sources have different risk-return expectations and investment horizons, so they will suit different types and stages of projects. Many subnational governments in the global North have access to well-developed domestic, if not global, capital markets to raise and steer finance for urban investment (Banhalmi-Zakar et al., 2016).

However, investments in ex-ante urban climate adaptation may prove less attractive to these financiers than other opportunities because of their long maturities and high risk (Keenan, Chu and Peterson, 2019) (see also Table 6.11). Many generate economic returns primarily through avoided losses from climate impacts, which are difficult to measure and are, in any case, more attractive to funders than financiers (Kaufman, 2014). Ex post, insurance already plays a critical role in protecting urban households, firms, and other stakeholders from the full economic costs of high-severity, low-frequency events by sharing risk over time and space. Insurance can also be designed to incentivize risk-reducing behaviours and investments (Banhalmi-Zakar et al., 2016; Paddam and Wong, 2017). Some researchers suggest that, in urban environments, insurance practices are helping to establish adaptation and risk as a new area of public health and public protection. For example, local governments are using new risk transfer instruments, such as reinsurance and catastrophe bonds, to fund investments in resilience projects and disaster recovery (Collier and Cox, 2021). However, private-sector insurance's commercial feasibility depends on more robust estimates of current and future risks, and premiums commensurate with the ability and willingness of consumers to pay. Therefore, ex-ante investments must complement insurance schemes to improve climate modeling and reduce climate risk (Surminski, Bouwer and Linnerooth-Bayer, 2016). The private sector also faces practical barriers to invest in adaptation.

Table 6.11 Barriers to finance adaptation in urban areas (Richmond et al., 2021)

Barrier Application to urban adaptation Barriers to adaptation finance	

Poor policy Environment	Municipal policy environment lacks conditions supportive to private adaptation investment (e.g., lack of requirements that private sector organizations operating in cities implement climate risk mitigation strategies or invest in systemic resilience).
Poor institutional environment	Legal and regulatory infrastructure in the city lacks clarity of purpose towards addressing urban climate risks (e.g., no limitations on development in high climate risk areas).
Poor market environment	Market environment is unsupportive towards adaptation investment (e.g., lack of creditworthy partner municipalities for private sector engagement).
High cost of projects and unknown value add	The value or benefit of the technology is uncertain; private sector actors do not sufficiently consider climate risk in decisions; upfront costs of technology are high.
Lack of technical capacity	Prospective users of technology do not have technical capacity to implement (e.g., limited or siloed expertise in implementing resilient urban infrastructure solutions).
Limitations of private insurance	Insurance has to date largely not been engaged in cities to efficiently transfer risk or incentivize adaptive action and the private insurance industry is facing considerable risk associated with the accelerating impacts of climate change in

National governments typically determine the fiscal transfers that subnational governments receive and the taxes, fees, and charges they permit to collect (see for example (CBO, 2016)). Local governments may strengthen their own-source revenue collection and management capacities to exploit these funding streams better and improve their balance sheets, but their total budget will be limited to these funding sources (Ahmad et al., 2019). The amount of local public funding available for urban adaptation depends on the relationships across different government levels.

Similarly, mobilizing private finance for urban adaptation projects demands robust institutional, fiscal, and regulatory frameworks, which are typically national authorities' responsibility. For local governments to access private finance for adaptation may require national (or in federal countries, state) governments to reform policies and rules governing municipal borrowing, public-private partnerships, land value capture instruments, and other financing mechanisms (Ware and Banhalmi-Zakar, 2017). Such fiscal reforms tap into fundamental political and policy issues, such as local governments' autonomy or the tariff-setting powers of national ministries (Gorelick, 2018; White and Wahba, 2019).

Access to private finance can support infrastructure development through private provisioning, public-private Partnerships (PPP), and public debt arrangements (*high confidence*) (see also 6.4.1.2). Private provisioning attracts coastal adaptation investment when returns are high (e.g., when there is a real estate market associated with it) (Bisaro and Hinkel, 2018). Public-private partnerships attract investments from dredging and construction companies that involve a large share of operational costs (Bisaro and Hinkel, 2018). Public debt instruments appear less successful in supporting investment in adaptation infrastructure. Real estate firms focus on adaptation actions if they perceive climate change impacts such as flooding may impact their activity, mostly focusing on adaptation action as a means to gain competitive advantage (Teicher, 2018).

There have been numerous attempts to innovate in climate finance, for example, mobilising community and cooperative forms of finance, or crowdfunding which have already proven effective in the context of mitigation (De Broeck, 2018). A well-studied instrument in urban environments is land-value capture. Land-value capture refers to communities' ability to capture the benefit of increased land values that result from public investment or other government actions (Germán and Bernstein, 2020). There is considerable potential to mobilize land-value capture for adaptation (*limited evidence, medium agreement*), but its potential remains unexplored (Dunning and Lord, 2020). While there are numerous examples of the mobilization of land-value capture to finance sustainable development action (Li and Love, 2019; Wang, Samsura and van der Krabben, 2019), there is limited evidence of its use in climate adaptation (see case study 6.2). These innovations are particularly important in contexts were resources are very constrained, such as in the financing of adaptation in African cities (See box 6.7).

Corruption in urban adaptation and disaster risk management finance is a considerable but little researched challenge observed from all world regions (Sanderson et al., 2021). Corruption generates maladaptation increasing risk, for example where infrastructure is constructed with faulty design, substandard materials and inadequate maintenance (Kabir et al., 2021). More widely, corruption increases vulnerability and reduces capacity by damaging the body politic, distorting markets and reducing economic growth (Alexander, 2017). The construction and infrastructure industries are repeatedly identified as sources of corruption (GIACC, 2020; Chan and Owusu, 2017; Sanderson et al., 2021). Corruption and misuse of climate finance is exacerbated by limited public access to information, political considerations in finance decision-making and lack of accountability for decisions and actions (Kabir et al., 2021). In construction Owusu et al (2019) found causes included too-close relationships, poor professional ethical standards, negative industrial and working conditions, negative role models and inadequate sanctions throughout the phases of construction. Post-disaster response and reconstruction, and periods of surge funding following international or national policy priorities are especially vulnerable to corruption with increased funding and pressure to lower norms of financial management (Imperiale and Vanclay, 2021). Mixed delivery mechanisms have been shown to reduce corruption, for example where civil society organizations are involved in project approval stages. Though there is also a risk that civil society organisations will themselves become entangled in corruption. International donors have a role to play in working with government and civil society to promote wider scrutiny and transparency of financing processes and project delivery through promoting media and press freedom and legislation for access to information to reduce corruption by enhancing transparency and accountability (Kabir et al., 2021).

Expanding the resource envelope available for adaptation investment is often beyond the authority or competency of city governments. Sovereign and state governments have critical roles to play in providing funding or securing finance for adaptation investments. Such role is particularly important where the impacts of climate change are distributed inequitably across a country so that the costs borne by a city may exceed local budgets.

[START BOX 6.7 HERE]

Box 6.8: Challenges to Investment in Adaptation in African Cities

In Africa, new investment in institutions and other enabling conditions for climate-resilient urban development (Robins, 2018) While several studies reveal the net economic benefit of climate-resilient, low-carbon African cities (Global Commission on Economy and Climate, 2017), structural impediments remain to the mobilization of investment for the types of public good infrastructure that would unlock this benefit (Dodman et al., 2017).

Since the 1960s, Gross Capital Formation (sometimes called Gross Domestic Investment) has been less than 22% in Africa, whilst in East Asian countries, it has risen to 42% (OECD, 2016). Africa faces an estimated 40% infrastructure financing gap, but this gap is almost certainly higher in the continent's rapidly growing cities (Baker & McKenzie, 2015). Relative poverty, weak or absent local fiscal systems, and contested tenure that prevents land being used as collateral, have restricted investment in African cities (Berrisford, Cirolia and Palmer, 2018; Dodman et al., 2017). Sub-Saharan African countries are reaching the 40%-urban threshold at national per capita incomes of around $1,000 per annum, significantly poorer than South-East Asian and Latin American cities at the same level of urbanization (Freire, Lall and Leipziger, 2014). Absolute poverty, in conjunction with weak revenue collection and low levels of investment, render conventional infrastructure finance difficult (Smolka, 2013; Global Commission on Economy and Climate, 2017; Berrisford, Cirolia and Palmer, 2018; Cirolia and Mizes, 2019). Sprawled urban development in Africa might make the provision of public services, both more energy-intensive and three times more expensive than high-density developments (Collier and Venables, 2016).

Data on private finance in African cities are inadequate (OECD, 2017), but all of Africa secured just 3.5% ($46 billion) of global FDI, despite a 10.9% increase in 2018 (UNCTAD, 2019). Mining and the extraction and processing of fossil fuels accounted for almost a third of greenfield FDI in Africa in 2018 (UNCTAD, 2019). The FDI secured by cities has tended to serve an urban elite and has been used to build shopping malls, housing settlements, and airlines (Watson, 2015). It is also unevenly distributed across the continent and within cities. Five countries, Egypt, South Africa, Congo, Morocco, and Ethiopia accounted for more than half the total FDI in 2018 (UNCTAD, 2019), leaving large parts of Africa's growing cities described by financiers as "high risk" and their citizens deemed "unbankable" (UCLG, 2016).

Private financiers have begun entering public-private partnerships with African cities, often supported by bilateral agreements between the respective countries, including the growing number of Asian and Middle-Eastern countries contributing to infrastructure in African cities (Cirolia and Rode, 2019). In the absence of enforceable spatial plans and strong urban governance, the risk remains that individual investment projects that are completed will aggregate to create urban systems that are at risk from climate change through the locking-in of inequality, urban sprawl, flooding and greenhouse gas emissions (Dodman et al., 2017; Wachsmuth, Cohen and Angelo, 2016). These risks will constitute a future burden for asset owners, financiers, and insurers and cause a progressive hemorrhaging of economic opportunities in Africa's urban centres (UCLG, 2016).

Securing climate finance for urban development is contingent upon robust multi-level governance arrangements (Tait and Euston-Brown, 2017; OECD/UN-Habitat, 2018). Such investments are needed for cities that do not yet have the balance sheets or rate-paying citizens required to enter financial markets on favourable terms. Similarly, Central Banks have a crucial role in managing the transition risks within cities and limiting the systemic impact of stranded urban assets due to technology shifts or sea-level rise (Safarzyńska and van den Bergh, 2017).

New energy, water, and sanitation technologies alter the public good nature of urban services and offer novel opportunities for private sector financiers and blended finance. Still, financial sector innovation remains necessary if technological innovation is to be scaled (Cities Climate Finance Leadership Alliance, 2015; European Environment Agency, 2020). UNEP has cited anecdotal evidence of a "quiet revolution" towards a more developmental and sustainable global finance sector, in part due to global Environmental, Social, and Governance requirements, and industry initiatives within the financial and insurance sectors (UNEP, 2015). Scope remains to strengthen Development Finance Institutions programmes such as the World Bank's City Creditworthiness Programme and the activities of China's ExIm Bank with a bespoke urban climate dimension.

[END BOX 6.7 HERE]

6.4.6 Monitoring and Evaluation Frameworks for Adaptation used in Cities, Settlements and Infrastructures

Urban adaptation plans can focus attention on the needs of marginalised or vulnerable communities including the elderly, children and the disabled (Dahiya and Das, 2020; Yang, Lee and Juhola, 2021). However, monitoring and evaluation (M&E) frameworks for adaptation are far from being fully developed and operationalized both in theory and in practice for cities, settlements, and infrastructures. See also Section 17.5 for an assessment of monitoring and evaluation in climate adaptation. Despite significant experience on the application in other sectors (e.g., health, water, industry, or business) or with other climate change objectives (e.g., emissions reduction), the assessment of adaptation efforts has been to date under-theorized in current urban adaptation literature (Berrang-Ford et al., 2019; Leiter et al., 2019; Olazabal et al., 2019b). There is also limited evaluation of new social innovations of the last two decades, including participatory budgeting, social financing, crowdfunding, and low-cost urban infrastructure that can be enabling conditions for transformative urban adaptation (Dahiya and Das, 2020; Caprotti et al., 2017).

The challenges related to the evaluation of adaptation progress (lack of methods, agreed metrics, data, and definitions, including the ambiguity of the concept of "adaptation") have been widely recognised after the Paris agreement by multiple organisations, including the OECD, the World Bank, the European Environment Agency, the Global Environment Facility (Ford et al., 2015; Magnan, 2016; Bours, McGinn and Pringle, 2014). Monitoring and evaluation systems in urban areas will necessarily be incremental and additive, and will have to build on existing indicator systems (Solecki and Rosenzweig, 2020). There is a need to develop practical and efficient frameworks to assess adaptation progress across all levels of public and private decision-making. This should include the assessment and consideration of top-down adaptations alongside informal, bottom-up, community actions, or corporate-led programs developed to reduce vulnerabilities and climatic risks and increase resilience (high confidence, high agreement).

On the one hand, there is a need to guarantee that planned adaptation actions are efficient, just and equitable (Olazabal et al., 2019b), including being able to disaggregate for example by gendered impacts. On the other hand, there is a need to observe if and how environmental, social and economic vulnerability and climatic risk conditions evolve with time. Surveillance, monitoring and evaluation facilitate adaptation decision-making by linking three aspects (Berrang-Ford et al., 2019): (1) changing vulnerabilities and risks, (2) established adaptation goals and targets, and (3) adaptation efforts put in place. The process will help evaluate whether current adaptation efforts are sufficient or adequate, thus, enabling the learning process that adaptation action requires (Haasnoot, van't Klooster and Van Alphen, 2018; Klostermann et al., 2018).

Monitoring and evaluation of Government led urban adaptation in major cities around the globe is largely missing (Araos et al., 2016; Olazabal et al., 2019a). This reveals: (1) a lack of awareness by local adaptation managers about the critical importance of monitoring and evaluation systems in adaptation decision-making, (2) inadequacy, irrelevancy, or underuse of available monitoring and evaluation resources, or (3) a lack of knowledge, capacity, and resources to make monitoring and evaluation work in practice at city scale.

Olazabal et al (2019b) argue that six components are at least required to make monitoring and evaluation operational for urban adaptation planning: (1) the definition of a context-specific tailored system adapted to existing local institutions, (2) the definition of a responsible party (public authority, department, group or organization) that will be in charge of monitoring and evaluation system management, (3) the definition and assignation of the appropriate budget over time, (4) the identification of monitoring objectives and indicators, (5) the definition of a method and process to evaluate outcomes of the monitoring process and eventually, (6) the reporting process (how and who the outputs will be reported to). Klostermann et al. (2018) emphasize the importance of learning through iterative cycles of selection of monitoring objectives, procedures, data collection and evaluation, and inputs to adaptation policy and planning processes (see also discussion of evaluation and learning in section 17.5.1.7). Yet, practical exemplary approaches are still missing.

The IPCC's Fifth Assessment Report acknowledged the lack of standard metrics to measure and monitor success in urban adaptation and suggested a list of indicators that could be developed, while also taking note of the localized nature of adaptation (see also (Rufat et al., 2015)). However, predominant approaches are typically not conducted at the appropriate scale to inform adaptation decision making (Ford et al., 2018). While some scholars advocate the use of a unifying indicator of social vulnerability (Spielman et al., 2020), other scholars propose to develop flexible sets of comparable indicators that can be adjusted to different contexts (Leiter et al., 2019). Risk-based approaches are seen as an alternative in a context where the monitoring of decision-relevant variables in urban climate adaptation planning is essential to link climatic risk assessment and action (Hallegatte and Engle, 2019; Kingsborough, Borgomeo and Hall, 2016; McDermott and Surminski, 2018). Because of the need to define normative frameworks for risk evaluation - what is acceptable, for what purpose and for how long (Galarraga et al., 2018) - these approaches may offer an opportunity for the generation of a shared understanding on goals and limitations of adaptation (McDermott and Surminski, 2018). However, risk-based indicators may also create a bias towards quantifiable variables that tend to be based on climatic modelling outputs, engineering, or financial assessments. Based on this and various examples of urban development projects, Hallegatte and Engle (2019) claim it is important to consider output-based indicators and process-based indicators that talk about government, voice, and empowerment. Overall, dozens of indicator-based approaches to assess climate adaptation have been proposed across the scientific and policy literature, especially in the broader framework of (community) resilience assessment tools (Sharifi, 2016; Feldmeyer et al., 2019), and in different sectors, e.g., the climate benefits of nature-based solutions (Kabisch et al., 2016; Donatti et al., 2020). Although these efforts may help to mainstream the evaluation of adaptation in current city evaluation initiatives, the development of comprehensive monitoring and evaluation systems is lacking.

There is little evidence on how best to make monitoring and evaluation approaches practical at the local scale. Cities worldwide face important social, environmental, and economic conflicts related to resource inequality, poverty, environmental pollution, and social tensions that coexist with climatic risks. It makes sense to integrate climate change adaptation assessment goals and needs into existing frameworks for the sake of efficiency. This will benefit small urban areas and cities in developing regions that often face data scarcity and may also find available indicators irrelevant to their realities and, thus, be required to adjust them (Simon et al., 2016). Efforts to coordinate frameworks for the assessment of sustainability (e.g., Local Agenda, sustainability appraisals), resilience (e.g., 100 Resilient Cities, new standards for urban resilience), GHG emissions reporting (e.g., Global Covenant of Mayors for Energy & Climate) can be deployed to learn about contexts. However, they need to be applied with caution as enforcing external requirements may lead to local tensions during their application (see for example (Roberts et al., 2020)). In a context where adaptation efforts need to be aggregated and evaluated across nations (Magnan, 2016) and their implications on wider objectives such as sustainable development and social justice need to be assessed (Long and Rice, 2019), urban adaptation monitoring and evaluation can inform national and international processes that enable a global stocktake of adaptation.

6.4.7 Enabling Transformations

Growing awareness of the interlocking of drivers of urban change and vulnerability has motivated an interest in transformational approaches to adaptation action in cities, settlements, and infrastructure. While the idea of transformation has been adopted across the field, there is no consensus about what an urban transformation that addresses adaptation means. There is no one single transformative solution or approach relevant in every case (Chu, Schenk and Patterson, 2018; Shi, 2019; Goh, 2019). What constitutes 'urgent' and 'far-reaching' transformation depends on the local community's expectations and ideas (Choko et al., 2019).

Transformation is often approached as a process of institutional transformation, akin to the process described in section 6.4.2 (see, for example (Duijn and van Buuren, 2017)). Transformation engages with critiques of adaptation or risk reduction as an individual responsibility (Sou, 2018). The idea is to use transformation to focus on coordinating collective efforts (Haque et al, 2014). The coordination of multiple actors is a condition to enable transformative institutions (Torabi et al, 2018) and link adaptation action to development efforts (Chu et al, 2017; Roberts and O'Donoghue, 2013). The role of communities and citizens in such an approach to transformation is ambiguous. Sometimes communities and citizens are presented as critical agents of transformation (Limthongsakul et al, 2017). Other times, however, they are simply situated within strong and durable networks that provide the institutional setting to build resilience (Danière et al., 2016). Despite the political nature of transformative approaches and the evidence that transformative approaches rely on protest and political activism, few authors recognise this strategy (but see (Bahadur and Tanner, 2014; Chu, Anguelovski and Roberts, 2017; Dierwechter and Wessells, 2013)).

Transformation is also more than a single instance of institutional change. Historical perspectives on transformation enable an understanding of the chain of institutional changes that ultimately lead to significant or far reaching reconfiguration of infrastructure and service provision (Rojas et al, 2015).. Paradigm changes, such as new engagements with nature and green infrastructure, will improve adaptation outcomes (Roberts et al., 2012). Changes of paradigms, however, are not inherently positive and may clash with existing interests or involve trade-offs with other priorities. When care is taken to ensure greater inclusion in urban decision making, disadvantaged, vulnerable communities are less likely to be disadvantaged. For example, indigenous traditions of nature management provide entry points for the sustainable management of resources, such as seed banks, urban agriculture, and the local management of watersheds and floods, may be at odds with conventional structures of expert knowledge (Cid-Aguayo, 2016; Chandra and Gaganis, 2016). These traditions are vital both because of the solution space that they open in the local context and how they serve to create resilience through collective and intergenerational learning (Chandra and Gaganis, 2016).

While aspects of transformative capacity identified in the literature may facilitate far-reaching change, there is limited evidence of actual transformations as an outcome of adaptation. While community-led resilience agendas may tackle poverty-related issues, they struggle to tackle city-wide structural forms of inequality (Chu, 2018b). Processes of shared learning and co-production of knowledge can reinforce existing power dynamics and be limited by technical framings of vulnerability that marginalize political issues (Orleans Reed et al., 2013). These issues are especially acute in relation to land-use decisions where short-term fiscal and commercial interests conflict with long-term vulnerability reduction objectives (Brown, Dayal and Rumbaitis Del Rio, 2012). It can be difficult for adaptation actions to target cities' underlying political-economic structure, such as entrenched political-economic interests, elite influence over decision-making, or neoliberal planning logics that maintain and reproduce inequality (Chu, Anguelovski and Roberts, 2017). Urban resilience plans may be formulated in disconnection from broader development strategies, which leads to a limited ability to tackle underlying structures of political power and urban development practices (Weinstein et al, 2019). Evidence from Kolkata demonstrates the limitations of resilience plans to address underlying conditions of vulnerability, including the commodification of hazardous land, under-provision of informal settlements, and spatial segregation of the urban poor (Rumbach, 2017).

Planning for transformative adaptation is more likely where communities can learn collectively (*medium evidence, medium agreement*) (Restemeyer, van den Brink and Woltjer, 2017; Kabisch et al., 2017; Fraser et al., 2017; Putri, Dalimunthe and Prasojo). Greater citizen engagement facilitates implementing specific measures for radical policymaking or the mainstreaming of environmental knowledge into adaptation practices (Reed et al, 2015). DIY planning, in which stakeholders focus on creating and improving specific urban spaces they inhabit, has led to urban greening experiments led by civil society that change paradigms of urban and environmental management (Cloutier, Papin and Bizier, 2018). Social learning may occur through combinations of activism and collaboration with and between informal settlement dwellers, as shown in adaptation experiences in informal settlements in Hanoi and Bangkok (Danière et al., 2016).. The adaptation process can benefit from the inclusion of multiple sources of knowledge for social learning, including universities but also communities and citizens (Chu, 2018b). Citizens assemblies are increasingly recognized as spaces for transformative adaptation (Muradova, Walker and Colli, 2020), although their potential influence at different government levels is still not fully understood.

The integration of multiple forms of knowledge leads to social learning (*medium evidence, high agreement*). Indigenous knowledge and local knowledge can provide essential insights into community needs and experiences of housing and urban infrastructure to inform climate adaptation, including improper waste disposal, inadequate drainage, and poor sanitation, but there is significant variation in community knowledge networks (Roy et al., 2018b; Douglas et al, 2018; Waters and Adger, 2017). It is important to identify and address barriers to the incorporation of Indigenous knowledge and local knowledge, such as the dominance of scientific knowledge, oppression and/or racism and fragmentation of knowledge including gender and generational divides (see Burke and Heynen, 2014; Whyte, 2017; Victor, 2015; Lövbrand et al., 2015; Kelly, 2019).The incorporation of Indigenous knowledge in urban decision making requires a constructive dialogue with scientists and urban planners.

Indigenous knowledge and local knowledge have an important role to play in urban planning and management. They can support impact detection and evaluation in urban areas (Codjoe et al, 2014), weather forecasting in urban areas (Magee et al., 2016; Ebhuoma and Simatele, 2019), climate change adaptation in urban agriculture (Wahab and Popoola, 2018; Solomon et al., 2016), urban food security (Simatele and Simatele, 2015), planning and managing urban solid waste (Kosoe et al, 2019), urban flood management (Thorn et al, 2015; Jameson and Baud, 2016; Hooli, 2016), drought perception and coping strategies (Saboohi et al., 2019), and ecological restoration and urban commons management (Nagendra, 2016; Nagendra and Mundoli, 2019). They can help define baselines for past climate and ecological change providing an historical perspective on changes in urban commons such as lakes and trees (Nagendra, 2016) as well as past climatic changes or climate baselines (Ajayi and Mafongoya, 2017) and Shifting Baseline Syndrome (Fernández-Llamazares et al., 2015; Soga and Gaston, 2018) (see Businger et al., 2018 for a review of Hurricane history in Hawaiian newspapers; also Wickman, 2018). Incorporating Indigenous knowledge and local knowledge can help generate more people-oriented and place-specific approaches leading to adaptation policies that foster identity, dignity, self-determination, and better collective decision-making and capacity to act (Preston, 2017; McShane, 2017) (see also 6.1).

Envisioning development alternatives through adaptation as a first step towards transformative adaptation can leverage social learning. Experiences of migration, length of residence, and the density of local social-networks impact social learning opportunities and underscore why context-specific social education is vital (Waters and Adger, 2017; Karunarathne and Lee, 2020). Learning across and between communities can be enhanced when care is taken to understand local challenges. Given power relationships, cultural needs, and community aspirations, a top-down approach to information sharing is generally less effective than community partnerships and co-created knowledge at surfacing visions and strategies for getting past baked-in, unequal and unsustainable development assumptions and practices (*medium evidence, high agreement*)

(Clemens et al., 2016; Thi Hong Phuong, Biesbroek and Wals, 2017; Fitzgerald and Lenhart, 2016; Fisher and Dodman, 2019). Social learning in formal and informal urban contexts is also enhanced when care is taken to ensure multiple stakeholders have opportunities to understand a variety of viewpoints, values, resources, and ideals, and that these view-points are clearly identified in decision making (Thi Hong Phuong, Biesbroek and Wals, 2017). However much social learning still happens only after a crisis, for example in urban water adaptation and new knowledge is often frustrated by the lock in of powerful local institutions and groups (Johannessen et al., 2019). Social learning is, however, only one component of the development of climate-resilient pathways. System perspectives theorize the possibility of tipping points, leverage points, or disruptive technologies to challenge the stable regime to create a broader reconfiguration (Chapter 17; O'Neill et al., 2018).

Case Studies

Case Study 6.1: Urbanization and Climate Change in the Himalayas – Increased Water Insecurity for the Poor

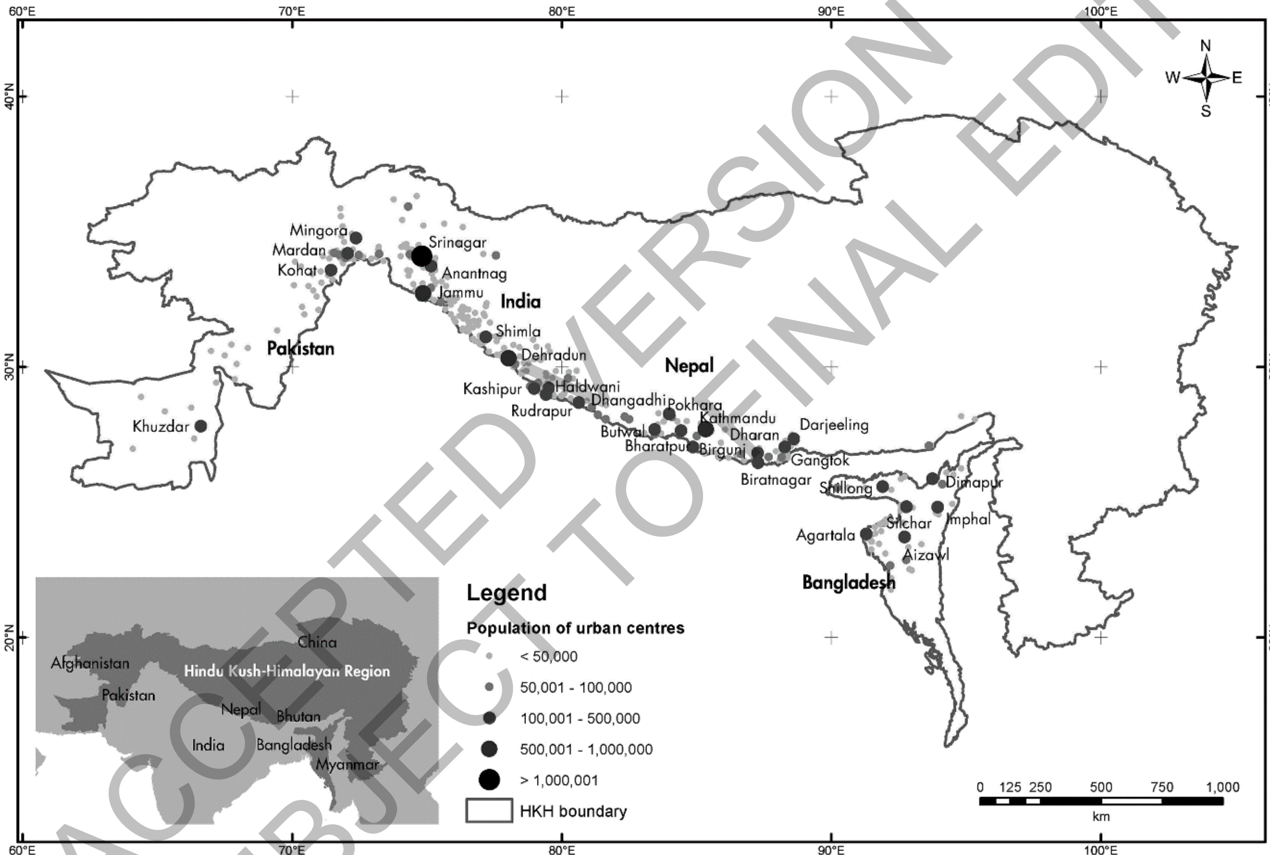

Figure 6.6 Urbanisation in Hindu-Kush Himalayan Region Figure based on (Singh et al., 2019b)

The Hindu Kush Himalayan region extends roughly over 3,500 km covering eight countries - Afghanistan, Pakistan, Nepal, China, India, Bhutan, Bangladesh, and Myanmar. Projections show that by 2050, more than 50% of the population in Hindu Kush countries will live in cities (UNDESA, 2014). The region is home to 10 major river basins that feed south and south-east Asia. In 2017, the total population in the ten major river basins with their headwaters in the region was around 1.9 billion, including 240 million in the mountain and hills of the Hindu Kush (Wester et al., 2019). The region is characterized by unique mountain topography, climate, hydrology, and hydrogeology. Each one of these factors plays an important role in determining the availability of water for people living in the Himalayas (Nepal, Flügel and Shrestha, 2014; Scott et al., 2019; Prakash and Molden, 2020). The total landmass that can support physical infrastructure for towns to develop is much less in the Hindu Kush Himalayan region as compared to the plains. Due to this physical constraint, the process of urbanization is slow in the region. Only 3 per cent of the total population in the region live in larger cities and 8 per cent in smaller towns (Singh et al., 2019b). However, there has been an increase in urbanization largely due to regional imbalances in providing economic opportunities for the poor. People from rural areas are flocking to the nearest urban centres in search of employment and other economic opportunities (Singh and Pandey, 2019). As a result, the share of urban population is increasing in the region, while that of the rural population is declining.

One of the major challenges of urbanization in the Himalayas is sprawling small towns with populations of under 100,000 (see Figure 6.6). These towns are expected to become major urban centres with a decade due to high growth rate. A recent study by Maharjan et al. (2018) on migration documented that 39% of rural communities have at least one migrant, of whom 80% are internal and the remaining 20% are international. Around 10 per cent of the migration is reported as environmental displacement. Most of the migration is of male which forms an important aspect of gendered vulnerability (Sugden et al., 2014; Goodrich, Prakash and Udas, 2019). The ever-expanding urban population in the Himalayas generates many challenges especially in the context of climate change adaptation. First, unplanned urbanization is causing significant changes in land use and land cover with recharge areas of springs being reduced. Most of the towns in Hindu Kush Himalayan region meet their water needs using supplies from springs, ponds, and lakes which largely interlinked systems, Water insecurity in hill towns are becoming an order of the day (Virk et al., 2019; Bharti et al., 2019; Singh et al., 2019a; Sharma et al., 2019). Second, climate-induced changes in the physical environment include increased rainfall variability. Due to this, heavy rains are becoming frequent and are leading to more landslides. Third, global warming has increased the average temperature in the Himalayas which has caused glacier melt and subsequent change in hydrological regimes of the region. One of the contributing factors of glacial decline is also the deposition of black carbon (Gautam et al., 2020; Gul et al., 2021) which is contributed by burning of crop residue in Punjab (Kant et al., 2020). These critical stressors – climatic and non-climatic, are adversely affecting the socio-ecology of urban conglomerations in the region (Pervin et al., 2019). Encroachment or degradation of natural water bodies and the disappearance of traditional water systems such as springs are evident (Shah and Badiger, 2018; Sharma et al., 2019). While water availability in these towns has been adversely affected by the climatic and socio-economic changes, demand for water has increased greatly (Molden, Khanal and Pradhan, 2018). Some of the towns are major tourist attractions that create a floating population in peak tourist seasons challenging the carrying capacities of the towns. The residents must cope with water scarcity as the demand for water increases in peak seasons and water distribution through the public water supply systems becomes highly inequitable (Raina, Gurung and Suwal, 2018). The usual challenges of utilities being inefficient applies in these areas too though it becomes much more critical as the sources of water are limited and the local geology limits the ability to access groundwater. All these processes are resulting in increased water insecurity for the poor and marginalised in urban towns of Hindu Kush (Prakash and Molden, 2020). To cope with the scarcity situation, people are adapting through various means such as rationing of intra-household water access, groundwater extraction to access water supply (Virk et al., 2019; Bharti et al., 2019; Sharma et al., 2019). This is due to lack of long-term strategies and options provided by utilities.

Case Study 6.2: Semarang, Indonesia

The City of Semarang, on the northern coast of Central Java in Indonesia, has a population of nearly 1.8 million (CBS, 2019). The city has experienced rapid urbanization over last three decades, with the population almost doubling and density reaching 4,650 people per square kilometre (Handayani and Rudiarto, 2014; Handayani et al., 2020b). Semarang is vulnerable to sea level rise, tidal flooding, and inundation (Suhelmi and Triwibowo, 2018; Yuniartanti, Handayani and Waskitaningsih, 2016), risks which are worsened by land subsidence along the coast (Abidin et al., 2013). Globally, land subsidence is a notable compounder of climate change-induced sea level rise and coastal flooding (Bagheri et al., 2021). In Semarang, the land subsidence rate is projected to be up to 60 millimetres per year (Abidin et al., 2013; Bott et al., 2021). Approximately 20% of the city's coastline is characterized as extremely vulnerable due to sea level rise and enhanced land subsidence (Husnayen et al., 2018), with the north-eastern portions of the city experiencing larger subsidence than the rest (Yastika, Shimizu and Abidin, 2019). Associated public health and sanitation risks are also evident, including increasing outbreaks of dengue fever and diarrhoea (Pratama et al., 2017; Indonesia Ministry of Health, 2020).

The City of Semarang first engaged with climate change in 2009, when the Rockefeller Foundation launched the Asian Cities Climate Change Resilience Network (ACCCRN), an initiative to develop resilience capacity across secondary and rapidly growing cities in South and Southeast Asia (Reed et al., 2015). Semarang was a pilot city for ACCCRN from 2009 to 2016, when it introduced a participatory approach to planning and decision-making that challenged the government-dominated tradition in the city, and in turn played a key role in Semarang's climate adaptation and resilience planning process (Orleans Reed et al., 2013; Moench, 2014; Kernaghan and Da Silva, 2014). A City Team was formed in 2010 consisting of City Environmental Agency (BLH – *Badan Lingkungan Hidup*), Regional Disaster Management Agency (BPBD - *Badan Penanggulangan Bencana Daerah*), Water Resources Management Office (PSDA - *Kantor Dinas Pengelolaan Sumber Daya Air*), Regional Planning and Development Agency (BAPPEDA - *Badan Perencanaan Pembangunan Daerah*), local universities, and NGOs such as the Bintari Foundation, with technical support from Mercy Corps Indonesia (Nugraha and Lassa, 2018).

The City Team was first established within the City Environment Agency (BLH) but was then transferred to the Development and Planning Agency (BAPPEDA) (Lassa, 2019). This corresponded to a shift in framing of climate change from an environmental priority to encompassing broader development issues such as economic development, housing, and infrastructure delivery. By asserting that climate change affects the operations of every critical sector across the city, the number of municipal agencies involved in climate change programming increased significantly (Setiadi, 2015). Most notably, this approach helped the municipal health agency to recognize the relationship between climate change and health (Setiadi, 2015),and helped to shift the emphasis of dengue fever management towards a more proactive community-based health early warning system (Pratama et al., 2017). In 2017, these measures helped to reduced dengue fever infection rates by 56% compared to 2011-2016 levels (Indonesia Ministry of Health, 2020). ACCCRN also supported policy experimentation through implementing rainwater harvesting facilities and a community-based flood early warning system (Archer and Dodman, 2015; Yuniartanti, Handayani and Waskitaningsih, 2016; Sari and Prayoga, 2018). These projects were designed in conjunction with national government investments in flood management infrastructure, which led to a reduction in the city's inundated area by 24% or approximately 1% of the total urban area (Semarang City Government, 2016).

Building on Semarang's ACCCRN experience, the city then became a member of the Rockefeller Foundation's 100 Resilient Cities (100RC) program between 2016 and 2018. As in ACCCRN, this new process emphasized stakeholder involvement, with the previous City Team recast as a team of City Resilience Officers (CRO), which was in turn led by the City Mayor and received strategic advisory support from the City Secretary. Semarang synthesized its experiences in climate adaptation planning through the *Resilient Semarang Strategy* published in May 2016 (Semarang City Government, 2016). The *Resilient Semarang Strategy* (2016) acknowledged that urban resilience must be pursued in a comprehensive and inclusive manner and highlighted 18 strategies across 6 themes –water and new energy, new economy, disaster and disease, integrated mobility, transparency of public information, and competitive human resource – to be mainstreamed into the revision of the Mid-Term Regional Development Plan (RPJMD - *Rencana Pembangunan Jangka Menengah Daerah*) of 2016-2021. City Resilience Officers were formally appointed to serve on the RPJMD team, thereby formalizing climate resilience as a critical item on the RPJMD program list.

100RC engagement allowed Semarang's resilience programs to appear on 100RC's "marketplace" of municipal projects, allowing them to be connected with bi-/multi-lateral donor resources, while continuing to align projects with goals articulated within the Mid-Term Regional Development Plan. The 100RC marketplace is a *resilience platform* that showcases particular initiatives of 100RC network cities to potential *resilience partners*, thereby attracting investment and donor support to Semarang's resilience programs. Examples include the Water as Leverage (WaL) project that has been working to conserve urban water resources in the face of climate change since 2018 (Handayani et al., 2020a; Laeni et al., 2021) and the Transboundary Flood Risk Management Through Governance and Innovative Information Technology Program (TRANSFORM) that has been helping Semarang tackle flood risks beyond city boundaries through reforestation, development of dry wells and swales in upstream areas, as well as promoting cross-region dialogue (Global Resilience Partnership, 2018). Other collaborations focused on developing resilience indicators (ARUP, 2018; Rangwala et al., 2018). For example, the Zurich Flood Resilience Program implemented resilience measurement tools in 16 sub-districts along the West Flood Canal. Results of the assessment were then used to develop local disaster contingency plans.

The conclusion of the Rockefeller Foundation's formal engagement in Semarang in 2018 has brought forth questions about continued financial and institutional support for climate adaptation action in the city.

Increasing land subsidence will also likely overwhelm current efforts to incrementally adapt to sea level rise and coastal flooding (Abidin et al., 2013). Still, the Semarang case study does highlight several key lessons for urban climate governance in secondary rapidly urbanizing cities in the Global South. First, transnational institutions and partnerships are critical enablers (Aisya, 2019; Setiadi, 2015; Chu, Hughes and Mason, 2018; Handayani et al., 2020a). Institutions such as the Rockefeller Foundation foster programmes and investment in the city, leverage access to adaptation funding, accelerate climate mainstreaming into wider urban sectors, and promote better knowledge management (Setiadi, 2016). However, such opportunities are also supported by the city's ability to further mobilize its own resources in the long-term and remove its dependency on the national government and transnational supporters (Handayani et al., 2020a). Second, scaling up of programmes and replication of adaptation actions are increasingly important to close the gap between planning and implementation (Setiadi, 2016). It is evident that increased community empowerment and participation can help fill this gap (Hadi, 2018; Miladan, 2016) but this must also be evidence-based to ensure its applicability and effectiveness (Suarma et al., 2018). Questions remain around how to determine and assess evidence-based participatory adaptation at the local level. Third, sustainable financing (from both external and internal sources) to support proposed adaptation strategies is essential as it allows for more capacity building, technology transfer, and program implementation in the long run (Handayani et al., 2020a; Laeni et al., 2021; Hadi, 2017). An example is the development of a water retention on the eastern coast of Semarang using a collaborative financing model, which helped further adaptation by protecting water resources for local industries as well as promote the idea of land value capture for community residents.

Case study 6.3: Institutional Innovation to Improve Urban Resilience: Xi'xian New Area in China

Located in Northwest China and the Silk Road Economic Belt, Xi'Xian covers a total of 882 square kilometres of the border zone of two cities of Xi'an and Xianyang, Shaanxi province. Xi"xian accommodates a registered population of 1.06 million with a planned area of 272 square kilometers reserved for urban development. As a new engine for promoting the West Development Strategy and people-centred urbanization in the northwest China, Xi'xian has paved the way for China's ecological city agenda since January 2014.

Xi'xian aims to build a 'modern garden city' when it was selected as national demonstration sites for Sponge City (SC) during 2015-2018 and Climate Resilient City (CRC) during 2017-2020. Under the changing climate, the old cities of Xi'xian suffers urban heat island, drying and water scarcity, heavy rains and waterlogging, thunderstorm and so on, which bring adverse effects to transportation, construction, cultural relics tourism resources, and other industries (Ma, Yan and Zeyu, 2021). Sponge City status requires innovation to reduce flood risk through design to absorb, store, and purify rainfall and storm water in an ecologically friendly way that reduces dangerous and polluted runoff. When required, the stored water is released and added to the urban water supply (MoHURD, 2014). As Climate Resilient City the aim is to adapt to climate risk and environmental change, by integrating climate resilience into urban renewal and revitalization.

In practice, building ecological cities in China has focused more on hard measures than institutional innovation (Li et al., 2020). Among one of nineteen national-level New Areas in China, Xi'xian enjoys special preferential policies in the fields of fiscal autonomy, investment and tax policy and permission in land utility for industrial development purpose. These policy freedoms allow Xi'Xian to explore adaptation options. This has opened engagement with business through an urban construction investment group sponsored and invested in jointly by Xi'Xian Management Committee (administrative authority) and local enterprises (Wei and Zhao, 2018). Second, the municipal government has simplified administrative systems to reduce the project waiting period from evaluation to approval to 50 days. Third, a green financial mechanism creates a leverage effect for national funding, including the first provincial Green Sponge Development Fund (1.2 billion RMB) and in Shaanxi, special funding from the Urbanization Development Fund (2.64 billion RMB). Furthermore, a public-private partnership model with a whole-lifecycle-management approach has been introduced, raising funding of 1.24 billion RMB with a packaged project including public pipelines and sewage water treatment facilities.

Such institutional and financial support have allowed Xi'xian to implement a Pilot Construction Plan and Three-year Action Plan for Adapting to Climate Change. In 2020, Xixian formed an urban ecology system including 21 square meters of green space per capita. The old cities' underground drainage pipe network has been replaced by sponge designs such as green corridors, grass ditches, water storage gardens, and recessed green spaces. The 10 waterlogging prone points in Xi'xian New Area have been eliminated and the green area has alleviated urban heat, with average temperature about 1 degree lower than the neighboring densely populated mega-cities of Xi'an and Xianyang. Groundwater in the New Area has also risen by 3.43 meters compared with 2015.

At the end of 2020, Xi'xian New Area has built 2.4 million square meters of modern garden cities, more than 50 kilometers of sponge roads, 1.4 million square meters of resilient park green space and established a green coverage of more than 50% of the urban space. The target of becoming a green city in which everyone can "see green in 100 meters, step into garden every 300 meter" has been realized (Ma et al., 2021). The urban parks and green spaces play a role in regulating local microclimate and also improve the urban environmental amenities for residents. In a comprehensive performance assessment for the Climate Resilient Cities facilitated by the Climate Change Department of the Ministry of Ecology and Environment (MEE), the Xi'xian ranked the No.9 among all of the twenty eight pilot cities.

Case Study 6.4: San Juan: Multi-Hazard Risk and Resilience in Puerto Rico and its Urban Areas

This case study illustrates multi-hazard risk and reviews the formation of a multi-stakeholder adaptation governance regime as one response to this.

In two weeks in 2017 Puerto Rico experienced two powerful hurricanes, Irma (category 5) and María (category 4). The compound effects decimated the island's power, water, communications, and transportation infrastructure and an estimated 2,975 people lost their lives (Irvin-Barnwell et al., 2020; Santos-Burgoa et al., 2018). Soon after, while many homes still had no electricity or roofs and the tree canopy was still bare, Puerto Ricans were faced with cascading effects including environmental health impacts from air pollution, extreme heat and mosquitoes (Ortiz et al., 2020). In 2020, while still recovering Puerto Ricans experienced earthquakes, extreme African dust events, intense coastal and urban floods, and the COVID-19 pandemic (Keck, 2020; NASA Explore Earth, 2020; NASA/JPL-Caltech, 2020). These events continue to unveil unresolved conditions of social vulnerability and its root causes in economic poverty, social inequities, aged and deteriorating infrastructure, and population loss (Bonilla and LeBrón, 2019). Combined with limited past investment in climate change adaptation and underlying governance challenges including corruption, bankruptcy, and political crisis (Holladay et al., 2019) this has constrained a more climate resilient development for Puerto Rico.

It is in this context that government, academic institutions and local civil society have taken important steps and often joint action towards mitigation and adaptation. Federal funding included US$20 billion of disaster recovery funding with US$8 billion allocated for adaptation and resilience projects, such as flood risk mitigation. During the year 2020, the Federal Emergency Management Agency (FEMA) approved US$13 billion to rebuild the power grid and education system (Delgado, 2020). These programs allow communities and local governments to plan and implement strategies and build new infrastructure that reduces risks and builds long-term adaptive capacities. The Government of Puerto Rico also approved two key climate adaptation policies in 2019. The Puerto Rico Mitigation, Adaptation and Resilience to Climate Change Law (Law 33, Senate Bill PS 773) established, for the first time in the island's history, a legal framework that acknowledges that the climate is changing and threatens the quality of life. The law recognizes important scientific projections for the island, including an increase of 0.5 to 1 meter in sea levels by 2015 and maximum temperatures of up 2.5 C and precipitation decrease of up to 50% by 2100 (Gould et al., 2018). The law generated the formation of an Expert and Advisory Committee on Climate Change to develop the plan with specific recommendations and present it to the Legislature within a year of the passing of the law in 2020. Along with strategies to specifically protect and build the resilience of urban and rural communities to future climate disasters, the law establishes sustainable development goals, including water and food security, urban planning and densification, and transition to renewable and alternative forms of energy. The energy target is reinforced by another key state policy approved in 2019 in response to the failed energy infrastructure during Hurricane María, the Puerto Rico Energy Public Policy Act (Senate Bill PS 1121). This law calls for a transition to 100% renewable and alternative energy by 2050.

Puerto Rico has a strong science base that produced extensive knowledge on climate change and sustainability long before Hurricane María. The Puerto Rico Climate Change Council has collected and synthesized scientific information for Puerto Rico since before its formation in 2009. Many Puerto Rican scientists were also editors and authors on Chapter 20: US Caribbean Region for 4th US National Climate Assessment (Gould et al., 2018). The National Institute of Island Energy and Sustainability (INESI in Spanish) recently published a catalog with more than 60 scientists and experts working on energy and sustainability innovations in the University of Puerto Rico (UPR) system. The scientific community became very active after the hurricane in efforts to empower local groups and communities to build more sustainable and resilient futures. UPR Environmental Health scientists worked with communities to design and implement risk reduction action plans, including nature-based solutions, through the Community Climate Actions Plans and the Puerto Rico Community Resiliency Initiative sponsored by Fundación Comunitaria de Puerto Rico and Education Development Center-Regional Education Laboratories, Northeast and Islands. A successful example of these alliances is the development of the First Solar Power Community in Toro Negro, Puerto Rico. These initiatives were inspired by principles of human-centered design, a problem-solving approach that starts with the people impacted the most by the problem to be solved. In San Juan, the capital and major urban centre of the island, scientists from UPR and the US Forest Service International Institute of Tropical Forestry worked with local stakeholders and communities to develop sustainable and transformative urban futures with the support of the Urban Resilience to Extreme Events Sustainability Research Network (UREx SRN). The UREx SRN is a knowledge network of ten cities in the US and Latin America and twenty other institutions building scientific knowledge, models, and participatory tools to build resilience and transformative capacities for cities.

Perhaps the greatest source of adaptive capacity that emerged after the hurricane came from the civic sector and community-based organizations and local residents. Hundreds of non-profit and grassroots organizations became active in disaster recovery and are now catalyzing actions to advance social transformation and sustainable development. In the energy sector, numerous communities and NGOs developed new action plans to promote transitions to renewable energy and community-based micro grids, such as the Queremos Sol initiative (https://www.queremossolpr.com/), and the establishment of solar panels in community centers and residences by the Puerto Rico Community Foundation and Resilient Power Puerto Rico. The San Juan Bay Estuary Program, an NGO in the San Juan metropolitan area, launched alongside the Clinton Global Initiative the development of a Watershed-Based Mitigation Plan, the first watershed-based plan for the metro region. The organization has established resilience hubs to support the community with critical resources, communications, and energy supply during an emergency. In many of the most isolated areas across the island where government aid did not reach them for months, the communities that self-organized during recovery are also leading examples of community social-ecological resilience. In Utuado, one of the hardest hit areas by the hurricane, their main community organization known as COSSAO (Corporación de Servicios de Salud y Desarrollo Socioeconómico, El Otoao) emerged from the hurricane with a strong and holistic sustainable development vision - the Tetuan Reborn initiative - to improve the socio-economic status and health of community members while building capacity for disaster resilience through various initiatives. The long-term outcome of this initiative is to support efforts toward self-empowerment within neighbourhoods by identifying and designing viable solutions to hurricane- related and economic development challenges specific to the local context including constructing a primary health care clinic, a public health promoter programme, pursuing farms rehabilitation, promoting agritourism, agro-therapy and education (Holladay et al., 2019).

Adaptation efforts, however, continue to face many governance hurdles. Up to 2020, only 2-3% of the US$20 million Federal Government recovery funds had been spent with hundreds of families that lost their homes or roofs in 2017 yet to receive the help they need (Colón Almenas, 2020). Lack of administrative capacities, coordination across sectors and efforts, transparency and accountability are some of the governance barriers that keep recovery and transformation efforts from materializing (Lamba Nieves and Marxuach, 2020). Puerto Ricans are now contending with the reality that the disaster they are experiencing is not an outcome of a singular event but of multiple hazards converging with pre-existing vulnerabilities and low adaptive capacities creating severe multi-hazard risk to the island (Eakin, Muñoz-Erickson and Lemos, 2018; Gould et al., 2018). Many Puerto Ricans now question when the disaster began and when it ended because they have been living in a state of chronic crisis (Bonilla and LeBrón, 2019).

Case Study 6.5: Climate-resilient Pathways in Informal Settlements in Cities in Sub-Saharan Africa

Informal settlements account for over three-quarters of residential areas in sub-Saharan Africa and have grown rapidly over the last three decades (Visagie and Turok, 2020). Informal settlements will remain home to a significant proportion of the urban population of this region which is projected to grow by 2.5 times between 2020 and 2050 (UNDESA, 2018), driven by a complex set of underlying factors including socio-economic conditions, inadequate planning systems, local and foreign investment patterns, and rural to urban migration (De Longueville et al., 2020). Yet residents of informal settlements are often excluded from macro-level visions and policies that seek to make cities safer and improve resilience (Adenle et al., 2017; Pelling et al., 2018b). This case study compares the experience of collective action to manage risk in the informal settlements of Freetown, Sierra Leone with other cases in Sub-Saharan Africa. These examples show how local knowledge and capacity, engagement of policy makers in meaningful ways with residents of informal communities, and institutional change, can combine to deliver adaptation outcomes at a city scale (Kareem et al., 2020).

Despite their diversity and differences across the continent (Kovacic et al., 2019), informal settlements are frequently located in hazard-prone areas, with residents living in precarious housing conditions on marginal lands (Badmos et al., 2020; Kironde, 2016), lacking essential services and risk reducing infrastructure, and often developing outside the legal systems intended to record land tenure and ownership (Satterthwaite et al., 2020; Adelekan et al., 2015). Consequently, they are particularly vulnerable to climate change, and the urban poor residents suffer disproportionate burdens and losses from natural hazards, which undermines urban resilience (Williams et al., 2019). Recent impacts from flooding have brought wide-spread devastation to urban poor residents in major coastal urban centres including Accra, Lagos, Freetown, Maputo, and Dar es Salaam, resulting in injury and death, displacement of people, loss of assets, destruction of public infrastructure, and disruption to livelihoods and economies (Douglas et al., 2008; Adelekan, 2010; Yankson et al., 2017; Allen et al., 2017). Flooding and long-term inundation also lead the spread of diseases and health risks (Sverdlik, 2011; Zerbo, Delgado and González, 2020). Climate change will also bring stresses such as city-wide reductions in freshwater availability, and heat waves that have particularly severe consequences for residents of poorly built homes in informal settlements (Pasquini et al., 2020; Kayaga et al., 2021; Wilby et al., 2021).

In response to these risks, a wide range of adaptation efforts have been implemented in cities across sub-Saharan Africa (Hunter et al., 2020). In Freetown, informal settlement residents have led data generation efforts that capture the value of local knowledge in understanding climate risk. Through partnerships with NGOs and research institutions, informal settlement residents have mapped climate hazard hotspots using geo-referenced tools, producing both digital and hardcopy outputs that serve as a blueprint for climate-informed community development discourses (Allen et al., 2020b; Visman et al., 2020). Similarly, residents of informal settlements in Dar es Salaam, Tanzania, have profiled community climate and health risks by using an adaptation of the 'Action at the Frontline' methodology developed by the Global Network of Civil Society Organisations for Disaster Reduction (GNDR). Locally-informed risk profiles support the development of community action plans based on prioritization and ranking of scaled-down interventions that communities can collectively do on their own (Osuteye et al., 2020). This process highlights the lived experiences of climate change, and allows communities to develop deliberation spaces, communal solidarity and cohesion, and share adaptation strategies (Sakijege et al., 2014). Such sharing and peer-to-peer learning is particularly useful because adaptive capacities are unevenly distributed among exposed populations (Ajibade and McBean, 2014). The community-generated assessments and data consider the range of environmental, socio-economic, and political factors that contribute to a better understanding of how climate change affects the vulnerability of low-income urban residents, and how this changes over time.

Data that is generated and owned by residents of informal settlements provides a basis for making the risks facing these neighbourhoods more visible to city planners, and for enabling collaboration between a range of urban stakeholders (Dobson, 2017). In Freetown, this process has been led by the Federation of the Urban and Rural Poor (FEDURP) and the Centre for Dialogue on Human Settlement and Poverty Alleviation (CODOHSAPA). The FEDURP belongs to the global Slum Dwellers International network, committed to empowering poor residents in urban spaces and has a presence in several other African cities (Macarthy et al., 2017). With the support of CODOHSAPA, FEDURP coordinates Community Development Committees (CDC) and Community Disaster Management Committees (CDMC) in nearly all the informal settlements in the city. Both CODOHSAPA and FEDURP work closely with the local research institution, the Sierra Leone Urban Research Centre (SLURC). SLURC has played an essential role in curating spaces for continuous learning and relationship-building between FEDURP and community residents, including the formation of "Community Learning Platforms" (CLP) for mixed groups of community actors (City Learning Platform, 2019) to build their capacities to address climate risk collectively. This is done by drawing on the data, agency and mobilisation potential of community organizations in informal settlements. In the coastal settlement of Cockle Bay at the western end of the city, uncontrolled traditional land reclamation ("banking") along the shores progressively exposed residents to perennial floods from tidal surges, and the settlement received regular threats of evictions from city authorities. However, residents have drawn on their climate risk knowledge and hazard profiling to self-manage a process of action planning resulting in a decision to prohibit further land reclamation. It also identified and demarcated an exterior boundary of the settlement and planned and constructed new drainage channels to carry away run-off water within the community (Allen et al., 2017). The community organizations have subsequently successfully negotiated with the Ministry of Environment to formalise this new exterior boundary, which has led to the authorities dropping their threats of evictions.

The approach taken in Freetown demonstrates a pathway to adaptation that is based on a more people-centred approach to urban planning that understands the aspirations of urban residents, addresses climate risk, and advances sustainable development (Woodcraft et al., 2020; Fraser et al., 2017). It further provides an example of the ways in which different sources and scales of data can be co-produced (Kovacic et al., 2019) and targeted interventions can be co-designed with community residents (Musango et al., 2020). The community-generated data on climate and health risks and the subsequent strategic action plans developed through local community organizations' work have been recognized and incorporated into a new city-wide initiative led by the Office of the Mayor, dubbed Transform Freetown (Allen et al., 2020a). The action has expanded the political space for the urban poor's collectives to strategically engage in urban resilience planning, highlighting the value and potential of participatory processes and community-generated data.

Cross-Working-Group Box URBAN: Cities and Climate Change

Authors: Xuemei Bai (Australia), Vanesa Castan Broto (United Kingdom/Spain), Winston Chow (Singapore), Felix Creutzig (Germany), David Dodman (Jamaica/United Kingdom), Rafiq Hamdi (Belgium), Bronwyn Hayward (New Zealand), Şiir Kılkış (Turkey), Shuaib Lwasa (Uganda), Timon McPhearson (USA), Minal Pathak (India), Mark Pelling (United Kingdom), Diana Reckien (Germany), Karen Seto (USA), Ayyoob Sharifi (Japan/Iran), Diána Ürge-Vorsatz (Hungary)

Introduction

This Cross-Working Group Box on Cities and Climate Change responds to the critical role of urbanisation as a megatrend impacting climate adaptation and mitigation. Issues associated with cities and urbanization are covered in substantial depth within all three Working Groups (including WGI Box TS.14, WGII Chapter 6 'Cities, settlements and key infrastructure'; WGII regional chapters; WGII Cross-Chapter Paper 'Cities and settlements by the sea'; WGIII Chapter 8 'Urban systems and other settlements'). This Box highlights key findings from Working Groups II and III and substantial gaps in literature where more research is urgently needed relating to policy action in cities. It describes methods of addressing mitigation and adaptation in an integrated way across sectors and cities to advance sustainable development and equity outcomes; and assesses the governance and finance solutions required to support climate resilient responses.

Urbanisation: A Megatrend Driving Global Climate Risk and Potential For Low-Carbon and Resilient Futures

Severe weather events, exacerbated by anthropogenic emissions are already having devastating impacts on people who live in urban areas, on the infrastructure that supports these communities and those of many other distant places (*high confidence*) (Cai et al., 2019; Folke et al., 2021). Between 2000 and 2015, the global population in locations that were affected by floods grew by 58-86 million (Tellman et al., 2021). The direct economic costs of all extreme events reached 210-268 billion USD in 2020 (Aon, 2021) or about $0.7 billion per day – this figure does not include knock-on costs in supply chains or days off work lost so that the actual economic costs could be far higher. Depending on RCP, between half (RCP2.6) and three-quarters (RCP8.5) of the global population could be exposed to periods of life-threatening climatic conditions arising from coupled impacts of extreme heat and humidity by 2100 (see WGII 6.2.2.1; WGII Figure 6.3; (Mora et al., 2017a; Zhao et al., 2021; Huang et al., 2019)).

The interdependencies between infrastructure, services and networks driven by urban production and consumption mean that urban systems are now global – remittance flows and investments reach into rural places shaping natural resource use far from the city and bring risk to the city when these places are impacted by climate change. This urbanization megatrend (Kourtit, Nijkamp and Scholten, 2015) amplifies as well as shapes the potential impacts of climate events. It provides the economic and institutional framework for integrating the aims and approaches that can deliver mitigation, adaptation and sustainable development (*medium evidence, high agreement*) (Zscheischler et al., 2018; Dawson et al., 2018; Tsavdaroglou et al., 2018). For cities facing flood damage wide-ranging impacts have been recorded on other urban areas (Simpson et al., 2021; Carter et al., 2021) as production and trade is disrupted (Shughrue et al., 2020). In the absence of integrated mitigation and adaptation across and between infrastructure systems and local places, impacts that bring urban economies to a standstill can extend into supply chains or across energy networks causing power outages.

Urban settlements are drivers of climate change, generating about 70 percent of global CO2eq emissions (*high confidence*) (WGI Box TS.14; WGIII 8 ES; WGII 6.1, WGII 6.2). This global impact feeds back to cities through the exposure of infrastructure, people and business to the impacts of climate related hazards. In especially the larger cities this climate feedback is exacerbated by local choices in urban design, land-use, building design, and human behaviour (Viguié et al., 2020) that shape local environmental conditions. Local and global conditions influence the nature of hazards in urban centres: urban form can add up to two degrees to warming, concretisation of open space can increase run-off, and building height and orientation influences wind direction and strength (WGII 6.3).

Building today for resilience and lower emissions is far easier than retrofitting tomorrow. As urbanisation unfolds its legacy continues to be the locking in of emissions and vulnerabilities (*high confidence*) (Ürge-Vorsatz et al., 2018; Seto et al., 2016). Retrofitting, disaster reconstruction and urban regeneration programmes offer scope for strategic direction changes to low-carbon and high resilience urban form and function if they are inclusive in design and implementation. Rapid urban growth means new investment, new buildings and infrastructure, new demands for energy and transport and new questions about what a healthy and fulfilling urban life can be. The US$90 trillion expected to be invested in new urban development by 2030 (NCE, 2018), is a global opportunity to place adaptation and mitigation directly into urban infrastructure and planning, social policy including education and health care and environmental management (Ürge-Vorsatz et al., 2018). If this opportunity is missed, if business as usual urbanisation persists, then social and physical vulnerability will be not be so easily confronted.

The benefits of actions taken to reduce GHG emissions and climate stressors diminish with delayed action, indicating the necessity for rapid responses. Delaying the same actions for increasing the resilience of infrastructure from 2020 to 2030 is estimated to have a median cost of at least US$1 trillion (Hallegatte et al., 2019) while also missing the carbon emissions reductions required in the narrowing window of opportunity to limit global warming to 1.5°C (WGI). In contrast, taking integrated actions towards mitigation, adaptation and sustainable development will provide multiple benefits for the health and wellbeing of urban inhabitants and avoid stranded assets (WGII 6.3, WGII 17; WGIII 5; WGIII 8.2; Cross-Chapter Box FEASIB in Chapter 18).

The Policy-Action Gap: Urban Low-Carbon and Climate Resilient Development

Cities are critical places to realize actions on both adaptation and mitigation simultaneously with potential co-benefits that extend far beyond cities (*medium evidence high agreement*) (Grafakos et al., 2020; Göpfert, Wamsler and Lang, 2019). Given rapid changes in the built environment, transforming the use of materials and the land intensiveness of urban development including in many parts of the Global South in the next decades will be critical, as well as mainstreaming low-carbon development principles in new urban development in all regions. Much of this development will be self-built and 'informal' - and new modes of governance and planning will be required to engage with this. Integrating mitigation and adaptation now rather than later, through reshaping patterns of urban development and associated decision-making processes, is a prerequisite for attaining resilient and zero carbon cities.

While more cities have developed plans for climate adaptation and mitigation since AR5, many remain to be implemented (*limited evidence, high agreement*) (Araos et al., 2017; Olazabal and De Gopegui, 2021; Aguiar et al., 2018). A review of local climate mitigation and adaptation plans across 885 urban areas of the European Union suggests mitigation plans are more common than adaptation plans, and that city size, national legislation, and international networks can influence the development of local climate plans with an estimated 80% of cities with above 500,000 inhabitants having a mitigation and/or an adaptation plan (Reckien et al., 2018b).

Integrated approaches to tackle common drivers of emissions and cascading risks provide the basis for strengthening synergies across mitigation and adaptation and managing possible trade-offs with sustainable development (*limited evidence, medium agreement*) (Grafakos et al., 2019; Landauer, Juhola and Klein, 2019). Analysis of 315 local authority emission reduction plans across the European Union reveals that the most common policies cover municipal assets and structures (Palermo et al 2020). Estimates of emission reductions by non-state and sub-state actors in ten high-emitting economies projected GHG emissions in 2030 would be 1.2–2.0 GtCO2e/year or 3.8%–5.5% lower compared to scenario projections for current national policies (31.6–36.8 GtCO2e/year) if the policies are fully implemented and do not change the pace of action elsewhere (Kuramochi et al 2020). The value of integrating mitigation and adaptation is underscored in the opportunities for decarbonizing existing urban areas, and investing in social, ecological, and technological infrastructure resilience (WGII 6.4). Integrating mitigation and adaption is challenging (Landauer, Juhola and Klein, 2019) but can provide multiple benefits for the health and wellbeing of urban inhabitants (Sharifi, 2020).

Effective climate strategies combine mitigation and adaptation responses, including through linking adaptive urban land use with GHG emission reductions (*medium evidence, high agreement*) (Xu et al., 2019; Patterson et al., 2021). For example, urban green and blue infrastructure can provide co-benefits for mitigation and adaptation (Ürge-Vorsatz et al., 2018) and is an important entry point for integrating adaptation and mitigation at the urban level (Frantzeskaki et al., 2019). Grey and physical infrastructure such as sea defences can immediately reduce risk, but can also transfer risk and limit future options. Social policy interventions including social safety nets provide financial security for the most at risk and can manage vulnerability both determined by specific hazards or independently. Hazard independent mechanisms for vulnerability reduction – such as population wide social security - provide resilience in the face of unanticipated cascading impacts or surprise and novel climate related hazard exposure. Social interventions can also support, or be led by ambitions to reach the Sustainable Development Goals (Archer, 2016). Climate resilient development invites planners to plan interventions and monitor the effectiveness of outcomes beyond individual projects and across wider remits that reach into sustainable development. Curbing the emission impacts of urban activities to reach net zero in the next decades while improving the resilience of urban areas necessitates an integrated response now.

Key gaps in knowledge include urban enabling environments; how smaller settlements, low-income communities living in slums and informal settlements – but also those in rental housing spread across the city; and actions to reduce supply chain risk can be supported to accelerate equitable and sustainable adaptation in the face of financial and governance constraints (Birkmann et al., 2016; Shi et al., 2016; Dulal, 2019; Rosenzweig et al., 2018b).

Enabling Action

Innovative governance and finance solutions are required to manage complex and interconnected risks across essential key infrastructures, networks and services and meet basic human needs in urban areas (*medium confidence*) (Moser et al., 2019; Colenbrander, Dodman and Mitlin, 2018). There are many examples of ‘ready-to-use’ policy tools, technologies and practical interventions for policy makers seeking to act on adaptation and mitigation (Keenan, Chu and Peterson, 2019; Bisaro and Hinkel, 2018; Chirambo, 2021). Tax and fiscal incentives for business and individuals can help support city-wide change behaviour towards low carbon and risk reducing choices. Change can start where governments have most control – in public sector institutions and investment but the challenge ahead requires partnership with private sector and community actors acting at scale and with accountability. Urban climate governance and finance needs to address urban inequalities at the forefront if the urban opportunity is to realise the ambition of the Sustainable Development Goals.

Increasing investment at pace will put pressure on governance capability and transparency and accountability of decision making (*medium confidence*) (WG II 6.6.4.5). Urban climate action that actively includes local actors and is built on an evidence base open to independent scrutiny is more likely to avoid unintended, negative maladaptive impacts and mobilise a wide range of local capacities. In the long-run this is also more likely to carry public support, even if some experiments and investments do not deliver the intended social benefits. Legislation, technical capacity and governance capability is required to be able to absorb additional finance. About US$ 384 billion of climate finance has been invested in urban areas per year in recent years. This remains at about 10% of the annual climate finance that would be necessary for low-carbon and resilient urban development (Negreiros et al., 2021). Rapid deployment of funds to stimulate economies in recovery from COVID-19 have highlighted the pitfalls of funding expansion ahead of policy innovation and capacity building. The result can be an intensification of existing urban forms – exactly the kinds of choices and preferences that have contribute to risk creation and its concentration amongst those with little public voice or economic power.

Iterative and experimental approaches to climate adaptation and mitigation decision-making co-generated in partnership with communities, can advance climate resilient decarbonisation (*medium evidence, high agreement*) (Caldarice, Tollin and Pizzorni, 2021; Culwick et al., 2019; van der Heijden and Hong, 2021). Conditions of complexity, uncertainty and constrained resources require innovative solutions which are both adaptive and anticipatory. Complex interactions among multiple agents in times of uncertainty makes decision making about social, economic, governance, and infrastructure choices challenges and can lead decision-makers to postpone action. This is the case for those balancing household budgets, residential investment portfolios and city-wide policy responsibilities. Living with climate change requires changes to business-as-usual design making. Codesign and collaboration with communities through iterative policy experimentation can point the way towards climate resilient development pathways (Ataöv and Peker, 2021). Key to successful learning is transparency in policy making, inclusive policy processes and robust local modelling, monitoring and evaluation which are not yet widely undertaken (Ford et al., 2019; Sanchez Rodriguez, Ürge-Vorsatz and Barau, 2018).

The diversity of cities' experiences of climate mitigation and adaptation strategies brings an advantage for those city government and other actors willing to 'learn together' (*limited evidence, high agreement*) (Bellinson and Chu, 2019; Haupt and Coppola, 2019). While contexts are varied, policy options are often similar enough for the sharing of experiments and policy champions. Sharing expertise can build on existing regional and global networks, many of which have already placed knowledge, learning and capacity building at the centre of their agendas. Learning from innovative forms of governance and financial investment, and strengthening coproduction of policy through inclusive access to knowledge and resources, can help address mismatches in local capacities, strengthen wider Sustainable Development Goals and COVID-19 Recovery agendas (limited evidence, medium agreement). Perceptions of risk can greatly influence the reallocation of capital and shift financial resources (Battiston et al., 2021). Coupling mitigation and adaptation in an integrated approach offers opportunities to enhance efficiency, increases the coherence of urban climate action, generates cost savings and provides opportunities to reinvest the savings into new climate action projects to make all urban areas and regions more resilient.

Local governments play an important role in driving climate action across mitigation and adaptation as managers of assets, regulators, mobilizers and catalysts of action, but few cities are undertaking transformative climate adaptation or mitigation actions (*limited evidence, medium agreement)* (Heikkinen, Ylä-Anttila and Juhola, 2019). Local actors are providers of infrastructure and services, regulators of zoning, and can be conveners and champions of an integrated approach for mitigation and adaptation at multiple levels 9Limited evidence high confidence). New opportunities in governance and finance can enable cities to pool resources together and aggregate interventions to innovate ways of mobilizing urban climate finance at scale (White and Wahbah, 2019; Simpson et al, 2019; Colenbrander et al, 2019). However, research increasingly points towards the difficulties faced during the implementation of climate financing in situ, such as for example, the fragmentation of structures of governance capable of managing large investments effectively (Mohammed et al, 2019).

Scaling up transformative place-based action for both adaptation and mitigation requires enabling conditions including land-based financing, intermediaries and local partnerships (*medium evidence, high agreement*) (Chaudhuri et. al, 2021, Tirumala and Tiwari, 2021(Chu et al., 2019). Governance structures that combine actors working at different levels with different mix of tools are effective in addressing challenges related to implementation of integrated action while cross-sectoral coordination is necessary (Singh et al., 2020). Joint institutionalization of mitigation and adaptation in local governance structures can also enable integrated action (Göpfert et al., 2020; Hurlimann et al., 2021). However, the proportion of international finance that reaches local recipients remains low, despite the repeated focus of climate policy on place-based adaptation and mitigation (Manuamorn, 2019). Green financing instruments that enable local climate action without exacerbating current forms of inequality can jointly address mitigation, adaptation and sustainable development. Climate finance that also reaches beyond non-state enterprises, including SMEs, communities and NGOs, and is responsive to the needs of urban inhabitants, including disabled individuals and different races or ethnicities is essential for inclusive and resilient urban development (Colenbrander et al, 2019; Gabaldon-Estevan et al, 2019; Frenova, 2020). Developing networks that can exert climate action at scale is another priority for climate finance.

The urbanisation megatrend is an opportunity to transition global society. Enabling urban governance to avert cascading risk and achieve low-carbon, resilient development will involve coproduction of policy and planning, rapid implementation and greater cross sector coordination, monitoring and evaluation (*limited evidence, medium agreement)* (Grafakos et al., 2019; Di Giulio et al., 2018). New constellations of responsible actors are required to manage hybrid local-city or cross-city risk management and decarbonisation initiatives (*limited evidence, medium agreement*). These may increasingly benefit from linkages across more urban and more rural space as recognition of cascading and systemic risk brings recognition of supply chains, remittance flows and migration trends as vectors of risk and resilience. Urban governance will be better prepared in planning, prioritizing and financing the kind of measures that can reduce GHG emissions and improve resilience at scale and pace when considering a view of cascading risks and carbon lock-ins globally, while acting locally to address local limitations and capacities, including the needs and priorities of urban citizens (Udelsman Rodrigues, 2019; Colenbrander et al, 2018).

[END CROSS-WORKING GROUP BOX URBAN HERE]

[START FAQ6.1 HERE]

FAQ6.1: Why and how are cities, settlements, and different types of infrastructure especially vulnerable to the impacts of climate change?

Cities, settlements and infrastructure become vulnerable when investment decisions fail to take the risks of climate change fully into account. Such failures can result from a lack of understanding, competing priorities, a lack of finance or access to appropriate technology. Around the world, smaller cities and poorer populations are often most vulnerable and suffer the most over time, while large cities can register the greatest losses to individual events.

The world is urban. Billions of people live in towns and cities. Hardly anyone, even in remote rural locations, is separated from the flows of trade that connect the world and are held together by networks of transport and communication infrastructure systems. Connected networks once broken can cascade out, multiplying impacts across urban and rural areas. When major manufacturing centres or regionally important ports are impacted, global trade suffers. For example, flooding in Bangkok in 2011 led to a global shortage in semiconductors and a slowdown in the global computer manufacturing.

Despite cities generating wealth, additional vulnerability to climate change is being created in urban areas every day. Demographic change, social and economic pressures and governance failures that drive inequality and marginality mean that increasing numbers of people who live in towns and cities are exposed to flooding, temperature extremes and water or food insecurity. This leads to an adaptation gap, where rich neighbourhoods can afford strategies to reduce vulnerability while poorer communities are unable to do the same. Although this would be so even without a changing climate, climate change increases the variability and extremes of weather, exposing more people, businesses and buildings to floods and other events. The combination of rising vulnerability and increasing exposure translates to a growth in the number of people and properties at risk from climate change in cities worldwide.

Around the world, vulnerability is rising but differs considerably between and within urban areas. Settlements of up to 1 million people are the most rapidly expanding and also amongst the most vulnerable. These settlements often have limited community level organisation and might not have a dedicated local government. Coping with rapid population growth under conditions of climate change and constrained capacity is a major challenge. For large cities, multiple local governments and well organised community-based organisations interact with large businesses and national political parties in a complicated cocktail of interests that can interfere with planning and action to reduce vulnerability.

For the poorest living in urban slums, informal settlements or renting across the city, lack of secure tenure and inadequate access to basic services compound vulnerability. But even the wealthy in large cities are not fully protected from climate change related shocks. Just like breaks in infrastructure between towns and rural settlements, big city infrastructure can be broken by even local landslides, floods or temperature events with consequences cascading across the city. Electricity blackouts are the most common and can affect water pumping, traffic regulation, streetlights as well as hospitals, schools and homes. Still, it is the urban poor and marginalised who experience the greatest exposure, most vulnerability and least capacity to cope.

Rounds of exposure and impact can reduce the capacity of survivors to cope with future events. As a result, the already vulnerable and exposed become more vulnerable over time, increasing urban inequalities. But this need not be the case. Focussing on vulnerability reduction is not easy, it requires joined up action across social and economic development sectors together with critical infrastructure planning. It often also means partnering local government with informal and community-based actors. But there is considerable experience globally on what works and how to deliver reduced vulnerability for the urban poor and for cities as a whole. The challenge is to scale up this experience and accelerate its application to keep pace with climate change and address the adaptation gap.

[END FAQ6.1 HERE]

[START FAQ6.2 HERE]

FAQ6.2: What are the key climate risks faced by cities, settlements, and vulnerable populations today, and how will these risks change in a mid-century (2050) 2°C warmer world?

Climate change will interact with the changing physical environment in cities and settlements to create or exacerbate a range of risks. Rising temperatures and heat waves will cause human illness, morbidity as well as infrastructure degradation and failures, while heavy rainfall and sea-level rise will worsen flooding. Low-income groups and other vulnerable populations will be affected most severely because of where they live and their limited ability to cope with these stresses.

Cities and settlements are constantly changing. Their populations grow and shrink, economic activities expand or decline, and political priorities shift. The risks that cities and their residents face are influenced by both urban change and climate change. The seriousness of these risks into the 21st Century will be shaped by the interactions between drivers of change including population growth, economic development and land use change.

In a warming world, increasing air temperature makes the Urban Heat Island effect in cities worse. One key risk is heat waves in cities that are likely to affect half of the future global urban population with negative impacts on human health and economic productivity. Heat and built infrastructure such as streets and houses interact with each other and magnify risks in cities. For instance, higher urban temperatures can cause infrastructure to overheat and fail, as well as increase the concentration of harmful air pollutants such as ozone.

The density of roads and buildings in urban areas increases the area of impermeable surfaces, which interact with more frequent heavy precipitation events to increase the risk of urban flooding. This risk of flooding is greater for coastal settlements due to sea level rise and storm surges from tropical cyclones. Coastal inundation in the Miami-Dade region in Florida, USA, is estimated to have caused over USD465 million in lost real estate value between 2005 and 2016, and it is likely that coastal flood risks in the region beyond 2050 will increase without adaptation to climate change.

Within cities, different groups of people can face different risks. Many low-income residents live in informal settlements alongside coasts or rivers, which greatly heightens exposure and vulnerability to climate-driven hazards. In urban areas in Ghana, for example, risks from urban flooding can compound health risks, and have resulted in outbreaks of malaria, typhoid and cholera. Those outbreaks have been shown to disproportionately affect poorer communities.

Severe risks in cities and settlements also arise from reduced water availability. As urban areas grow, the amount of water required to meet basic needs of people and industries increases. When increased demand is combined with water scarcity from lower rainfall due to climate change, water resource management becomes a critical issue. Low-income groups already face major challenges in accessing water, and the situation is likely to worsen due to growing conflicts over scarce resources, increasing water prices, and diminishing infrastructure provisions in ever-expanding informal settlements.

These key risks already differ greatly between cities, and between different groups of people in the same city. By 2050 these discrepancies are likely to be even more apparent. Cities with limited financial resources, regulatory authority and technical capacities are less equipped to respond to climate change. People who already have fewer resources and constrained opportunities face higher levels of risk because of their vulnerability. As a result of this, key risks vary not only over time as climate change is felt more strongly. They also vary over space – between cities exposed to different hazards and with different abilities to adapt – and between social groups, meaning between people who are more or less affected and able to cope.

[START FAQ6.3 HERE]

FAQ6.3: What adaptation actions in human settlements can contribute to reducing climate risks and building resilience across building, neighbourhood, city, and global scales?

Settlements bring together many activities, so climate action will be most effective if it is integrated and collaborative. This requires (i) embedding information on climate change risks into decisions; (ii) building capacity of communities and institutions; (iii) using both nature-based and traditional engineering approaches; (iv) working in partnership with diverse local planning and community organisations; and, (v) sharing best practice with other settlements.

Settlements bring together people, buildings, economic activities and infrastructure services, and thus integrated, cross-sector, adaptation actions offer the best way to build resilience to climate change impacts. For example, actions to manage flood risk include installing flood proofing measures within and outside properties, improving capacity of urban drainage along roads, incorporating nature-based solutions within the urban areas, constructing flood defences, and managing land upstream of settlements to reduce runoff.

Adaptation actions will be more effective if they are implemented in partnership with local communities, national governments, research institutions, and the private and third sector. Climate action should not be considered as an additional or side action to other activities. Rather, climate action should be mainstreamed into existing processes, including those that contribute to the UN Sustainable Development Goals (2015) and New Urban Agenda adopted at the UN Conference on Housing and Sustainable Urban Development (Habitat III) in 2016. Cities are already coming together through international networks to share good practice about adaptation actions, speeding up the dissemination of knowledge.

This integrated approach to adaptation in human settlements needs to be supported by various other actions, including potential co-benefits with carbon emissions reductions, public health, and ecosystem conservation goals. First, information on climate risks needs to be embedded into the architectural design, delivery and retrofitting of housing, transportation, spatial planning and infrastructure across neighbourhood and city scales. This includes making information on climate impacts widely available, updating design standards, and strengthening regulation to avoid development in high-risk locations. Second, the capacity of communities needs to be strengthened, especially amongst those in informal settlements, the poorest and other vulnerable groups including minorities, migrants, women, children, elderly, disabled, and people with serious health conditions such as obesity. This involves raising awareness, incorporating communities into adaptation processes, and strengthening regulation, policies and provision of infrastructure services. Third, nature-based solutions should be integrated to work alongside traditional ‘grey’ or engineered infrastructure. Vegetation corridors, greenspace, wetlands and other green infrastructure can be woven into the built environment to reduce heat and flood risks, whilst providing other benefits such as health and biodiversity.

Although even the largest city covers only a small area of the planet, all settlements are part of larger catchments from which people, water, food, energy, materials, and other resources support them. Actions within cities should be mindful of wider impacts and avoid displacing issues elsewhere.

[END FAQ6.3 HERE]

[START FAQ6.4 HERE]

FAQ6.4: How can actions that reduce climate risks in cities and settlements also help to reduce urban poverty, enhance economic performance, and contribute to climate mitigation?

If carefully planned, adaptation actions can reduce exposure to climate risk as well as reduce urban poverty, advance sustainable development and mitigate greenhouse gas emissions. When adaptation responses are equitable, and if a range of voices are heard in the planning process, the needs of the disadvantaged are more likely to be addressed and wider societal benefits can be maximized.

Urbanization is a global trend which is interacting with climate change to create complex risks in cities and settlements, especially for those that already have high levels of poverty, unemployment, housing informality, and backlogs of services. Many cities and settlements are seeing increasing action to manage climate risks. On top of reducing communities’ exposure to climate risk, adaptation actions can have benefits for reducing urban poverty and enhancing economic performance in ways that reduce inequality and advance sustainability goals. Adaptation actions, however, can also have unintended consequences. That is why care needs to be taken to ensure climate adaptation planning and development of new infrastructure does not exacerbate inequality or negatively impact other sustainable development priorities. Climate adaptation planning is most effective when it is sensitive to the diverse ways that low-income and minority communities are more likely to experience climate risk, including women, children, migrants, refugees, internally displaced peoples, racial/ethnic minority groups, among others.

Adapting to climate change can have benefits for reducing greenhouse gas emissions and urban inequalities. In cities where growing numbers of people live in informal settlements, introducing risk-reducing physical infrastructure such as piped water, sanitation, drainage systems can enhance the quality of life of the community. At the same time, those measures can increase health outcomes and reduce urban inequalities by reducing exposure to flooding or heat impacts. In less developed countries, less than 60% of the urban population have access to piped water which, in turn, impacts their health and well-being. Increasingly, housing is being built better to manage heat risk through insulation, changing building orientation or to flood risk by raising structures, which then contributes to wellbeing and ability to work. Improvements to early warning systems can help people evacuate rapidly in case of storm surges or flooding. Although the most vulnerable often do not get these warnings in time.

Carefully planned nature-based solutions, such as public green space, improved urban drainage systems and storm water management, can deliver both health and development benefits. When these adaptation actions succeed, water, waste and sanitation can be improved to better manage climate risk and provide households and cities with better services. Many nature-based solutions entail bringing back plants and trees into cities which also helps to reduce the concentration of heat-trapping greenhouse gases in the atmosphere.

When care is taken to ensure that adaptation responses are equitable, and that a range of voices are heard in planning, the needs of the disadvantaged are more likely to be addressed. For example, a study that looked at transport plans across 40 cities in Portugal saw that some urban communities have prioritised the needs of disadvantaged users such as the elderly and disabled, while at the same time reducing urban transport emissions while enhancing public wellbeing and equity of transport. On the other hand, in some cities, there is evidence of emerging trade-offs associated with climate adaptation actions where sea walls and temporary flood barriers were erected in economically valuable areas and not is less well-off areas. Going forward, it is important to ensure that vulnerable groups' needs are carefully considered both in terms of climate and other risks as this has not been sufficiently done in the past.

[END FAQ6.4 HERE]

[START FAQ6.5 HERE]

FAQ6.5: What policy tools, governance strategies, and financing arrangements can enable more inclusive and effective climate adaptation in cities and settlements?

Inclusive and effective climate adaptation requires efforts are all levels of governance, including the public sector, the private sector, the third sector, communities and intermediaries such as universities or think tanks. Inclusive and effective adaptation requires action fit for the diverse conditions in which it is needed. Collaborative dialogues can help to map both adaptation opportunities and potential negative impacts.

There is no one-size-fits-all approach to ensure that climate adaptation efforts have positive results and include the concerns of everyone affected. Cities and local communities are diverse, and thus they have diverse perspectives on what responses to prioritize. Moreover, adaptation efforts may impact people's lives in very different ways. Policy tools, strategies and financial arrangements for adaptation can include all society sectors and address socio-economic inequalities. Planning and decision-making must respond to marginalized voices and future generations (including children and youth).

Efforts to adapt to climate change can be incremental, reformist, or transformational, depending on the scale of the change required. Incremental action may address specific climate impacts in a given place, but do not challenge the social and political institutions that prevent people from bouncing back better. Reformist action may address some of the social and institutional drivers of exposure and vulnerability, but without addressing the underlying socio-economic structures that drive differential forms of exposure. For example, social protection measures may improve people's capacity to cope with climate impacts, but that improved capacity will depend on maintaining such protection measures. Transformative action involves fundamental changes in political and socio-economic systems, oriented towards addressing vulnerability drivers (e.g., socio-economic inequalities, consumption cultures). All forms of adaptation are relevant to deliver resilient futures because of the variability of conditions in which adaptation action is needed.

Local and regional governments play an essential role in delivering planning and institutional action suited to local conditions in cities and settlements. Potential strategies can span multiple sectors and scales, ranging from land use management, building codes, critical infrastructure designs and community development actions, to different legal, financial, participatory decision-making and robust monitoring and evaluation arrangements. NGOs or third sector organisations can also play a coordinating role by building dialogues across governments, the private sectors, and communities through effective communication and social learning. Local action tends to falter without the support of national governments as they are often facilitators of resources and finance. They can create institutional frameworks that facilitate (rather than impede) local action. National governments also play a crucial role in the development of large-scale infrastructures.

Private actors can also drive adaptation action. The evaluation of private-led infrastructure and housing projects suggests that the prioritization of profit, however, may have a detrimental impact on the overall resilience of a place. New institutional models such as public-private partnerships respond to the shortcomings of both the public and private sectors. Still, the evidence of them facilitating the inclusion of multiple actors is mixed.

The private sector can mobilize finance. However, the forms of finance available for adaptation are limited and directed to huge projects that do not always address local adaptation needs. Private actors tend to join adaptation projects when there is an expectation of large profits, such as in interventions that increase real estate value. Private-led adaptation can lead to ‘gentrification’ whereby low-income populations are relocated from urban centres and safer settlements. Models that enable the collaboration between public, private and civil society sectors have greater potential to mobilise adaptation finance in inclusive ways.

Forms of collaborative planning and decision-making can create dialogues for a sustainable future in cities, settlements and infrastructure systems. Adaptation action needs multiple approaches. For example, adaptation needs both actions that depend on dialogues between multiple actors (e.g., urban planning and zoning) and action that follows strong determination and leadership (e.g., declarations of emergency and target commitments). There are adaptation actions that depend on place-based conditions (e.g., flood defences) and those that require considering interactions across scales (e.g., regulatory frameworks). The growth of adaptation capacities, fostering dialogues, empowered communities, multi-scalar assessments, and foresight within current institutions can support effective and inclusive adaptation action that is also sustained in the long term.

Date of Draft: 1 October 2021

Notes: TSU Compiled Version

Table of Contents

Executive Summary

Climate-related illnesses, premature deaths, malnutrition in all its forms, and threats to mental health and wellbeing are increasing *(very high confidence[1])*. Climate hazards are a growing driver of involuntary migration and displacement (*high confidence*) and are a contributing factor to violent conflict *(high confidence)*. These impacts are often interconnected, are unevenly distributed across and within societies, and will continue to be experienced inequitably (*very high confidence*). Cascading and compounding risks affecting health due to extreme weather events have been observed in all inhabited regions, and risks are expected to increase with further warming (*very high confidence*). [7.1.3, 7.1.4, Cross-Chapter Box COVID in Chapter 7, 7.2.1, 7.2.2, 7.2.3, 7.2.4, 7.3.1, 7.3.2, 7.3.3, 7.4.1, 7.4.4, Cross-Chapter Box HEALTH in Chapter 7, Cross-Capter Box ILLNESS in Chapter 2]

Since AR5, new evidence and awareness of current impacts and projected risk of climate change on health, wellbeing, migration, and conflict emerged, including greater evidence of the detrimental impacts of climate change on mental health (*very high confidence*). New international agreements were reached on climate change (Paris Agreement), disaster risk reduction (Sendai Agreement), sustainable development (the SDGs), urbanisation (The New Urban Agenda), migration (Global Compact for Safe, Orderly and Regular Migration), and refugees (Global Compact on Refugees) that, if achieved, would reduce the impacts of climate change on health, wellbeing, migration, and conflict (*very high confidence*). However, the challenges with implementing these agreements are highlighted by the COVID-19 pandemic, which exposed systemic weaknesses, at community, national, and international levels in the ability of societies to anticipate and respond to global risks *(high confidence)*. Incremental changes in policies and strategies have proven insufficient to reduce climate-related risks to health, wellbeing, migration, and conflict, highlighting the value of more integrated approaches and frameworks for solutions across systems and sectors that are embodied in these new international agreements *(high confidence)* [7.1.3, 7.2.1, 7.4.1, 7.4.2, 7.4.3, 7.4.6, Cross-Chapter Box COVID in Chapter 7]

With proactive, timely, and effective adaptation, many risks for human health and wellbeing could be reduced and some potentially avoided (*very high confidence*). A significant adaptation gap exists for human health and well-being and for responses to disaster risks (*very high confidence*). Most Nationally Determined Contributions to the Paris Agreement from low- and middle-income countries identify health as a priority concern. National planning on health and climate change is advancing, but the comprehensiveness of strategies and plans need to be strengthened and implementing action on key health and climate change priorities remains challenging *(high confidence)*. Multisectoral collaboration on health and climate change policy is evident, with uneven progress, and financial support for health adaptation is only 0.5% of dispersed multilateral climate finance projects *(high confidence)*. This level of investment is insufficient to protect population health and health systems from most climate-sensitive health risks (*very high confidence*) [7.4.1, 7.4.2, 7.4.3].

Climate resilient development has a strong potential to generate substantial co-benefits for health and wellbeing, and to reduce risks of involuntary displacement and conflict (*very high confidence*). Sustainable and climate-resilient development that decreases exposure, vulnerability, and societal inequity, and that increases timely and effective adaptation and mitigation more broadly, has the potential to reduce but not necessarily eliminate climate change impacts on health, wellbeing, involuntary migration, and conflict *(high confidence)*. This development includes, but is not limited to, greenhouse gas emissions reductions through: clean energy and transport; climate resilient urban planning; sustainable food systems that lead to healthier diets; universal access to health care and social protection systems; wide-scale, proactive adaptive capacity building for climate change; and, achievement of the Sustainable Development Goals *(very high confidence)*. Meeting the objectives of the Global Compact for Safe, Orderly, and Regular Migration, and building inclusive and integrative approaches to climate resilient peace would help prevent health risks related to migration and conflict (*high agreement, medium evidence*)**.** The net global financial gains from these co-benefits to health and well-being, including avoided hospitalizations, morbidity, and

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

premature deaths, exceed the financial costs of mitigation (*high confidence*) As an example of co-benefits, the financial value of health benefits from improved air quality alone is projected to be greater than the costs of meeting the goals of the Paris Agreement *(high confidence)*. All pathways to climate resilient development, including those for the health and healthcare systems, involve balancing complex synergies and trade-offs between development pathways and the options that underpin climate mitigation and adaptation pathways (*very high confidence*). [7.4.6, Cross-Capter Box HEALTH in Chapter 7, Cross-Chapter Box MIGRATE in Chapter 7].

Key transformations are needed to facilitate climate resilient development pathways for health, well-being, migration and conflict avoidance *(high confidence)*. The transformational changes will be more effective if they are responsive to regional, local, and Indigenous Knowledge, and consider the many dimensions of vulnerability, including those that are gender- and age-specific *(high confidence)*. A key pathway toward climate resilience in the health sector is universal access to primary health care, including mental health care (*high confidence*). Investments in other sectors and systems that improve upon the social determinants of health have the potential to reduce vulnerability to climate-related health risks (*high confidence*). Links between climate risks, adaptation, migration, and labour markets highlight the value of providing better mobility options as part of transformative change *(medium confidence)*. Strong governance and gender-sensitive approaches to natural resource management reduce the risk of intergroup conflict in climate-disrupted areas *(medium confidence).* [7.4.6, Cross-Chapter Box COVID in Chapter 7, Cross-Chapter Box HEALTH in Chapter 7, Cross-Chapter Box GENDER in Chapter 18, Cross-Chapter Box INDIG in Chapter 18, Cross-Capter Box MIGRATE in Chapter 7]

Observed Impacts

Climate hazards are increasingly contributing to a growing number of adverse health outcomes (including communicable and non-communicable diseases) in multiple geographical areas *(very high confidence)*. The net impacts are largely negative at all scales *(very high confidence),* and there are very few examples of beneficial outcomes from climate change at any scale *(high confidence)*. While malaria incidence has declined globally due to non-climatic socio-economic factors and health system responses, a shift to higher altitudes has been observed as the climate warms *(very high confidence)*. Climate variability and change (including temperature, relative humidity, and rainfall) and population mobility are significantly and positively associated with observed increases in dengue globally, chikungunya virus in Asia, Latin America, North America, and Europe *(high confidence)*, Lyme disease vector *Ixodes scapularis* in North America *(high confidence)*, and Lyme disease and Tick-Borne Encephalitis vector *Ixodes ricinus* in Europe *(medium confidence)*. Higher temperatures (*very high confidence*), heavy rainfall events *(high confidence),* and flooding *(medium confidence)* are associated with an increase of diarrheal diseases in affected regions, including cholera *(very high confidence)*, other gastro-intestinal infections *(high confidence)*, and foodborne diseases due to Salmonella and Campylobacter *(medium confidence).* Floods have led to increases in vector-borne and water-borne diseases and to disturbances of public health services *(high confidence)*. Climate extremes increase the risks of several types of respiratory tract infections *(high confidence)*. Climate-related extreme events such as wildfires, storms, and floods are followed by increased rates of mental illness in exposed populations (*very high confidence*). [7.2.1, 7.2.2, 7.2.3, 7.2.4, 7.2.5]

Several chronic, non-communicable respiratory diseases are climate-sensitive based on their exposure pathways (e.g., heat, cold, dust, small particulates, ozone, fire smoke, and allergens) *(high confidence),* although climate change is not the dominant driver in all cases. Worldwide, rates of adverse health impacts associated with small particulate matter exposure have decreased steadily due to decreasing primary emissions *(very high confidence)*, while rates of adverse health impacts from ozone air pollution exposure have increased *(very high confidence)***.** Exposure to wildland fires and associated smoke has increased in several regions (*very high confidence*). Spring pollen season start dates in northern mid-latitudes are occurring earlier due to climate change, increasing the risks of allergic respiratory diseases *(high confidence)*. [7.2.3.2.]

Heat is a growing health risk due to burgeoning urbanization, an increase in high temperature extremes, and demographic changes in countries with aging populations *(very high confidence)*. Potential hours of work lost due to heat has increased significantly over the past two decades (*high confidence*). Some regions are already experiencing heat stress conditions at or approaching the upper limits of labour productivity *(high confidence).* A significant proportion of warm season heat-related mortality in temperate regions is linked to observed anthropogenic climate change, (*medium confidence*) but greater evidence is required for tropical regions. For some heatwave events over the last two decades, associated health impacts can be at least partially attributed to observed climate change (*high confidence*). Extreme heat has negative impacts on mental health, wellbeing, life satisfaction, happiness, cognitive performance, and aggression (*medium confidence*). [7.2.4.1, 7.2.4.5]

Climate variability and change contribute to food insecurity, which can lead to malnutrition, including undernutrition, overweight, obesity; and to disease susceptibility in low- and middle-income countries (*high confidence*). Populations exposed to extreme weather and climate events may consume inadequate or insufficient food, leading to malnutrition and increasing the risk of disease (*high confidence*). Children and pregnant women experience disproportionately greater adverse nutrition and health impacts *(high confidence)*. Climatic influences on nutrition are strongly mediated by socio-economic factors (*very high confidence*). [7.2.4.4, 7.3.1]

Extreme climate events act as both direct drivers (e.g., destruction of homes by tropical cyclones) and as indirect drivers (e.g., rural income losses during prolonged droughts) of involuntary migration and displacement *(very high confidence).* Most documented examples of climate-related displacement occur within national boundaries, with international movements occurring primarily within regions, particularly between countries with contiguous borders *(high confidence)*. Global statistics collected since 2008 by the Internal Displacement Monitoring Centre show an annual average of over 20 million people internally displaced by weather-related extreme events, with storms and floods the most common drivers *(high confidence).* The largest absolute number of people displaced by extreme weather each year occurs in Asia (South, Southeast and East), followed by sub-Saharan Africa, but small island states in the Caribbean and South Pacific are disproportionately affected relative to their small population size (*high confidence*). Immobility in the context of climate risks can reflect vulnerability and lack of agency but can also be a deliberate choice of people to maintain livelihoods, economic considerations and social and cultural attachments to place (*high confidence*). [7.2.6, Cross-Chapter Box MIGRATE in Chapter 7].

Climate hazards have affected armed conflict within countries (medium confidence), but the influence of climate is small compared to socio-economic, political, and cultural factors *(high confidence).* Climate increases conflict risk by undermining food and water security, income and livelihoods, in situations where there are large populations, weather-sensitive economic activities, weak institutions and high levels of poverty and inequality *(high confidence).* In urban areas, food and water insecurity and inequitable access to services has been associated with civil unrest where there are weak institutions *(medium confidence)*. Climate hazards are associated with increased violence against women, girls and vulnerable groups and the experience of armed conflict is gendered *(medium confidence)*. Adaptation and mitigation projects implemented without consideration of local social dynamics have exacerbated non-violent conflict *(medium confidence)*. [7.2.7]

Projected Risks and Vulnerabilities

A significant increase in ill health and premature deaths from climate-sensitive diseases and conditions is projected due to climate change *(high confidence)*. An excess of 250,000 deaths per year by 2050 attributable to climate change are projected just due to heat, undernutrition, malaria, and diarrheal disease, with more than half of this excess mortality projected for Africa (compared to a 1961-1991 baseline period, for a mid-range emissions scenario) *(high confidence)*. Risks for heat-related morbidity and mortality, ozone-related mortality, malaria, diseases carried by Aedes sp. mosquitoes, Lyme disease, and West Nile fever, with the temperature at which risk transitions occur, from moderate to high to very high, contingent on future development pathways *(high confidence)*. [7.3.1]

Climate change is projected to significantly increase population exposure to heat waves (*very high confidence*). Models suggest exposure increases 16 times under RCP4.5/SSP3 and 36 times under RCP8.5/SSP3, with the impact of warming amplified under development pathways that do not foster sustainable development. Globally, the impact of projected climate change on temperature-related mortality is expected to be a net increase under RCP4.5 to RCP8.5, even with adaptation (*high confidence).* Strong geographical differences in heat-related mortality are projected to emerge later this century, mainly driven by growth in regions with tropical and subtropical climates *(very high confidence).* [7.3.1]

The burdens of several climate-sensitive food-borne, water-borne, and vector-borne diseases are projected to increase under climate change, assuming no additional adaptation *(very high confidence)*. The distribution and intensity of transmission of malaria is expected to decrease in some areas and increase in others, with increases projected mainly along the current edges of its geographic distribution in endemic areas of Sub-Saharan Africa, Asia, and South America *(high confidence)*. Dengue risk will increase, with a larger spatio-temporal distribution in Asia, Europe, and sub-Saharan Africa under RCPs 6.0 and 8.5, potentially putting another 2.25 billion people at risk *(high confidence).* Higher incidence rates are projected for Lyme disease in the northern hemisphere *(high confidence)* and for transmission of *Schistosoma mansoni* in eastern Africa *(high confidence)*. [7.3.1, Cross-Chapter Box ILLNESS in Chapter 2]

Increasing atmospheric concentrations of carbon dioxide and climate change are projected to increase diet-related risk factors and related non-communicable diseases globally, and increase undernutrition, stunting, and related childhood mortality particularly in Africa and Asia, with outcomes depending on the extent of mitigation and adaptation *(high confidence)*. These projected changes are expected to slow progress towards eradication of child undernutrition and malnutrition *(high confidence)*. Higher atmospheric concentrations of carbon dioxide reduce the nutritional quality of wheat, rice, and other major crops, potentially affecting millions of people at a doubling of carbon dioxide *(very high confidence)* [7.3.1].

Climate change is expected to have adverse impacts on wellbeing and to further threaten mental health (*very high confidence*). Children and adolescents, particularly girls, as well as people with existing mental, physical, and medical challenges and elderly people, are particularly at risk. Mental health impacts are expected to arise from exposure to high temperatures, extreme weather events, displacement, malnutrition, conflict, climate-related economic and social losses, and anxiety and distress associated with worry about climate change (*very high confidence*) [7.3.1.11]

Future climate-related migration is expected to vary by region and over time, according to future climatic drivers, patterns of population growth, adaptive capacity of exposed populations, and international development and migration policies (*high confidence*). The wide range of potential outcomes is reflected in model projections of population displacements by 2050 in Latin America, Sub-Saharan Africa and South Asia due to climate change, which vary from 31 million to 143 million people, depending on assumptions made about future emissions and socio-economic development trajectories *(high confidence)*. With every additional one degree Celsius of warming, the global risks of involuntary displacement due to flood events have been projected to rise by approximately 50% *(high confidence)*. High emissions/low development scenarios raise the potential for higher levels of migration and involuntary displacement *(high confidence)* and increase the need for planned relocations and support for people exposed to climate extremes but lacking the means to move (*high confidence*) [7.3.2, Cross-Chapter Box MIGRATE in Chapter 7].

Climate change may increase susceptibility to violent conflict, primarily intrastate conflicts, by strengthening climate-sensitive drivers of conflict *(medium confidence)*. Future violent conflict risk is highly mediated by socio-economic development trajectories (high confidence) and so trajectories that prioritise economic growth, political rights and sustainability are associated with lower conflict risk *(medium confidence)*. Future climate change may exceed adaptation limits and generate new causal pathways not observed under current climate variability *(medium confidence).* Economic shocks are currently not included in the models used and some projections do not incorporate known socio-economic predictors of conflict *(medium confidence)*. As such, future increases in conflict-related deaths with climate change have been estimated, but results are inconclusive *(medium confidence)*.

Solutions

Since AR5, the value of cross-sectoral collaboration to advance sustainable development has been more widely recognized, but despite acknowledgement of the importance of health adaptation as a key component, action has been slow *(high confidence)*. Building climate resilient health systems will require multi-sectoral and multisystem and collaborative efforts at all governance scales (*very high confidence*)

[7.4.1, 7.4.2]. Globally, health systems are poorly resourced in general, and their capacity to respond to climate change is weak, with mental health support being particularly inadequate (*very high confidence*). The health sectors of some countries have focused on implementing incremental changes to policies and measures to fill the adaptation gap (*very high confidence*). As the likelihood of dangerous risks to human health continue to increase, there is greater need for transformational changes to health and other systems (*very high confidence*). This highlights an urgent and immediate need to address the wider interactions between environmental change, socioeconomic development, and human health and wellbeing *(high confidence)*. [7.4.1, 7.4.2, 7.4.3]

Targeted investments in health and other systems, including multi-sectoral, integrated approaches, to protect against key health risks can effectively increase resilience (*high confidence*). Increased investment in strengthening general health systems, along with targeted investments to enhance protection against specific climate-sensitive exposures (e.g., hazard early warning and response systems, and integrated vector control programs for vector-borne diseases) will increase resilience, if implemented to at least keep pace with climate change *(high confidence).*

- The future effects of climate change on vector borne diseases can be significantly offset through enhanced commitment to and implementation of integrated vector control management approaches, disease surveillance, early warning systems, and vaccine development *(very high confidence).* [7.4.1, 7.4.2]
- Adaptation options for future climate risks associated with water-borne and food-borne diseases include improving access to potable water, reducing exposure of water and sanitation systems to flooding and extreme weather events, and improved (including expanded) early warning systems *(very high confidence).* [7.4.1, 7.4.2]
- Adaptation options for future extreme heat risks include heat action plans that incorporate early warning and response systems for urban and non-urban settings; tried, tested, and iteratively updated response strategies targeting both the general population and vulnerable groups such as older adults or outside workers; and effective stakeholder communication plans (*high confidence*). These short-term responses can be complemented by longer term urban planning and design, including Nature-based Solutions that mitigate urban heat island effects *(high confidence)* [7.4.1, 7.4.2, 7.4.3]
- Adaptation options to reduce the future risks of malnutrition include access to healthy, affordable diverse diets from sustainable food systems *(high confidence)*; health services including maternal, child and reproductive health (*high confidence*); nutrition services, nutrition and shock sensitive social protection, water and sanitation and early warning systems *(high confidence)*; and risk reduction schemes such as insurance *(medium confidence)*. [7.4.2.1.3]

The COVID-19 pandemic has demonstrated the value of coordinated and multi-sectoral planning, social protection systems, safety nets, and other capacities in societies to cope with a range of shocks and stresses *(high confidence)*. The pandemic posed a severe shock to many socio-economic systems, resulting in substantial changes in vulnerability and exposure of people to climate risks (*high confidence*). The pandemic underscores the interconnected and compound nature of risks, vulnerabilities, and responses to emergencies that are simultaneously local and global *(high confidence).* Pathways to climate resilient development can be pursued simultaneously with recovering from the COVID-19 pandemic *(high confidence).* The COVID-19 pandemic has aggravated climate risks, demonstrated the global and local vulnerability to cascading shocks, and illustrated the importance of integrated solutions that tackle ecosystem degradation and structural vulnerabilities in human societies *(high confidence)*. [Cross-Chapter Box COVID in Chapter 7]

Transitioning toward equitable, low-carbon societies has multiple benefits for health and wellbeing *(very high confidence)*. Benefits for health and wellbeing can be gained from wide-spread, equitable access to affordable renewable energy (*high confidence*); active transport (e.g., walking and cycling) (*high confidence*); green buildings and nature-based solutions, such as green and blue urban infrastructure (*high confidence*), and by transitioning to a low-carbon, wellbeing-oriented and equity-oriented economy consistent with the aims of the Sustainable Development Goals *(high confidence)*. Plant-rich diets consistent with international recommendations for healthy diets, could contribute to lower greenhouse gas emissions while also generating health co-benefits, such as reducing ill health related to over-consumption of animal-based products *(high confidence)* [7.4.2*,* Cross-Chapter Box HEALTH in Chapter 7, 7.4.4]

Reducing future risks of involuntary migration and displacement due to climate change is possible through cooperative international efforts to enhance institutional adaptive capacity and sustainable development *(high confidence).* Institutional and cross-sectoral efforts to build adaptive capacity, coupled with policies aimed at ensuring safe and orderly movements of people within and between states, can form part of climate-resilient development pathways that reduce future risks of climate-related involuntary migration, displacement, and immobility *(medium confidence)*. In locations where permanent, government-assisted relocation becomes unavoidable, active involvement of local populations in planning and decision-making increases the likelihood of successful outcomes *(medium confidence)*. People who live on small island states do not view relocation as an appropriate or desirable means of adapting to the impacts of climate change *(high confidence)* [7.4.3, Cross-Chapter Box MIGRATE in Chapter 7]

Adaptation and development build peace in conflict-prone regions by addressing both the drivers of grievances that lead to conflict and vulnerability to climate change *(high confidence).* Environmental peacebuilding through natural resource sharing, conflict-sensitive adaptation, and climate-resilient peacebuilding offer promising avenues to addressing conflict risk but their efficacy is still to be demonstrated through effective monitoring and evaluation *(high confidence)*. However, formal institutional arrangements for natural resource management have been shown to contribute to wider cooperation and peacebuilding *(high confidence)* and gender-based approaches provide underutilised pathways to achieving sustainable peace *(medium confidence)*. Inclusion, cross-issue and cross-sectoral integration in policy and programming, and approaches that incorporate different geographical scales and work across national boundaries, can support climate resilient peace *(high confidence)* [7.4.5; 7.4.6].

7.1 Introduction

This chapter assesses peer-reviewed and selected grey literature published since the IPCC's Fifth Assessment Report (AR5) on the impacts and projected future risks of climate change for health, wellbeing, migration and conflict, taking into consideration determinants of vulnerability and the dynamic structure of human populations and communities. Particular attention is given to potential adaptation challenges and actions, as well as the potential of co-benefits for health associated with mitigation actions. AR5 presented strong evidence-based statements regarding the *likely*[2] impacts of climate change on health, migration, and conflict in two separate chapters on Human Health (Chapter 11) and Human Security (Chapter 12). The present chapter covers all topics found in AR5 Chapter 11 and sections 12.4 (Migration and Mobility Dimensions of Human Security), 12.5 (Climate Change and Armed Conflict), and 12.6 (State Integrity and Geopolitical Rivalry), and provides additional, expanded assessment of mental health impacts, gender dimensions of climate risks, and solution pathways.

7.1.1 Major Health-related Statements in AR5

AR5 stated with very high confidence that the health of human populations is sensitive to climate change (Smith et al., 2014). Specific observations of current impacts included the expansion of the geographical ranges of some diseases into previously unaffected areas and changes in the distributions of some food-, water- and vector-borne diseases *(high confidence)*. Increasing future health risks were projected from injury, disease, and death due to more intense heat waves and fires *(very high confidence)*, undernutrition in poor regions *(high confidence)*, food- and water-borne diseases *(very high confidence),* and vector-borne diseases *(medium confidence)*. AR5 found that climate change is a multiplier of existing health vulnerabilities, including insufficient access to safe water and improved sanitation, food insecurity, and limited access to health care and education, and that the most effective measures to reduce vulnerability in the near term are programmes that implement and improve basic public health *(very high confidence)*. Opportunities for co-benefits from mitigation actions were identified, through such actions as reducing local emission of short-lived climate pollutants from energy systems *(very high confidence)* and transport systems that promote active travel *(high confidence)*. The significant growth in peer-reviewed publications on links between climate change and human health and wellbeing since AR5 allowed for a more detailed and wider reaching assessment in the present chapter and stronger confidence statements for many climate-sensitive health outcomes.

7.1.2 Major Statements About Migration and Conflict in AR5

Key statements made in AR5 Chapter 12 (Human Security) about the impacts of climate change on migration were that climate change will have significant impacts on forms of migration that compromise human security, and that mobility is a widely used strategy to maintain livelihoods in response to social and environmental changes (*high agreement, medium evidence*). Research on the influence of climate change and climate extremes on multiple forms of migration (including voluntary migration, involuntary displacement, and immobility) has expanded significantly since AR5, which has allowed for a more robust assessment in this chapter, with migration also featuring in most other sectoral and regional chapters of this report as well. With respect to violent conflict, AR5 Chapter 12 found that people living in places affected by violent conflict are particularly vulnerable to climate change (*medium evidence, high agreement*), that some of the factors that increase the risk of violent conflict within states are sensitive to climate change (*medium evidence, medium agreement*). and that climate change will lead to new challenges to states and will increasingly shape both conditions of security and national security policies (*medium evidence, medium agreement*). As with other subjects assessed in this chapter, there has been significant growth in the number of assessable studies, but there remain shortcomings with respect to the availability of evidence regarding the specific nature of causal linkages and the attributability of particular outcomes to climate events or conditions.

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

7.1.3 Important Developments Since AR5

7.1.3.1 International Agreements

Since AR5, several new international agreements came into effect that have implications for international responses to climate risks assessed in this chapter. The 2015 Paris Agreement, which explicitly mentions health in three separate sections, set new goals for adaptation, and established a working group to study the effects of climate change on population displacement. The seventeen United Nations (UN) Sustainable Development Goals (SDGs) for 2030, adopted in 2015, are all important for building adaptive capacity in general, with goals 13 ("Climate Action") and 3 ("Good Health and Wellbeing") being directly relevant for this chapter. Other SDG goals contain specific targets that are also relevant for this chapter, including Target 10.7 ("Well-managed migration policies"), Target 8.3 ("Decent work for all") and Target 5.4 ("Promotion of peaceful and inclusive societies") (Piper, 2017). The 2015 Sendai Framework for Disaster Risk Reduction, puts an emphasis on health and wellbeing (Aitsi-Selmi and Murray, 2016) In 2018, UN members states negotiated Global Compacts for Safe, Orderly and Regular Migration and on Refugees that, taken together with the Paris Agreement, provide pathways for coordinated international responses to climate-related migration and displacement (Warner, 2018). Since AR5, the UN system has been reforming its Peace and Security agenda, as part of a larger series of reforms initiated by the Secretary-General in 2017, and under the 2018 Climate Security Mechanism.

7.1.3.2 IPCC Special Reports

All three post-AR5 IPCC Special Reports considered some of the research that is assessed here in greater detail. The 2018 report on 1.5° C (SR1.5) included a review of climate change and health literature published since AR5 and called for further efforts for protecting health and wellbeing of vulnerable people and regions (Ebi et al., 2018b), and highlighted links between climate change hazards, poverty, food security, migration, and conflict. The 2019 Special Report on Climate Change and Land (SRCCL) (SRCCL, 2019) emphasized the impacts of climate change on food security; highlighted links between reduced resilience of dryland populations, land degradation migration, and conflict; and raised concerns about the impacts of climate extremes. The 2019 Special Report on the Ocean and Cryosphere in a Changing Climate (Pörtner et al., 2019) detailed how changes in the cryosphere and ocean systems have impacted people and ecosystem services, particularly food security, water resources, water quality, livelihoods, health and wellbeing, infrastructure, transportation, tourism, and recreation, as well as the culture of human societies, particularly for Indigenous peoples. It also noted the risks of future displacements due to rising sea levels and associated coastal hazards.

7.1.4 Interpretation of "Health and Wellbeing" Used in This Chapter

Assessing the links between human health, wellbeing, and climate change is a new task for AR6, reflecting a broad perspective on health that increasingly acknowledges the importance of wellbeing and its interactions with individual and population health. The World Health Organization (WHO) defines health as "a state of complete physical, mental and social wellbeing and not merely the absence of disease or infirmity" (Organization, 1946). Although this chapter assesses physical health, mental health, and general wellbeing separately, they are interconnected; any type of health problem can reduce overall wellbeing, and vice versa. For example, a child receiving inadequate nutrition may not be sick, but is experiencing a clear threat to wellbeing that has implications for future physical and mental health.

There is no consensus definition of wellbeing, but it is generally agreed that it includes a predominance of positive emotions and moods (e.g. happiness) compared with extreme negative emotions (e.g. anxiety), satisfaction with life, a sense of meaning, and positive functioning, including the capacity for unimpaired cognitive functioning and economic productivity (Diener and Tay, 2015) (Piekałkiewicz, 2017). A capabilities approach (Sen, 2001) focuses on the opportunity for people to achieve their goals in life (Vik and Carlquist, 2018) or the ability to take part in society in a meaningful way: the result of personal freedoms, human agency, self-efficacy, an ability to self-actualize, dignity and relatedness to others (Markussen et al., 2018). An Indigenous perspective on wellbeing is broad and typically incorporates a healthy relationship with the natural world (Sangha et al., 2018); emotional and mental health have also been linked to a strong cultural identity (Butler et al., 2019);(Dockery, 2020). "Health" itself is sometimes described as including relationships between humans and nature as well as links to community and culture (Donatuto et al., 2020);(Dudgeon et al., 2017)

Subjective wellbeing is consistently associated with personal indicators such as higher income, greater economic productivity, better physical health (Diener and Tay, 2015);(Delhey and Dragolov, 2016);(De Neve et al., 2013), and environmental health; and associated with societal indicators such as social cohesion and equality (Delhey and Dragolov, 2016). In a global sample of over 1 million people obtained between 2004-2008 via the Gallup World Poll, annual income and access to food were strong predictors of subjective wellbeing, and a healthy environment, particularly access to clean water, was also associated even when household income was controlled (Diener and Tay, 2015). Access to green spaces is also associated with wellbeing (high confidence) (Lovell et al., 2018);(Yuan et al., 2018).

7.1.5 Toward Socio-Ecological Perspectives on Health, Wellbeing, and Loss and Damage

Since the AR5, more comprehensive frameworks for framing and studying global health issues, including planetary health, 'one health', and eco-health, have gained traction. These frameworks share an ecological perspective, emphasize the role of complex systems, and highlight the need for interdisciplinary approaches related to human health research and practice (Lerner and Berg, 2015);(Zinsstag et al., 2018);(Whitmee et al., 2015);(Steffen et al., 2015). These frameworks increasingly shape the evidence related to climate change health impacts and response options, highlight the dynamics of complex systems in risk management, and direct risk management efforts in new directions.

Building on these frameworks and perspectives, there is increasing overlap in literature on global health, climate change impacts, and estimates of loss and damage. The Global Burden of Disease study for 2019 now includes non-optimal temperature as a risk factor (Murray et al., 2020). Work by social scientists continues to explore how climate change indirectly affects resource availability, productivity, migration, and conflict (Burke et al., 2015a);(Carleton and Hsiang, 2016);(Hsiang et al., 2017), bringing multiple lines of inquiry together to study the associations between global environmental changes, socio-economic dynamics, and impacts on health and wellbeing. Morbidity associated with migration and displacement, especially in the context of small island states, has been called out as a non-material form of loss and damage (Thomas and Benjamin, 2020);(McNamara et al., 2021). Social costs of carbon estimates have been updated to include excess mortality associated with climate change, increasing estimates substantially (Dressler, 2021).

7.1.6 Developments Relevant to Tracking and Assessing Climate Change Impacts on Health

Since AR5 there has been a steady increase in standardized, globally scoped, data-driven health impact assessments, signified by the ongoing Global Burden of Disease study (James et al., 2018) that now includes scenario-based projections (Foreman et al., 2018) and its linkages with other global priorities, including the SDGs (Fullman et al., 2017). Attention has turned from prioritizing specific diseases like HIV/AIDS, malaria, and tuberculosis, to strengthening health systems and providing universal health coverage (Chang et al., 2019), accompanying an ongoing emphasis on the social determinants of health. Several climate-sensitive health outcomes are now tracked in the annual Lancet Countdown reports (Watts et al., 2015);(Watts et al., 2017);(Watts et al., 2018b);(Watts et al., 2019);(Watts et al., 2021). The Global Burden of Disease study is beginning to examine climate sensitive disease burdens, incorporate temperature as a risk factor(Murray et al., 2020), and project future cause-specific disease burdens in a warming world (Burkart et al., 2021). Although not assessed in this chapter, there are numerous ongoing assessments of climate change impacts on health and wellbeing being undertaken by national and local health authorities that continue to generate insights into climate-related health impacts and suggest response options relevant for decision makers.

While the knowledge base regarding global health has increased, a comprehensive framework is not in place that fully integrates health, wellbeing, and environmental impacts from climate change allowing for the cumulative assessment of their impact. Moreover, significant cracks in the foundation of global health governance that affect preparedness and adaptive capacity for climate change, among other threats, have been laid bare (Phelan et al., 2020); (Defor and Oheneba-Dornyo, 2020); (Ostergard et al., 2020); (A, 2021). While attention to climate change and health has increased (Watts et al., 2019) and there is evidence of increasing adaptation activity in the health sector (Watts et al., 2019), there is also continued evidence of substantial adaptation gaps (UNEP, 2018);(UNEP, 2021) including gaps in humanitarian response capacity for climate-related disasters (Watts et al., 2021), that appear to be widening as adverse climate change impacts on health and wellbeing accrue.

7.1.7 Hazards, Exposure and Vulnerability in the Context of Human Health, Wellbeing and Changing Structure of Communities

7.1.7.1 Possible Climate Futures and Hazards from AR6 WGI

This chapter uses the conceptual framing described in Chapter 1, in which risks emerging from climate change are described in terms of hazard, exposure, and vulnerability, with adaptation and climate-resilient development being responses that have the potential to reduce or modify risk. The observed and projected future risks to health, wellbeing, involuntary population displacements, and conflict identified in this chapter are associated with a range of hazards that are manifested at a variety of geographical and temporal scales. These include observed and projected changes in climate normals, changes in the frequency, duration, and or severity of extreme events, and hazards such as rising sea levels and extreme temperatures where the impacts have only begun to be widely experienced. The 2021 report of IPCC Working Group I provides an assessment of observed and projected changes in these hazards and is the backdrop against which assessments of future risks and adaptation options identified in the present chapter should be considered. The exposure to such hazards of populations, infrastructure, ecosystem capital, socio-economic systems, and cultural assets critical to health and wellbeing varies considerably across and within regions. Exposure is also projected to vary across and within regions over time, depending on future greenhouse gas (GHG) emissions pathways and development trajectories (Figures 7.1 a and b). For this reason, region-specific assessments of climate-related risks for health, displacement and conflict are found in each of the regional chapters of this report in addition to the general assessment that appears in this chapter.

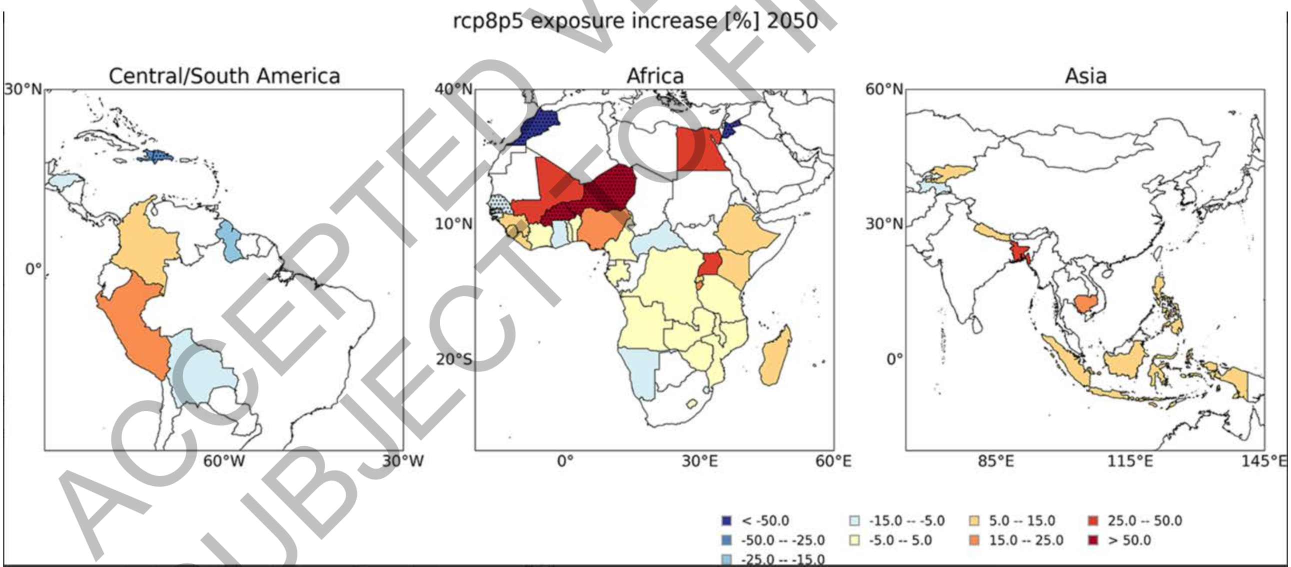

Figure 7.1a: Projected exposure of poor people to floods in selected regions by 2050 under a high emissions scenario (RCP 8.5) (Winsemius et al., 2018)

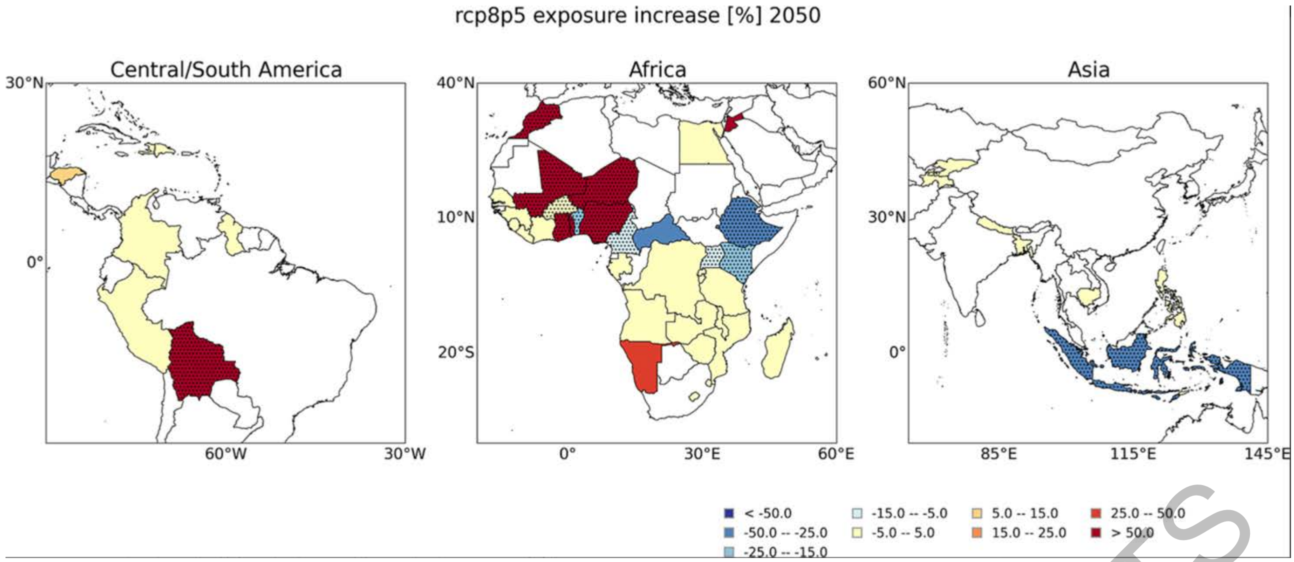

Figure 7.1b: Projected exposure of poor people to droughts in selected regions by 2050 under a high emissions scenario (RCP 8.5) (Winsemius et al., 2018)

7.1.7.2 *Differential Vulnerability and Cascading Effects*

Vulnerability to climate change varies across time and location, across communities, and among individuals within communities, and reflects variations and changes in macro-scale non-climatic factors (such as changes in population, economic development, education, infrastructure, behaviour, technology, and ecosystems) and individual- or household-specific characteristics, such as age, socioeconomic status, access to livelihood assets, pre-existing health conditions and ability, among others (Program, 2016); Chapter 1).

Many direct and indirect effects of climate change pose multiple threats to human health and wellbeing, and can occur simultaneously, resulting in compounding or cascading impacts for vulnerable populations. For example, many of the long-term impacts of climate change on non-communicable diseases and injury described in sections 7.2 and 7.3 are associated with future increases in air temperatures and levels of air pollution; in many regions, and especially in large urban centres in Asia and Africa, these particular hazards are already causing substantial increases in morbidity and mortality due to respiratory illnesses (Tong et al., 2016). Climate change can therefore be expected to magnify such health risks over the long term.

At the same time, urban populations will also be experiencing indirect risks through climate change impacts on food and potable water systems, variations in the distribution and seasonality of infectious diseases, and growing demand for shelter due to increased in-migration. The accumulation of these risks over time can be expected to generate accelerating declines in community resilience and health, with future vulnerability potentially expanding in a non-linear fashion (Dilling et al., 2017);(Liang and Gong, 2017);(El-Zein and Tonmoy, 2017);see also Chapter 6). Further, although each individual risk in isolation may be transitory or temporary for the individuals or groups exposed, taken cumulatively the impacts could create conditions of chronic lack of wellbeing, and early-life experiences with specific illnesses and conditions could have lifelong consequences (Watts et al., 2015);(Otto et al., 2017);(Organization, 2018a). In this context, there is a distinct need for greater longitudinal research on vulnerability to multiple climatic and non-climatic health and wellbeing hazards over time (Fawcett et al., 2017). There is also need for more research to identify critical thresholds in social vulnerability to climate change (Otto et al., 2017); these include rapid, stepwise changes in vulnerability that emerge from changes in exposure (for example, air temperatures above which mortality rates or impacts on pre-natal health accelerate (Arroyo et al., 2016);(Ngo and Horton, 2016);(Abiona, 2017);(Auger et al., 2017); (Molina and Saldarriaga, 2017); (Zhang et al., 2017b)) and thresholds in adaptation processes (such as when rural out-migration rates grow due to climate-related crop failures (McLeman, 2017).

In virtually all of the research identifying particular climate-related risks to health, wellbeing, migration and conflict, specific types of individuals are identified as having higher levels of vulnerability and exposure to climate-related health hazards: people who are impoverished, undernourished, struggle with chronic or repeated illnesses, live in insecure housing in polluted or heavily degraded environments, work in unsafe conditions, are disabled, have limited education, and/or have poor access to health and social infrastructure (Organization, 2018a). Their disproportionate exposure to ongoing climate hazards and their inability to recover from extreme events, increase not only their own vulnerability, but also that of the wider communities in which they live (USGCRP, 2016). Highly vulnerable populations are not evenly distributed across regions (Figure 7.2) nor within countries. Yet even those fortunate enough to live in better neighbourhoods with greater financial means, higher-paying jobs, and good access to resources and services, may experience adverse climate-related outcomes through community-level interactions and linkages (Haines and Ebi, 2019). Increased inequity itself threatens wellbeing, and an effective response to climate change should not only avoid increased inequity but identify ways in which to reduce existing inequity.

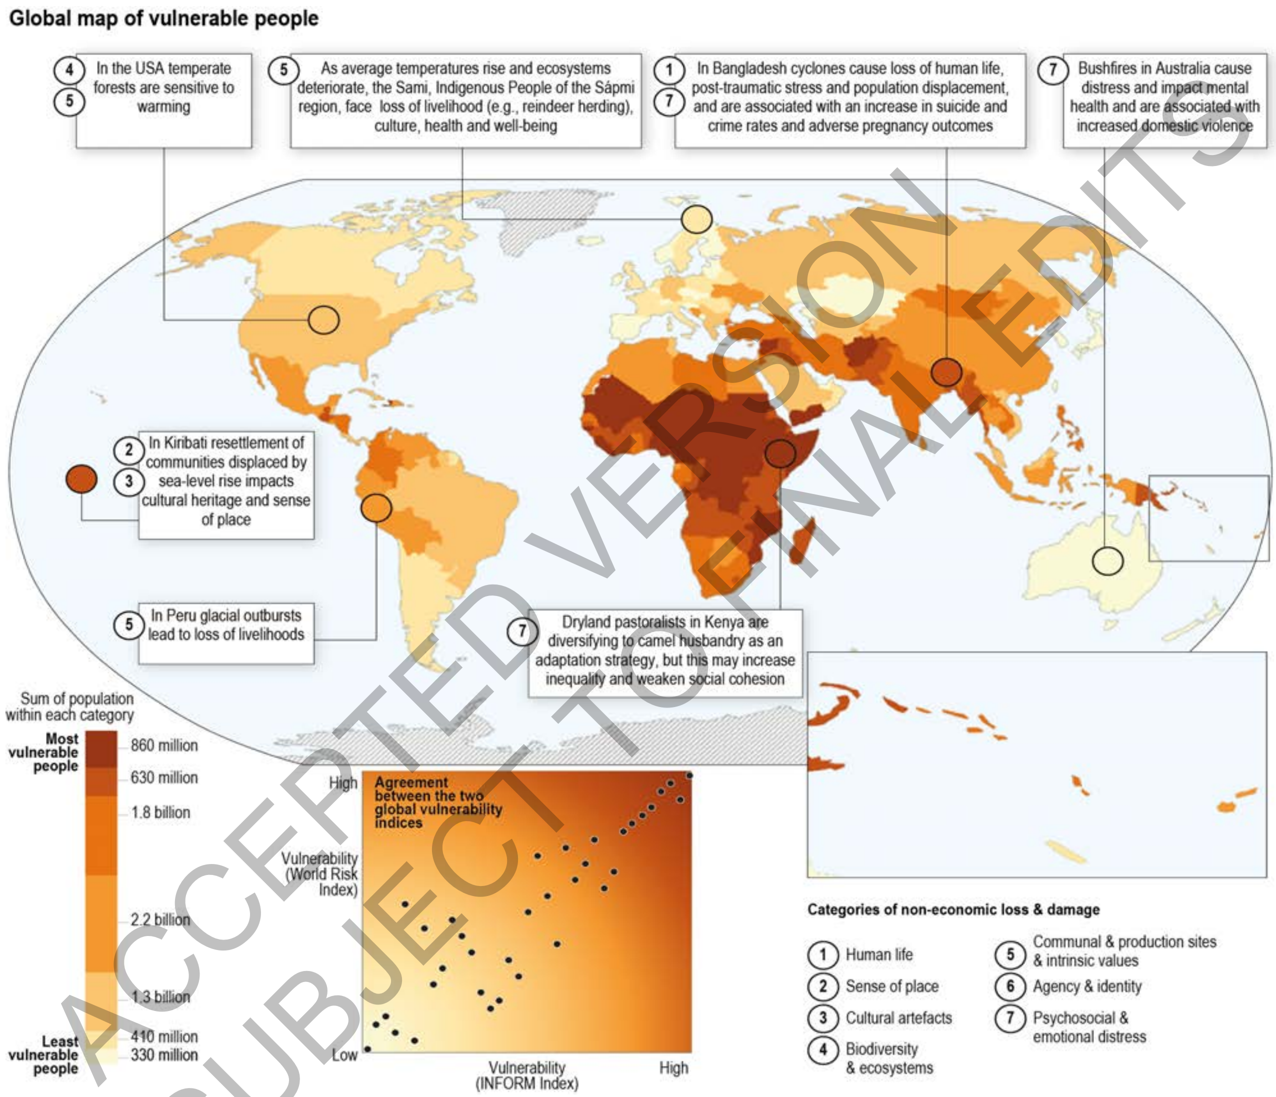

Figure 7.2: Global distribution of vulnerable people from two indices, with examples (from Technical Summary, this report)

7.1.7.3 Heightened Vulnerability to Climate-related Impacts on Health and Wellbeing experienced by specific groups and through specific pathways

7.1.7.3.1 Women and Girls

Climate change poses distinct risks to women’s health. Vulnerability to climate-related impacts on health and wellbeing shows notable differentiations according to gender, beyond implications for pregnant women. In many societies, differential exposure to such risks relate to gendered livelihood practices and mobility options. Pregnancy and maternal status heighten vulnerability to heat, infectious diseases, foodborne infections, and air pollution (Arroyo et al., 2016);(Ngo and Horton, 2016);(Zhang et al., 2017b). Extreme heat events, high ambient temperatures, high concentrations of airborne particulates, water-related illnesses, and natural hazards are associated with higher rates of adverse pregnancy outcomes such as spontaneous abortion, stillbirth, low birth weight, and preterm birth (Arroyo et al., 2016);(Ngo and Horton, 2016);(Abiona, 2017);(Auger et al., 2017);(Molina and Saldarriaga, 2017); (Zhang et al., 2017b). Women and girls are at greater risk of food insecurity (FAO, 2018; (Alston and Akhter, 2016), which is particularly problematic in combination with the nutritional needs associated with pregnancy or breastfeeding. Women and girls are more likely to die in extreme weather events (Garcia and Sheehan, 2016);(Yang et al., 2019). Women are also expected to face a greater mental health burden in a changing climate (Manning and Clayton, 2018). Further, climatic extremes and water scarcity are associated with increases in violence against girls and women (Anwar et al., 2019); (Opondo et al., 2016); (Le Masson et al., 2016);(Udas et al., 2019).

7.1.7.3.2 Children

Children often have unique pathways of exposure and sensitivity to climate hazards, given their immature physiology and metabolism, and high intake of air, food, and water relative to their body weight as compared with adults (USGCRP, 2016). Climate change is expected to increase childhood risks of malnutrition and infectious disease for children in low-income countries through its impacts on household food access, dietary diversity, nutrient quality, water, and changes in maternal and childcare access and breastfeeding (Tirado, 2017);(FAO et al., 2018); (Perera, 2017)). Children living in locations with poor sanitation are especially vulnerable to gastro-intestinal illnesses, with future rates of diarrheal diseases among children expected to rise under many climate change scenarios (Cissé et al., 2018);(WHO, 2014). Outdoor recreational opportunities for children may be reduced by extreme weather events, heat, and poor air quality (Evans, 2019)). Children and adolescents are particularly vulnerable to post-traumatic stress after extreme weather events, and the effects may be long-lasting, with impacts even on their adult functioning (Brown et al., 2017; UNICEF, 2021);(Thiery et al., 2021)

7.1.7.3.3 Elderly

Population age structures and changes over time have a significant influence on vulnerability to the impacts of weather and climate. Older adults (generally defined as persons aged 65 and older) are disproportionately vulnerable to the health impacts associated with climate change and weather extremes, including a greater risk of succumbing to waterborne pathogens, due to less well-functioning thermoregulatory mechanisms, greater sensitivity to dehydration, changes in immune systems, and greater likelihood of having pre-existing chronic illnesses such as diabetes or respiratory, cardiovascular, and pulmonary illnesses (Benmarhnia et al., 2016);(Diaz et al., 2015);(Mayrhuber et al., 2018);(Paavola, 2017). Older adults may be less prompt in seeking medical attention when suffering from gastrointestinal illness, which can lead to dehydration (Haq and Gutman, 2014). Åström et al. (2017) anticipate heat-related mortality among the elderly in Europe to rise in the 2050s under RCP 4.5 and RCP 8.5 in the absence of significant preventative measures. In a study of the combined effects of warming temperatures and an aging population in Korea, Lee & Kim (Lee and Kim, 2016) projected a four- to six-fold increase in heat-related mortality by the 2090s when accounting for temperature and age structure.

7.1.7.3.4 Socio-economically Marginalized Populations and People with Disabilities

People living in poverty are more likely to be exposed to extreme heat and air pollution, and have poorer access to clean water and sanitation, accentuating their exposure to climate change-associated health risks (UNEP, 2021);(FAO et al., 2018). Poverty influences how people perceive the risks to which they are exposed, how they respond to evacuation orders and other emergency warnings, and their ability to evacuate or relocate to a less risk-prone location (USGCRP, 2016). Poorer households, who often live in highly exposed locations, are more likely to be forced into low-agency migration as a means of adapting to climate risks, and at the same time are the most likely to be immobile or trapped in deteriorating circumstances where migration would be a preferred response (Leichenko and Silva, 2014);(Fazey et al., 2016);(Sheller, 2018). Climate emergencies disproportionally affect people with disabilities because of their inherent vulnerabilities, which may impair their ability to take protective action; they are also frequently excluded from adaptation planning (Gaskin et al., 2017)

7.1.7.3.5 Urban vs Rural Populations

Rural and urban populations are often exposed to different types of climate-related health risks. For example, because of the urban heat island and high concentrations of motor vehicle pollution and industrial activity, people who live in urban areas may have higher rates of exposure to extreme heat stress and air-quality-related respiratory illnesses than rural counterparts (Hondula et al., 2014);(Heaviside et al., 2016);(Macintyre et al., 2018);(Schinasi et al., 2018). Conversely, rural populations, especially those dependent on resource-based livelihoods, may have a greater exposure to climate impacts on food production or natural hazard events, which have subsequent effects on household nutrition and food security (Springmann et al., 2016a); see also Chapters 5 & 6 of this report).

7.1.7.3.6 Indigenous People

Indigenous Peoples, especially those that live in geographically isolated, resource-dependent, and/or impoverished communities, are often at greater risk of health impacts of climate change (Ford et al., 2020) (USGCRP, 2016). The close interconnection of land-based livelihoods and cultural identity of many Indigenous groups exposes them to multiple health- and nutrition related hazards (Durkalec et al., 2015);(Sioui, 2019), with potential implications for community social relations and for individuals' mental health (Cunsolo Willox et al., 2013);(Cunsolo Willox et al., 2015). Climate change risk exposures may be complicated by changes in lifestyle, diet, and morbidity driven by socio-economic processes, further increasing health risks for Indigenous peoples (Jaakkola et al., 2018). Environmental consequences of climate change can also affect social ties and spiritual wellbeing, in part because land is often an integral part of their culture and spiritual identity.

[INSERT BOX 7.1 HERE]

Box 7.1: Indigenous Peoples' Health and Wellbeing in a Changing Climate

The Indigenous population worldwide is estimated at 476 million people spread across all geographic regions of the world (CIAT and and, 2021). Indigenous Peoples globally represent a large heterogeneity of people in terms of living conditions and social determinants of health. There is no simple definition of who is Indigenous. In this text, we refer to Indigenous Peoples as people self-identified and organized as Indigenous, according to the principles of the International Work Group for Indigenous Affairs (IWGIA), an International NGO with observer status at the United Nations. In addition, the United Nations describes Indigenous Peoples as "distinct social and cultural groups that share collective ancestral ties to the lands and natural resources where they live, occupy or from which they have been displaced" (Organization, 2021). A common experience among Indigenous Peoples are historical traumas related to overseas and/or settler/industrial colonisation.

Studies on climate change as it affects the health of Indigenous Peoples generally focus on non-displaced Indigenous groups, i.e., Indigenous people maintaining culturally important elements of a land-based traditional lifestyle. Here we use an eco-medicine perspective, in which the impacts of climate change on health are divided into primary, secondary, and tertiary effects; discussed below (Butler and Harley, 2010). Many analyses of Indigenous health in relation to climate change use the One Health concept (Mackenzie and Jeggo, 2019); (see 7.1.5).

Current Impacts of Climate Change on Health and Wellbeing of Indigenous Peoples

Primary health effects of climate change include the immediate physical effects on human health, such as health hazards due to high temperatures, extreme weather events, or accidents from exposure to a climate-related hazards. For example, in arid and semi-arid areas, an increased frequency of severe droughts is associated with immediate health problems related to overheating, and lack of water for drinking, sanitation and livestock (Hall and Crosby, 2020);(Mamo, 2020);(Rankoana, 2021). In many cases, the possibilities for Indigenous people to apply traditional strategies to mitigate droughts by migration are limited by competing land use, environmental protection, and national borders, with many examples across Africa (Mamo, 2020). In the Jordan river valley, the second most water stressed area in the world, water resources are not equally distributed to Indigenous Bedouin people, amplifying their immediate health threat during predictable as well as unpredictable droughts (Mamo, 2020).

In Arctic and sub-Arctic areas, higher temperatures with increased numbers of freeze-thaw cycles during the winter means increased occurrences of transport-related accidents in Indigenous communities due to weaker ice on travel routes that cross lakes, rivers and sea, along with changes in the snow cover and increased risk of avalanches (Durkalec et al., 2015);(Jaakkola et al., 2018). Impeded access to health care during extreme weather conditions is a primary health risk for Indigenous Peoples living in remote areas (Amstislavski et al., 2013);(Hall and Crosby, 2020);(Mamo, 2020).

Pastoralists in many regions may experience changes in livestock behaviour due to climate change, leading to increased mobility-related health hazards (Jaakkola et al., 2018);(Mamo, 2020). Indigenous Peoples living in low lying coastal areas and small island states face long term risk of flooding and the stresses of resettlement (Maldonado et al., 2021);(McMichael and Powell, 2021)).

Extreme rainfall, flooding, storms, heat waves, and wildfires lead to individual health hazards that may include injuries and thermal and respiratory traumas (Mamo, 2020) There are many examples when emergency responses to extreme events have ignored the needs of displaced Indigenous Peoples (Mendez et al., 2020);(Maldonado et al., 2021). Population-based quantitative studies documenting the direct effects of these events on Indigenous Peoples are rare. In Mexico, respiratory diseases are almost twice as common among Indigenous people compared to non-Indigenous (de Leon-Martinez et al., 2020). In Alaska and Northern Canada alarming levels of respiratory stress and disease has been reported among Inuit and First Nation communities in relation to wildfires (Howard et al., 2021), as well as increased mold in houses due to flooding resulting from increased precipitation (Furgal and Seguin, 2006);(Harper et al., 2015);(Norton-Smith et al., 2016). Climate and housing related respiratory stress is also a risk factor for severe COVID-19 infection, which has been highlighted in recent literature from an Indigenous health perspective (de Leon-Martinez et al., 2020).

Secondary effects relate to ecosystem changes, for example, increased risk of the acute spread of airborne, soilborne, vector-borne, food-, and water-borne infectious diseases (Hueffer et al., 2019). Higher proportions of climate-related infectious diseases are reported among Indigenous groups compared to their non-Indigenous neighbours, with examples from Torres Strait, Australia, showing a greater proportion of tuberculosis, dengue, Ross River virus, melioidosis, and nontuberculous mycobacterial infections (Hall et al., 2021) and in the Republic of Sakha, Russia, high levels of zoonoses (Huber et al., 2020a). Increasing levels of livestock and canine diseases are also reported (Mamo, 2020);(Bogdanova et al., 2021);(Hillier et al., 2021). Another secondary health effect is an increase in human-animal conflicts, for example human-elephant conflicts in Namibia due to plant food scarcity (Mamo, 2020), human-bear conflicts in Arctic regions within Canada (Wilder et al., 2017), human-tiger conflicts in Bangladesh (Haque et al., 2015), and increased predatory pressure on Indigenous Peoples' livestock and game worldwide (Haque et al., 2015);(Jaakkola et al., 2018);(Mukeka et al., 2019);(Mamo, 2020);(Terekhina et al., 2021). Undernutrition and metabolic disturbances associated with overnutrition and obesity due to decreased availability or safety of local and traditional foods, and increased dependency on imported substitutes, affect many Indigenous Peoples worldwide (Amstislavski et al., 2013);(Zavaleta et al., 2018);(Houde et al., 2020);(Jones et al., 2020);(Akande et al., 2021);(Bogdanova et al., 2021);(Bryson et al., 2021), especially severe for pregnant women and small children (Mamo, 2020);(Olson and Metz, 2020);(Bryson et al., 2021); these are amplified by the combination of warming and the COVID-19 situation (Zavaleta-Cortijo et al., 2020). Decreased access to wild plants and animals as food sources and medicine due to climate change is another threat to the health and wellness of Indigenous communities (Greenwood and Lindsay, 2019);(Mamo, 2020);(CIAT and and, 2021);(Rankoana, 2021);(Teixidor-Toneu et al., 2021).

Tertiary effects relate to culture-wide changes; for example, all forms of malnutrition due to climate-driven changes in food systems; and anxiety, mental illness, and suicidal thoughts related to cultural and spiritual losses. A wide range of tertiary, culture-related effects of climate change have been documented for Indigenous Peoples. These include anxiety, distress and other mental health impacts due to direct and indirect processes of dispossession of land and culture related to the combination of climate change in and other factors (Richmond and Ross, 2009);(Bowles, 2015);(Norton-Smith et al., 2016);(Jaakkola et al., 2018);(Fuentes et al., 2020);(Mamo, 2020);(Middleton et al., 2020b);(Middleton et al., 2020a);(Olson and Metz, 2020);(Timlin et al., 2021). Increased risks of conflict and abuse, including violence and homicide against females, and/or resulting from environment activism, are other tertiary health threats for Indigenous Peoples (Mamo, 2020). Between 2017 and 2019, close to 500 Indigenous people were killed for activism in 19 different countries (Mamo, 2020). In Uganda, climate change drives Indigenous men to increase their distance and time from home and their families in search of water, food, and water, leading to an increase in sexual violence against Indigenous women and girls in their communities (Mamo, 2020).

Gender inequities amplify the tertiary health effects of climate change (Williams, 2018);(Garnier et al., 2020). In an Inuit community, for instance, women reported a higher level of mental stress related to climate change than men (Harper et al., 2015). Adverse pregnancy outcomes and altered developmental trajectories have also been associated with climate change (Hall et al., 2021). Indigenous Batwa women in Uganda reported experiencing more severe circumstances of food insecurity during pregnancy due to drought and unpredictable seasons negatively impacting agricultural practices (de Leon-Martinez et al., 2020). More studies with a gender perspective on climate change as a determinant of Indigenous Peoples' health are needed, along with the perspectives of Indigenous children and youth, displaced individuals, and communities in urban settings (Kowalczewski and Klein, 2018).

Because cultural continuity is a recognized health factor (Lemelin et al., 2010);(de Leon-Martinez et al., 2020);(Middleton et al., 2020b) displaced Indigenous people may suffer from climate change by worrying about impacts on non-displaced relatives and family, and from traditional food staples turning into expensive commodified products. This is a knowledge gap with lasting implications not only on physical environments (Guo et al., 2018). Social connections and knowledge pathways are disrupted, leading to a decreased ability to share locally harvested and cultivated foods (King and Furgal, 2014);(Neufeld et al., 2020).

Tertiary effects of climate change on Indigenous Peoples' health are primarily described in smaller case studies and not designed in a way allowing for systematic international comparisons, which represents an important and significant gap in our understanding of these often-complex associations and impacts (Middleton et al., 2020b).

Future Risks for Indigenous People's Health and Wellbeing in a Changing Climate

Future risks for Indigenous Peoples' health and wellbeing in a changing climate will result foremost from exacerbations of observed impacts. Primary and secondary health risks are expected to increase as the frequency and/or severity of climate hazards grow in many regions. As one example, melting permafrost in the Siberian Arctic is projected to lead to more outbreaks of anthrax (Bogdanova et al., 2021). Tertiary health threats are expected to persist even with strong global initiatives to mitigate greenhouse gases (Butler and Harley, 2010). Climate change is expected to compound non-climatic processes that lead to social exclusion and land dispossession that underlay health inequalities experienced by Indigenous peoples (Huber et al., 2020a).

Options and Opportunities for Reducing Future Risks and Building Capacity/Resilience for Indigenous Peoples' Health and Wellbeing

Indigenous organizations worldwide stress the importance of applying a rights-based approach in responding to climate change (Mamo, 2020). Although Indigenous Peoples are often identified as being vulnerable to climate change, this framing does not always reflect the diverse responses and adaptations of Indigenous Peoples to these on-going challenges (Nursey-Bray et al., 2020). An emerging body of research is focusing on the strength and resilience of Indigenous communities globally as they adapt to these complex changes (Whyte, 2018);(CIAT and and, 2021).

During droughts and water shortages, for example, Indigenous pastoralists may face additional challenges if water supply assistance provides only for human needs and neglects water requirements of livestock (Mamo, 2020). Indigenous knowledge on how to adapt to drought, through storing and sharing strategies, for example, is valuable (Fatehpanah et al., 2020);(Mamo, 2020).

Indigenous Peoples have been adapting to changes in their environments since time immemorial by developing new practices and techniques (CIAT and and, 2021). Their beliefs, value systems, and principles include core elements and common values such as reciprocity, solidarity, co-responsibility, and community that are expressed in the dynamism of their knowledge systems (Lewis et al., 2020);(Schramm et al., 2020b). The relevance of these knowledge systems, which are holistic and tied to relationships between all living things, cannot be ignored at this critical time (Garnier et al., 2020).

The health and equity impact of climate change for Indigenous Peoples make mitigation efforts critical (Jones et al., 2020), which includes policies and actions consider the effects of colonization. Colonization constrains the design and diversity of potential climate and health responses through its historic and ongoing suppression of Indigenous knowledge systems that are critical in supporting community-led actions to reduce future risks (Billiot et al., 2019; Reid et al., 2019) (Nursey-Bray et al., 2020).

Four Brief Case Studies to Illustrate the Innovativeness of Indigenous Peoples' Adaptation to Climate Risks

Bedouin Pastoralists' Grazing Practices Decrease the Risk of Wildfires in Israel and Increase Food Sovereignty.

Wildfires are a main cause of deforestation in Israel, and in recent years climate stress decreased the forest resilience to fires (Klein et al., 2019). The original landscape, a shrubland or maquis consisting mostly of oak and pistacia, has been used since time immemorial as grazing land for goats, sheep, and camels belonging to Indigenous Bedouin people (Degen and El-Meccawi, 2009). Competing land use has reshaped the landscape with pine monocultures and cattle farming, reducing the availability of land suitable for herding goats the Indigenous way (Perevolotsky and Sheffer, 2011). In addition, since 1950, plant protection legislation has decreased Bedouin forest pastoralism in Israel, by defining Indigenous black goats as an environmental threat (FAOLEX, 2021). In nature reserves where no human interference has been allowed, these areas have regenerated into herbaceous shrublands susceptible to wildfires (Turco et al., 2017). Meanwhile, urbanized Bedouin exist on lower incomes and experience higher level of unemployment compared to other citizens, and some keep non-pastoralized livestock in cities as a strategy for food sovereignty (Degen and El-Meccawi, 2009). In 2019, many severe wildfires occurred in Israel due to extreme heat waves and, in response, plant protection legislation was appealed, allowing Bedouin pastoralists to graze their goats in areas from which they had been excluded. The amount of combustible undergrowth subsequently decreased, reducing the risk for wildfire and their related impacts, while simultaneously facilitating Indigenous food sovereignty among the Bedouin (Mamo, 2020).

Gardening in the Ashes of Wildfires in the Pacific Northwest as a Strategy to Decrease Food Insecurity and Increase Connections With the land

In the central interior of what is now known as British Columbia, 2017 was an especially severe wildfire season, with over 1.3 million hectares of land burned and 65,000 people displaced (Timler and Sandy, 2020). The unceded and ancestral lands of the Tsilhqot'in, Dakelh, and Secwépemc were impacted by two of the largest fires (Verhaeghe et al., 2017). Communities affected by the BC wildfires subsequently started Indigenous gardens closer to home, to protect medicine and food plants and thereby sustaining relationships with these plants, the land, and community (Timler and Sandy, 2020). As there are cultural teachings for fire to cleanse the territory and the land, community members and plants previously isolated became better connected because of the wildfires. The regrowth of plants is part of the healing relationship between people, plants, and other animals (Timler and Sandy, 2020). The wildfires were seen as events to catalyse action and emphasize the importance of relationships to support foodways and gardening as responsibility.

Widening our understanding of gardening, in the face of climate change and colonialism, can support health and healing for Indigenous and non-Indigenous Peoples. Gardening as a means of Indigenous food sovereignty has long been utilized by a variety of Indigenous groups within Canada and elsewhere to address circumstances of chronic food insecurity and support health and wellness (Johnson-Jennings et al., 2020);(Timler and Sandy, 2020). The concept of gardening as both a Euro-Western agricultural practice and Indigenous practice encourages an increased reverence and connection with the land, and wider engagement with the natural world (Whyte, 2018). Much of this is because Indigenous Knowledge and land management practices encompass processes that are known to be synergistic and sustainable (Ottenhoff, 2021). Indigenous worldviews offer a different perspective on social resilience to environmental change, one that is based on moral relationships of responsibility that connect humans to animals, plants, and habitats (Grey and Patel, 2015). These responsible practices not only ensure ecosystems are maintained for future generations. They centre the moral qualities necessary to carry out the responsibilities of consent, reciprocity, and trust.

Moral qualities of responsibility are the foundation for relying on each other when facing environmental challenges (Whyte, 2018);(Miltenburg et al., 2021).

To restore these sustainable relationships, a resurgence is needed of community roles and responsibilities (Cidro et al., 2015), as well as a reconsideration of the concept of food security and the role of gardening within diverse Indigenous contexts. Offering individual or community gardening as a solution to "food insecurity", a Euro-centric measure of health, ignores colonial contexts and sovereignty (Borrows, 2019);(Timler and Sandy, 2020). Indigenous communities have historic, ongoing, and evolving gardening and food gathering practices, including a wide variety of land-based and aquatic foods (Turner and Turner, 2008);(Mt. Pleasant, 2016). Euro-Western science is beginning to recognize these longstanding relationships (Kamal et al., 2015);(Hatfield et al., 2018);(Timler and Sandy, 2020). For many Indigenous communities, reconnecting with ancestral foodways holds the potential not only to address food security, but to provide the community cohesion, self-esteem, and wellness (Gordon et al., 2018).

A New Food Composition Database in Uganda May Guide Local Health Policy Workers in Healthy Eating Based on Indigenous Foods

In sub-Saharan Africa, climate change is an emerging risk factor for undernutrition, particularly in countries that rely on subsistence agriculture (Sorgho et al., 2020). In Uganda, negative health effects associated with climate change are being observed, including increased rates of food insecurity, with the highest rates recorded among the Batwa of Kanungu District, Uganda, where 97% of households are severely food insecure (Patterson et al., 2017). For many Indigenous Peoples, food security in a changing climate is a growing concern (Guyot et al., 2006);(Patterson et al., 2017). Locally harvested Indigenous foods have been adversely impacted by climate change, while connection to land is being disrupted by processes of colonization, discrimination, and lack of representation in decision-making groups, thereby restricting adaptive capacity for Indigenous communities (Bryson et al., 2021). In Uganda, the Indigenous Batwa have experienced significant disparities resulting from the forced eviction from their territory, dispossessing them of their land and ability to provide Indigenous foods to their families (Patterson et al., 2017);(Scarpa et al., 2021).

Nutrient specific knowledge of lndigenous foods is limited among many communities in Africa**.** A new food composition database in Uganda was constructed in dialogue with knowledge keepers from the Batwa and Bakiga Peoples, to assess the nutrient density of these locally harvested foods (Scarpa et al., 2021). As in other lower resource settings, no food composition tables are available for southwestern Uganda. The only existing food database was designed for central and eastern Uganda; it does not include common recipes and local foods consumed by Batwa and Bakiga communities (Scarpa et al., 2021). Using a community-based approach and collaboration with local nutritionists, a list of foods was collected through focus group discussions, an individual dietary survey, and market assessments. Including these locally familiar foods ultimately supports a focus on Indigenous justice and the importance of valuing Indigenous food systems and practices, which in many contexts have been found to have superior nutritional and environmental benefits for communities (Kuhnlein et al., 2013);(Scarpa et al., 2021). This new and unique database including Indigenous foods will not only guide local nutrition and health initiatives, but also contribute towards policies related to Indigenous food sovereignty and resilience to climate change.

Decreased Fragmentation of Winter Grazing Increases Mental and Spiritual Wellbeing in Reindeer Herding Sámi and Decreases their Dependency on Fossil Fuels

Sami are the Indigenous people of Northernmost Scandinavia and the Kola Peninsula of Russia, whose livelihoods have been traditionally sustained by reindeer herding, hunting, fishing and small-scale farming (Nilsson et al., 2011). Climate change is threatening core conditions for reindeer herding, with Sami pastoralists describing the situation as 'facing the limit of resilience' (Furberg et al., 2011). Sami pastoralists stress that an ability to continue reindeer herding is a prerequisite for their mental and spiritual health (Jaakkola et al., 2018).

In a pilot project for climate adaptation of reindeer herding run by the Swedish Sami Parliament, reindeer herding management plans (in Swedish, *renbruksplaner*) were used as a tool to develop strategies for climate adaptation (Walkepää, 2019). Four Sami reindeer herding cooperatives participated in the pilot study. They all agreed that climate change means that grazing patterns need to change. Traditionally, mountain reindeer graze in the Scandinavian mountains close to Norway in summertime, and in the coastal areas close to the Gulf of Bothnia in wintertime, representing a total migration route of up to 400 kilometres one-way. Rising temperatures are causing spring to occur earlier in the coastal winter grazing land, before the calving areas in the summer land are suitable for grazing and free from snow. When the snow cover disappears, the herds are dispersed, so it is important to migrate while snow is still present (Walkepää, 2019). Migration routes are being destabilized by weaker ice cover on water and by hazardous weather events. Competing land use due to infrastructure, extractive industries, tourism, and energy production makes it difficult to find alternative grazing land. Supplementary feeding and increased use of trucks to transport reindeer is one result. Herds that are dispersed due to bad snow conditions have an increased exposure to predators (Walkepää, 2019 (Walkepää, 2019);(Uboni et al., 2020). By working strategically to secure adequate winter grazing and reduce fragmentation of grazing areas more generally represents win-win strategies for achieving decreased mental stress levels while reducing herders' consumption of fossil fuels (Walkepää, 2019).

[END BOX 7.1]

7.1.7.3.7 Vulnerability Experienced through Food Systems

Stresses and shocks associated with climate change are drivers of food and nutrition security, particularly in sub-Saharan Africa, Asia, and Latin America (Betts et al., 2018). The most vulnerable groups include smallholder farmers, pastoralists, agricultural laborers, poorer households, refugees, Indigenous groups, women, children, the elderly, and those who are socio-economically marginalized (FAO et al., 2018);(SRCCL, 2019)*(high confidence)*. Men, women, children, the elderly and chronically ill have different nutritional needs, and these vulnerabilities may be amplified by gendered norms and differential access to resources, information and power (SRCCL, 2019). Extreme climate events have immediate and long-term impacts on food and nutrition insecurity of poor and vulnerable communities, including when women and girls need to undertake additional duties as laborers and caregivers (FAO et al., 2018).

7.1.7.3.8 Health Vulnerability Experienced through Water and Sanitation Systems

Water and sanitation systems are particularly vulnerable to extreme weather events, and damage to such systems can lead to contamination of drinking water and subsequent adverse health impacts (Howard et al., 2016);(Khan et al., 2015);(Sherpa et al., 2014). In areas with only very simple traditional excreta disposal facilities (e.g. latrines) and traditional sources of water (e.g. unprotected wells), the repeated occurrence of floods and other extreme events can negatively affect water quality at household and community levels, and increase the burden of food-borne and water-borne diseases (Cissé et al., 2016);(Khan et al., 2015);(Kostyla et al., 2015).

7.1.8 Visual Guide to this Chapter

Figure 7.3 provides a visual guide to this chapter. Section 7.1 has summarized major global frameworks and highlighted groups that exhibit heightened vulnerability to the climatic risks assessed in this chapter. Section 7.2 assesses observed impacts on health and wellbeing, migration and conflicts that have emerged from interactions of climate and weather-related hazards, exposure to such hazards, and vulnerability of communities and systems, while Section 7.3 assesses projected future risks. Section 7.4 assesses adaptation responses to climate risks, opportunities for transformative change, co-benefits, and how solutions for reducing climate impacts on health, wellbeing, migration, and conflicts may form part of wider climate resilient development pathways.

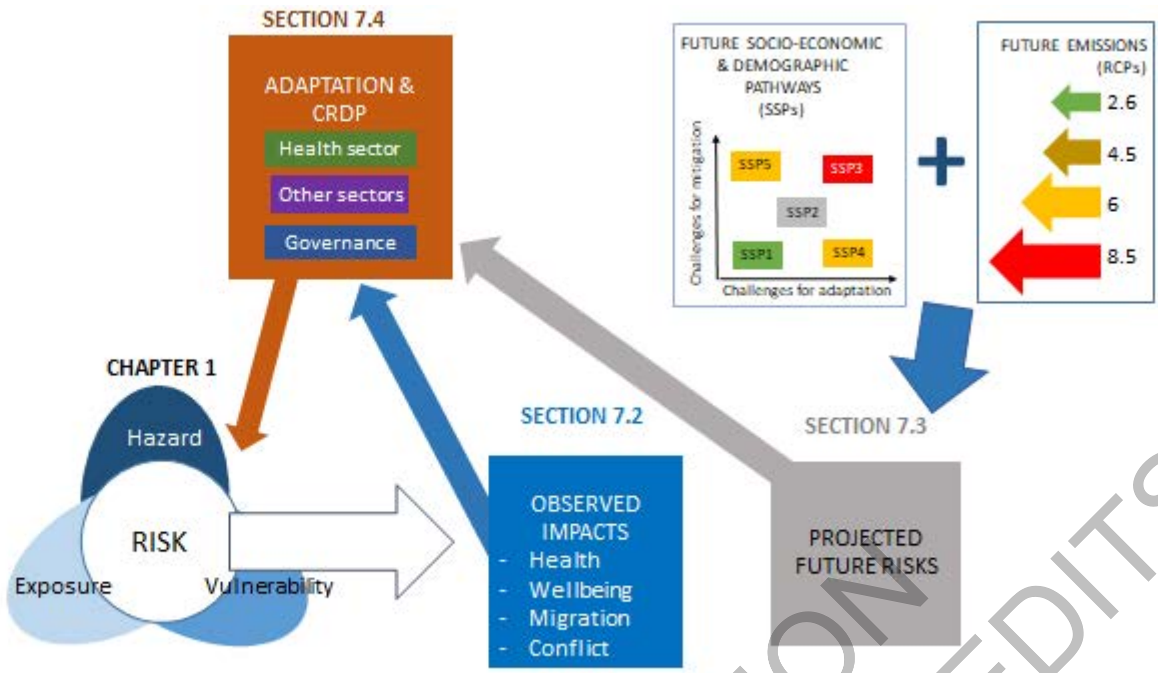

Figure 7.3: Structure of the chapter following a pathway from hazard, exposure and vulnerabilities to observed impacts, projected risks and solution space of adaptation and resilient development

7.2. Observed Impacts of Climate Change on Health, Wellbeing, Migration and Conflict

7.2.1 Observed Impacts on Health and Wellbeing

Eleven categories of diseases and health outcomes have been identified in this assessment as being climate-sensitive through direct pathways (e.g., heat, floods) and indirect pathways mediated through natural and human systems and economic and social disruptions (e.g. disease vectors, allergens, air and water pollution, and food system disruption) (high confidence). A key challenge in quantifying the specific relationship between climate and health outcomes is distinguishing the extent to which observed changes in prevalence of a climate sensitive disease or condition are attributable directly or indirectly to climatic factors as opposed to other, non-climatic, causal factors (Ebi et al., 2020). A subsequent challenge is then determining the extent to which those observed changes in health outcomes associated with climate are attributable to events or conditions associated with natural climate variability versus persistent human induced shifts in the mean and/or the variability characteristics of climate (i.e., anthropogenic climate change). The context within which the impacts of climate change affect health outcomes and health systems is described in this chapter as being a function of risk, which is in turn a product of interactions between hazard, exposure and vulnerability (Chapter 1), with the impacts in turn having the potential to reinforce vulnerability and/or exposure to risk (Figure 7.4).

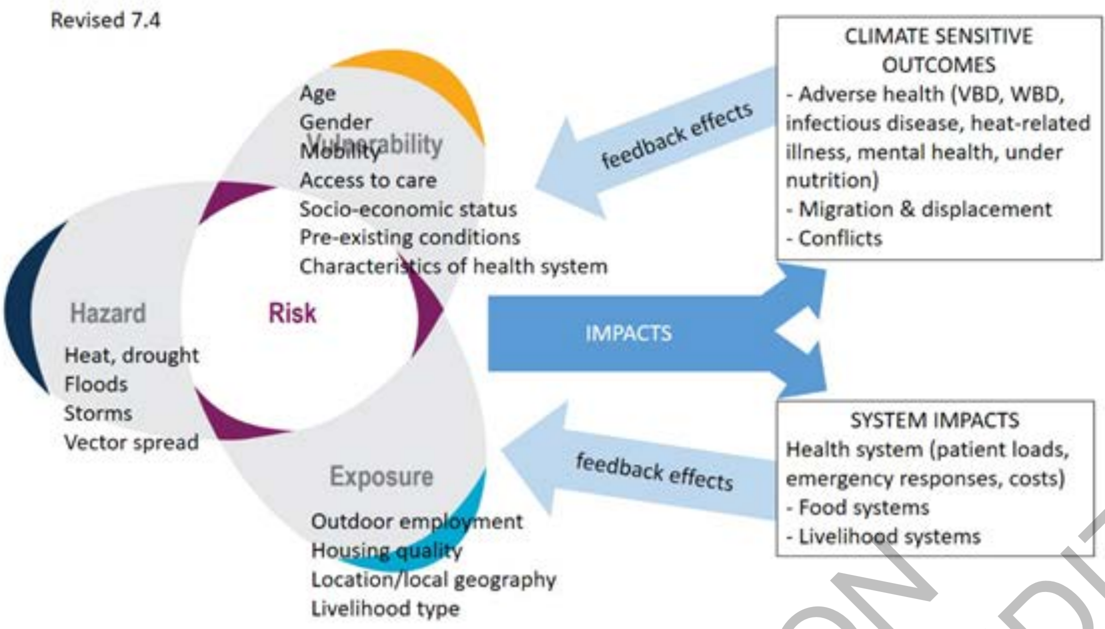

Figure 7.4: Interactions between hazard, exposure and vulnerability that generate impacts on health systems and outcomes, with selected examples.

[START BOX 7.2 HERE]

Box 7.2: The Global Burden of Climate-sensitive Health Outcomes Assessed in this Chapter

Global statistics for death and loss of health are increasingly described in terms of *burden*, which describes gaps between a population's actual health status and what its status would be if its members lived free of disease and disability to their collective life expectancy (Shaffer et al., 2019). Burden for each disease/health outcome is estimated by adding together the number of years of life a person loses because of early death (Years of Life Lost (YLL)) and the number of years a person lives with disability (Years of Life lived with Disability (YLD)) from the considered outcome. The resulting statistic, the Disability Adjusted Life Year (or DALY) represents the loss of one year of life lived in full health. The total global burden of disease (Collaborators and Injuries, 2020), expressed in DALYs, is what the world's health systems must manage, and is reported annually in Global Burden of Disease Study (Collaborators and Injuries, 2020). The estimated current global burden of climate sensitive diseases and conditions described in this chapter, and the geographical regions most affected, are summarized in Table Box 7.2.1. As was observed in the Health chapter of AR5, the "background climate-related disease burden of a population is often the best single indicator of vulnerability to climate change - doubling of risk of disease in a low disease population has much less absolute impact than doubling of the disease when the background rate is high."

The global magnitude of climate-sensitive diseases was estimated in 2019 to be 39,503,684 deaths (69.9 % of total annual deaths) and 1,530,630,442 DALYs (Collaborators and Injuries, 2020). Of these, cardiovascular diseases comprised the largest proportion of climate-sensitive diseases (32.8% of deaths, 15.5% DALYs). The next largest category consists of respiratory diseases – with chronic respiratory disease contributing to 7% of deaths and 4.1% of DALYs and respiratory infection and tuberculosis contributing to 6.5% of deaths and 6% of DALYs. The observed trend of climate-sensitive disease deaths since 1990 is marked by increasing cardiovascular mortality and decreasing mortality from respiratory infections, enteric diseases, and other infectious diseases (Collaborators and Injuries, 2020).

Table Box 7.2.1: Global burden of climate-sensitive health risks assessed in this chapter (in order of assessment) (Collaborators and Injuries, 2020) and synthesis of major observed and projected impacts in most affected regions. Blue represents an increase in positive health impacts, green represents an increase in negative health impacts, and purple represents an increase in both positive and negative impacts, but not necessarily equal. The confidence level refers to the both the attributed observed and projected changes to climate change. No assessment means the evidence is insufficient for assessment.

Legend

Climate Change Impacts		**Confidence**	
Positive health impacts		*Very high*	****
Negative health impacts		*High*	***
Positive and negative impacts		*Medium*	**
No assessment		*Low*	*

[END BOX 7.2 HERE]

7.2.2 Observed Impacts on Communicable Diseases

7.2.2.1 Observed Impacts on Vector-borne Diseases

Climate-sensitive vector-borne diseases (VBDs) include mosquito-borne diseases, rodent-borne diseases and tick-borne diseases. Many infectious agents, vectors, non-human reservoir hosts, and pathogen replication rates can be sensitive to ambient climatic conditions. Elevated proliferation and reproduction rates at higher temperatures, longer transmission season, changes in ecology, and climate-related migration of vectors, reservoir hosts, or human populations contribute to this climate sensitivity (J. and R., 2020);(Semenza and Paz, 2021). Age-standardized disability-adjusted life year (DALY) rates for many VBDs have decreased over the last decade due to factors unrelated to climate. Vulnerability to VBD is strongly determined by sociodemographic factors (e.g., children, the elderly and pregnant women are at greater risk) with exposure to vectors being strongly influenced by various factors including socioeconomic status, housing quality, health care access, susceptibility, occupational setting, recreational activity, conflicts and displacement (J. and R., 2020);(Semenza and Paz, 2021). Figure 7.5 illustrates how climatic and non-climatic drivers and responses determine VBD outcomes.

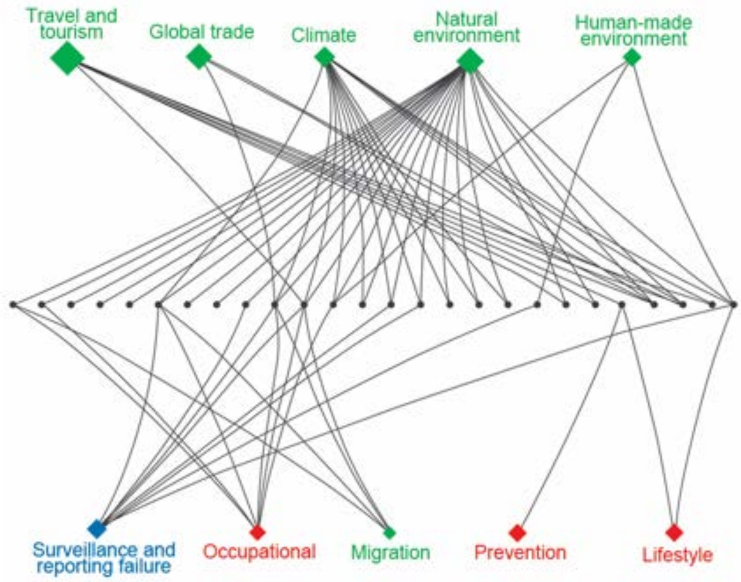

Figure 7.5: Analysis of the underlying drivers of infectious disease threat events (IDTE) detected in Europe during 2008–2013 by epidemic intelligence at the European Centre of Disease Prevention and Control. Seventeen drivers were identified and categorized into 3 groups: globalization and environment (green), sociodemographic (red), and public health system (blue). The drivers are illustrated as diamond shapes and arranged in the top and bottom row, the sizes of which are proportional to the overall frequency of the driver. Here IDTE (epidemics or first autochthonous cases) of VBD are illustrated as a horizontal row of dots in the middle. These empirical data include IDTE of VBD such as West Nile fever, malaria, dengue fever, chikungunya, or Hantavirus infection. Source: (Semenza et al., 2016)

Evidence has increased since AR5 that the vectorial capacity has increased for dengue fever, malaria, and other mosquito borne diseases, and that higher global average temperatures are making wider geographic areas more suitable for transmission (very high confidence). Transmission rates of malaria are directly influenced by climatic and weather variables such as temperature, with non-climatic socio-economic factors and health system responses counteracting the climatic drivers *(very high confidence).* The burden of malaria is greatest in Africa, where more than 90% of all malaria-related deaths occur (M'Bra et al., 2018);(Caminade et al., 2019). Between 2007 and 2017, DALYs for malaria have decreased by 39% globally. Malaria is mainly caused by five distinct species of plasmodium parasite (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae*, *Plasmodium ovale*, *Plasmodium knowlesi*), transmitted by Anopheline mosquitoes. Evidence suggests that in highland areas of Colombia and Ethiopia, malaria has shifted in warmer years toward higher altitudes, indicating that, without intervention, malaria will increase at higher elevations as the climate warms (Siraj et al., 2014);(Midekisa et al., 2015). Each year, local outbreaks of malaria occur due to importation, in areas from which it was once eradicated, such as Europe, but the risk of re-establishment is considered low.

The transmission of dengue fever is linked to climatic and weather variables such as temperature, relative humidity, and rainfall (high confidence). The dengue virus is carried and spread by *Aedes* mosquitoes, primarily *Aedes aegypti*. Dengue has the second highest burden of VBDs, with the majority of deaths occurring in Asia (Bhatt et al., 2013). Since 1950, global dengue burden has grown, attributable to a combination of climate-associated expansion in the geographic range of the vector species and non-climatic factors such as globalized air traffic, urbanization, and ineffective vector abatement measures. Temperature, relative humidity, and rainfall variables are significantly and positively associated with increased dengue case incidence and/or transmission rates globally, including in Vietnam (Phung et al., 2015);(Xuan le et al., 2014), Thailand (Xu et al., 2019a), India (Mutheneni et al., 2017);(Rao et al., 2018);(Mala and Jat, 2019), Indonesia (Kesetyaningsih et al., 2018), the Philipines (Carvajal et al., 2018), the United States (Lopez et al., 2018);(Pena-Garcia et al., 2017);(Duarte et al., 2019);(Rivas et al., 2018);(Silva et al., 2016a), Jordan (Obaidat and Roess, 2018), and Timor-Leste (Wangdi et al., 2018). Variation in winds, sea surface temperatures and rain over the tropical eastern Pacific Ocean (El Nino Southern Oscillation) have been linked to increased dengue incidence in Colombia (Quintero-Herrera et al., 2015);(McGregor and Ebi, 2018);(Pramanik et al., 2020) and its interannual variation successfully forecasted in Ecuador using ENSO indices as predictors (Petrova et al., 2019). The observed lag time between climate exposures and increased dengue incidence is approximately 1–2 months (Chuang et al., 2017);(Lai, 2018);(Chang et al., 2018).

Changing climatic patterns are facilitating the spread of chikungunya virus (CHIKV), Zika, Japanese encephalitis and Rift Valley Fever in Asia, Latin America, North America and Europe (high confidence). Climate change may have facilitated the emergence of CHIKV as a significant public health challenge in some Latin American and Caribbean countries (Yactayo et al., 2016);(Pineda et al., 2016), and contributed to a chikungunya outbreak in Italy in 2017 (Rocklov et al., 2019) and in Europe (Chadsuthi et al., 2016);(Mascarenhas et al., 2018);(Morens and Fauci, 2014). The Zika virus outbreak in South America in 2016 was preceded by 2007 outbreaks on Pacific islands and followed a period of record high temperatures and severe drought conditions in 2015 (Paz and Semenza, 2016);(Tesla et al., 2018). Increased use of household water storage containers during the drought is correlated with a range expansion of *Aedes aegypti* during this period, increasing household exposure to the vector (Paz and Semenza, 2016). Changing climate also appears to be a risk factor for the spread of Japanese encephalitis to higher altitudes in Nepal (Ghimire and Dhakal, 2015) and in southwest China (Zhao et al., 2014). In Eastern Africa, climate change may be a risk factor in the spread of Rift Valley Fever (Taylor et al., 2016a).

Changes in temperature, precipitation, and relative humidity have been implicated as drivers of West Nile fever in southeastern Europe (medium confidence). The average temperature and precipitation prior to the exceptional 2018 West Nile outbreak in Europe was above the 1981–2010 period average, which may have contributed to an early upsurge of the vector population (Marini et al., 2020);(Haussig et al., 2018);(Semenza and Paz, 2021). In 2019 and in 2020, West Nile fever was first detected in birds and subsequently in humans in both Germany and Netherlands, respectively (Ziegler et al., 2020);(Vlaskamp et al., 2020).

Climate change has contributed to the spread of the Lyme disease vector Ixodes scapularis, and a corresponding increase in cases of Lyme disease in North America (high confidence), and of the spread of the Lyme disease and Tick-Borne Encephalitis vector Ixodes ricinus in Europe (medium confidence). In Canada, there has been a geographic range expansion of the black-legged tick *I. scapularis,* the main vector of *Borrelia burgdorferi*, the agent of Lyme disease. Vector surveillance of *I. scapularis* has identified strong correlation between temperatures and the emergence of tick populations, their range and recent geographic spread, with recent climate warming coinciding with a rapid increase in human Lyme disease cases (Clow et al., 2017);(Cheng et al., 2017);(Gasmi et al., 2017);(Ebi et al., 2017). *Ixodes ricinus*, the primary vector in Europe for both Lyme borreliosis and tick-borne encephalitis is sensitive to humidity and temperature (Daniel et al., 2018);(Estrada-Peña and Fernández-Ruiz, 2020) (*high confidence*). There has been an observed range expansion to higher latitudes in Sweden and to higher elevations in Austria and the Czech Republic.

Rodent-borne disease outbreaks have been linked to weather and climate conditions in a small number of studies published since AR5, but more research is needed in this area. In Kenya, a positive association exists between precipitation patterns and *Theileria*-infected rodents, but for *Anaplasma*, *Theileria* and *Hepatozoon*, the association between rainfall and pathogen varies according to rural land-use types (Young et al., 2017). Weather variability plays a significant role in transmission rates of haemorrhagic fever with renal syndrome (HFRS) (Hansen et al., 2015);(Xiang et al., 2018);(Liang et al., 2018);(Fei et al., 2015);(Xiao et al., 2014);(Vratnica et al., 2017);(Roda Gracia et al., 2015);(Monchatre-Leroy et al., 2017);(Bai et al., 2019). In Chongqing, HFRS incidence has been positively associated with rodent density and rainfall (Bai et al., 2015).

7.2.2.2 Observed Impacts on Water-borne Diseases

Important water-borne diseases (WBDs) include diarrhoeal diseases (such as cholera, shigella, cryptosporidium and typhoid), schistosomiasis, leptospirosis, hepatitis A and E and poliomyelitis (Cisse, 2019);(Houéménou et al., 2021);(Hassan et al., 2021);(Archer et al., 2020);(Mbereko et al., 2020);(Fan et al., 2021). The number of cases of water-borne diseases is considerable, and even in high-income countries water-borne illness continues to be a concern (Cissé et al., 2018);(Kirtman et al., 2014);(Levy et al., 2018);(Murphy et al., 2014);(Brubacher et al., 2020);(Lee et al., 2021). Nevertheless, diarrhoea mortality has declined substantially since 1990, although there are variations by country, and the global burden of WBD has decreased in line with vaccination coverage of some WBDs (such as polio and cholera), poverty reduction and improved sanitation and hygiene (Jacob and Kazaura, 2021);(Mutono et al., 2020);(Lee et al., 2019);(Semenza and Paz, 2021);(Jacob and Kazaura, 2021); (Mutono et al., 2020).

Drinking water containing pathogenic microorganisms is the main driver of the burden of WBDs (Murphy et al., 2014);(Lee et al., 2021);(Chen et al., 2021b);(Musacchio et al., 2021). WBDs outbreaks, particularly intestinal diseases, are attributable to a combination of the presence of particular pathogens (bacteria, protozoa, viruses or parasites) and the characteristics of drinking water systems in a given location (Bless et al., 2016);(Ligon and Bartram, 2016);(Mutono et al., 2021);(Ferreira et al., 2021).

[START BOX 7.3 HERE]

Box 7.3: Cascading Risk Pathways Linking Waterborne Disease to Climate Hazards

The causal linkages between climate variability and change and incidence of waterborne diseases follows multiple direct and indirect pathways, often as part of a cascading series of risks (Semenza, 2020). For example, extreme precipitation can result in a cascading hazard or disease event with implications of greater magnitude than the initial hazard, especially if there are pre-existing vulnerabilities in critical infrastructure and human populations (Semenza and Paz, 2021). Intense or prolonged precipitation can flush pathogens in the environment from pastures and fields to groundwater, rivers and lakes, consequently infiltrating water treatment and distribution systems (Howard et al., 2016);(Khan et al., 2015);(Sherpa et al., 2014);(Cissé et al., 2016);(Kostyla et al., 2015); Chapter 4). Table 7.3.1 shows the variety and complexity of pathways between climate hazard and waterborne disease outcomes (Semenza, 2020).

Table Box 7.3.1: Pathways between climate hazard and waterborne disease outcomes (source: (Semenza, 2020)

Cascading risk pathways from heavy rain and flooding
Storm runoff yields water turbidity which compromises water treatment efficiency Storm runoff and floods mobilizes and transports pathogens Overwhelmed or damaged infrastructure compromises water treatment efficiency Floods overwhelm containment system and discharge untreated wastewater Floods damage critical water supply and sanitation infrastructure Floods displace populations towards inadequate sanitation infrastructure
Cascading risk pathways from drought
Low water availability augments travel distance to alternate (contaminated) sources Intensified demand and sharing (e.g. with livestock) of limited water resources decreases water availability and quality Intermittent drinking water supply results in cross-connections with sewer lines and water contamination Uncovered household water containers are a source of vector breeding Poor hygiene due to decreased volume of source water and increased concentration of pathogens Exposure to accumulated human excrements and animal manure
Cascading risk pathways from increasing temperature
Extended transmission season for opportunistic pathogens Permissive temperature for the replication of marine bacteria Enhanced pathogen load in animal reservoirs (e.g., chicken) Pathogen survival and proliferation outside of host Wildfires during heat waves degrade water quality Exposure to contaminated water due to higher water consumption Behaviour change due to extended season; e.g., food spoilage during barbeque
Cascading risk pathways from sea-level rise
Population displacement due to powerful storm surges Disruption of drinking water supply and sanitation infrastructure due to inundation Decline in soil and water quality due to saline intrusion into coastal aquifers

Seawater infiltration into drinking water distribution and sewage lines

Table Notes:
Examples are purposely not exhaustive and should be considered illustrative.

[END BOX 7.3 HERE]

Since AR5 there is a growing body of evidence that increases in temperature (very high confidence), heavy rainfall (high confidence), flooding (medium confidence) and drought (low confidence) are associated with an increase of diarrheal diseases. In the majority of studies there is a significant positive association observed between waterborne diseases and elevated temperatures, especially in areas where water, sanitation and hygiene deficiencies are significant (Levy et al., 2018);(Carlton et al., 2016);(Levy et al., 2018);(Sherpa et al., 2014);(Guzman Herrador et al., 2015);(Levy et al., 2016);(Lo Iacono et al., 2017). In Ethiopia, South Africa and Senegal, increases in temperatures are associated with increases in diarrhoea, while in Ethiopia, Senegal and Mozambique, increases in monthly rainfall are associated with an increase in cases of childhood diarrhea (Azage et al., 2015);(Thiam et al., 2017);(Horn et al., 2018). Similar associations between weather and diarrhoea have been observed in Cambodia, China, Bangladesh, Pacific Island Countries and the Philippines (McIver et al., 2016a);(McIver et al., 2016b);(Liu et al., 2018);(Wu et al., 2014);(Matsushita et al., 2018). Heavy precipitation events have been consistently associated with outbreaks of waterborne diseases in Europe (including Scandinavia), USA, UK and Canada (Guzman Herrador et al., 2015);(Levy et al., 2016);(Lo Iacono et al., 2017);(Curriero et al., 2001);(Guzman Herrador et al., 2016);(Levy et al., 2018);(Semenza and Paz, 2021).

Impacts of floods include outbreaks of waterborne diseases, with such events disproportionately affecting the young, elderly and immunocompromised (Suk et al., 2020);(Guzman Herrador et al., 2015);(Levy et al., 2016);(Lo Iacono et al., 2017);(Zhang et al., 2019a). Water shortage and drought have been found associated with diarrheal disease peaks (Epstein et al., 2020b);(Subiros et al., 2019);(Boithias et al., 2016 while some reviews found insufficient or limited evidence of the effects of drought on diarrhea {Levy, 2016, Untangling the Impacts of Climate Change on Waterborne Diseases: a Systematic Review of Relationships between Diarrheal Diseases and Temperature, Rainfall, Flooding, and Drought);(Asmall et al., 2021);(Epstein et al., 2020b);(Subiros et al., 2019);(Boithias et al., 2016) (Ramesh et al., 2016).

Heavy rainfall and higher than normal temperatures are associated with increased cholera risk in affected regions (very high confidence). Cholera is an acute diarrheal disease typically caused by the bacterium *Vibrio cholerae* that can result in severe morbidity and mortality. Maximum and minimum temperatures and precipitation have been negatively associated with cholera cases and cholera outbreaks have occurred in several regions after natural disasters, including cholera incidence increasing three-fold in Africa El Niño-sensitive regions (Mpandeli et al., 2018);(Amegah et al., 2016);(Escobar et al., 2015);(Jutla et al., 2017);(Asadgol et al., 2019);(Moore et al., 2018);(Moore et al., 2017);(Camacho et al., 2018);(Pörtner et al., 2019); Cross-Chapter Box ILLNESS in Chapter 2; Box 3.3).

Heavy rainfall, warmer weather and drought are linked to increased risks for other gastro-intestinal (GI) infections (high confidence). As temperature increases bacterial causes of GI infection appear to increase and this association is variably influenced by humidity and rainfall (Ghazani et al., 2018);(Levy, 2016). In New York it has been found that every 1°C increase in temperature was correlated with a 0.70-0.96% increase in daily hospitalization for GI infections (Lin et al., 2016). In the Philippines, leptospirosis and typhoid fever showed an increase in incidence following heavy rainfall and flooding events (Matsushita et al., 2018).

7.2.2.3 Observed Impacts on Food-borne Diseases

Food-borne diseases (FBDs) refer to any illness resulting from ingesting food that is spoiled or contaminated by pathogenic bacteria, viruses, parasites, toxins, pesticides and/or medicines (WHO, 2015d). FBD risks are present throughout the food chain, from production to consumption, and most often arise due to contamination at source and from improper handling, preparation and/or food storage (Smith and Fazil, 2019);(Semenza and Paz, 2021). As with waterborne disease, FBD outbreaks can follow multiple causal pathways as climatic risk factors interact with food production and distribution systems, urbanization and population growth, resource and energy scarcity, decreasing agricultural productivity, price volatility, modification of diet trends, new technologies and the emergence of antimicrobial resistance (Lake, 2018);(Yeni and Alpas, 2017). The burden of FBDs is also linked to malnutrition as reduced immunity increases susceptibility to various foodborne pathogens and toxins (FAO, 2020).

A strong association exists between increases in food-borne diseases and high air and water temperatures and longer summer seasons (very high confidence). The risks occur through complex transmission pathways throughout the food chain and the wide range of foodborne pathogens (Cisse, 2019);(Hellberg and Chu, 2016);(Lake and Barker, 2018);(Park et al., 2018b);(Smith and Fazil, 2019). Food-borne pathogens of most concern are those having low infective doses, a significant persistence in the environment and high stress tolerance to temperature change (e.g. enteric viruses, *Campylobacter spp*., *E. coli* STEC strains, *Mycobacterium avium,* tuberculosis complexes, parasitic protozoa and *Salmonella*) (Lake, 2018);(Lake, 2017);(Lake and Barker, 2018);(Smith and Fazil, 2019);(Authority) et al., 2020);(Semenza and Paz, 2021). Priority risks include marine biotoxins, mycotoxins, salmonellosis, vibriosis, transfer of contaminants due to extreme precipitation, floods, increased use of chemicals (plant protection products, fertilizers, veterinary drugs) in the food chain, and potential residues in food (Authority) et al., 2020);(Organization, 2018b).

There is a strong association observed between the increase in average ambient temperature and increases in Salmonella infections (high confidence). Most types of *Salmonella* infections lead to salmonellosis, while some other types (*Salmonella* Typhi and *Salmonella* Paratyphi) can lead to typhoid fever or paratyphoid fever. The transmission to humans of the non-typhoidal *Salmonella* infection, one of the most widespread foodborne diseases, occurs usually through eating foods contaminated with animal faeces. Studies conducted in Australia (Milazzo et al., 2016), New Zealand (Lal et al., 2016), the UK (Lake, 2017), South Korea (Park et al., 2018a);(Park et al., 2018c);(Park et al., 2018a), Singapore (Aik et al., 2018) and Hong Kong, SAR of China (Wang et al., 2018a);(Wang et al., 2018b) have shown that *Salmonella* outbreaks are strongly associated with temperature increases.

Significant associations exist between food-borne diseases due to Campylobacter, precipitation and temperature (medium confidence). The timing of heat-associated Campylobacteriosis events varies across countries, whilst infection rates in the UK appear to decline immediately after periods of high rainfall (Djennad et al., 2019);(Lake et al., 2019);(Rosenberg et al., 2018);(Yun et al., 2016);(Weisent et al., 2014). This suggests the association with climate may be indirect and due to weather conditions that encourage outdoor food preparation and recreational activities (Lake, 2017);(Semenza and Paz, 2021).

Outbreaks of human and animal Cryptococcus have been reported as being associated with a combination of climatic factors, and shifts in host and vector populations (Chang and Chen, 2015);(Rickerts, 2019). The prevalence of childhood cryptosporidiosis, which is the second leading cause of moderate-to-severe diarrhoea among infants in the tropics and subtropics, shows associations with population density and rainfall, with contamination due to Cryptosporidium spp. being 2.61 times higher during and after heavy rain (Lal et al., 2019);(Young et al., 2015);(Khalil et al., 2018). Studies from Ghana, Guinea Bissau, Tanzania, Kenya and Zambia show a higher prevalence of Cryptosporidium during high rainfall seasons, with some peaks observed before, at the onset or at the end of the rainy season (Squire and Ryan, 2017).

7.2.2.4 Respiratory Tract Infections

Climatic risk factors for respiratory tract infections (RTIs) due to multiple pathogens (bacteria, viruses, fungi) include temperature and humidity extremes, dust storms, extreme precipitation events, and increased climate variability. Amongst a range of RTIs, pneumonia and influenza represent a significant disease burden (Ferreira-Coimbra et al., 2020);(Lafond et al., 2021);(McAllister et al., 2019);(Wang et al., 2020c). The drivers of pneumonia incidence are complex and include a range of possible non-climate as well as climate factors. For example, chronic diseases (e.g., lung disease, chronic obstructive pulmonary disease, asthma) and other comorbidities, a weak immune system, age, gender, community, passive smoking, air pollution, and childhood immunization may confound the climate pneumonia relationship (Miyayo et al., 2021).

In temperate regions, the incidence of pneumonia is higher in the winter months, but the exact causes of this seasonality remain debated (Mirsaeidi et al., 2016). With regards to temperature, various J-shaped, U-shaped, or V-shaped temperature-pneumonia relationships have been reported in the literature (Huang et al., 2018);(Kim et al., 2016);(Liu et al., 2014);(Qiu et al., 2016);(Sohn et al., 2019) with such relationships dependent of location. Humidity also appears important but like temperature its effect is not consistent across studies - low temperatures and low humidity (Davis et al., 2016), high temperatures and high humidity (Lam et al., 2020) and low temperatures and high humidity (Miyayo et al., 2021) have all been found to be associated with an increased incidence of pneumonia.

Day to day variations in temperature also appear important. For Australia, increases in emergency visits for childhood pneumonia are associated with sharp temperature drops (Xu et al., 2014). Large inter-daily changes in temperature are important for respiratory disease incidence in Guangzhou, China (Lin et al., 2013) and Shanghai (Lei et al., 2021) while rapidly changing and extreme temperatures during pregnancy have been linked to childhood pneumonia (Miao et al., 2017);(Zeng et al., 2017);(Zheng et al., 2021)). In tropical and subtropical areas of Africa and Asia, pneumonia incidence has been reported to be higher during the rainy season, pointing to a positive association between pneumonia patterns and temperature and precipitation (Chowdhury et al., 2018a);(Lim and Siow, 2018);(Paynter et al., 2010).

The degree to which the timing, duration and magnitude of local influenza virus epidemics is dependent on climate factors is poorly understood (Lam et al., 2020). Further, a host of non-climate confounders are likely to influence the incidence of seasonal influenza (Caini et al., 2018). This poses a number of challenges for making reliable climate-based epidemiological forecasts for influenza (Gandon et al., 2016). Although no association between anomalous climate conditions and influenza have been reported in some locations (Lam et al., 2020), generally, low winter temperatures and humidity in temperate regions and periods of high humidity and precipitation in the tropical and subtropical regions have been linked to outbreaks of influenza (Deyle et al., 2016);(Soebiyanto et al., 2015);(Tamerius et al., 2013). However, the climate sensitivity of influenza may be more complex than this with both high and low humidity, the amount and intensity of precipitation and solar activity/sunshine and latitude also important (Axelsen et al., 2014);(Chong et al., 2020b);(Geier et al., 2018);(Park et al., 2019);(Qu, 2016);(Smith et al., 2017);(Wang et al., 2017c);(Zhao et al., 2018a). Moreover, the shape of the climate variable influenza relationship may be conditioned on influenza type (Chong et al., 2020a). Further distinct periods of weather variability characterised by rapid inter-daily changes in temperature may act as precursors to influenza epidemics as has been demonstrated for the marked 2017-18 influenza season and others across the US (Liu et al., 2020a);(Zhao et al., 2018a). For the Eastern Mediterranean, such rapid weather changes are associated with the 'Cyprus Low', with the timing and magnitude of seasonal influenza related to the inter-annual frequency of this particular weather regime (Hochman et al., 2021). Potentially, large-scale modes of climatic variability such as El Niño Southern Oscillation (ENSO) and the Indian Ocean Dipole, which strongly moderate the frequency of weather regimes in some parts of the world, could affect influenza pandemic dynamics. However, studies conducted to date report inconsistent results. Some point to an increased (decreased) severity of seasonal influenza during El Nino (La Nina) (Oluwole, 2015),(Oluwole, 2017), while others find influenza to be more severe and frequent when coinciding with La Niña events (Chun et al., 2019);(Flahault et al., 2016);(Shaman and Lipsitch, 2013). This raises the possibly of non-stationary associations between large-scale modes of climatic variability and influenza dynamics (Onozuka and Hagihara, 2015) as found for other diseases (Kreppel et al., 2014), something that might be expected given El Niño's time-varying impact on global precipitation and temperature fields and associated impacts on health outcomes (McGregor and Ebi, 2018).

7.2.2.5 Other Water Shortage and Drought-associated Diseases

Water shortage and drought are associated with skin diseases (Schachtel et al., 2021);(Lundgren, 2018);(Andersen and Davis, 2017);(Kaffenberger et al., 2017);(Andersen and Davis, 2017), trachoma (Ramesh et al., 2016), and violence (Epstein et al., 2020a),

Cross-Chapter Box COVID: COVID-19

Authors: Maarten van Aalst (Netherlands, Chapter 16), Guéladio Cissé (Mauritania/Switzerland/France, Chapter 7), Ayansina Ayanlade (Nigeria, Chapter 9), Lea Berrang-Ford (United Kingdom/Canada, Chapter

16), Rachel Bezner Kerr (Canada/USA, Chapter 5), Robbert Biesbroek (Netherlands, Chapter 13), Kathryn Bowen (Australia, Chapter 7), Martina Angela Caretta (Sweden, Chapter 4), So-Min Cheong (Republic of Korea, Chapter 17), Winston Chow (Singapore, Chapter 6), Mark John Costello (New Zealand/Norway/Ireland, Chapter 11, CCP1), Kristie Ebi (USA, Chapter 7), Elisabeth Gilmore (USA/Canada, Chapter 14), Bruce Glavovic (South Africa/New Zealand, Chapter 18, CCP2), Walter Leal (Germany, Chapter 8), Stefanie Langsdorf (Germany, TSU), Elena Lopez-Gunn (Spain/United Kingdom, Chapter 4), Ruth Morgan (Australia, Chapter 4), Aditi Mukherji (India, Chapter 4), Camille Parmesan (France/ United Kingdom /USA, 2), Mark Pelling (United Kingdom, Chapter 6), Elvira Poloczanska (United Kingdom, TSU), Marie-Fanny Racault (United Kingdom/France, Chapter 3), Diana Reckien (Germany/Netherlands, Chapter 17), Jan C. Semenza (Sweden, Chapter 7), Pramod Kumar Singh (India, Chapter 18), Stavana E. Strutz (USA), Maria Cristina Tirado von der Pahlen (Spain/USA, Chapter 7), Corinne Schuster-Wallace (Canada), Alistair Woodward (New Zealand, Chapter 11), Zinta Zommers (Latvia, Chapter 17)

Introduction

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which causes Coronavirus Disease 2019 (COVID-19), emerged in late 2019, halfway through the preparation of the IPCC WGII Sixth Assessment Report. This Cross-Chapter Box assesses how the massive shock of the pandemic and its response measures interact with climate-related impacts and risks, as well as its significant implications for risk management and climate resilient development.

COVID-19 and environmental connections

Infectious diseases may emerge and spread through multiple climate-related avenues, including direct effects of climatic conditions on disease reproduction and transmission and various indirect effects, often interlinked with ecosystem degradation (high confidence). Climate change is affecting the risk of emerging infectious diseases by contributing to factors that dive the movements of species, including vectors and reservoirs of diseases, into novel human populations and vice-versa (*high confidence*) {2.4.2.7; 5.2.2.3; Cross-Chapter Box Illness in Chapter 2; SRCCL; IPBES 2020}. The spillover of some emerging infectious diseases from wildlife into humans is associated with live animal-human markets, intensified livestock production and climate-related movements of humans and wild animals into new areas that alter human-animal interactions. {2.4.2.7} {Chapter 3} {5.2.2.3} {7.2} {Cross-Chapter Box ILLNESS in Chapter 2} {Cross-Chapter Box MOVING PLATE in Chapter 5}.

Human to human transmission is the prominent driver in the spread of the COVID-19 pandemic, rather than climatic drivers (high confidence). There is emerging literature on the environmental determinants of COVID-19 transmission, incidence and mortality rates, with initial evidence suggesting that temperature, humidity and air pollution contribute to these patterns (Brunekreef et al., 2021); (Xiong et al., 2020);(Zhang et al., 2020b); IPCC WGI AR6 Cross-Chapter Box). Climate change is altering environmental factors like temperature and seasonality that affect COVID-19 transmission (Choi et al., 2021).

The impact of COVID-19 containment measures resulted in a temporary reduction in greenhouse gas emissions and reduced air pollution *(high confidence)* (IPCC WGI TS and Cross-Chapter Box 6.1}. However, global and regional climate responses to the radiative effect were undetectable above internal climate variability due to the temporary nature of emission reductions. They, therefore, do not result in detectable changes in impacts or risks due to changes in climate hazards (IPCC WGI TS and Cross-Chapter Box 6.1; (Naik et al., 2021).

Cascading and compounding risks and impacts

The COVID-19 pandemic posed a severe shock to many socio-economic systems, resulting in substantial changes in vulnerability and exposure of people to climate risks (*high confidence*). The disease and response measures significantly affected human health, economic activity, food production and availability, health services, poverty, social and gender inequality, education, supply chains, infrastructure maintenance, and the environment. These COVID-19 impacts interact with many risks associated with climate change (IMF, 2020), often through a cascade of impacts across numerous sectors (van den Hurk et al., 2020). Beyond

COVID-19-related mortality and long-term COVID, mortality from other diseases (some of which may also have a climate-related component), as well as maternal and neonatal mortality, increased because of disruption in health services (Barach et al., 2020);(Maringe et al., 2020);(Zadnik et al., 2020); (Goyal et al., 2021). In addition, a rapid rise in poverty has disproportionately affected poorer countries and people (Ferreira et al., 2021), and thus increased their vulnerability. After many years of steady declines, extreme poverty increased by about 100 million people in 2020 (Bank, 2021). The effects of the pandemic increased food insecurity and malnourishment, which increased by 1.5 percentage points to around 9.9 per cent in 2020 after being virtually unchanged for the previous five years (FAO et al., 2021).

During the pandemic, extreme weather and climate events such as droughts, storms, floods, wildfires and heatwaves continued, resulting in disastrous compounding impacts (*high confidence*). Between March and September 2020, 92 extreme weather events coincided with the COVID-19 pandemic, affecting an estimated 51.6 million people; additionally, 431.7 million people were exposed to extreme heat, and 2.3 million people were affected by wildfires (Walton and van Aalst, 2020). The COVID-19 pandemic, in combination with extreme events, affected disaster preparedness, response and safe evacuations, while physical distancing regulations reduced the capacity of temporary shelters (Pacific), 2020); (Tozier de la Poterie et al., 2020);(Network, 2020); (Bose-O'Reilly et al., 2021). Complex humanitarian emergencies were aggravated, with vulnerable populations facing the combined risks of conflict, displacement, COVID-19 and climate impacts (FSIN, 2020). Compounding events are not only found in low-income countries but also in medium- and high-income countries, for instance in the case of COVID-19 and heatwaves (Network, 2020); (Bose-O'Reilly et al., 2021).

Responses and implications for adaptation and climate resilience development

The pandemic underscores the interconnected and compound nature of risks, vulnerabilities, and responses to emergencies that are simultaneously local and global (high confidence). COVID-19 is often considered a more "explosive" risk than the more gradual anthropogenic climate change. However, many climate-related risks do already appear as severe shocks at smaller scales, and infrequent or unprecedented extreme weather related events often warrant similar rapid responses (Dodds et al., 2020); (Gebreslassie, 2020); (Hynes et al., 2020); (Phillips et al., 2020); (Schipper, 2020); (Semenza et al., 2021); illustrated in Figure Cross-Chapter Box COVID in Chapter 7). Individuals, households, sub-national and national entities, and international organizations have generally delayed responses or denied the pandemic's severity before responding at the scale and urgency required; a pattern that resembles international action on climate change required; a pattern that resembles international action on climate change (Polyakova et al., 2020), (Shrestha et al., 2020).

Improved contingency and recovery planning, including disease mitigation measures, were crucial in responding to the pandemic in similar ways to those seen in the aftermath of climate-related disasters (Guo et al., 2020); (Ebrahim et al., 2020); (Baidya et al., 2020); (Shultz et al., 2020); (Mukherjee et al., 2020). The pandemic highlighted the lack of global and country-specific capacity to respond to an unexpected and unplanned-for event and the need to implement more flexible detection and response systems (Ebi et al., 2021b).

It also exposed underlying vulnerabilities, such as the lack of water access and health care in select low- and middle-income countries and among Indigenous and marginalised groups in high-income countries (see section 4.4.3, Box 4.3 and 5.12.1). Increased risks of COVID-19 transmission emerged in crowded areas such as urban settings, refugee camps, detention centres, and some workplaces, including in rural settings(Brauer et al., 2020); (Ramos et al., 2020); (Staddon et al., 2020); (Haddout et al., 2020). Public health responses to the COVID-19 pandemic, such as mandates for social distancing and advice for frequent handwashing, underlined the need for access to water and sanitation facilities and wastewater management. However, they have also interfered with access sometimes, for example, in evacuation and shelter infrastructure during climate-related disasters (Armitage and Nellums, 2020);(Adelodun et al., 2020); (Poch et al., 2020);(Hallema et al., 2020);(Patel et al., 2020); (Espejo et al., 2020).

The experience of COVID-19 demonstrates that many warnings about the risks of the emergence of zoonotic transmission ("delay is costly", "adapt early", and "prevention pays") did not result in sufficient political attention, funding, and pandemic prevention. In some countries, there has been an increased awareness of risks and the real or perceived trade-offs associated with risk management (e.g., economy vs. health; impacts vs. adaptation). Building trust, participatory processes and establishing stronger relationships with communities and other civic institutions may enable a recalibration in how the government responds to crises and society-government relationships more generally (Amat and et al., 2020); (Deslatte, 2020)

The management of the COVID-19 pandemic has highlighted the value of scientific (including medical and epidemiological) expertise and the importance of fast, accurate, and comprehensive data to inform policy decisions and to anticipate and manage risk (high confidence). It underscores the importance of effective communication of scientific knowledge (Semenza et al., 2021), decision-making under uncertainty, and decision frameworks that navigate different values and priorities. Successful policy responses were based on the emerging data, medical advice and collaboration with a wider set of societal stakeholders beyond public health experts. For instance, experience in Aotearoa New Zealand highlights the importance of pandemic responses attuned to the needs of different socio-cultural groups and Indigenous people in particular. Their strengths-based COVID-19 response goes beyond identifying vulnerabilities to unlocking the resources, capabilities and potential that might otherwise be latent in communities (McMeeking and Savage, 2020). As far as the value of information for risk management is concerned, compared to the initial uncertainties regarding COVID-19, data about near- and longer term climate-related hazards is generally very good; however, high-quality and dense meteorological data are often still lacking in lower income countries (Otto et al., 2020). Health data are particularly difficult to obtain in real-time, as is the case for biodiversity data, which has a time lag of years before being made available, and for which there is no coordinated monitoring, hampering effective risk management (Navarro et al., 2017). Therefore, both epidemiological and meteorological forecasts would benefit from more focus on (1) decision support, (2) conveying uncertainty, and (3) capturing vulnerability (Coughlan de Perez et al., 2021).

There is a considerable evidence base of specific actions that have co-benefits for reducing pandemic and climate change risks while enhancing social justice and biodiversity conservation (high confidence). The pandemic highlighted aspects of risk management that have long been recognised but are often not reflected in national and international climate policy: the value of addressing structural vulnerability rather than taking specific measures to control single hazards and drivers of risk, and the importance of decision-making capacities and transparency, the rule of law, accountability, and addressing inequities (or social exclusion) (reviewed by (Pelling et al., 2021), see also Figure Cross-Chapter Box COVID in Chapter 7).

Comprehensive and integrated risk management strategies can enable countries to address both the current pandemic and increase resilience against climate change and other risks (Reckien, 2021); (Semenza et al., 2021); (Ebi et al., 2021b). In particular, given their immense scale, COVID-19 recovery investments may offer an opportunity to contribute to Climate-Resilient Development Pathways through a green, resilient, healthy and inclusive recovery (*high confidence*) (Sovacool et al., 2020);(Rosenbloom and Markard, 2020); (Lambert et al., 2020); (Boyle et al., 2020); (Bouman et al., 2020); (Pacific), 2020);(Brosemer et al., 2020);(Dodds et al., 2020); (Hynes et al., 2020); (Markard and Rosenbloom, 2020); (Phillips et al., 2020); (Schipper, 2020); (Willi et al., 2020); (Semenza et al., 2021);(Pasini and Mazzocchi, 2020);(Meige et al., 2020); (Pelling et al., 2021). However, windows of opportunity to enable such transitions are only open for a limited period and need to be swiftly acted upon to effect change (*high confidence*) (chapter 18, (Weible et al., 2020); (Reckien, 2021). Initial indications suggest that only US$1.8 trillion of the >US$17 trillion COVID-19-related stimulus financing by G20 countries and other major economies that was committed until mid-2021 contributed to climate action and biodiversity objectives, with significant differences between countries and sectors (Economics, 2021). Moreover, responses to previous crises (e.g., the 2008-2011 global financial crisis) demonstrate that despite high ambitions during the response phase, opportunities for reform do not necessarily materialize (Bol et al., 2020), (Boin et al., 2005). In addition, heightened societal and political attention to one crisis often comes at the cost of other policy priorities (*high confidence*) (Maor, 2018); (Tosun et al., 2017), which could affect investments for climate-resilient development (Hepburn et al., 2020); (WHO, 2020a);(Bateman et al., 2020); (Meige et al., 2020); (Semenza et al., 2021).

In summary, the emerging literature suggests that the COVID-19 pandemic has aggravated climate risks, demonstrated the global and local vulnerability to cascading shocks, and illustrated the importance of integrated solutions that tackle ecosystem degradation and structural vulnerabilities in human societies. This highlights the potential and urgency of interventions that reduce pandemic and climate change risks while enhancing compound resilience, social justice and biodiversity conservation (see Figure Cross-Chapter Box COVID.1 in Chapter 7).

[END CROSS-CHAPTER BOX COVID HERE]

7.2.3 Observed Impacts on Non-communicable Diseases

Non-communicable diseases (NCDs) are those that are not directly transmitted from one person to another person, and impose the largest disease burden globally. NCDs constitute approximately 80% of the burden of disease in high-income countries; the NCD burden is lower in low- and middle-income countries but expected to rise (Bollyky et al., 2017). NCDs constitute a large group of diseases driven principally by environmental, lifestyle, and other factors; those identified as being climate sensitive include non-infectious respiratory disease, cardiovascular disease, cancer, and endocrine disease including diabetes. There are, additionally, potential interactions between multiple climate-sensitive NCDs and food security, nutrition, and mental health.

The literature on climate change and NCDs continues to develop. More recently, scientists have identified key gaps in the calculation of the global burden of disease due to environmental health factors (Shaffer et al., 2019).

7.2.3.1 Cardiovascular Diseases

Cardiovascular diseases (CVD) are a group of disorders of the heart and blood vessels that include coronary heart disease, cerebrovascular disease, peripheral arterial disease, rheumatic heart disease, congenital heart disease, deep vein thrombosis and pulmonary embolism. CVDs are the leading cause of death globally and over three quarters of the world's CVD deaths now occur in low- and middle-income countries (Roth et al., 2020).

Climate change affects the risk of CVD through high temperatures and extreme heat (assessed in 7.2.4.1) and through other mechanisms (medium confidence), though the degree to which non-temperature risks may increase remains unclear. For example, exposure to air pollutants including particulate matter, ozone (via its precursors), black carbon, oxides of nitrogen, oxides of sulphur, hydrocarbons and metals can invoke pro-inflammatory and prothrombotic states, endothelial dysfunction and hypertensive responses (Giorgini et al., 2017);(Stewart et al., 2017). Winter peaks in CVD events, associated with greater concentrations of air pollutants, have been reported in a range of countries and climates (Claeys et al., 2017);(Stewart et al., 2017); however, the association between air pollution, weather and CVD events is complex and seems to differ in cold *versus* warm months, particularly for gaseous pollutants such as ozone (Shi et al., 2020).

Climate change is projected to increase the number and severity of wildfires (Liu et al., 2015b);(Youssouf et al., 2014) and the evidence for wildfire smoke-related CVD morbidity and mortality is suggestive of increased CVD morbidity and mortality risk (Chen et al., 2021a)including significant increases in certain cardiovascular outcomes (e.g., cardiac arrests) (Dennekamp et al., 2015). CVD risks to highly exposed populations, such as fire firefighters, are clearer (Navarro et al., 2019), and could increase with additional exposure driven by climate change.

Other climate related mechanisms that may increase CVD risk include hot weather-related reduction in physical activity (Obradovich et al., 2017), sleep disturbance (Obradovich et al., 2017), and dehydration (Lim et al., 2015);(Frumkin and Haines, 2019) . There is little literature on how changes in winter weather may affect these risks. Sea level rise-related saline intrusion of groundwater (Taylor et al., 2012) may increase the salt intake of affected populations, a risk factor for hypertension that has been observed to increase blood pressure in exposed populations (Talukder et al., 2017);(MA. et al., 2018).

7.2.3.2 Non-communicable Respiratory Diseases

Lung diseases, including asthma, chronic obstructive pulmonary disease (COPD), and lung cancer, comprise the largest subsets of non-communicable pulmonary disease (Ferkol and Schraufnagel, 2014). Overall, the global burden of non-communicable lung disease including all chronic lung disease and lung cancer is substantial, responsible for 10.6% of deaths and 5.9% of DALYs globally in 2019 (Vos et al., 2020).

Several non-communicable respiratory diseases are climate sensitive based on their exposure pathways (very high confidence). Multiple exposure pathways contribute to non-communicable respiratory disease (Deng et al., 2020), some of which are climate-related, (Rice et al., 2014), including mobilization and transport of dust (Schweitzer et al., 2018 (Schweitzer et al., 2018); changes in concentrations of air pollutants such as small particulates (PM2.5) and ozone formed by photochemical reactions sensitive to temperature (Hansel et al., 2016), increased wildland fires and related smoke exposure (Johnston et al., 2002);(Reid et al., 2016); increased exposure to ambient heat driving reduced lung function and exacerbations of chronic lung disease (Collaco et al., 2018) (Jehn et al., 2013);(McCormack et al., 2016);(Witt et al., 2015); and modification of aeroallergen production and duration of exposure (Ziska et al., 2019).

Burdens of allergic disease, particularly allergic rhinitis and allergic asthma may be changing in response to climate change (medium confidence). (D'Amato et al., 2020);(Eguiluz-Gracia et al., 2020), (Deng et al., 2020), (Demain, 2018). This is supported by evidence showing an increase in the length of the North American pollen season attributable to climate change (Ziska et al., 2019), an association between timing of spring onset and higher asthma hospitalizations presumed to be due to higher pollen exposure (Sapkota et al., 2020), and other evidence linking aeroallergen exposure with a worsening burden of allergic disease (Demain, 2018);(Poole et al., 2019).

7.2.3.3 Cancer

Climate change is likely to increase the risk of several malignancies (high confidence), though the degree to which risks may increase remains unclear. Cancers, also known as malignant neoplasms, include a heterogeneous collection of diseases with various causal pathways, many with environmental influences. Malignant neoplasms impose a substantial burden of disease globally, responsible for slightly over 10 million deaths and 251 million DALYs globally in 2019 (Vos et al., 2020). Climatic hazards affect exposure pathways for several different chemical hazards associated with carcinogenesis (Portier et al., 2010). Most relevant literature has focused on elaborating potential pathways and producing qualitative or quantitative estimates of effect, though there is limited literature on current and projected impacts.

The vast majority of elaborated pathways point to increased risk; for example, there is concern that climate change may alter the fate and transport of carcinogenic polyaromatic hydrocarbons (Domínguez-Morueco et al., 2019) and increase mobilization of carcinogens such as bromide (Regli et al., 2015), persistent organic pollutants including polychlorinated-biphenyls that have accumulated in areas contaminated by industrial runoff (Miner et al., 2018), and radioactive material (Evangeliou et al., 2014). Exposure to these known carcinogens can occur through multiple environmental media and can be increased by climate change, for example through increased flooding related to extreme precipitation events and mobilization of sediment where carcinogens have accumulated (León et al., 2017);(Santiago and Rivas, 2012). In addition, there is concern that changes in ultraviolet light exposure related to shifts in precipitation may increase the incidence of malignant melanoma, particularly for outdoor workers (Modenese et al., 2018). Other harmful pathways include migration of and increased exposure to liver flukes, which cause hepatobiliary cancer (Prueksapanich et al., 2018) and introduction of infectious diseases such as schistosomiasis that increase cancer risk due to climate-related migration (Ahmed et al., 2014). Increased exposure to carcinogenic toxins via multiple pathways is also a concern. Aflatoxin exposure, for example, is expected to increase in Europe (Moretti et al., 2019), India (Shekhar et al., 2018), Africa (Gnonlonfin et al., 2013);(Bandyopadhyay et al., 2016), and North America (Wu et al., 2011). Other carcinogenic toxins originate from cyanobacteria blooms (Lee et al., 2017a), which are projected to increase in frequency and distribution with climate change (Wells et al., 2015);(Paerl et al., 2016);(Chapra et al., 2017).

7.2.3.4 Diabetes

Individuals suffering from diabetes are at higher risk of heat-related illness and death (medium confidence). Extreme weather events and rising temperatures ihave been found ncreasing morbidity and mortality in patients living with diabetes, especially in those with cardiovascular complications (Méndez-Lázaro et al., 2018; Zilbermint, 2020) (Hajat et al., 2017). Evidence suggests that the local heat loss response of skin blood flow (SkBF) is affected by diabetes-related impairments, resulting in lower elevations in SkBF in response to a heat or pharmacological stimulus. Thermoregulatory sweating may also be diminished by type 2 diabetes, impairing the body's ability to transfer heat from its core to the environment (Xu et al., 2019b). Observed higher rates of doctor consultations by patients with type-2 diabetes, and diabetics with cardiovascular comorbidities increased their rates of medical consultation during hot days, but there was no heightened risk with renal failure or neuropathy comorbidities.

People with chronic illness/es are at particular risk during and after extreme weather events due to treatment interruptions and lack of access to medication (medium confidence). The impacts of extreme weather events on the health of chronically ill people are due to a range of factors including disruption of transport, weakened health systems including drug supply chains, loss of power, and evacuations of populations (Ryan et al., 2015a). Evacuations also pose specific health risks to older adults (especially those who are frail, medically incapacitated, or residing in nursing or assisted living facilities) and may be complicated by the need for concurrent transfer of medical records, medications and medical equipment (Becquart et al., 2018);(Quast and Feng, 2019);(USGCRP, 2016). Emergency room visits after Hurricane Sandy rose among individuals with type-2 diabetes (Velez-Valle et al., 2016).

7.2.4 Observed Impacts on Other Climate-sensitive Health Outcomes

7.2.4.1 Heat and Cold Related Mortality and Morbidity

E*xtreme heat events and extreme temperature have well documented, observed impacts on health, mortality (very high confidence) and morbidity (high confidence).* AR5 described the thermoregulatory mechanisms and responses, including acclimatization, linking heat, cold and health, and these have been further confirmed by recent studies and reviews (e.g., (Giorgini et al., 2017);(Ikaheimo, 2018);(McGregor et al., 2015);(Stewart et al., 2017);(Schuster et al., 2017);(Zhang et al., 2018b). The health impacts of heat manifest clearly in periods of extreme heat often codified as heatwaves. For example, heatwaves across Europe (2003), Russia (2010), India (2015) and Japan (2018) resulted in significant death tolls and hospitalizations (McGregor et al., 2017), (Hayashida et al., 2019). Heat continues to pose a significant health risk due to increases in exposure, an outcome of changes in the size and spatial distribution of the human population, mounting vulnerability and an increase in extreme heat events (high confidence) (Harrington et al., 2017; Liu et al., 2017);(Mishra et al., 2017);(Rohat et al., 2019a; Rohat et al., 2019b; Rohat et al., 2019c);(Watts et al., 2019). Furthermore, some regions are already experiencing heat stress conditions approaching the upper limits of labour productivity and human survivability (high confidence). These include the Persian Gulf and adjacent land areas, parts of the Indus River Valley, eastern coastal India, Pakistan, north-western India, the shores of the Red Sea, the Gulf of California, the southern Gulf of Mexico, and coastal Venezuela and Guyana (Krakauer et al., 2020);(Li et al., 2020);(Raymond et al., 2020);(Saeed et al., 2021);(Xu et al., 2020).

Notwithstanding the variety of methods applied, estimates of the world's current population exposed to extreme heat indicate very large numbers and an increase since pre-industrial times. For example, Li et al (2020) estimate that globally and annually, 1.28 billion people experience heatwave conditions similar to that of the lethal Chicago 1995 event compared to 0.99 billion under a preindustrial climate. Further, for the 150 most populated cities of the world, a 500% increase in the exposure to extreme heat events occurred over the period 1980 – 2017 (Li et al., 2021), while for the period 1986–2005, the total exposure to dangerous heat in Africa's 173 largest cities was 4.2 billion person-days per year (Rohat et al., 2019a). Globally the present exposure to heatwave events is estimated to be 14.8 billion person-days per year, with the greatest cumulative exposures measured in person-days occurring across southern Asia (7.19 billion), sub-Saharan Africa (1.43 billion) and North Africa and the Middle East (1.33 billion) (Jones et al., 2018).

The country level percentage of mortality attributable to non-optimum temperature (heat and cold) has been found to range from 3·4% to 11·00% (Gasparrini et al., 2015);(Zhang et al., 2019b). Heat as a health risk factor has largely been overlooked in low and middle-income countries, (Campbell et al., 2018) (Green et al., 2019);(Dimitrova et al., 2021). For 2019, the Global Burden of Disease report estimates the burden of DALYs attributable to low temperature was 2.2 times greater than the burden attributable to high temperature. However, this global figure obscures important regional variations. Countries with a high socio-demographic index - mainly mid-latitude high income temperate to cool climate countries -, were found to have a cold-related burden 15.4 times greater than the heat-related burden, while for warm lower income regions, such as south Asia and sub-Saharan Africa, the heat-related burden was estimated to be 1.7 times and 3.6 times greater respectively (Murray et al., 2020). For countries where data availability permits, there is evidence that extreme heat (and extreme cold) leads to higher rates of premature deaths (Armstrong et al., 2017);(Cheng et al., 2018);(Costa et al., 2017).
Rapid changes and variability in temperatures are observed to increase heat-related health and mortality risks, the outcomes varying across temperate and tropical regions (Guo et al., 2016);(Cheng et al., 2019); (Kim et al., 2019a);(Tian et al., 2019);(Zhang et al., 2018b);(Zhao et al., 2019).

Several lines of evidence point to a possible decrease in population sensitivity to heat, albeit mainly for high-income countries (high confidence), arising from the implementation of heat warning systems, increased *awareness, and improved quality of life.* (Sheridan and Allen, 2018). Evidence manifests as, a general decrease in the impact of heat on daily mortality(Diaz et al., 2018);(Kinney, 2018);(Miron et al., 2015), a decline in the relative risk attributable to heat (Åström et al., 2018);(Barreca et al., 2016);(Petkova et al., 2014), and an increase in the minimum mortality temperature (MMT) (Åström et al., 2018);(Folkerts et al., 2020);(Follos et al., 2021);(Chung et al., 2018);(Todd and Valleron, 2015); (Yin et al., 2019). It is difficult to draw conclusions regarding trends in heat sensitivity for low to middle-income countries and specific vulnerable groups as these are under-represented in the literature (Sheridan and Allen, 2018). Trends in heat sensitivity are likely to be scale and situation dependent as considerable inter-city variability in changes in heat sensitivity as measured by trends in heat-related mortality or MMT (Follos et al., 2021);(Kim et al., 2019a);; (Lee et al., 2021) exist as well as variability amongst different population groups (Lu et al., 2021).

Temperature interacts with heat-sensitive physiological mechanisms via multiple pathways to affect health. In the worst cases these lead to organ failure and death (Mora et al., 2017a; Mora et al., 2017b). Excess deaths during extreme heat events occur predominantly in older individuals and are overwhelmingly cardiovascular in origin *(very high confidence)*. A higher occurrence of CVD mortality in association with prolonged period of low temperatures has been well documented globally (Giorgini et al., 2017);(Stewart et al., 2017); however, there is growing evidence that cardiovascular deaths are more related to heat events than cold spells (Chen et al., 2019);(Liu et al., 2015a);(Bunker et al., 2016). Whilst there is strong association between ambient temperature and cardiovascular events globally, there are complex interactions and modulators of individual response (Wang et al., 2017b). Further, some CVD morbidity sub-groups such as myocardial infarction and stroke hospitalization display temperature sensitivity, while others do not (Bao et al., 2019);(Sun et al., 2018);(Wang et al., 2016). Although older adults have inherent sensitivities to temperature-related health impacts (Bunker et al., 2016);(Phung et al., 2016), children can also be affected by extreme heat (Xu et al., 2014). Cardiovascular capacity/health is also a critical determinant of individual health outcomes (Schuster et al., 2017). Medications to treat CVD diseases, such as diuretics and beta-blockers, may impair resilience to heat stress (Stewart et al., 2017). Other mediating factors in the causal pathway range from alcohol consumption (Cusack et al., 2011);(Epstein and Yanovich, 2019) and obesity (Speakman, 2018) to pre-existing conditions such as diabetes and hyperlipidaemia, and urban characteristics (Chen et al., 2019), (Sera et al., 2019).

Under extreme heat conditions, increases in hospitalizations have been observed for fluid disorders, renal failure, urinary tract infections, septicaemia, general heat stroke as well as unintentional injuries (Borg et al., 2017);(Phung et al., 2017);(Goggins and Chan, 2017);(Hayashida et al., 2019);(Hopp et al., 2018);(Ito et al., 2018);(Kampe et al., 2016);(McTavish et al., 2018);(Ponjoan et al., 2017);(van Loenhout et al., 2018). Hospitalisations and mortality due to respiratory disorders also occur during heat events with the interactive role of air quality important for some locations but not others (Krug et al., 2019);(Pascal et al., 2021);(Patel et al., 2019). Increased levels of heat-related hospitalisation also manifest in elevated levels of emergency services call out (Cheng et al., 2016);(Guo, 2017);(Papadakis et al., 2018);(Williams et al., 2020).

Heat and cold related health outcomes vary by location (Dialesandro et al., 2021);(Hu et al., 2019);(Phung et al., 2016), suggesting outcomes are highly moderated by socio-economic, occupational and other non-climatic determinants of individual health and socio-economic vulnerability (Åström et al., 2020);(McGregor et al., 2017);(McGregor et al., 2017);(Schuster et al., 2017), (Benmarhnia et al., 2015);(Watts et al., 2019) (*high confidence*). For example, access to air conditioning is an important determinant of heat-related health outcomes for some locations (Guirguis et al., 2018);(Ostro et al., 2010). Although there is a paucity of global level studies of the effectiveness of air conditioning for reducing heat-related mortality, a recent assessment indicates increases in air conditioning explains only part of the observed reduction in heat-related excess deaths, amounting to 16.7% in Canada, 20.0% in Japan, 14.3% in Spain and 16.7% in the US (Sera et al., 2020).

Significant effects of heat exposure are evident in sport and work settings with exertional heat illness leading to death and injury (Adams and Jardine, 2020). Although most studies of heat-related sports injuries refer to high-income countries, these point to an increasing number of heat injuries with widening participation in sport and an increasing frequency of extreme heat events. The highest rates of exertional heat illness are reported for endurance type events (running, cycling, adventure races), American football and athletics (Gamage et al., 2020); (Grundstein et al., 2017);(Kerr et al., 2020);(McMahon et al., 2021);(Yeargin et al., 2019). The health, safety and productivity consequences of working in extreme heat are widespread (Ma et al., 2019);(Morabito et al., 2021);(Kjellstrom et al., 2019);(Orlov et al., 2020);(Smith et al., 2021);(Vanos et al., 2019);(Varghese et al., 2020);(Williams et al., 2020). Occupational heat strain in outdoor workers manifests as dehydration, mild reduction in kidney function, fatigue, dizziness, confusion, reduced brain function, loss of concentration and discomfort (Al-Bouwarthan et al., 2020);(Boonruksa et al., 2020);(Habibi et al., 2021);(Levi et al., 2018);(Venugopal et al., 2021);(Xiang et al., 2014). In the case of the armed forces, a global review of the available literature points to a slightly higher incidence of heat stroke in men compared to women but a higher proportion of heat intolerance and greater risk of exertional heat illness amongst women (Alele et al., 2020). There is also some evidence that for healthcare workers, the risk of occupational heat stress heightened during the COVID-19 pandemic due to the need to wear personal protective equipment (Foster et al., 2020);; (Lee et al., 2020);(Messeri et al., 2021). Based on a systematic review of the literature, one study estimates global costs from heat-related lost work time were USD 280 billion in 1995 and USD 311 billion in 2010 with low- and middle-income countries and countries with warmer climates possessing greater losses as a proportion of GDP (Borg et al., 2021). Other global level assessments note an increase in the potential hours of work lost due to heat over the period 2000 –2018; in 2018, 133·6 billion potential work hours were lost amounting to 45 billion hours more than in 2000 (Watts et al., 2019). Further, for China heat-related productivity losses have been estimated at 9·9 billion hours in 2019, equivalent to 0·5% of the total national work hours for that year with Guangdong province, one of the warmest regions in China, accounting for almost a quarter of the losses (Cai et al., 2021).

Wide ranging knowledge regarding the specific detection and attribution of heat and cold-related mortality/morbidity to observed climate change is lacking. Although there has been an observed increase in winter season temperatures for a number of regions, to date there is variable evidence for a consequential reduction in winter mortality and susceptibility to cold over time due to milder winters - some countries demonstrate decreasing trends, other countries stable or even increasing trends in cold-attributable mortality fractions over time (e.g. (Arbuthnott et al., 2020);(Åström et al., 2013);(Diaz et al., 2019);(Hajat, 2017);(Hanigan et al., 2021);(Lee et al., 2018b). While there is a burgeoning literature on the attribution of extreme heat events to climate change (e.g. (Vautard et al., 2020)), the number of studies that assess the extent to which observed changes in heat-related mortality may be attributable to climate change is small (Ebi et al., 2020). During the 2003 European heatwave, anthropogenic climate change increased the risk of heat-related mortality by approximately 70% and 20% for London and Paris respectively (Mitchell et al., 2016). For the severe heat event across Egypt in 2015, the impact on human discomfort was 69% (±17%) more likely due to anthropogenic climate change (Mitchell, 2016) and for Stockholm, Sweden it has been estimated that mortality due to temperature extremes for 1980–2009 was double what would have occurred without climate change (Åström et al., 2013). To date there has only been one multi-country attempt to quantify the heat-related human health impacts that have already occurred due to climate change. Based on an analysis of 732 locations spanning 43 countries, for the period 1991–2018, the study found that on average, 37.0% (inter-quartile range 20.5–76.3%) of warm-season heat-related deaths can be attributed to anthropogenic climate change, equivalent to an average mortality rate of 2.2/100,000 (median: 1.67/100,00; interquartile range: 1.08 - 2.34/100,000) Regions with a high attributed percentage (> 50%) include southern and western Asia (Iran and Kuwait), Southeast Asia (Philippines and Thailand) and several countries in Central and South America. Those with lower values (<35%) include western Europe (Netherlands, Germany, Switzerland), eastern Europe (Moldova, Czech Republic, Romania), southern Europe (Greece, Italy, Portugal, Spain), North America (USA) and eastern Asia (China, Japan, South Korea) (Vicedo-Cabrera et al., 2021). Due to data restrictions some of the poorest and most susceptible regions to climate change and increases in heat exposure, such as West and East Africa (Asefi-Najafabady et al., 2018);(Sylla et al., 2018) and South Asia, could not be included in the analysis (Mitchell, 2021).

7.2.4.2 Injuries Arising from Extreme Weather Events Other than Heat and Cold

Injuries comprise a substantial portion of the global burden of disease. In 2019, injuries comprised 9.82% of total global DALYs and 7.61% of deaths (Vos et al., 2020). The causal pathways for many injuries, particularly those from heat and extreme weather events, flooding, and fires, exhibit clear climate sensitivity (Roberts and Arnold, 2007);(Roberts and Hillman, 2005), as do some injuries occurring in occupational settings (Marinaccio et al., 2019);(Sheng et al., 2018), but a comprehensive assessment of climate sensitivity in injury causal pathways has not been done. Certain groups, including Indigenous Peoples, children, and elders (Ahmed et al., 2020) are at greater risk for a wide range of injuries. Extreme events impose substantial disease burden directly as a result of traumatic injuries, drowning, and burns and large mental health burdens associated with displacement (Fullilove, 1996), depression, and post-traumatic stress disorder, but the overall injury burden associated with extreme weather is not known. It is known that the Asia-Pacific region experienced the highest relative burden of injuries from extreme weather in recent decades (Hashim and Hashim, 2016).

Extreme weather imposes a substantial morbidity and mortality burden that is quite variable by location and hazard. The proportion of this burden related to injuries specifically is not established. From 1998-2017 there were 526,000 deaths from 11,500 extreme weather events, and the average annual attributable all-cause mortality incidence in the ten most affected countries was 3.5 per 100,000 population (Eckstein et al., 2017). Rates can be much higher, however; mortality incidence in Puerto Rico and Dominica from extreme weather were 90.2 and 43.7 per 100,000 population in 2017, respectively (Eckstein et al., 2017). Not all of these deaths are from injuries, and the proportion of mortality and morbidity associated with injuries varies by location and hazard. One review found that one-year post-event prevalence rates for injuries associated with extreme events (floods, droughts, heatwaves, and storms) in developing countries ranged from 1.4% to 37.9% (Rataj et al., 2016). Other literature has documented an increase in risk of motor vehicle accidents in association with extreme precipitation (Liu et al., 2017);(Stevens et al., 2019) and temperature (Leard and Roth, 2019)and in association with sandstorms (Islam et al., 2019), and an increased risk of traumatic occupational injuries associated with temperature extremes, particularly extreme heat, likely from fatigue and decreased psychomotor performance (Varghese et al., 2019).

There is clear evidence of climate sensitivity for multiple injuries from floods, fires, and storms, but limited evidence regarding current injury burden attributable to climate change. It is *as likely as not* that climate change has increased the current burden of disease from injuries related to extreme weather, particularly in low-income settings *(low confidence)*. Approximately 120 million people are exposed to coastal flooding annually (Nicholls et al., 2007), causing an estimated 12,000 deaths (Shultz et al., 2005)and there is significant concern for worsening associated with climate change (Shultz et al., 2018a);(Shultz et al., 2018b);(Woodward and Samet, 2018)but very limited quantification of attributable burden. As for projected exposures, there is sufficient evidence to assess risks related to flooding only, though there is very limited literature highlighting increased morbidity and mortality an increase in fires in sub-zero temperatures that are thought to be highly attributed to climate change (Metallinou and Log, 2017).

7.2.4.3 Observed Impacts on Maternal, Fetal, and Neonatal Health

Maternal and neonatal disorders accounted for 3.67% of total global deaths and 7.83% of global DALYs in 2019 (Vos et al., 2020). Children and pregnant women have potentially higher rates of vulnerability and/or exposure to climatic hazards, extreme weather events, and undernutrition (Garcia and Sheehan, 2016), (Sorensen et al., 2018), (Chersich et al., 2018). Available evidence suggests that heat is associated with higher rates of preterm birth (Wang et al., 2020a) low birthweight, stillbirth, and neonatal stress (Cil and Cameron, 2017);(Kuehn and McCormick, 2017) and with adverse child health (Kuehn and McCormick, 2017). Extreme weather events are associated with reduced access to prenatal care and unattended deliveries (Abdullah et al., 2019) and decreased paediatric health care access (Haque et al., 2019).

7.2.4.4 Observed Impacts on Malnutrition

Climate variability and change contribute to food insecurity that can lead to malnutrition, including undernutrition, overweight, obesity; and to disease susceptibility, particularly in low- and middle-income countries (high confidence). Since AR5, analyses of the links between climate change and food expanded beyond undernutrition to include the impacts of climate change on a wider set of diet and weight-related risk factors and their impacts on NCDs, along with the role of dietary choices for GHG emissions (SRCCL, 2019 including dietary inadequacy (deficiencies, excesses, or imbalances in energy, protein, and micronutrients), infections, and sociocultural factors {Global, 2020, Global Nutrition Report: Action on equity to end malnutrition). Undernutrition exists when a combination of insufficient food intake, health, and care conditions results in one or more of underweight for age, short for age (stunted), thin for height (wasted), or functionally deficient in vitamins and/or minerals (micronutrient malnutrition or "hidden hunger"). Food insecurity and poor access to nutrient dense food contribute not only to undernutrition, but also to obesity and susceptibility to non-communicable diseases in low- and middle-income countries (FAO et al., 2018);(Swinburn et al., 2019).

Globally, more than 690 million people are undernourished, 144 million children are stunted (chronic undernutrition), 47 million children are wasted (acute undernutrition), and more than 2 billion people have micronutrient deficiencies (FAO, 2020). More than 135 million people across 55 countries experienced acute hunger requiring urgent food, nutrition, and livelihoods assistance in 2019 (FSIN/GNAFC, 2020). The COVID-19 pandemic is projected to increase the number of acutely food insecure people to 270 million people (FSIN, 2020) and worsen malnutrition levels (FAO et al., 2020); (Rippin et al., 2020)). The relationships between climate change and obesity vary based on geography, population subgroups, and/or stages of economic growth and population growth. (An et al., 2017). Increasing temperatures could contribute to obesity through reduced physical activity, increased prices of produce, or shifts in eating patterns of populations toward more processed foods. (An et al., 2018). In the largest global study to date exploring the connections between child diet diversity and recent climate, data from 19 countries in six regions (Asia, Central America, North Africa, South America, Southeast Africa, and West Africa) indicated significant reductions in diet diversity associated with higher temperatures and significant increases in diet diversity associated with higher precipitation (Niles et al., 2021).

Climate change can affect the four aspects of food security: food production and availability, stability of food supplies, access to food, and food utilization (SRCCL, 2019). Access to sufficient food does not guarantee nutrition security. Extreme weather and climate events can result in inadequate or insufficient food consumption, increasing susceptibility to infectious diseases (Rodriguez-Llanes et al., 2016);(Gari et al., 2017);(Kumar et al., 2016);(Lazzaroni and Wagner, 2016 but also to being overweight or obese, and susceptibility to non-communicable diseases in LIMICs {FAO, 2018, The State of Food Security and Nutrition in the World 2018);(Swinburn et al., 2019).

Nearly half of all deaths in children under 5 are attributable to undernutrition, putting children at greater risk of dying from common infections (2021). Undernutrition in the first 1,000 days of a child's life can lead to stunted growth, which can result in impaired cognitive ability and reduced future school and work performance and the associated costs of stunting in terms of lost economic growth can be of the order of 10% of GDP per year in Africa (UNICEF/WHO/WBG, 2019).

At the same time, diseases associated with high-calorie, unhealthy diets are increasing globally, with 38.3 million overweight children under five years of age (GNR, 2018), 2.1 billion adults are overweight or obese and the global prevalence of diabetes almost doubled in the past 30 years (Swinburn et al., 2019). Unbalanced diets, such as diets low in fruits and vegetables and high in red and processed meat, are the number one risk factor for mortality globally and in most regions (Collaborators, 2018b);(Collaborators, 2019).

Socio-economic factors that mediate the influence of climate change on nutrition include cultural and societal norms; governance, institutions, policies, and fragility; human capital and potential; social position and access to healthcare, education, and food aid (Rozenberg, 2017); Alkerwi et al. 2015;(Tirado, 2017);(FAO et al., 2018);(Report, 2020). Extreme events may affect access to adequate diets, leading to malnutrition and increasing the risk of disease (Beveridge et al., 2019);(Rodriguez-Llanes et al., 2016);(Gari et al., 2017);(Kumar et al., 2016);(Lazzaroni and Wagner, 2016);(Thiede and Gray, 2020).

7.2.4.5 Observed Impacts on Exposure to Chemical Contaminants

Climate change in northern regions, including Arctic ecosystems, is causing permafrost to thaw, creating the potential for mercury (Hg) to enter the food chain (medium agreement, low evidence), as Methyl mercury (MeHg) is highly neurotoxic and nephrotoxic and bioaccumulates and biomagnifies throughout the food chain via dietary uptake of fish, seafood, and mammals. Mercury methylation processes in aquatic environments have been found exacerbated by ocean warming, coupled with more acidic and anoxic sediments (FAO, 2020). Consumption of mercury-contaminated fish has been found linked to neurological disorders due to methyl mercury poisoning (i.e., Minamata disease) that is associated withlimate change-contaminant interactions that alter the bioaccumulation and biomagnification of toxic and fat-soluble persistent organic pollutants, such as persistent organic pollutants (POPs) and polychlorinated biphenyls (PCBs) (J.J. et al., 2017) in seafood and marine mammals (*medium confidence)*. Indigenous peoples have a higher exposure to such risks because of the accumulation of such toxins in traditional foods (J.J. et al., 2017). Contamination of food with PCBs and dioxins that have a range of adverse health impacts (Lake et al., 2015).

Chapter 5 (5.4.3, 5.5.2.3, 5.8.1, 5.8.2, 5.8.3, 5.9.1, 5.11.1, 5.11.3, 5.12.3) discusses the possible impacts of climate change on food safety, including exposure to toxigenic fungi, PCBs, and other persistent organic pollutants, mercury, and harmful algal blooms.

Climate change may affect animal health management practices, potentially leading to an increased use of pesticides or veterinary drugs (such as preventive antimicrobials) that could result in increased levels of residues in foods (high agreement, medium/low evidence). (Beyene et al., 2015); (FAO and WHO, 2018);(Authority) et al., 2020);(Authority) et al., 2020); (MacFadden et al., 2018)).

7.2.5 Observed Impacts on Mental Health and Wellbeing

7.2.5.1 Observed Impacts on Mental Disorders

A wide range of climatic events and conditions have observed and detrimental impacts on mental health (very high confidence). The pathways through which climatic events affect mental health are varied, complex and interconnected with other non-climatic influences that create vulnerability. The climatic exposure may be direct, such as experiencing an extreme weather event or prolonged high temperatures, or indirect, such as mental health consequences of undernutrition or displacement. Exposure may also be vicarious, with people experiencing decreased mental health associated with observing the impact of climate change on others, or simply with learning about climate change. Non-climatic moderating influences range from an individual's personality and pre-existing conditions, to social support, to structural inequities (Gariepy et al., 2016);(Hrabok et al., 2020);(Nagy et al., 2018);(Silva et al., 2016b). Depending on these background and contextual factors, similar climatic events may result in a range of potential mental health outcomes, including anxiety, depression, acute traumatic stress, post-traumatic stress disorder, suicide, substance abuse, and sleep problems, with conditions ranging from being mild in nature to those that require hospitalization (Berry et al., 2010);(Cianconi et al., 2020);(Clayton et al., 2017);(Ruszkiewicz et al., 2019);(Bromet et al., 2017);{Lowe, 2019, Posttraumatic Stress and Depression in the Aftermath of Environmental Disasters: A Review of Quantitative Studies Published in 2018}. The line between mental health and more general wellbeing is permeable, but in this section we refer to diagnosable mental disorders, conditions that disrupt or impair normal functioning through impacts on mood, thinking, or behaviour.

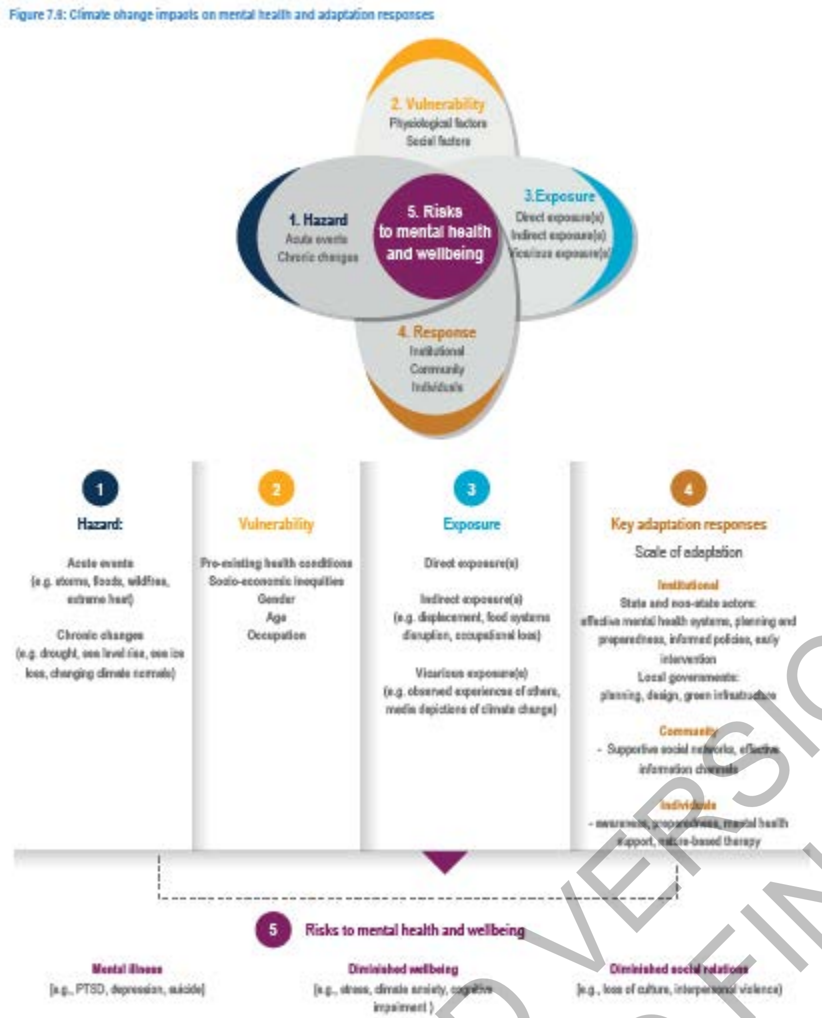

Figure 7.6: Climate change impacts on mental health and key adaptation responses

There is an observable association between high temperatures and mental health decrements (high confidence), with an additional possible influence of increased precipitation (medium agreement, medium evidence). Heat-associated mental health outcomes include suicide (Williams et al., 2015a);(Carleton, 2017);(Burke et al., 2018);(Kim et al., 2019b);(Thompson et al., 2018), (Schneider et al., 2020);(Cheng et al., 2021);(Baylis et al., 2018);(Obradovich et al., 2018); psychiatric hospital admissions and ER visits for mental disorders (Hansen et al., 2008);(Wang et al., 2014);(Chan et al., 2018);(Mullins and White, 2019);(Yoo et al., 2021), experiences of anxiety, depression, and acute stress (Obradovich et al., 2018);(Mullins and White, 2019), and self-reported mental health (Li et al., 2020). In Canada, Wang et al. (2014) found an association between mean heat exposure of 28°C within 0 to 4 days of exposure and greater hospital admissions for mood and behavioural disorders (including schizophrenia, mood, and neurotic disorders). A US study found mental health problems increased by 0.5% when average temperatures exceeded 30°C, compared to averages between 25–30°C; a 1°C warming over 5 years was associated with a 2% increase in mental health problems (Obradovich et al., 2018). Another study found a 1°C rise in monthly average temperatures over several decades was associated with a 2.1% rise in suicide rates in Mexico and a 0.7% rise in suicide rates in the US (Burke et al., 2018). A systematic review of published research using a variety of methodologies from 19 countries (Thompson et al., 2018) found increased risk of suicide associated with a 1°C rise in ambient temperature.

Discrete climate hazards including storms have significant negative consequences for mental health (very high confidence). (Kessler et al., 2008);(Boscarino et al., 2013);(Boscarino et al., 2017);(Obradovich et al., 2018), floods (Baryshnikova and Pham, 2019), heatwaves, wildfires, and drought (Hanigan et al., 2012);(Carleton, 2017);(Zhong et al., 2018) (Charlson et al., 2021).A large body of research identifies impacts of extreme weather events on post-traumatic stress disorder, anxiety, and depression; much of the research has been done in the U.S. and the UK, but a growing number of studies find evidence for similar impacts on mental health in other countries, including Spain (Foudi et al., 2017), Brazil (Alpino et al., 2016), Chile (Navarro et al., 2016), Small Island Developing States (Kelman et al., 2021), and Vietnam (Pollack et al., 2016). Approximately 20–30% of those who live through a hurricane develop depression and/or post-traumatic stress disorder (PTSD) within the first few months following the event (Obradovich et al., 2018);(Schwartz et al., 2015);(Whaley, 2009), with similar rates for people who have experienced flooding (Waite et al., 2017);(Fernandez et al., 2015). Studies conducted in South America and Asia indicate an increase in post-traumatic stress disorders and depressive disorders after extreme weather events (Rataj et al., 2016). Evidence is lacking for African countries (Otto et al., 2017). Children and adolescents are particularly vulnerable to post-traumatic stress after extreme weather events (Brown et al., 2017);(Hellden et al., 2021);(Kousky, 2016), and increased susceptibility to mental health problems may linger into adulthood (Maclean et al., 2016).

Wildfires have observed negative impacts on mental health (high confidence). This is due to the trauma of the immediate experience and/or subsequent displacement and evacuation (Dodd et al., 2018);(Brown et al., 2019);(Psarros et al., 2017);(Silveira et al., 2021b), Subclinical outcomes, such as increases in anxiety, sleeplessness, or substance abuse are reported in response to wildfires and extreme weather events, with impacts being pronounced among those who experience greater losses or are more directly exposed to the event; this may include first responders.

Mental health impacts can emerge as result of climate impacts on economic, social and food systems (high confidence). For example, malnutrition among children has been associated with a variety of mental health problems (Adhvaryu et al., 2019);(Hock et al., 2018);(Yan et al., 2018), as has food insecurity among adults (Lund et al., 2018). The economic impacts of droughts have been associated with increases in suicide, particularly among farmers (Carleton, 2017);(Edwards et al., 2015);(Vins et al., 2015); those whose occupations are likely to be affected by climate change report that it is a source of stress that is linked to substance abuse and suicidal ideation (Kabir, 2018). Studies of Indigenous Peoples often describe food insecurity or reduced access to traditional foods as a link between climate change and reduced mental health (Middleton et al., 2020b). The loss of family members, e.g. due to an extreme weather event, increases the risk of mental illness (Keyes et al., 2014). Individuals in low and middle-income countries may be more severely impacted due to lesser access to mental health services and lower financial resources to help cope with impacts, compared with high-income countries (Abramson et al., 2015).

Anxiety about the potential risks of climate change and awareness of climate change itself can affect mental health even in the absence of direct impacts (low confidence). There is not yet robust evidence about the prevalence or severity of climate change-related anxiety, sometimes called ecoanxiety, but national surveys in the U.S., Europe, and Australia show that people express high levels of concern and perceived harm associated with climate change (Steentjes et al., 2017), (Clayton and Karazsia, 2020);(Cunsolo and Ellis, 2018);(Helm et al., 2018). (Leiserowitz et al., 2017);(Reser et al., 2012);(Steentjes et al., 2017). In a U.S. sample, perceived ecological stress, defined as personal stress associated with environmental problems, predicted depressive symptoms (Helm et al., 2018);in a sample of Filipinos, climate anxiety was correlated with lower mental health (Reyes et al., 2021), and a non-random study in 25 countries showed positive correlations between negative emotions about climate change and self-rated mental health (Ogunbode et al., 2021). However, an earlier study found no correlation between climate change worry and mental health issues (Berry and Peel, 2015). Because the perceived threat of climate change is based on subjective perceptions of risk and coping ability as well as on experiences and knowledge (Bradley et al., 2014), even people who have not been directly affected may be stressed by a perception of looming danger (Clayton and Karazsia, 2020). Not surprisingly, those who have directly experienced some of the effects of climate change may be more likely to show such responses. Indigenous Peoples, whose culture and wellbeing tend to be strongly linked to local environments, may be particularly likely to experience mental health effects associated with changes in environmental risks; studies suggest connections to an increase in depression, substance abuse, or suicide in some Indigenous Peoples (Canu et al., 2017);(Cunsolo Willox et al., 2013);(Middleton et al., 2020b);(Jaakkola et al., 2018).

7.2.5.2 Observed Impacts on Wellbeing

*Overall, research suggests that climate change has already had negative effects on subjective wellbeing (medium confidence). C*limate change can affect wellbeing through a number of pathways, including loss of access to green and blue spaces due to damage from storms, coastal erosion, drought, or wildfires; heat; decreased air quality; and disruptions to one's normal pattern of behaviour, residence, occupation, or social interactions (Hayward and Ayeb-Karlsson, 2021). For example, substantial evidence shows a negative correlation between air pollution and subjective wellbeing or happiness (Apergis, 2018);(Cunado and de Gracia, 2013);(Lu, 2020);(Luechinger, 2010);(Menz and Welsch, 2010);(Orru et al., 2016);(Yuan et al., 2018);(Zhang et al., 2017a); in the reverse direction, there is evidence not only that time in nature but more specifically a feeling of connectedness to nature are both associated with wellbeing (Martin et al., 2020) and healthy ecosystems offer opportunities for health improvements (Pretty and Barton, 2020). Negative emotions such as grief - often termed 'solastalgia'(Albrecht et al., 2007) -- are associated with the degradation of local or valued landscapes (Eisenman et al., 2015);(Ellis and Albrecht, 2017);(Polain et al., 2011);(Tschakert et al., 2017);(Tschakert et al., 2019), which may threaten cultural rituals, especially among Indigenous Peoples (Cunsolo and Ellis, 2018);(Cunsolo et al., 2020). Studies conducted in the Solomon Islands and in Tuvalu found qualitative and quantitative evidence of experiences of climate change and worry about the future, with negative impacts on respondents' wellbeing (Asugeni et al., 2015);(Gibson et al., 2020).

Heat is one of the best-studied aspects of climate change observed to reduce wellbeing (high confidence). Higher summer temperatures are associated with decreased happiness and ratings of wellbeing (Carleton and Hsiang, 2016);(Miles-Novelo and Anderson, 2019). (Connolly, 2013);(Noelke et al., 2016);(Baylis et al., 2018);(Moore et al., 2019);(Wang et al., 2020b). A study of 1.9 million Americans, (Noelke et al., 2016) found that exposure to one day averaging 21–27 °C was associated with reduced wellbeing by 1.6% of a standard deviation, and days above 32°C were associated with reduced wellbeing by 4.4% of a standard deviation relative to a reference interval of 10–16 °C. A similar relationship between heat and mood has been observed in China, where expressed mood began to decrease when the average daily temperature was over 20°C (Wang et al., 2020b). The causal mechanism is unclear, but could be due to impacts on health, economic costs, social interactions (Belkin and Kouchaki, 2017);(Osberghaus and Kühling, 2016), or reduced quality or quantity of sleep (Fujii et al., 2015);(Obradovich et al., 2017);(Obradovich and Migliorini, 2018). Heat has also been associated with interpersonal and intergroup aggression, and increases in violent crime (Heilmann et al., 2021);(Mapou et al., 2017);(Tiihonen et al., 2017). For the most part, studies have measured daily response to average daily temperatures and are unable to predict whether the effect is cumulative in response to a sequence of unusually warm days. However, there is no evidence that adaptation occurs over time to eliminate the negative response to very warm temperatures (Moore et al., 2019). Some research has found a negative effect of extreme cold on wellbeing (Yoo et al., 2021); increasing winter temperatures associated with climate change could serve to compensate for the impact of increased summer temperatures. However, the effect of high temperatures is typically found to be stronger than the effect of low temperatures, and in some cases no detrimental impacts of cold weather are found (Almendra et al., 2019);(Mullins and White, 2019).

Climate change also threatens wellbeing defined in terms of capabilities, or the capacity to fulfil one's potential and fully participate in society. Heat can limit labour capacity, one study estimating that 45 billion hours of labour productivity were lost in 2018 compared to 2000 due to high temperatures (Watts et al., 2019). Both heat and air pollution also impair human capabilities through a negative effect on cognitive performance (Taylor et al., 2016b), and even impair skills acquisition, reducing the ability to learn (Park et al., 2021) and affecting marginalized groups more strongly (Park et al., 2020), although findings are inconsistent and depend in part on the nature of the task *(low confidence).*

Systematic reviews have found an association between higher ambient levels of fine airborne particles and cognitive impairment in the elderly, or behavioural problems (related to impulsivity and attention problems) in children (Power et al., 2016);(Yorifuji et al., 2017);(Younan et al., 2018) (Zhao et al., 2018b) (*medium confidence*). Malnutrition has also been associated with reduced educational achievement and long-term decrements in cognitive function (Acharya et al., 2019);(Asmare et al., 2018);(Na et al., 2020);(Kim et al., 2017);(Talhaoui et al., 2019).

7.2.6 Observed Impacts on Migration

Consistent with peer-reviewed scholarship and with the UNFCCC Cancun Adaptation Framework section 14(f) and the Paris Agreement, this Chapter assesses the impacts of climate change on four types of migration: 1) adaptive migration (i.e where migration is an outcome of individual or household choice); (2) involuntary displacement (i.e. where people have few or no options except to move); (3) organized relocation of populations from sites highly exposed to climatic hazards; and (4) immobility (i.e. an inability or unwillingness to move from areas of high exposure for cultural, economic or social reasons) (see Cross-Chapter Box MIGRATE).

A general theme across studies from all regions is that climate-related migration outcomes are diverse (high confidence) and may be manifest as decreases or increases in migration flows, and lead to changes in the timing or duration of migration, and to changes in migration source locations and destinations. Multi-country studies of climatic impacts on migration patterns in Africa have found that migration exhibits weak, inconsistent associations with variations in temperatures and precipitation, and that migration responses differ significantly between countries, and between rural and urban areas (Gray and Wise, 2016);(Mueller et al., 2020). Multidirectional findings such as these are also common in single-country studies from multiple regions (A.Call et al., 2017);(Nawrotzki et al., 2017);(Cattaneo et al., 2019);(Kaczan and Orgill-Meyer, 2020). The diversity of potential migration and displacement outcomes reflects (1) the variable nature of climate hazards in terms of their rate of onset, intensity, duration, spatial extent, and severity of damage caused to housing, infrastructure, and livelihoods; and (2) the wide range of social, economic, cultural, political and other non-climatic factors that influence exposure, vulnerability, adaptation options and the contexts in which migration decisions are made (Neumann and Hermans, 2015);(McLeman, 2017);(Barnett and McMichael, 2018);(Cattaneo et al., 2019);(Hoffmann et al., 2020) (*high confidence*).

Weather events and climate conditions can act as direct drivers of migration and displacement (e.g. destruction of homes by tropical cyclones) and as indirect drivers (e.g. rural income losses and/or food insecurity due to heat- or drought-related crop failures that in turn generate new population movements) (high confidence). Extreme storms, floods and wildfires are strongly associated with high levels of short- and long-term displacement, while droughts, extreme heat and precipitation anomalies are more likely to stimulate longer term changes in migration patterns (Kaczan and Orgill-Meyer, 2020);(Hoffmann et al., 2020). Longer term environmental changes attributable to anthropogenic climate change - such as higher average temperatures, desertification, land degradation, biodiversity loss and sea level rise - have had observed effects on migration and displacement in a limited number of locations in recent decades but are projected to have wider-scale impacts on future population patterns and migration, and are therefore assessed in section 7.3.2 (Projected Risks).

[START CROSS-CHAPTER BOX MIGRATE HERE]

Cross-Chapter Box MIGRATE: Climate-related Migration

Authors: David Wrathall (Chapter 8), Robert McLeman (Chapter 7), Helen Adams (Chapter 7), Ibidun Adelekan (Chapter 9), Elisabeth Gilmore (Chapter 14), Francois Gemenne (Chapter 8), Nathalie Hilmi (Chapter 18), Ben Orlove (Chapter 17), Ritwika Basu (Chapter 18), Halvard Buhaug (Chapter 16), Edwin Castellanos (Chapter 12), David Dodman (Chapter 6), Felix Kalaba (Chapter 9), Rupa Mukerji (Chapter1 8), Karishma Patel (Chapter 1), Chandni Singh (Chapter 10), Philip Thornton (Chapter 5), Christopher Trisos (Chapter 9), Olivia Warrick (Chapter 15); Vishnu Pandey (Chapter 4),

Key messages on migration in this report

Migration is a universal strategy that individuals and households undertake to improve wellbeing and livelihoods in response to economic uncertainty, political instability and environmental change (*high confidence*). Migration, displacement, and immobility that occur in response to climate hazards are assessed in general in Chapter 7, with specific sectoral and regional dimensions of climate-related migration assessed in sectoral and regional chapters 5 to 15 [Table Cross-Chapter Box MIGRATE.1] and involuntary immobility and displacement being identified as a representative key risk in Chapter 16 [16.2.3.8, 16.5.2.3.8]. Since AR5 there has been a considerable expansion in research on climate-migration linkages, with five key messages from the present assessment report warranting emphasis:

Climatic conditions, events and variability are important drivers of migration and displacement (high confidence) [Table Cross-Chapter Box MIGRATE.1], with migration responses to specific climate hazards being strongly influenced by economic, social, political and demographic processes (high agreement, robust evidence)[7.2.6, 8.2.1.3]. Migration is among a wider set of possible adaptation alternatives, and often emerges when other forms of adaptation are insufficient [5.5.1.1, 5.5.3.5, 7.2.6, 8.2.1.3, 9.7.2]. Involuntary displacement occurs when adaptation alternatives are exhausted or not viable, and reflects non-climatic factors that constrain adaptive capacity and create high levels of exposure and vulnerability (*high confidence*) [Cross-Chapter Box SLR in Chapter 3, 4.3.7, 7.2.6, Box 8.1, 10.3, Box 14.7]. There is strong evidence that climatic disruptions to agricultural and other rural livelihoods can generate migration (*high confidence*) [5.5.4, 8.2.1.3, 9.8.3, Box 9.8].

Specific climate events and conditions may cause migration to increase, decrease, or flow in new directions (high confidence), and the more agency migrants have (i.e. the degree of voluntarity and freedom of movement), the greater the potential benefits for sending and receiving areas (high agreement, medium evidence) [5.5.3.5, 7.2.6, 8.2.1.3, Box 12.2]. Conversely, displacement or low-agency migration is associated with poor outcomes in terms of health, wellbeing and socio-economic security for migrants, and returns fewer benefits to sending or receiving communities (*high agreement, medium evidence*) [4.3.7, 4.5.7, Box 8.1, 9.7.2, 10.3, Box 14.7].

Most climate-related migration and displacement observed currently takes place within countries (high confidence) [4.3.7, 4.5.7, 5.12.2, 7.2.6]. The climate hazards most commonly associated with displacement are tropical cyclones and flooding in most regions, with droughts being an important driver in Sub-Saharan Africa, parts of South Asia and South America (*high confidence*) [7.2.6.1, 9.7.2, 10.4.6.3, 11.4.1, 12.5.8.4, 13.8.1.3, 14.4.7.3]. Currently observed international migration associated with climatic hazards is considerably smaller, relative to internal migration, and is most often observed as flowing between states that are contiguous, have labour-migration agreements, and/or longstanding cultural ties (*high agreement, robust evidence*) [4.3.7, 4.5.7, 5.12.2, 7.2.6].

In many regions, the frequency and/or severity of floods, extreme storms, and droughts is projected to increase in coming decades, especially under high-emissions scenarios [AR6 WGI Ch12], raising future risk of displacement in the most exposed areas (high confidence) [7.3.2.1]. Additional impacts of climate change anticipated to generate future migration and displacement include mean sea level rise that increases flooding and saltwater contamination of soil and/or groundwater in low-lying coastal areas and small islands (*high confidence*) [7.3.2.1, Cross-Chapter Box SLR in Chapter 3], and more frequent extreme heat events that threaten the habitability of urban centres in the tropics and arid/semi-arid regions (*medium agreement, medium evidence*), although the links between heat and migration are less clear [7.3.2.1].

There is growing concern among researchers about the future prospects of immobile populations: groups and individuals that are unable or unwilling to move away from areas highly exposed to climatic hazards (high confidence) [4.6.9, 7.2.6.2, Box 8.1, Box 10.2]. Involuntarily immobile populations may be anticipated to require government interventions to continue living in exposed locations or to relocate elsewhere (*high agreement, medium evidence)* [Box 8.1]. Managed retreat and organized relocations of people from hazardous areas in recent years have proven to be politically and emotionally charged, socially disruptive and costly (*high confidence*) [7.4.5.4].

Climate-migration interactions and outcomes

Figure Cross-Chapter Box MIGRATE.1 presents a simplified framework for understanding how migration and displacement may emerge from the interactions of climatic and non-climatic factors, based on the risk framework introduced in Chapter 1, in which climatic risks are represented as emerging from interactions of hazard, exposure and vulnerability in a characteristic propeller-shaped diagram [1.3]. Voluntary migration can be used by households in particular locations for adapting to climate hazards, while less voluntary forms of migration and involuntary displacement emerge when other forms of adaptation (referred to in Figure Cross-Chapter Box MIGRATE.1 as *in situ* adaptation) are inadequate. The success of migration – expressed in Figure Cross-Chapter Box MIGRATE.1 as changes in future risks to the wellbeing of migrants, sending and destination communities — is heavily influenced by the political, legal, cultural and socio-economic conditions under which it occurs. Groups and individuals that are involuntary immobile may find that their exposure, vulnerability and risk increase over time. Table Cross-Chapter Box MIGRATE.1 summarizes the range of potential migration outcomes that may emerge from this dynamic, and indicates specific sections in sectoral and regional chapters of the report that describe examples of each.

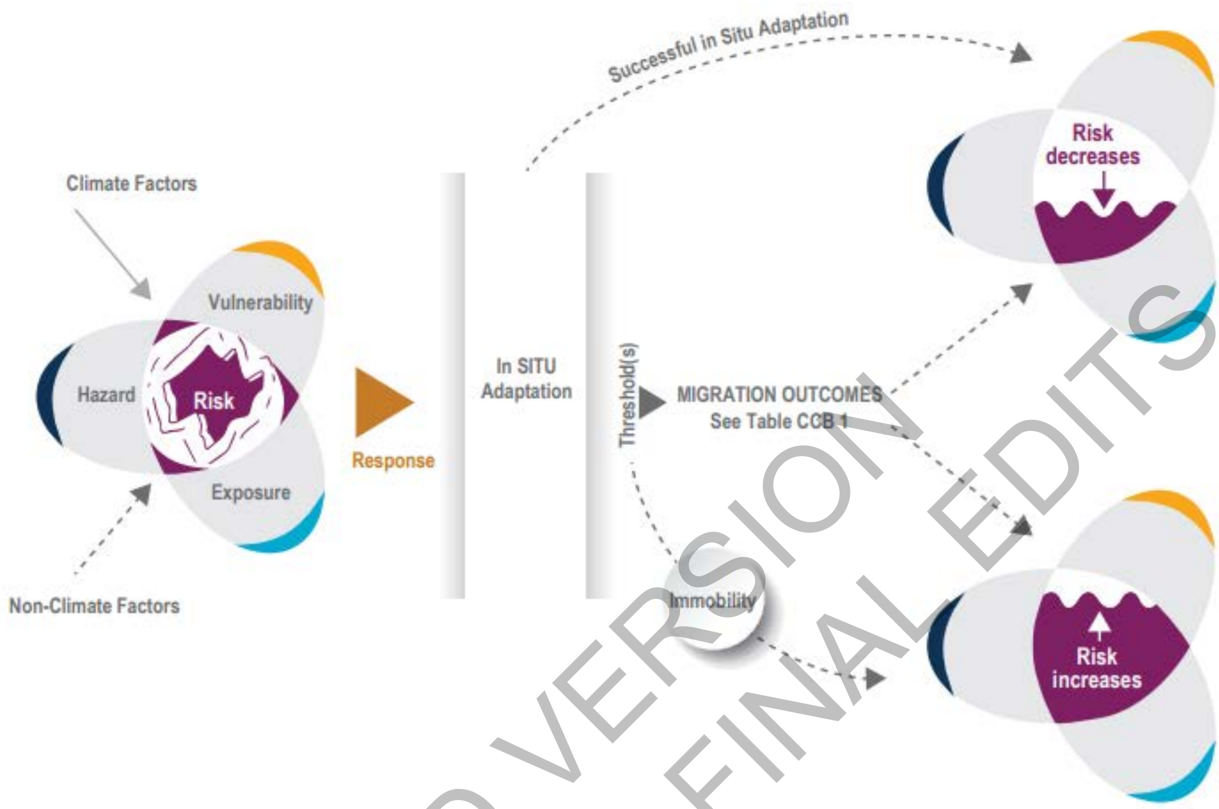

Figure Cross-Chapter Box MIGRATE.1: General interactions between climatic and non-climatic processes, adaptation, potential migration outcomes and implications for future risk. Adapted from (McLeman et al., 2021).

Table Cross-Chapter Box MIGRATE.1: Typology of climate-related migration and examples in sectoral and regional chapters of AR6

Type of climate-related migration	**Characteristics**	**Recent/current examples**	**Examples in literature**	**References in AR6**
Temporary and/or seasonal migration	Frequently used as a risk-reduction strategy by rural households in less-developed regions with highly seasonal precipitation. Includes transhumance	Pastoralists in sub-Saharan Africa; seasonal farm workers in South Asia; rural-urban labour migration in Central America	(Afifi et al., 2016), (Call et al., 2017);(Piguet et al., 2018);(Borderon et al., 2019);(Cattaneo et al., 2019);(Hoffmann et al., 2020);(Lopez-i-Gelats et al., 2015) ; (Lu et al., 2016)(detecting climate networks); (Kaczan and Orgill-Meyer, 2020)	Chapter 5.5.1.1; 5.5.3.5; Chapter 7.2.6; Chapter 8.2.1.3; Chapter 9.8.3; Chapter 13 Box 13.2
Indefinite or permanent migration	Less common than temporary or seasonal migration, particularly when the whole household permanently relocates.	Numerous examples in all regions	See reviews listed in cell above	Chapter 7.2.6; Chapter 8.2.1.3; Chapter 10 Box 10.2

Internal migration	Movements within state borders, most common form of climate-related migration	Numerous examples in all regions	See reviews in cells above	Chapter 4.3.7; Chapter 5.5.4; 5.10.1.1; Chapter 7.2.6; Chapter 9.7.2; 9.11-Box 9.8; Chapter 10.3.3, 10.2 10.4.6.3, Box 10.2; Chapter 11.4.1; Chapter 12.5.8.4; Chapter 13.8.1.3; Chapter 14.4.7.3; Chapter 15.3.4.6
International migration	Less common than internal migration; most often occurs between contiguous countries within the same region; often undertaken for purpose of earning wages to remit home	Cross-border migration within South and Southeast Asia, Sub-Saharan Africa	See reviews in cells above; also (Veronis et al., 2018);(McLeman, 2019);(Cattaneo and G., 2016);(Missirian and Schlenker, 2017);(Schutte et al., 2021)	Chapter 4.3.7; 4.5.7; Chapter 5.12.2; Chapter 7.2.6

Rural-urban or rural-rural	Typically internal, but may also flow between contiguous states; may be for temporary or indefinite periods; migration may be undertaken by an individual household member or the entire household; may be followed by remittances	Drought migration in Mexico, East Africa, South Asia	See reviews in cells above; also (Adger et al., 2015);(Gautier et al., 2016);(Nawrotzki et al., 2017);(Wiederkehr et al., 2018);(Robalino et al., 2015);(Borderon et al., 2019);(Murray-Tortarolo and Martnez, 2021)	Chapter 5.13.4; Chapter 7.2.6; Chapter 6.2.4.3; Chapter 8.2.1.3; Chapter 9.8.1.2; Chapter 12.5.8.4; Chapter 14.4.7.1
Displacement	Households are forced to leave homes for temporary or indefinite period; typically occurs as a result of extreme events and starts with seemingly temporary evacuation; risk is expected to rise in most regions due to sea level rise	Tropical cyclones in Caribbean, Southeast Asia, Bay of Bengal region;	(Islam and Shamsuddoha, 2017);(Desai et al., 2021); see annual reports of Internal Displacement Monitoring Centre for global statistics	Cross-Chapter Box SLR in Chapter 3; Chapter 4.3.7; 4.5.7; Cross-Chapter Box MOVING PLATE in Chapter 5; Chapter 7.2.6.1; Chapter 8 Box 8.1; Chapter 9.7.2; 9.9.2; Chapter 10.3; Chapter 14 Box 14.7; Chapter 15.3.4.6; CCP2.2.2

Planned/organized resettlement	Initiated in areas where settlements become permanently uninhabitable; requires assistance from governments/institutions. Government-sponsored sedentarisation of pastoral populations	Fiji; Carteret Islands, Papua New Guinea; US Gulf of Mexico coast and coastal Alaska	(Marino and Lazrus, 2015);(Hino et al., 2017);(McNamara et al., 2018);(McMichael and Katonivualiku, 2020);(Tadgell et al., 2017);(Arnall, 2014);(Wilmsen and Webber, 2015)	Chapter 4.6.9; Chapter 5.14.1; 5.14.2; Chapter 7.4.4.4; Chapter 10.4.6; Chapter 15.5.3; CCP 2.2.2; CCP 6.3.2;
Immobility	Adverse weather or climatic conditions warrant moving, but households are unable to relocate because of lack of resources, or choose to remain because of strong social, economic or cultural attachments to place	Examples in most regions	(Adams, 2016);(Zickgraf, 2018);(Nawrotzki and DeWaard, 2018);(Farbotko et al., 2020)	Chapter 4.6.9; Chapter 7.2.6.2; Chapter 8. Box 8.1; Chapter 10 Box 10.2

Policy implications

Future migration and displacement patterns in a changing climate will depend not only on the physical impacts of climate change, but also on future policies and planning at all scales of governance (high confidence) [4.6.9, 5.14.1&2, 7.3.2, 7.4.4, 8.2.1.3, Box 8.1, CCP 6.3.2]. Policy interventions can remove barriers to and expand the alternatives for safe, orderly and regular migration that allows vulnerable people to adapt to climate change (*high confidence*) [7.2.6]. With adequate policy support, migration in the context of climate change can result in synergies for both adaptation and development [5.12.2, 7.4.4, 8.2.1.3]. Migration governance at local, national and international levels will influence to a great extent the outcomes of climate-related migration, for the migrants themselves as well as for receiving and origin communities [5.13.4, 7.4.4, 8.2.1.3]. At the international level, a number of relevant policy initiatives and agreements have already been established and merit continued pursuit, including Global Compacts for Safe, Orderly and Regular Migration and for the protection of Refugees; the Warsaw International Mechanism of the UNFCCC; the Sustainable Development Goals; the Sendai Framework for Disaster Risk Reduction; and, the Platform on Disaster Displacement provide potential migration governance pathways [7.44]. Policy and planning decisions at regional, national and local scales that relate to housing, infrastructure, water provisioning, schools and healthcare are relevant for successful integration of migrants into receiving communities [5.5.4, 5.10.1.1, 5.12.2, 9.8.3]. Policies and practices on movements of people across international borders are also relevant to climate-related migration, with restrictions on movement having implications for the adaptive capacity of communities exposed to climate hazards [7.4.4.2, Box 8.1]. Perceptions of migrants and the framing of policy discussions in receiving communities and nations are important determinants of the future success of migration as an adaptive response to climate change [7.4.4.3] (*high agreement, medium evidence*).

Reducing the future risk of large-scale population displacements, including those requiring active humanitarian interventions and organized relocations of people, requires the international community to meet the requirements of the Paris Agreement and take further action to control future warming (high confidence) [Cross-Chapter Box SLR in Chapter 3, 7.3.1, Box 8.1]. Current emissions pathways lead to scenarios for the period between 2050 and 2100 in which hundreds of millions of people will be at risk of displacement due to rising sea levels, floods, tropical cyclones, droughts, extreme heat, wildfires and other hazards, with land degradation exacerbating these risks in many regions [7.3.2, IPCC Special report on Land 2019, Cross-Chapter Box SLR in Chapter 3]. At high levels of warming, tipping points may exist, particularly related to sea level rise, that, if crossed, would further increase the global population potentially at risk of displacement [IPCC 2021 Cross-Chapter Box 12.1]. Populations in low-income countries and small-island states that have historically had low greenhouse gas emissions are at particular risk of involuntary migration and displacement due to climate change, reinforcing the urgency for industrialized countries to continue lowering greenhouse gas emissions, to support adaptive capacity-building initiatives under the UNFCCC, and to meet objectives expressed in the Global Compacts regarding safe, orderly and regular migration, and the support and accommodation of displaced people [4.3.7, 4.5.7, 5.12.2, 7.4.5.5, 8.4.2, Box 8.1, Cross-Chapter Box SLR].

[END CROSS-CHAPTER BOX MIGRATE HERE]

The diversity of potential migration and displacement outcomes reflects the scale and physical impacts of specific climate hazard events and the wide range of social, economic, cultural, political and other non-climatic factors that influence exposure, vulnerability, adaptation options and the contexts in which migration decisions are made (high confidence). The diversity in drivers, contexts and outcomes make it difficult to offer simple generalizations about the relationship between climate change and migration. The characteristics of climatic drivers vary in terms of their rate of onset, intensity, duration, spatial extent, and severity of damage caused to housing, infrastructure, and livelihoods; the potential migration responses to these are further mediated by cultural, demographic, economic, political, social, and other non-climatic factors operating across multiple scales (Neumann and Hermans, 2015);(McLeman, 2017);(Barnett and McMichael, 2018);(Cattaneo et al., 2019);(Hoffmann et al., 2020).

Climate-related migration and displacement outcomes display high variability in terms of migrant success, often reflecting pre-existing socio-economic conditions and household wealth (high confidence). The decision to migrate or remain in place when confronted by climatic hazards is strongly influenced by the range and accessibility of alternative, *in situ* (i.e., non-migration) adaptation options that may be less costly or disruptive (Cattaneo et al., 2019). Migration decisions (whether climate-related or not) are typically made at the individual or household level, and are influenced by a household's perceptions of risk, social networks, wealth, age structure, health, and livelihood choices (Koubi et al., 2016b);(Gemenne and Blocher, 2017). Households with greater financial resources and higher levels of educational attainment have greater capacity to adapt *in situ* (Cattaneo and Massetti, 2019);(Ocello et al., 2015) but are also better able to migrate, and with greater agency once such a decision is made (Kubik and Maurel, 2016), (Koubi et al., 2016b);(Riosmena et al., 2018);(Adams and Kay, 2019). By contrast, poor households with limited physical, social and financial resources have less capacity to adapt *in situ* and are often limited in their migration options (Nawrotzki and DeWaard, 2018), (Suckall et al., 2017), (Zickgraf et al., 2016). Thus, when poorer households do migrate after an extreme climate event, it is often in reaction to lost income or livelihood due to an extreme climate event and occurs with low voluntarity (Mallick et al., 2017), (Bhatta et al., 2015) and may perpetuate or amplify migrants' socio-economic precarity and/or their exposure to environmental hazards (Natarajan et al., 2019); see also Chapter 8 section 8.3.1).

Climate-related migration originates most often in rural areas in low- and middle-income countries, with migrant destinations usually being other rural areas or to urban centres within their home countries (i.e., internal migration) (medium confidence). Rural livelihoods and incomes based on farming, livestock rearing and/or natural resource collection, are inherently sensitive to climate variability and change, creating greater potential for migration as a response (Bohra-Mishra et al., 2017);(Viswanathan and Kumar, 2015). Drought events have been associated with periods of higher rural to urban migration within Mexico (Chort and de la Rupelle, 2016);(Leyk et al., 2017);(Nawrotzki et al., 2017; Murray-Tortarolo and Martnez, 2021)and Senegal (Nawrotzki and Bakhtsiyarava, 2017). Extreme temperatures are associated with higher rates of temporary rural out-migration in South Africa and in Bangladesh (Mastrorillo et al., 2016);(Call et al., 2017). In rural Tanzania, weather-related shocks to crop production have been observed to increase the likelihood of migration, but typically only for households in the middle of community wealth distribution (Kubik and Maurel, 2016)Weather-related losses in rice production have been associated with small-percentage increases in internal migration in India (Viswanathan and Kumar, 2015) and the Philippines (Bohra-Mishra et al., 2017). In East Africa, temporary rural-urban labour migration does not show a strong response to climatic drivers (Mueller et al., 2020). There is a small literature on mobility as adaptation in urban populations, with a focus on resettlement of flood-prone informal settlements within cities (Kita, 2017);(Tadgell et al., 2017).

Most documented examples of international climate-related migration are intra-regional movements of people between countries with shared borders (high agreement, medium evidence). Systematic reviews find few documented examples of long-distance, inter-regional migration driven by climate events (Veronis et al., 2018);(Kaczan and Orgill-Meyer, 2020);(Hoffmann et al., 2020). One macro-economic analysis found a correlation between migrant flows from low- to high-income countries and adverse climatic events in the source country (Coniglio and Pesce, 2015), another found that high heat stimulates higher rates of international migration from middle-income countries but typically not from low-income countries (Cattaneo and G., 2016), while other studies found international climate-related migration originates primarily from the agriculture-dependent countries (Cai et al., 2016);(Nawrotzki and Bakhtsiyarava, 2017). Small-sample studies of migrants to Canada from Bangladesh, Haiti, and sub-Saharan Africa suggest environmental factors in the source country can be a primary or secondary motivation for some migrants within larger flows of economic and family-reunification migrants (Veronis and McLeman, 2014);(Mezdour et al., 2015);(McLeman et al., 2017). Research on links between climate hazards and international movements of refugees and/or asylum seekers shows differing results. One study found that asylum applications in Europe increase during climate fluctuations, due to interactions with conflict (Missirian and Schlenker, 2017), and another found links between heat, drought, conflict and asylum-seeking migration originating in the Middle East between 2011 and 2015 (Abel et al., 2019). Other studies have found that asylum claims in Europe correspond minimally with climatic hazards in source countries (Schutte et al., 2021), with choices in baseline data, timeframes for analysis and methodological approaches likely explaining the inconsistent results across studies (Boas et al., 2019). Media reports and other studies in recent years suggest that climate change has driven large numbers of migrants to the US from Central America and to Europe from the Middle East and Africa, but empirical studies were not identified for this assessment.

7.2.6.1 Relative Importance of Specific Climatic Drivers of Migration and Displacement

Reliable global estimates of voluntary climate-related migration within and between countries are not available due to a general absence of concerted efforts to date to collect data of this specific nature, with existing national and global datasets often lacking information on migration causation or motivation. Better data are available for involuntary displacements within countries for reasons associated with weather-related hazards. Data collected annually since 2008 on internal displacements attributed to extreme weather events by the Internal Displacement Monitoring Centre (IDMC) indicate that extreme storms and floods are the two most significant weather-related drivers of population displacements globally. Because of improvements in collection sources and methods since it first began reporting data in 2008, upward trends since that year in the total reported annual number of people displaced should be treated cautiously; it is reasonable to conclude that the average annual rate currently exceeds 20 million people globally, with considerable interannual variation due to the frequency and severity of extreme events in heavily populated areas. Regional distribution of displacement events has been consistent throughout the period of IDMC data collection (*high confidence*), with displacement events occurring most often in East, Southeast, and South Asia; sub-Saharan Africa; the US; and the Caribbean region (Figure 7.7). Relative to their absolute population size, Small Island states experience a disproportionate risk of climate-related population displacements (Desai et al., 2021) (*high confidence*).

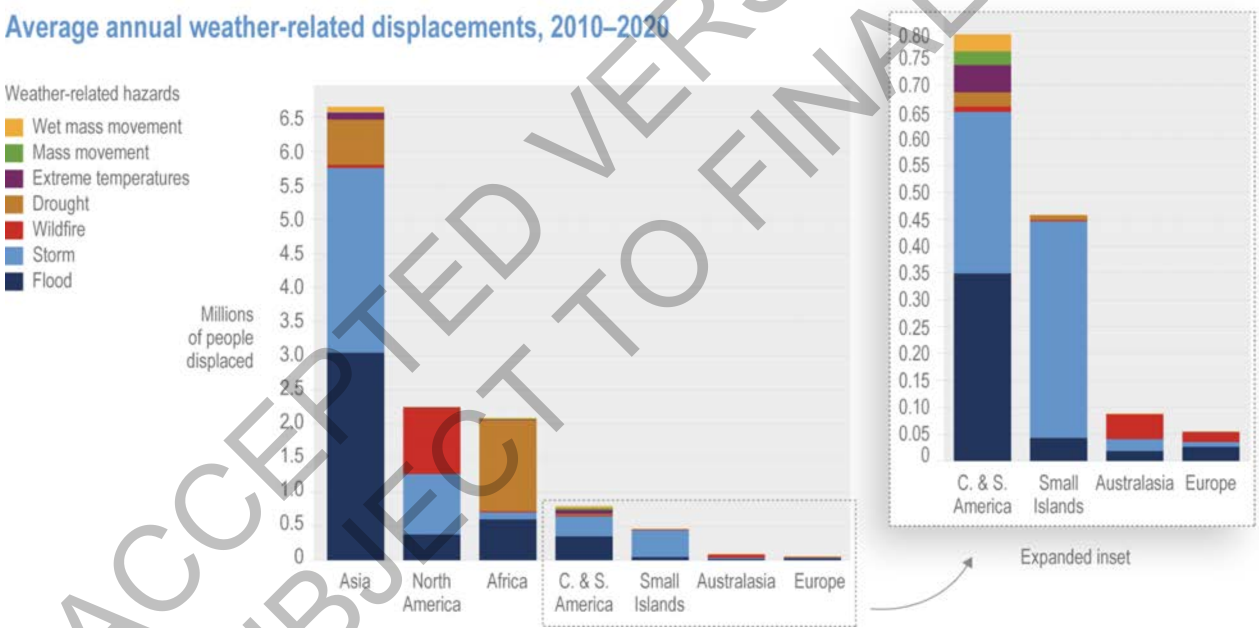

Figure 7.7: Average number of people displaced annually, 2010-2020 by selected weather-related events, by region and category of event. Source statistics provided by Internal Displacement Monitoring Centre.

Tropical cyclones and extreme storms are a particularly significant displacement risk in East and Southeast Asia, the Caribbean region, the Bay of Bengal region, and southeast Africa (IDMC 2020) (high confidence). The scale of immediate displacement from any given storm and potential for post-event migration depend heavily on the extent of damage to housing and livelihood assets, and the responsive capacity of governments and humanitarian relief agencies (Saha, 2016);(Islam et al., 2018);(Mahajan, 2020);(Spencer and Urquhart, 2018). In Bangladesh, the rural poor are most often displaced, with initial increases in short-term, labour-seeking migration followed by more permanent migration by some groups (Saha, 2016);(Islam and Hasan, 2016);(Islam and Shamsuddoha, 2017). Past hurricanes in the Caribbean basin have generated internal and interstate migration within the region, typically along pre-existing social networks, and to the US (Loebach, 2016);(Chort and de la Rupelle, 2016). In 2017, Hurricanes Irma and Maria caused widespread damage to infrastructure and health services, and a slow recovery response by authorities was followed by the migration of tens of thousands of Puerto Ricans to Florida and New York (Zorrilla, 2017);(Echenique and Melgar, 2018). In the US, coastal counties experience increased out-migration after hurricanes that flows along existing social networks (Hauer, 2017), with post-disaster reconstruction employment opportunities potentially attracting new labour migrants to affected areas (Ouattara and Strobl, 2014);(Curtis et al., 2015);(DeWaard et al., 2016);(Fussell et al., 2018).

Flood displacement can lead to increases or decreases in temporary or short-distance migration flows, depending on the local context (medium confidence). (Robalino et al., 2015);(Ocello et al., 2015);(Afifi et al., 2016);(Koubi et al., 2016b)Floods are a particularly important driver of displacement in river valleys and deltas in Asia and Africa, although large flood-related displacements have been recorded by IDMC in all regions. In Africa, populations exposed to low flood risks, as compared with other regions, are observed to have a greater vulnerability to displacement due to limited economic resources and adaptive capacity (Kakinuma et al., 2020). In areas where flooding is especially frequent, *in situ* adaptations may be more common, and out-migration may temporarily decline after a flood (Afifi et al., 2016), (Chen et al., 2017);(Call et al., 2017). Rates of indefinite or permanent migration tend not to change following riverine floods unless damage to homes and livelihood assets is especially severe and widespread, with household perceptions of short- and longer-term risks playing an important role (Koubi et al., 2016a).

Displacements due to droughts, extreme heat, and associated impacts on food and water security are most frequent in East Africa and, to a lesser extent, South Asia, and West and Southern Africa (Centre), 2020). Because droughts unfold progressively and typically do not cause permanent damage to housing or livelihood assets, there is greater opportunity for government and NGO interventions, and greater use of *in situ* adaptation options (Koubi et al., 2016b);(Koubi et al., 2016a);(Cattaneo et al., 2019). Drought-related population movements are most common in dryland rural areas of low-income countries, and occur after a threshold is crossed and *in situ* adaptation options are exhausted (Gautier et al., 2016);(Wiederkehr et al., 2018);(McLeman, 2017)). A time lag may ensue between the onset of drought and any observed population movements; one study of Mexican data found this lag to be up to 36 months after the event (Nawrotzki et al., 2017). The most common response to drought is an increase in short-distance, rural-urban migration (*medium confidence*), with examples being documented in Bangladesh, Ethiopia, Pakistan, sub-Saharan Africa, Latin America and Brazil (Neumann and Hermans, 2015);(Gautier et al., 2016);(Gautier et al., 2016);(Mastrorillo et al., 2016);(Baez et al., 2017);(Call et al., 2017);(Nawrotzki et al., 2017);(Jessoe et al., 2018)*;(Carrico and Donato, 2019)*;(Hermans and Garbe, 2019).

Few assessable studies were identified that examine links between wildfires and migration. Wildfire events are often associated with urgent evacuations and temporary relocations, which place significant stress on receiving communities (Spearing and M., 2020) but research in the US suggests fires have only a modest influence on future migration patterns in exposed areas (Winkler and D., 2021). More research, particularly in other regions, is needed.
