The most recent projections suggest that TC intensity is predicted to increase as climate continues to change (Walsh et al., 2016; Kossin et al., 2017). There are too few studies available to suggest potential future response trends of these ecosystems to this increased intensity, however it seems plausible that present resilience capacities may be adversely impacted (*medium confidence*) (Marler, 2014). Further, the potential for stressors such as forest fragmentation/degradation or IAS combining with these increasingly intense events to cause precipitating ecosystem cascades is a real concern (Goulding et al., 2016).
Continued high rates of habitat loss and degradation have been reported for many small islands as natural habitats continue to be cleared to meet increasing demands upon natural resources from rising human populations, agriculture, urbanisation, unsustainable tourism, overgrazing and fires. This increases the vulnerability of ecosystems within especially oceanic islands — where isolation has given rise to high levels of endemism but simple biotic communities, with low functional redundancy (Box CCP1.1). There is *high confidence* that climate change may exacerbate the effects of this habitat loss upon the biodiversity of these islands as the climate refugia (Table 15.3) and the upslope shifts of range-restricted, dispersal-limited and poorly competitive species, confined within narrow latitudinal (and decreasing altitudinal) gradients, are increasingly challenged by fragmented and degraded landscapes (e.g., Struebig et al., 2015a; IPBES, 2019). Additionally, high-altitude ecosystems such as cloud forests which harbour high levels of endemism are projected to shrink due to increasing atmospheric temperature and competition from upward-shifting lowland species (Taylor and Kumar, 2016a). These may ultimately increase the risk of multiple extinctions, negatively impacting upon global biodiversity levels (*high confidence*) (Taylor and Kumar, 2016a; Portner et al., 2021).

Analyses of historical and current threats indicate that IAS and disease have been the primary drivers of insular extinctions in modern history (Bellard et al., 2016). Impacts of IAS on islands are projected to increase with time due to synergies between climate change and other traditional drivers such as increasing global trade, tourism, agricultural intensification, over exploitation and urbanisation (Bellard et al., 2014; Russell et al., 2017). Changing climate conditions may not necessarily increase the rate of IAS introductions but is expected to improve chances of IAS establishment via (i) altering IAS transport and introduction mechanisms, (ii) increasing the impacts and distributions of existing IAS and (iii) altering the effectiveness of existing control strategies (Hellmann et al., 2008; Russell et al., 2017). These are likely to enhance IAS impacts on islands including: restructuring of ecological communities leading to declines and extinctions/extirpations in flora and fauna, habitat degradation, declining ecosystem functioning, services and resilience, and in extreme cases, potential community homogenisation (*high confidence*) (Russell and Blackburn, 2017; IPBES, 2019). Given the high degree of endemicity within oceanic islands and their associated vulnerabilities, such exacerbation by changing climate pose a serious threat to decreasing global biodiversity (*medium to high confidence*) (van Kleunen et al., 2015).

Compared to continents, terrestrial IAS are disproportionately prevalent on islands (almost three-quarters of global species currently threatened by IAS and disease are found on islands) and also generate stronger impacts (e.g., within alpine ecosystems of high islands) than on continents (*high confidence)*(Bellard et al., 2014; Bellard et al., 2016; Frazier and Brewington, 2019). Russell and Blackburn (2017) suggested a correlation between small island size and increased numbers of IAS. SIDS within the Indian Ocean and in particular, the Pacific SIDS region were reported to have significantly more IAS **(***medium confidence*), while the Caribbean and Atlantic SIDS have fewer numbers but faster accumulation of IAS. Finally, while there have been developments in the eradication of IAS on islands (Jones et al., 2016), there is sparse evidence and hence assessment of the degree to which measures designed to prevent introduction and to manage invasion pathways and establishment have been successful.

Table 15.3: Percentage of selected islands classified as refugia for biodiversity at increasing levels of warming. While protected land is still 'protected' this table demonstrates the difficulty of protecting lands which might be 'more resilient' to climate change under increasing levels of warming and current land use practices. Derived from current and future projected distributions of ~130,000 terrestrial fungi, plants, invertebrates and vertebrates (Warren et al., 2018a). Refugia =areas remaining climatically suitable for >75% of the species modelled (Warren et al., 2018b). **Projections:** based on mean impacts from 21 CMIP5 climate model patterns (no dispersal) and elevationally downscaled to 1km under interpolated warming levels derived from RCP 2.6, 4.5, 6.0 and 8.0 (Warren et al., 2018a). First column-set = % island/island chain classified as a refugia based on ***climate alone*** ; second column-set = % natural land projected to be climate refugia — illustrating potential refugia 'space' already lost to habitat conversion. **Colour Key**: white > 50%; yellow = 30%-50%; red = 17%-30% and dark red <17% of land classified as refugia.

[INSERT TABLE 15.3 HERE]

15.3.4 Observed Impacts and Projected Risks on Human Systems

15.3.4.1 Island Settlements and Infrastructure

As a result of slow onset ocean and climate changes and changes in extreme events, settlements and infrastructure of small islands are at growing risk due to climate change in the absence of adaptation measures (*high confidence*). Ocean acidification and deoxygenation, increased ocean temperatures and relative sea level rise are impacting marine, coastal and terrestrial biodiversity and ecosystem services, making settlements more exposed and vulnerable to climate-related hazards. Changes in rainfall patterns such as heavy precipitation result in annual flood events that damage major assets and result in a loss of human life. Examples of settlements where this has occurred are Port of Spain (Mycoo, 2014b; Mycoo, 2018a) , Haiti (Weissenberger, 2018), Viti Levu (Brown et al., 2017; Singh-Peterson and Iranacolaivalu, 2018), urban areas of Fiji and Kiribati (McAneney et al., 2017; Cauchi et al., 2021), Male', Maldives (Wadey et al., 2017), and Mahé, in the Seychelles (Etongo, 2019).

The main settlements of small islands are located along the coast and with decades of high density coastal urban development, their population, buildings and infrastructure are currently exposed to multiple climate change-related hazards (Kumar and Taylor, 2015; Mycoo, 2017) and face key risks (*high confidence*) (KR5 in Figure 15.5). In many small islands, population is concentrated in the Low Elevation Coastal Zone (LECZ) which is defined as coastal areas below 10 metres elevation. Approximately 22 million in the

Caribbean live below 6 metres elevation (Cashman and Nagdee, 2017) and an estimated 90% of Pacific Islanders live within 5 km of the coast, if Papua New Guinea is excluded (Andrew et al., 2019). In the Solomon Islands and Vanuatu, over 60% of the population lives within 1 km of the coast (Andrew et al., 2019). Most Pacific islands have ≥50% of their infrastructure within 500 metres of the coast (Kumar and Taylor, 2015), and in Kiribati, Marshall Islands and Tuvalu, >95% of the infrastructure is located in the LECZ (Andrew et al., 2019) (Figure 15.3). Sustainable development challenges including insufficient land use planning and land use competition contribute to increased vulnerability of human settlements to climate change in small islands (Kelman, 2014)(Mycoo, 2021).

Categories 4 and 5 TCs are severely impacting settlements and infrastructure in small islands. TC Maria in 2017 destroyed nearly all of Dominica's infrastructure and losses per unit of GDP amounted to more than 225% of the annual GDP (Eckstein et al., 2018). Destruction from TC Winston in 2016 amounted to more than 20% of Fiji's current GDP (Cox et al., 2018). Additionally, living conditions in human settlements are changing due to storm surge which is already penetrating further inland compared with a few decades ago (IPCC, 2018 Section 3.4.4.3; Brown et al., 2018).

A growing percentage of the population in small islands lives in informal settlements which occupy marginal lands leading to increased population exposure and vulnerability to climate-related hazards (Mycoo and Donovan, 2017). Unplanned settlements have compounded flooding brought on by slow onset hazards such as coastal and riverine flooding and fast onset events such as TCs and storm surges (Butcher-Gollach, 2015; Chandra and Gaganis, 2016; Mycoo, 2017). Unsustainable land use practices and difficulties in enforcing land use zoning and building guidelines in informal settlements make them highly vulnerable to such events (Butcher-Gollach, 2015; Mecartney and Connell, 2017; Mycoo, 2017; Mycoo, 2018b; Trundle et al., 2018; Mycoo, 2021).

TC intensification in the future is *likely* to cause severe damage to human settlements and infrastructure in small islands. Additionally, SLR is expected to cause significant loss and damage (Martyr-Koller et al., 2021). Based on SLR projections, almost all port and harbour facilities in the Caribbean will suffer inundation in the future (Cashman and Nagdee, 2017). In Jamaica and St Lucia, SLR and ESLs are projected to be key risks to transport infrastructure at 1.5°C unless further adaptation is undertaken (Monioudi et al., 2018). Similar findings were reported for Samoa (Fakhruddin et al., 2015). Even islands of higher elevation are expected to be threatened, given the high amount of infrastructure located near to the coast, for example Fiji (Kumar and Taylor, 2015).

15.3.4.2 Human Health and Well-being

Small islands face disproportionate health risks associated with changes in temperature and precipitation, climate variability, and extremes (Cross-Chapter Box INTERREG in Chapter 16; Key Risk 4 in Section 15.3.9, Figure 15.5). Climate change is projected to increase the current burden of climate-related health risks (Weatherdon et al., 2016; Ebi et al., 2018; Schnitter et al., 2019). Health risks can arise from exposures to extreme weather and climate events, including heatwaves; changes in ecological systems associated with changing weather patterns that can result, for example, in more disease vectors, or in compromised safety and security of water and food; and exposures related to disruption of health systems, migration, and other factors (see Cross-Chapter Box ILLNESS in Chapter 2; McIver et al., 2016; Mycoo, 2018a; WHO, 2018).

Extreme weather and climate events, particularly TCs, floods, drought, and heat waves can cause injuries, infectious diseases, and deaths (Box 15.1; Schütte et al., 2018). For example, category 5 TC Winston hit Fiji on 20 February 2016. During the national state of emergency (7 March and 29 May 2016), the World Health Organization portable toolkit for an early warning alert and response system (EWARS in a Box) was deployed within 24 hours; it recorded 34,113 cases of the nine syndromes among 326,861 consultations in a population of about 900,000; 48% of cases were influenza-like illnesses, 30% were acute watery diarrhoea, and 13% were suspected cases of dengue. There also were 583 cases of Zika-like illness (1.7% of all cases) and two large outbreaks of viral conjunctivitis (total of 880 cases). During TC Maria in Puerto Rico, there were more deaths per 100,000 among individuals living in municipalities with the lowest socioeconomic development and for men 65 years of age or older (Santos-Burgoa et al., 2018); this excess risk persisted for at least a year after the event. The first human cases of leptospirosis in the U.S. Virgin Islands occurred in

2017 after TC Irma and Maria. TCs also can affect treatment and care for people with non-communicable diseases, including exacerbation or complications of illness and premature death (Ryan et al., 2015).

Heat-related mortality and risks of occupational heat stress in small island states are projected to increase with higher temperatures (Hoegh-Guldberg et al., 2018; Mendez-Lazaro et al., 2018). Higher temperatures also can affect the productivity of outdoor workers (Taylor et al., 2021). Climate change, urbanization, and air pollution are risk factors for the rise of allergic diseases in Asia and the (Pawankar et al., 2020).

Tropical and sub-tropical islands face risks from vector-borne diseases, such as malaria, dengue fever, and the Zika virus. El Niño events can increase the risk of diseases such as Zika virus by increasing biting rates, decreasing mosquito mortality rates, and shortening the time required for the virus to replicate within the mosquito (Caminade et al., 2017). By combining disease prediction models with climate indicators that are routinely monitored, alongside evaluation tools it is possible to generate probabilistic dengue outlooks in the Caribbean and early warning systems (Oritz et al., 2015; Lowe et al., 2018). Projections suggest that more individuals will become at risk of dengue fever by the 2030s and beyond because of an increasing abundance of mosquitos and larger geographic range (Ebi et al., 2018). Projected increases in mean temperature could double the dengue burden in New Caledonia by 2100 (Teurlai et al., 2015). In the Caribbean, Saharan dust transported across the Atlantic can interact with Caribbean seasonal climatic conditions to become respirable and contribute to asthma presentations at the emergency department (See Table 15.5; Akpinar-Elci et al., 2015).

Ciguatera fish poisoning (CFP) is a foodborne illness caused by toxic dinoflagellate algae that proliferate on degraded coral reefs and that can contaminate reef fish; symptoms can remain for a few weeks to months. CFP occurs in tropical and subtropical regions, primarily in the South Pacific and Caribbean, but wherever reef fish are consumed (Traylor and Singhal, 2020). In the Caribbean Sea, increasing ocean temperatures are expected to stabilize or slightly decrease the incidence of CFP because of shifts in species distribution of dinoflagellates associated with CFP (Kibler et al., 2015). CFP is endemic in the Cook Islands and French Polynesia, where incidence is associated with sea surface temperature anomalies (Zheng et al., 2020). In the Canary Islands, tropicalization trends due to climate change are expected to increase CFP occurrence in the future (Rodriguez et al., 2017). In addition, in the Caribbean, increased density of *Sargassum* algae, possibly due to ocean temperature impacts on ocean currents compounded by agricultural pollution, may lead to increased respiratory illnesses (Resiere et al., 2018; Resiere et al., 2019; Resiere et al., 2020).

Climate driven changes in the ability to access locally grown or harvested food, either through environmental degradation or changes in extreme event magnitude and/or frequency, can increase dependence on imported food and increase rates of malnutrition and non-communicable diseases (Springmann et al., 2016; WHO, 2018; Savage et al., 2019; Lieber et al., 2020). Projections suggest that local food accessibility could be reduced by 3.2% in the low- and middle-income countries of the Western Pacific (including the Philippines, Fiji, Papua New Guinea, Solomon Islands, and other Pacific islands) by 2050, with approximately 300,000 associated deaths possible (Springmann et al., 2016). A climate change-related 20% decline in coral reef fish production in some Pacific Island countries by 2050 could exacerbate the population growth-driven gap between volume of fish needed for nutritional security and fish available through sustained harvest (Bell et al., 2013; Cauchi et al., 2019; Savage et al., 2019)).

Heavy reliance on aquifers and rainwater harvesting in small islands, particularly atolls, coupled with overcrowding, population growth, and contamination increase the risk of waterborne disease (McIver et al., 2014; Strauch et al., 2014; McIver et al., 2016). For example, seasonal rainfall in Kiribati is associated with waterborne disease (such as diarrhea, cholera, and typhoid fever). Future projections indicate increases in the number of days of heavy rainfall by 2050, suggesting future increases in risk in heavily populated areas (McIver et al., 2014). Damage to water and sanitation services can cause infectious disease outbreaks, such as the cholera outbreak that occurred in Haiti following TC Matthew (Raila and Anderson, 2017; Hulland et al., 2019).

Evidence is emerging of the mental health impacts of climate change. Tuvaluans are experiencing distress because of the local environmental impacts caused or exacerbated by climate change, and by hearing about the potential future consequences of climate change (Gibson et al., 2020).

15.3.4.3 Water Security

Climate change impacts on freshwater systems frequently exacerbate existing pressure, especially in locations already experiencing water scarcity (Section 15.3.3.2 and Cross-Chapter Box INTERREG in Chapter 16; Schewe et al., 2014; Holding et al., 2016; Karnauskas et al., 2016), making Water Security a Key Risk (KR4 in Figure 15.5) in small islands. Small islands are usually environments where demand for resources related to socio-economic factors such as population growth, urbanisation and tourism already place increasing pressure on limited freshwater resources. In many small islands, water demand already exceeds supply. For example, in the Caribbean, Barbados is utilising close to 100% of its available water resources and St. Lucia has a water supply deficit of approximately 35% (Cashman, 2014). On many Mediterranean islands, water demand regularly outstrips supply as a result of low average precipitation coupled with increasing water demand from economic activities such as irrigated agriculture and tourism (Hof et al., 2014; Papadimitriou et al., 2019).

Population growth plays a strong role in projected future water stress (Schewe et al., 2014). Combining projected aridity change (fractional change compared to historical climatology) with population projections derived from SSP2, shows that the SIDS with high projected population growth rates are expected to experience the most severe freshwater stress by 2030 under a 2°C warming threshold scenario (Karnauskas et al., 2018). For several SIDS (e.g., Belize and Jamaica), increasing aridity change is a prominent exacerbating factor, but for others (e.g., the Solomon Islands and Comoros) population growth is the main factor. A 1°C increase in temperature (from 1.7°C to 2.7°C) could result in a 60% increase in the number of people projected to experience a severe water resources stress in 2043–2071 (Schewe et al., 2014; Karnauskas et al., 2018). Research on Jamaica concluded that the ability of rainwater harvesting to meet potable water needs between the 2030s and 2050s will be reduced based on predicted shorter intense showers and frequent dry spells (Aladenola et al., 2016).

The Caribbean and Pacific regions have historically been affected by severe droughts (Peters, 2015; FAO, 2016; Barkey and Bailey, 2017; Paeniu et al., 2017; Trotman et al., 2017; Anshuka et al., 2018) with significant physical impacts and negative socio-economic outcomes. Water quality is affected by drought as well as water availability. The El Niño related 2015-16 drought in Vanuatu led to reliance on small amounts of contaminated water left at the bottom of household tanks (Iese et al., 2021). The highest land disturbance percentages have coincided with major droughts in Cuba (de Beurs et al., 2019). Drought has been shown to have an impact on rainwater harvesting in the Pacific (Quigley et al., 2016) and Caribbean (Aladenola et al., 2016), especially in rural areas where connections to centralised public water supply have been difficult. Increasing trends in drought are apparent in the Caribbean (Herrera and Ault, 2017) although trends in the western Pacific are not statistically significant (McGree et al., 2016).

Areas where a freshwater lens is thinner are most likely to be impacted by multiple climate stressors, and these areas tend to be in coastal zones where populations are likely to be most concentrated (Holding et al., 2016). In Barbados, where groundwater is relied upon for food production, urban use, and environmental needs, higher food prices are expected in the future if informed land use management and integrated water resources policy implementation are not implemented to manage groundwater in the short term, even with modest climate change threats (Gohar et al., 2019).

15.3.4.4 Fisheries and Agriculture

Fisheries provide small islands with opportunities for economic development, revenues, food security and livelihoods (Bell et al., 2018). Ten Pacific Island countries and territories derive between 5% and >90% of all government revenue (except grants) from access fees paid by industrial tuna-fishing fleets, mainly from distant-water fishing nations (Bell et al., 2018; SPC, 2019). Under a high greenhouse gas emissions scenario (RCP 8.5), the total biomass of three tuna species in the waters of ten Pacific SIDS could decline by an average of 13% (range = −5% to −20%) due to a greater proportion of fish occurring in the high seas (Bell et al., 2021), meanwhile projected increases have been anticipated for Ascension Island and Saint Helena in the South Atlantic (Townhill et al., 2021). Additionally, seafood plays an important role in achieving food security in many islands. In the Pacific, fish protein is estimated to make up 50-90% of animal protein consumption in rural areas, and 40-80% in urban areas (Bell et al., 2009; Hanich et al., 2018) with similar values reported for some Indian Ocean and Caribbean islands (e.g. Maldives, Antigua and Barbuda). It has been suggested that island nations may need to retain more of their tuna catch rather than relying solely on coastal fisheries to achieve food security in the future (Cross-Chapter Box MOVING PLATE in Chapter 5; Bell et al., 2015; Bell et al., 2018). Furthermore, small island fisheries can be severely impacted by extreme events such as TCs, yet rapidly recovering pelagic fisheries can help to alleviate immediate food insecurity pressures in some circumstances, helping to build resilience (Pinnegar et al., 2019).

Observed impacts of climate change on fish and fisheries in small islands include declines in reef-associated species due to coral bleaching or cyclone damage (Robinson et al., 2019; Magel et al., 2020), oceanic-scale shifts in the distribution of large pelagic fish and hence their fisheries (Erauskin-Extramiana et al., 2019), changes to the size structure or breeding behaviour of species (e.g. (Asch et al., 2018)(Sections 3.3.3.2 and 3.4.3.1)). Many studies of future fisheries productivity in a changing climate suggest that yields will fall as a result of ocean productivity reductions, local species extinction and/or migration (Nurse, 2011; Asch et al., 2018; Robinson et al., 2019). Asch et al. (2018) provided future projections for biodiversity and fisheries maximum catch potential in Pacific Island countries and territories. These authors concluded that 9 of 17 Pacific Island entities (Cook Islands, Federated States of Micronesia, Guam, Kiribati, Marshall Islands, Niue, Papua New Guinea, Solomon Islands, and Tuvalu) could experience ≥ 50% declines in maximum catch potential by 2100 relative to 1980–2000 under both an RCP 2.6 and RCP 8.5 scenario (*medium confidence*). In Wallis and Futuna, maximum catch potential was projected to increase slightly (around 10%) by 2050, later declining by the year 2100. Similar projections have now been provided for all countries worldwide, including Pacific, Caribbean, Atlantic, Mediterranean and Indian Ocean small islands (Cheung et al., 2018). The small islands that show the largest anticipated decrease in fisheries maximum catch potential by the end of the century (according to an RCP4.5 and RCP 8.5 scenario) included the Federated States of Micronesia, Kiribati, Nauru, Palau, Tokelau, Tuvalu, São Tomé and Príncipe, whereas some other small islands such as Bermuda, Easter Island (Chile), and Pitcairn Islands (UK), might actually witness increases in fish catch potential (*medium confidence*) (Cheung et al., 2018). Monnereau et al. (2017)showed that for the fisheries sector, small island states are generally more vulnerable to climate change impacts compared to continental least developed countries or coastal states because of their increased reliance on fisheries, the exposure of coastal communities to potential climatic threats and their limited adaptive capacity.

Projected impacts of climate change on agriculture and fisheries pose serious threats to dependent human populations (Ren et al., 2018; Hoegh-Guldberg et al., 2019), making the risk caused to livelihoods a Key Risk in small islands (KR7 in Figure 15.5). On small islands, despite biophysical commonalities (e.g., size and isolation), differences in economic status and level of dependence on agriculture and fisheries produce dynamic climate impacts (Balzan et al., 2018). Climate change is impacting agricultural production in small islands through slow-onset stressors such as rising average temperatures, shifting rainfall patterns, sea level rise and extreme events like TCs. For example, TC Pam, a Category 5 cyclone, devastated Vanuatu in 2015 and caused losses and damages to the agriculture sector valued at USD 56.5 million (64.1% of GDP) (Nalau et al., 2017) and TC Winston Winston in 2016 resulted losses and damages on the agriculture sector in Fiji valued at USD 254.7 million (Iese et al., 2020). In 2017, total loss and damage associated with hurricane Maria (category 5) amounted to 224% of Dominica's 2016 GDP (Barclay et al., 2019). Losses and damage in agriculture often led to people eating imported processed foods affecting their diet and nutrition (Haynes et al., 2020).Small Islands' communities are also witnessing the indirect effects of the covid-19 pandemic on agricultural systems (Hickey and Unwin, 2020). However, the limited diversity of agriculture production and reduced household incomes are contributing to low diet diversity (Iese et al., 2020). Bell and Taylor (2015) assessed the effects of climate change on specific sectors of agriculture in the Pacific islands region and found that, by 2090, staple food crops of taro, sweet potato, and rice are expected to suffer from moderate to high impact. Among export crops, coffee is expected to sustain the most significant impact due largely to increased temperatures in the highland areas of Papua New Guinea – a high production area (Bell et al., 2016). Livestock is an important protein source in some small islands and is particularly vulnerable to changes in temperature through heat stress (Bell and Taylor, 2015; Lallo et al., 2018). With the concentration of island people along (often reef-fringed) coasts, there is a comparatively large dependence on nearshore marine foods and coastal agricultural systems (Ticktin et al., 2018).

In the Caribbean, additional warming by 0.2°–1.0°C, could lead to a predominantly drier region (5%–15% less rain than present-day), a greater occurrence of droughts (Taylor et al., 2018) along with associated impacts on agricultural production and yield in the region (Gamble et al., 2017; Hoegh-Guldberg et al., 2019; Nicolas et al., 2020). Crop suitability modeling on several commercially important crops grown in Jamaica found that even an increase less than + 1.5 °C could result in a reduction in the range of crops that farmers may grow (Rhiney et al., 2018).

Sugar yield in Fiji could decline by 2–14% under projected scenarios (McGree et al., 2020). Farmers in some small islands have utilised Indigenous knowledge systems built on local ontology to sharpen their sensitivity to environmental conditions (Shah et al., 2018). However, projected climate change across the Pacific could undermine climate-sensitive agricultural livelihoods and exacerbate food insecurity challenges (McCubbin et al., 2017; Campbell et al., 2021).

Projected climate impacts on island agroecosystem services could accentuate a myriad of social and ecological risks (Campbell, 2021). Without proactive farm management practices, the projected impacts of climate change on drought patterns is a major threat to cocoa pollination services (Arnold et al., 2018). Many tropical island agroforestry crops are completely dependent on insect pollination and it is therefore important to understand the climatic drivers of changing conditions related to pollinator abundance. Coastal agroforestry systems in small Pacific islands are vital to national food security but native biodiversity is rapidly declining (Ticktin et al., 2018). Biodiversity loss from traditional agroecosystems is a major threat to food and livelihoods security in SIDS (UNEP, 2014a). Additionally, while coastal-lowland salinisation and more-frequent flooding attributable to SLR have impacted coastal agriculture on some islands (Cruz and Andrade, 2017; Wairiu, 2017), stronger TCs can sometimes shock island terrestrial food production warranting reconfiguration (Mertz et al., 2010; Duvat et al., 2016; Chakrabarti et al., 2017). Calls to conserve associated environments and to make terrestrial food production on islands more resilient to climate-driven shocks underscore concern about future food security (Connell, 2013; de Scally, 2014). Implicit in the latter is reversing the decades-long loss of Indigenous knowledge about food production in many island societies and incorporating it into future strategies (Mercer et al., 2014b; Janif et al., 2016).

15.3.4.5 Economies

Small-island economies vary greatly in their nature, history/trends, and viability under a changed climate. As elsewhere, few small island economies are overseen by governments that are adequately prepared for the economic impacts of climate change over the next few decades (Connell, 2013; Hay, 2013). In particular, the lack of diversity that characterizes most small-island economies means they are especially vulnerable to global (climate-driven) shocks (Cross-Chapter Box DEEP in Chapter 17), be these the impacts of extreme events or more gradual longer-term change, which makes the maintenance of traditional mechanisms for coping with such shocks in many island societies all the more important (Granderson, 2017; Wilson and Forsyth, 2018; Nunn and Kumar, 2019b). As a result, the risk from climate change to economies constitutes a Key Risk (KR7 in Figure 15.5) in small islands.

Many island environments have been commercially exploited by external interests for much of their recent history. This is especially common for timber, the wholesale removal of forests, especially on tropical islands, exposing land to heavy rain that leads to denudation and increases lowland sedimentation (Wairiu, 2017; Eppinga and Pucko, 2018). Negative aspects of both processes will be exacerbated by climate change, demonstrating the practical need for reforestation in many island contexts (Thomson et al., 2016).Some small-island economies are sustained by extractive industries such as mining, creating dependencies that lead to their environmental impacts being downplayed (Tserkezis and Tsakanikas, 2016; Shepherd et al., 2018). It is important to address these impacts as they will add to negative impacts of climate change (Clifford et al., 2019).

Many small-island economies are sustained by tourism and have invested heavily in associated infrastructure and capacity building (Cannonier and Burke, 2018). Some rural island communities have become dependent on tourism to the point that it would be difficult to revert to subsistence living (Lasso and Dahles, 2018). Coast-focused (beach-sea) tourism in island contexts is already being impacted by beach erosion, elevated high SST causing coral bleaching, and associated marine-biodiversity loss, as well as more intense TCs (Tapsuwan and Rongrongmuang, 2015; Parsons et al., 2018; Wabnitz et al., 2018). The Covid-19 pandemic travel disruption significantly affected Caribbean islands tourism sector by reducing incomes that would have been used to enhance climate resilience (Sheller, 2020). Many tourism interests downplay the impacts and future risks from climate change (Shakeela and Becken, 2015), a position that may be borne out by sustained/rising demand for small island vacationing in some locales (Katircioglu et al., 2019). A way forward is for island tourism to emphasize its low-carbon and sustainable attributes, and to encourage smaller-scale eco-friendly holiday opportunities (Lee et al., 2018), in other words for island nations to embrace a 'blue economy' in line with SDG14 to conserve and utilise their oceans for sustainable futures (Hampton and Jeyacheya, 2020; Hassanali, 2020).

Given the high cost of imported goods, especially foodstuffs, larger island jurisdictions are striving to transform their economies to favour locally produced or locally constituted materials that employ local people and reduce their cost of living. The exposure of this component of island economies varies, yet manufacturing/commercial operations are usually found in the lowest-lying areas, often on reclaimed lands. This makes them especially vulnerable to rising sea level, part of a larger issue around the disproportionate exposure of infrastructure on small islands to climate change (Fakhruddin et al., 2015; Kumar and Taylor, 2015).

It is challenging to disentangle the role of climate change from that of globalisation and development in recent changes to human livelihoods on small islands, given that the latter have characterised many – especially SIDS – within the last few decades. However, recent climate change is clearly implicated in livelihood deterioration in many island contexts (Hernandez-Delgado, 2015; Nunn and Kumar, 2018). For example, livelihood impacts of climate-driven stressors (including shoreline/riverbank erosion, flooding and erratic rainfall) in three Mahishkhocha island-chars (river-mouth sand islands of Bangladesh) have been amplified by inadequate/misguided policy (Saha, 2017).The subordination of IKLK in favour of external adaptation strategies has accelerated livelihood decline in many island contexts (Wilson and Forsyth, 2018). Although economic and financial development has the potential to reduce environmental (and livelihood) degradation in SIDS (Seetanah et al., 2019), it is also clear that uneven development can steepen core-periphery disparities, especially in archipelagic contexts, resulting in deteriorating rural/peripheral livelihoods at the expense of improving urban ones (Wilson, 2013; Sofer, 2015) and increased rural-urban migration (Birk and Rasmussen, 2014; Connell, 2015).

15.3.4.6 Migration

Climate-related migration is considered to be a particular issue for small islands because changes in extreme events and slow-onset changes affect increasingly highly exposed and vulnerable low-lying coastal populations, therefore causing a threat to small island habitability (KR9 in Figure 15.5) (Storey and Hunter, 2010; Kumar and Taylor, 2015; Duvat et al., 2017b; Weir and Pittock, 2017; Hoegh-Guldberg et al., 2018; Mycoo, 2018a; Rasmussen et al., 2018). A typology of climate-related migration is provided in Cross-Chapter Box MIGRATE in Chapter 7. It is assumed that climate-related migration will increase in small islands, however, as is the case globally, the causes, form and outcomes are highly context specific. Types of climate-related migration occur across a continuum of agency from involuntary displacement at one end to voluntary movement to strategically reduce risks and planned resettlement at the other end (Section 15.5.1, also see Chapter 7; Birk and Rasmussen, 2014; Betzold, 2015; McNamara and Des Combes, 2015; Gharbaoui and Blocher, 2016; Stojanov et al., 2017; Weir, 2020).

Studies do not provide sufficiently robust evidence to attribute the various forms of migration to anthropogenic climate change directly on small islands or to accurately estimate the current number of climate-related migrants (see Chapter 7). Climate events and conditions strongly interact with other environmental stressors and economic, social, political and cultural reasons for migrating (*robust evidence, high agreement*) (Birk and Rasmussen, 2014; Campbell and Warrick, 2014; Laczko and Piguet, 2014; Marino and Lazrus, 2015; Connell, 2016; Weber, 2016b; Stojanov et al., 2017; Cashman and Yawson, 2019).

Despite difficulties with attribution, the literature establishes that climate variability and extreme events and broad environmental pressures have contributed to some degree to human mobility on small islands over time (*medium evidence, high agreement*) (Birk and Rasmussen, 2014; Campbell, 2014a; Campbell and Warrick, 2014; Donner, 2015; Kelman, 2015a; Connell, 2016; Stojanov et al., 2017; Barnett and McMichael, 2018; Martin et al., 2018) and these studies can provide analogues from which to inform climate-migration responses (Birk and Rasmussen, 2014; Kelman, 2015a; Connell, 2016).

Similarly, studies do not provide robust evidence to project how the full range of climate drivers may influence migration patterns on small islands into the future, although studies are emerging that estimate populations affected as a consequence of projected SLR. Rasmussen et al. (2018) estimated current populations of the world that are potentially subject to permanent inundation from projected local mean SLR associated with global mean surface temperature stabilisation targets of 1.5°C, 2.0°C, and 2.5°C occurring at 2100. For the affected land area and population, this analysis included a subset of 58 SIDS, as defined by the United Nations, for which the results are shown in Table 15.4.

Table 15.4: Global mean sea level rise (SLR) at 2100 projections and associated population of SIDS exposed to permanent inundation for global mean surface temperature stabilisation targets of 1.5°C, 2.0°C and 2.5°C. Rasmussen et al. (2018)

Stabilised Warming at 2100[a]	1.5°C		2.0°C		2.5°C	
Percentile	*50*	*5th–95th*	*50th*	*5th–95th*	*50th*	*5th–95th*
Global-mean SLR (cm) by percentile[b]	48	28–82	56	28–96	58	37–93
SIDS population exposure (thousands) by percentile[c]	400	300-560	420	300-640	430	320-630

Table Notes:
(a) Above pre-industrial level.
(b) Values are centimeters above 2000 current era baseline.
(c) Potentially affected population due to local mean SLR. Local mean SLR projections used for individual SIDS take account of variations from the global mean due to factors such as glacial isostatic adjustment, gravitational changes from ice melting, deltaic subsidence and tectonic movements.

The aggregate figures of population that could potentially be affected by permanent inundation shown in Table 15.4 and Figure 15.3 mask important differences in relative exposure between individual SIDS. Further, population affected by permanent inundation does not take into account the change in the frequency of ESL events and associated water-level attenuation (as per Vafeidis et al., 2019), nor does it account for adaptation measures that may alleviate impacts, future population growth, or the extent to which populations could adaptively migrate (Section 15.5.3). However, Rasmussen et al. (2018)'s analysis shows that comparatively small changes in mean sea level can result in large increases in the frequencies of ESL events and, hence, the risk of coastal flooding of inhabited land, suggesting many areas of SIDS may become uninhabitable well before the time of permanent inundation (see also studies referenced in Section 15.3.3.1.1). A similar conclusion is drawn by Kulp and Strauss (2019) who show that land area home to 10% or more of the population of many SIDS is at risk of chronic coastal flooding or permanent inundation by 2100.

Duvat et al. (2021a) employed an integrated systems approach to analyse future risk to habitability in atoll islands, taking into account changes in various ocean and atmospheric climate drivers and a moderate adaptation scenario (i.e., adaptation responses that remain similar in nature and magnitude to currently observed responses). They found that, compared to present-day risk, additional risk to habitability in Male, Maldives, and Fogafale, Tuvalu, is minimal under a low emissions scenario (RCP2.6) at 2050, although it may become moderate for Male and high for Fogafale by 2090. Under a worse case emissions scenario (RCP 8.5), future risk to habitability in these two urban islands may increase slightly in 2050, but may increase to moderate-to-high (for Male') and high-to-very high (for Fogafale) by 2090.

Even where settlement locations and livelihoods remain secure, an increase in health diseases, decrease in the availability of potable water, and increasing exposure to extreme events may reduce habitability (Section 15.3.4.9.2; Campbell and Warrick, 2014; Storlazzi et al., 2018). For example, the Fijian coastal community of Vunidogoloa made the decision to relocate in response to regular inundation during high tides. Raising houses on stilts and constructing a seawall failed to prevent regular flood damage to buildings and the entire community eventually relocated as a 'last resort' adaptation measure to a site within customary land. The availability of customary land for the new site was a key factor of success in this relocation example although this will not guarantee success in every case as relocation may expose communities to new risks (McNamara and Des Combes, 2015; Piggott-McKellar et al., 2019a).

15.3.4.7 Culture

Small island societies have developed IKLK based responses to living in dynamic environments susceptible to climate variability and extremes, which are based in broader systems of culture and heritage (*high confidence*) (Barnett and Campbell, 2010; Lazrus, 2015; Nunn et al., 2017b; Bryant-Tokalau, 2018b; Nalau et al., 2018b; Perkins and Krause, 2018). As expanded upon in Section 15.6.5 cultural resources are thought to play an important role in climate change adaptation on small islands through contributing to adaptive capacity and resilience (McMillen et al., 2014; Petzold and Ratter, 2015; Nunn et al., 2017b; Warrick et al., 2017; Falanruw, 2018; Mondragón, 2018; Neef et al., 2018; Parsons et al., 2018; Perkins and Krause, 2018; Hagedoorn et al., 2019; 2020a) (*robust evidence, medium agreement)*. Thus, loss of culture (KR8 in Figure 15.5) threatens adaptive capacity.

Some studies from the Pacific suggest that climate-migration linked to reduced habitability (Section 15.3.4.6) can have particularly severe cultural implications in a small island context where community solidarity and cohesion linked to place-based identity are important aspects of adaptive capacity (Hofmann, 2014; Lazrus, 2015; Warrick et al., 2017). In Federated States of Micronesia, land is owned through the matrilineal system and hence puts women in the centre of decision-making. The deterioration and loss of land (through saltwater intrusion, flooding, drought, erosion) not only can lead to economic deprivation but it also compromises cultural identities: "Where land signifies political, social, and economic well-being, becoming bereft of land cuts off an important thread of people's sense of belonging" (Hofmann, 2017, p. 82) particularly for Chuuk women. Land degradation and loss involves the "interruption to the matrilineal transmission of land" (Hofmann, 2017;p. 82), the loss of identities, relationships, and their customary authority.

The unquantifiable and highly localised cultural losses resulting from climate drivers are less researched and less acknowledged in policy than physical and economic losses (Karlsson and Hovelsrud, 2015; Thomas and Benjamin, 2018a). In the Bahamas, prolonged displacement of the entire population of Ragged Island following Hurricane Irma (2017) highlighted the cultural losses that can result from climate-induced displacement from ancestral homelands. Threats to identity, sense of place and community cohesion resulted from displacement, although all were important foundational features of the Islanders' self-initiated rehabilitation efforts and eventual return. Nonetheless, non-economic losses were not accounted for by policy addressing displacement (Thomas and Benjamin, 2018a). In the case of Monkey River Village in Belize, coastal erosion is threatening the community's cemetery. Residents place significant spiritual and emotional value on the cemetery which serves important community functions, and thus, threats to it are perceived to be serious and necessary to be taken into account in any planned response (Karlsson and Hovelsrud, 2015). A similar situation exists on Carriacou in the West Indies where culturally and historically significant archaeological sites are being lost due to coastal erosion caused by a combination of sand mining and extreme climate-ocean events exacerbated by SLR (Fitzpatrick et al., 2006).

Population and settlement concentration in coastal areas and high exposure to climate-driven coastal hazards on small islands mean that threats to tangible cultural heritage (archaeological sites, buildings, historic sites, UNESCO World Heritage Sites etc.) are high (Marzeion and Levermann, 2014; Reimann et al., 2018), although few studies examine this issue specifically in a small island context. On the island of Barbuda, archaeological sites containing important information on historical ecology and climatic shifts are at risk from coastal erosion and hurricanes. This loss of heritage represents identity loss, as "learning about the past is a crucial exploration of self that grounds and connects people to places" (Perdikaris et al., 2017)(p. 145). Loss and damage to heritage sites may also impact tourism and thus have significant economic impacts for narrow small island economies (Section 15.3.4.5).

15.3.4.8 Transboundary Risks/Issues

Inter-regional transboundary impacts are those generated by processes originating in another region or continent well beyond the borders of an individual archipelagic nation or small island. Intra-regional transboundary impacts originate from a within-region source (e.g., the Caribbean). Some transboundary processes may have positive effects on the receiving small island or nation, though most that are reported have negative impacts (Table 15.5).

Table 15.5: Summary of inter- and intra-regional transboundary risks and impacts on small islands
[INSERT TABLE 15.5 HERE]

[START BOX 15.1 HERE]

Box 15.1: Key Examples of Cumulative Impacts from Compound Events: Maldives Islands and Caribbean Region

Cumulative Impacts of the Compound Events of the 1998-2016 Period in the Maldives Islands

Between 1998 and 2016, the Maldives Islands were affected by three major climate events, including the 1997-1998 ENSO event, the 2007 flood event and the 2016 ENSO event, and by one tectonic event, the 2004 Indian Ocean Tsunami (Morri et al., 2015). These events illustrate the cumulative and cascading risks that a series of events may cause in reef-dependent atoll contexts (Figure Box15.1).

The 1997-1998 ENSO event was severe in the Maldives and as a result the living coral cover dropped to <10% (Bianchi et al., 2003). Recovery was still in progress in 2004 when the tsunami caused further (although not quantitatively assessed (Gischler and Kikinger, 2006)) damage to the reef ecosystem. Post-1998 recovery ultimately took 15 years, (i.e., longer than following the 1987 ENSO event, after which recovery had only taken a few years) and also longer than in the neighbouring undisturbed Chagos atolls, thereby suggesting the alteration of the recovery capacity of the reef ecosystem by human-induced reef degradation and climate change (Morri et al., 2015; Pisapia et al., 2017). Mid-2016, a new ENSO event occurred, which reduced living coral cover by 75% (Perry and Morgan, 2017). Future recovery of the reef ecosystem, which is critical to both current livelihoods and economic activities (especially diving-oriented tourism and fishing) and to long-term island persistence, will mainly depend first on the frequency and magnitude of future bleaching events, which are expected to increase due to ocean warming, and second on the highly variable effects of anthropogenic disturbances locally (Perry and Morgan, 2017; Pisapia et al., 2017; Duvat and Magnan, 2019b).

Additionally, the 2004 Indian Ocean tsunami (Magnan, 2006) and the 2007 flood (Wadey et al., 2017) caused damage totalling 62% of the country's GDP (Luetz, 2017). The tsunami also downgraded the Maldives (now a middle-income country) to the Least Developed Countries category and caused within-country migration, with 30,000 people (9.6% of the country's population) displaced (Republic of Maldives, 2009). These successive events, which had cumulative devastating effects on the reef ecosystem and cascading effects on health and well-being, livelihoods and economy, highlighted the risk posed by limited recovery time to the whole social-ecological system as well as the detrimental effect of local human disturbances on reef recovery.

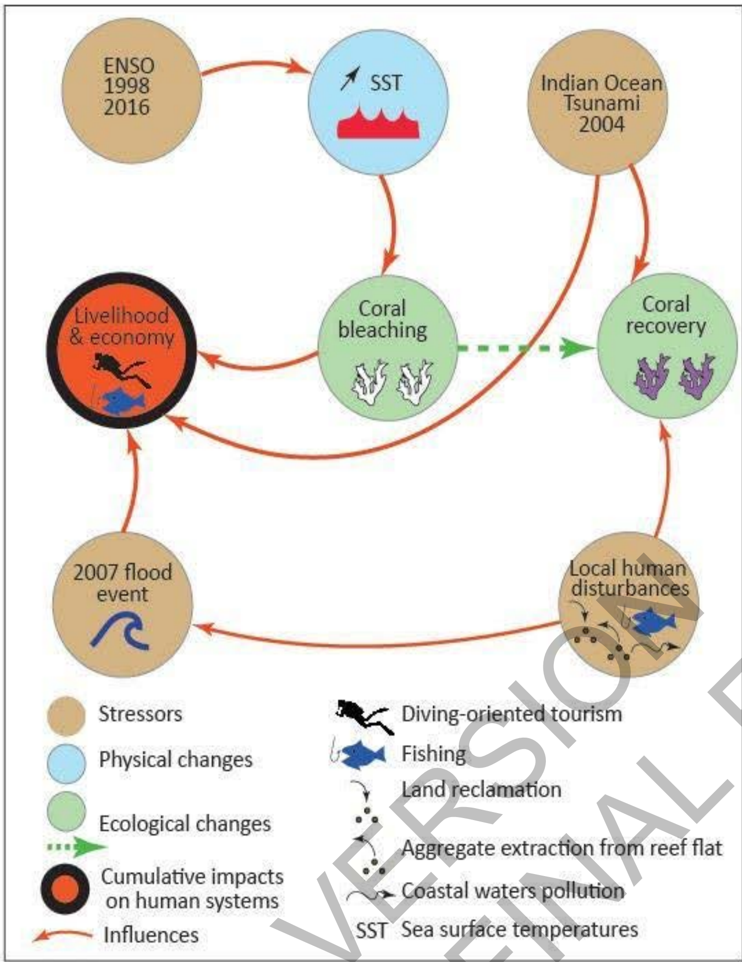

Figure Box15.1.1: Cascading and cumulative impacts of the compound events of the 1998-2016 period in the Maldives Islands.

Cumulative Impacts of the 2017 Hurricanes in the Caribbean Region

Among the 29 Caribbean SIDS, 22 were affected by at least one category 4 or 5 TC in 2017. These events highlighted how the pre-cyclone high exposure and vulnerability of these islands and their populations has caused a "cumulative community vulnerability" (Lichtveld, 2018, p. 28) that has amplified the impacts of these TCs, which will in turn increase the long-term vulnerability of affected islands. The exposure of these islands over their entire surface, combined with the concentration of people, and infrastructure, utilities and public services in flood-prone coastal areas, inadequate housing, limited access to healthy food and transportation, and unpreparedness explains widespread-to-total devastation (Shultz et al., 2018; Briones et al., 2019). The destruction of transport systems (Lopez-Candales et al., 2018) and island supply chains (Kim and Bui, 2019), which heavily depend on ports, roads, power and communications, made rescue logistically complex, explaining the lack of freshwater, food supplies, medications and fuel on some islands for several weeks after the event. This cumulative vulnerability caused "cascading public health consequences" (Shultz et al., 2018, p.9), including delayed (i.e., over the next year) mortality, physical injury during the clean-up and recovery phase, and increased the risk of chronic, vector-borne, contaminated water-related diseases, and mental sequelae (Kishore et al., 2018; Ferre et al., 2019).

The loss of mangroves (Branoff, 2018; Walcker et al., 2019; Taillie et al., 2020) and terrestrial forests (Eppinga and Pucko, 2018; Feng et al., 2018; Hu and Smith, 2018; Van Beusekom et al., 2018) exacerbated the cyclone-induced economic crisis. In the most affected islands, the destruction of buildings and outmigration generated a significant loss of tangible (e.g., museums) and intangible (e.g., traditional artistry) cultural heritage (Boger et al., 2019). Prolonged displacement of entire island populations (e.g., Ragged Island, the Bahamas; Barbuda) caused "non-economic loss and damage", including threats to health and well-being, and loss of culture, sense of place and agency (Thomas and Benjamin, 2019), which may further exacerbate the long-term vulnerability of concerned communities.

In early 2020, while island communities were still recovering from the 2017 hurricanes, the COVID-19 pandemic caused the closure of global transportation, with devastating socioeconomic impacts on tourism-dependent Caribbean economies (Sheller, 2020), illustrating how compounding crises increase island vulnerability to both climate and non-climate related events.

[START BOX 15.2 HERE]

Box 15.2: Loss and Damage and Small Islands

Loss and damage has a range of conceptualizations (Section 1.4.4.2; Cross-Chapter Box LOSS in Chapter 17) and is a critical issue for many small islands, closely related to issues of climate justice (Section 15.7). Small islands are already experiencing an array of negative climate change impacts while climate risks are projected to increase as global average temperatures rise (Section 15.3, 16.2; Cross-Chapter Paper 2). Barriers and limits to adaptation also contribute to greater levels of both economic and non-economic loss and damage for small islands (Sections 15.6, 16.4).

For SIDS in particular, loss and damage has negative implications for sustainable development (Benjamin et al., 2018). The costs of loss and damage, particularly from extreme events, can deplete national capital reserves (Noy and Edmonds, 2019). Thomas and Benjamin (2017) show how loss and damage can lead to an 'unvirtuous cycle of climate-induced erosion of development and resilience'. In this cycle, addressing loss and damage strains limited national resources, diverting public funding and other resources to address negative climate impacts. This in turn reduces resources and capacities which could be allocated to adaptation, building resilience and sustainable development, thereby increasing vulnerability to climate change and leading to further loss and damage where the cycle begins again. The cascading and cumulative impacts of extreme events experienced in Pacific and Caribbean SIDS exemplify that this cycle may already be in effect.

In addition to the strain on national resources that loss and damage currently presents, credit ratings of SIDS have recently begun to include vulnerability to climate change, which may have negative impacts on their abilities to borrow external funds, attract foreign investment or access concessional financing (Buhr et al., 2018; Volz et al., 2020). Costs of addressing loss and damage may also affect the ability of SIDS to repay external debt, thus endangering eligibility for future access to funding (Baarsch and Kelman, 2016; Klomp, 2017; Shutter, 2020). These factors may place SIDS in situations where they face mounting costs of climate change with eroding capacities and resources to address loss and damage.

In the international policy arena, small islands - as part of Alliance of Small Island States (AOSIS) - have been strong advocates for including loss and damage in the United Nations Framework Convention on Climate Change (UNFCCC); highlighting the increasing and irreversible risks that climate change poses for islands in particular (Roberts and Huq, 2015; Adelman, 2016; Mace and Verheyen, 2016). AOSIS, along with other developing countries and groups, have advocated that there is a pressing need for finance and resources to address loss and damage as well as greater integration of loss and damage in the UNFCCC and the Paris Agreement, including in capacity building, technology and the global stocktake (Benjamin et al., 2018; Nand and Bardsley, 2020).

[END BOX 15.2 HERE]

15.3.4.9 Key Risks in Small Islands

15.3.4.9.1 Key Risk approach

This section builds on cross-chapter work led by Chapter 16 of the WGII AR6 Report aimed at identifying and assessing Key Risks across sectors and regions (Section 16.5 and Supplementary Material 16.A.2). Key Risks (KRs) are the risks of most pressing concern that are caused or exacerbated by climate change in a given region. A KR is defined as a 'potentially' severe risk, which can either be already severe or projected to become severe in the future, as a result of (i) changes in associated climate-related hazards and/or the exposure and/or vulnerability of natural and human systems to these hazards, and/or of (ii) the adverse consequences of adaptation or mitigation responses to the risk. In line with the guidelines used in the WGII AR6 Report, the identification of KRs in small islands is based on the chapter authors' expert judgment, using scientific literature and five types of criteria: (1) Importance of the affected system or dimension of the system, which is a value judgment left to readers to make; (2) Magnitude of adverse consequences, based on their pervasiveness, degree and irreversibility, and on the potential for impact thresholds and cascading effects across the system; (3) Likelihood of adverse consequences, although this probability is rarely quantifiable for small islands due to limited downscaled data at a small island level; (4) Temporal characteristics of the risk, including its period of emergence, persistence over time and trend; and (5) Ability to respond to the risk, with the severity of the risk being inversely proportional to this ability.

15.3.4.9.2 Key Risks in small islands

Slow onset climate and ocean changes, and changes in extreme events, are expected to cause and/or to amplify nine KRs in small islands, through both direct (e.g., decrease in rainfall will increase water insecurity) and indirect, that is, cascading effects: for example, loss of terrestrial biodiversity and ecosystem services will increase water insecurity, which will in turn cause the degradation of human health and well-being (Figure 15.5, Table 15.6 and Table 16.A.4 in Chapter 16 Supplementary Material).

These KRs include loss of marine and coastal biodiversity and ecosystem services (*high confidence*) (KR1; for details on KR coverage, see Section 15.3.3.1); submergence of reef islands (*low confidence*) (KR2; Section 15.3.3.1.1); loss of terrestrial biodiversity and ecosystem services (*high confidence*) (KR3; Section 15.3.3.3); water insecurity (*medium-high confidence*) (KR4; Section 15.3.4.3); destruction of settlements and infrastructure (*high confidence*) (KR5; Section 15.3.4.1); degradation of human health and well-being (*low confidence*) (KR6; section 15.3.4.2); economic decline and livelihood failure (*high confidence*) (KR7; Sections 15.3.4.4 and 15.3.4.5); and loss of cultural resources and heritage (*low confidence*) (KR8; Section 15.3.4.7).

Risk accumulation and amplification through cascading effects from ecosystems and ecosystem services to human systems will likely cause reduced habitability of some small islands (*high confidence*) identified as the overarching KR (KR9). Habitability is understood as the ability of these islands to support human life by providing protection from hazards which challenge human survival; by assuring adequate space, food and freshwater; and by providing economic opportunities, which contribute to health and well-being; recognizing that both supportive ecosystems and socio-cultural conditions (i.e. beliefs and values, institutions and governance arrangements, sense of community and attachment to place) play a critical role in habitability (Duvat et al., 2021a). The reduction of island habitability is expected to cause increased migration, along the above-mentioned involuntary displacement to planned resettlement spectrum (Section 15.3.4.6), which may eventually lead to population movements from exposed areas and depopulation of some islands. This risk is the highest for atoll nations, where some islands might become uninhabitable over this century (Section 15.3.4.6; Storlazzi et al., 2018; Duvat et al., 2021a). Despite a lack of literature assessing the risk of reduced habitability in non-atoll islands, the latter are also expected to experience decreased habitability, especially in their coastal areas.

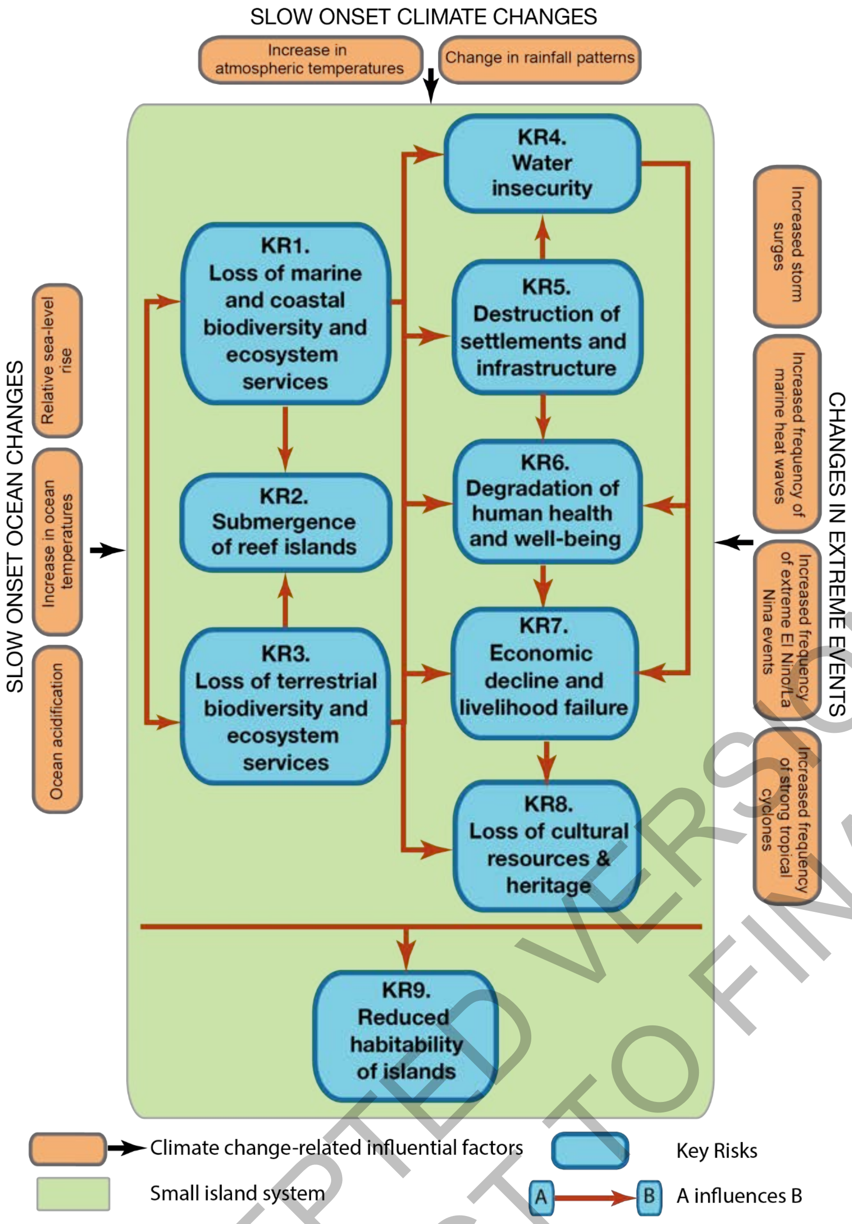

Figure 15.5: Key Risks in small islands. KR1 to 8 are interconnected as shown by arrows, which causes risk accumulation leading to reduced island habitability. The main interconnections are shown in this figure: for example, loss of marine and coastal and terrestrial biodiversity and ecosystem services (KR1 and KR3, respectively) are projected to cause the submergence of reef islands (KR2), water insecurity (KR4), destruction of settlements and infrastructure (KR5), degradation of human health and well-being (KR6), economic decline and livelihood failure (KR7), and loss of cultural resources and heritage (KR8). Importantly, Key Risks result from both direct effects (e.g. decrease in rainfall will increase water insecurity) and indirect effects (e.g. loss of terrestrial biodiversity and ecosystem services will increase water insecurity, which will in turn cause the degradation of human health and well-being).

15.4 Detection and Attribution of Observed Impacts of Climate Change on Small Islands

As highlighted in AR5, detection of climate change impacts on the fragile environments of small islands is challenging because of other non-climate drivers that affect small islands. Determination of attribution to incremental change of climate drivers is also challenging because of the natural climate variability. Therefore, there is limited scientific literature on observed impacts and attribution. A synthesis of findings on the impacts of climate change (Sections 15.3.3 and 15.3.4) shows that there is more information on impacts on ecosystems compared to human systems. There is *high confidence* in attribution to climate change of impacts on the coastal and marine as well as terrestrial ecosystems (Hansen and Cramer, 2015; Shope et al., 2016; van Hooidonk et al., 2016; Hoegh-Guldberg et al., 2017; Hughes et al., 2017b; Mentaschi et al., 2017; Shope et al., 2017; Vitousek et al., 2017; Wadey et al., 2017; Ford et al., 2018; Hughes et al., 2018; IPCC, 2018; Storlazzi et al., 2018; Bindoff et al., 2019) and *medium confidence* in attribution to climate change of impacts on livelihoods, economics and health (Figure 15.6; McIver et al., 2016; Eckstein et al., 2018; Santos-Burgoa et al., 2018; Schütte et al., 2018; WHO, 2018).

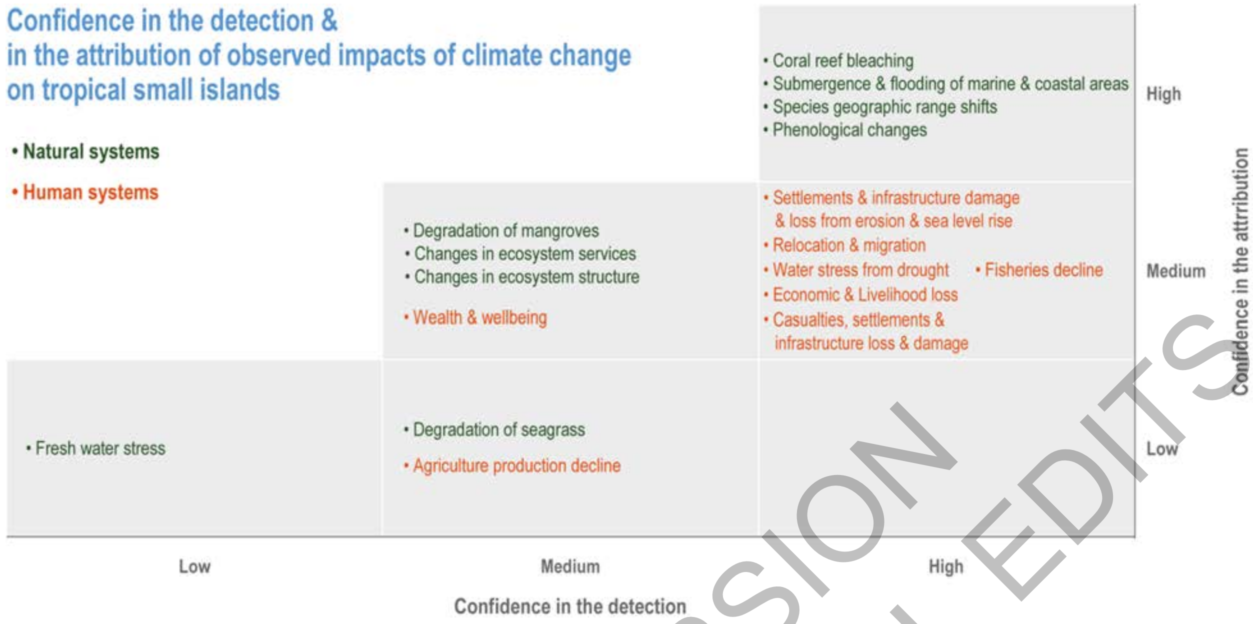

Figure 15.6: A comparison of the degree of confidence in the detection of observed impacts of climate change on tropical small islands with the degree of confidence in attribution to climate change drivers.

As Figure 15.6 shows there is *high confidence* that climate change causes changes in terrestrial ecosystems as well as coral reef bleaching through increases in sea surface temperature and submergence and flooding of coastal areas through sea level rise and increased wave height. With respect to casualties, settlements and infrastructure loss and damage, economic and livelihood loss, although confidence in detection is high, there is at present *medium confidence* in the attribution to climate change. *Medium confidence* in attribution frequently arises owing to the limited research available on small island environments.

15.5 Assessment of Adaptation Options and Their Implementation

Since AR5, small islands have experimented with new adaptation options, which has increased the lessons learnt from on-the-ground practices in these settings. Figure 15.7 shows some of the adaptation options that are being experimented with in small islands. This section covers most common adaptation actions and approaches across small islands and assesses the many constraints, enablers and limits to adaptation. Adaptation plays also a key role in climate resilient development and the insights emerging from small islands on this topic are discussed after the adaptation section.

15.5.1 Hard Protection

Seawalls have been a popular coastal protection measure on islands (Figure 15.7). An analysis of National Communications shows that 28% of coastal protection actions are seawalls, followed by breakwater structures and coastal protection units (Robinson, 2017a). Coastal protection infrastructure has been heavily invested, for example in the Caribbean region (Mycoo, 2014b) and Cuba (Mycoo, 2014a). A similar situation applies in many Indian Ocean islands, where coastal protection strategies are manifested by hard shoreline structures, many of which are proving challenging to maintain (Naylor, 2015; Betzold and Mohamed, 2017; Magnan and Duvat, 2018). In the Pacific the situation is different given that many islands have been occupied for millennia by indigenous communities with extant knowledge for coping with adversity (Granderson, 2017). The latter generally favours ‘soft’ shoreline structures for coastal protection although the building of seawalls has been rapid, especially in urban islands (Umeyama, 2012; Duvat, 2013; Magnan et al., 2018; Morris et al., 2018), and also in some rural islands (e.g., Tubuai, French Polynesia (Salmon et al., 2019)).

Many rural communities have uncritically emulated structures in urban contexts built and maintained with external finances. As a result, in many Pacific SIDS, seawalls have collapsed without additional funding available for repairs (Nunn and Kumar, 2018; Piggott-McKellar et al., 2020; Nunn et al., 2021). Similar cases have been recorded along the coast of Puerto Rico (Jackson et al., 2012) while on Indian Ocean islands (e.g., Seychelles), the shorelines are littered with broken seawalls and groynes (Duvat, 2009). In Samoa, seawalls close to Apia need constant investments to remain viable.

On small islands, another widespread issue with seawalls and other hard shoreline structures is that they invariably shift problems of shoreline erosion and lowland inundation elsewhere (Donner and Webber, 2014). Even surrounding entire islands with such structures, as has happened on Male' (Maldives), is not a long-term solution because of incidences of localised seawall collapse that can spread quickly if not addressed immediately (Naylor, 2015). Hard structures for coastal protection will become increasingly ineffective in the future, demonstrating the need for adaptation along most island coasts to become more transformative than has been the case over the past few decades. In the Bahamas, it has been suggested that coastal protection structures and strategies are implemented through "a rather piecemeal approach of single projects and small patches, partially resulting in maladaptation by further increasing processes of erosion" (Petzold et al., 2018)(p. 95). In the village of Lalomalava, Samoa, national adaptation funding was spent on erecting a seawall to protect the village, but the wall was not long enough to protect the whole village, leading some families and properties to face increasing impacts from large waves (Crichton and Esteban, 2018).

15.5.2 Accommodation and Advance as Strategies

In most small island contexts, the costs of adaptation through accommodation are prohibitive so that it has in most cases not been contemplated as a widespread option. However, accommodation measures such as the raising of dwellings and key infrastructure like coastal roads above ground level have been implemented to reduce the impacts of flooding in some islands (Figure 15.7). In the most populous islands of the Tuamotu atolls, French Polynesia, where between 48 and 98% of dwellings have already experienced flooding since the 1980s, elevated houses with floors built 1.5 m above ground level are subsidised by the Government as part of Risk Prevention Plans (Magnan et al., 2018). Despite this incentive, the opposition of the local authorities and population to these plans (which also include constraining setback guidelines) considerably limited implementation, hence elevated houses only represent 7% of the total housing stock. In the Philippines (Tubigon) and Indonesia (Jakarta area) residents have elevated their houses by building stilted houses or raising the floor using coral stones to face increased flooding (Jamero et al., 2017; Esteban et al., 2020). Also, in Puerto Rico houses have been raised to address flooding (Lopez-Marrero, 2010).

In some small island settings, land reclamation (i.e., land gain through infilling) has been implemented for decades to allow for infrastructure construction and to address land shortages arising from high population growth. For example, land reclamation in Port of Spain, the capital city of Trinidad, has long been used as a solution space to meet land for housing, industrial development and infrastructure provision (Mycoo, 2018b). Likewise, one third of the land area of Male', the capital island of the Maldives, results from land reclamation (Naylor, 2015). Land reclamation is also common in Pacific atoll countries and territories, where it occurs both in urban islands facing high population pressure, such as South Tarawa, Kiribati (Biribo and Woodroffe, 2013), Funafuti Atoll, Tuvalu (Onaka et al., 2017), and Rangiroa Atoll, French Polynesia (Duvat et al., 2019b), and in rural islands, e.g., Takapoto and Mataiva atolls, French Polynesia (Duvat et al., 2017b). In some cases, land reclamation has paved the way for land raising, which is increasingly considered to adapt to SLR in small islands contexts (Figure 15.7). For example, since the 1990s, the capital area of the Maldives has been expanded through the construction of a large new island, Hulhumale', which is still under construction and is built 60 cm higher than Male' to take into account SLR (Hinkel et al., 2018; Brown et al., 2020). More generally, in the Maldives, the 2004 Indian Ocean Tsunami has boosted island raising as part of the "safe island development programme" (Shaig, 2008). Recent studies suggest that land and island raising have some potential in small islands, especially in urban high-value areas where this can generate substantial revenues through the sale or lease of new land, and therefore leverage public adaptation finance (Bisaro et al., 2019).

15.5.3 Migration

Migration, including planned resettlement, is increasingly occurring in small islands to intentionally respond to or prepare for climate change impacts (Figure 15.7; Magnan et al., 2019). There is currently *limited evidence* and *low agreement* in the literature as to whether migration of various types is an effective strategy to adapt to localised impacts of climate change, as outcomes are highly context specific (Donner, 2015; McNamara et al., 2016; Hermann and Kempf, 2017; McMichael et al., 2019; Piggott-McKellar et al., 2019a; Tabe, 2019; Bertana, 2020; Weir, 2020).

In-situ adaptation options are frequently the preference of communities over resettlement (Jamero et al., 2017) and in many documented cases, relocation – both planned and autonomous – is an adaptation option of last resort due to high economic and socio-cultural cost (McNamara and Des Combes, 2015; Jamero et al., 2017; Crichton et al., 2020). In small islands, there is *medium evidence* and *high agreement* that the degree of migrant agency and choice in decisions about whether to move, where, when and how is an important determinant of success and therefore 'adaptiveness' (see Cross-Chapter Box MIGRATE in Chapter 7; McNamara and Des Combes, 2015; Hino et al., 2017; McMichael et al., 2019; Piggott-McKellar et al., 2019a; Bertana, 2020) . Two case studies of community relocation in Fiji (Denimanu and Vunidogoloa villages) recommend that participatory inclusion of all social groups in the relocation planning process, including in planning for livelihood sustainability in new locations, should be ensured in future planned community relocation to foster positive adaptive outcomes (Piggott-McKellar et al., 2019a).

There are few examples of highly 'successful' and therefore adaptive international resettlement or relocation in response to environmental pressures in history. For example, the experiences of Gilbertese resettled in the Solomon Islands highlight that tensions with host communities over land and resource rights and limited knowledge of new environments (such as where communities previously reliant on marine resources are resettled in high island locations) can create new vulnerabilities (Donner, 2015; Weber, 2016a; Tabe, 2019). Even where gradual international relocation is supported and planned through policy as in the case of Kiribati's "migration with dignity" strategy, strong cultural connection to land and uncertainty about life in receiving communities in Australia and New Zealand means that many remain opposed to indefinite or permanent migration (Allgood and McNamara, 2017; Hermann and Kempf, 2017). The same challenges could apply where domestic migration occurs between significantly different cultural, social and physical environments. However, planned migration for employment or education can reduce exposure in sending locations and spread risk through expanding economic opportunities and providing remittances, thus having inadvertent adaptation outcomes (Campbell, 2014a). Policies which support migration for employment by the most vulnerable - those that may wish to migrate but lack the resources to do so - may offer an adaptive strategy to environmental pressure, particularly where these incorporate adequate preparedness for life in host communities (Luetz, 2017; Curtain and Dornan, 2019; Drinkall et al., 2019). Research from the Maldives suggests that women and men do not possess equal capacities to use mobility as a strategy to adapt to climate change, with women less able to employ migration as an adaptation strategy due to gender roles, social expectations, economic structures, political laws and religious doctrines, and gender norms and cultural practices (Lama, 2018).

Forced relocation, involuntary displacement and low-agency migration (for example, due to low migrant financial resources, or limited participation in migration planning) is commonly associated with unsuccessful outcomes and can therefore be considered an impact of climate change rather than an adaptation strategy (Weber, 2016a; Thomas and Benjamin, 2017; Tabe, 2019). Resettlement of households, communities and larger island populations is increasingly discussed in the context of loss and damage when in-situ adaptation limits are thought to be reached. Limited data and research relating to adaptation limits, transformational adaptation, tolerable and intolerable risk levels in small islands, and limited ability to directly attribute climate change to migration decisions (in the context of both slow onset changes and extreme events) mean that policy applications are currently limited (Thomas and Benjamin, 2018b; Handmer and Nalau, 2019; Nand and Bardsley, 2020).

15.5.4 Ecosystem-based Measures

Small islands have focused increasingly on ecosystem-based adaptation (EbA) approaches and other Nature-Based Solutions that bring benefits both for the ecosystems and communities (Figure 15.7; Giffin et al., 2020). There is *robust evidence* on implementation of EbA approaches across small islands, yet *medium agreement* on the exact benefits of these activities (Mercer et al., 2012; Doswald et al., 2014; Nalau et al., 2018a) given the difficulties in quantifying benefits and the absence of monitoring and evaluation frameworks (Doswald et al., 2014). Traditionally, EbA activities, especially at national and regional scales, have predominantly focused on restoring or conserving coastal and marine ecosystems (e.g., coral reefs, mangrove forests and seagrass meadows), with less emphasis upon the services provided by natural inland forests (Mercer et al., 2012). Incorporation of forests is however increasing, in most cases as components of ridge to reef (Figure 15.4) (or DDR) projects (*limited to medium evidence*), and is geared towards integrated watershed management to establish downstream water security, erosion control and ultimately to protect the health of coral reef ecosystems (Förster et al., 2019).

Additionally, some islands are constructing climate-smart development plans such as improved management of existing and newly established protected areas, restoration of riparian zones, urban forests/trees, sub urban and peri urban home gardens, and improved agroforestry practices towards increasing resilience to changing climate conditions, wildfires as well as decreasing food insecurity (e.g., Pedersen et al., 2016; McLeod et al., 2019). Paired terrestrial and marine protected areas have shown that forest conservation and rehabilitation yield better outcomes for coral health as forests stabilize soils and prevent erosion and sequester groundwater pollutants (*limited to medium evidence, high agreement*) (Carlson et al., 2019). The success of protected areas is however undermined by weak governance due in part to limited financial resources which undermine management and the enforcement of regulations governing activity within them (Schleicher et al., 2019).

Since the 1990s, artificial reefs have been increasingly used in small islands to support reef restoration and reduce beach erosion, especially in the Caribbean region (e.g., Dominican Republic, Antigua, Grand Cayman, Grenada) and Indian Ocean (Maldives, Mauritius) (Fabian et al., 2013; Reguero et al., 2018). They have been more or less successful in reducing the destructive impacts of extreme events, depending on their technical characteristics and the local context. For example, while it resisted the waves generated by hurricanes Georges and Mitchell in 1998, the artificial reef (Reef Ball breakwater type) implemented at Gran Dominicus Resort, Dominican Republic, did not prevent significant beach erosion. In contrast, the coral reef restoration project implemented to "build a beach" on the resort island of Ihuru, North Male' Atoll, Maldives, was successful as it allowed beach expansion and prevented the erosive impacts of the 2004 Indian Ocean Tsunami on the beach (Fabian et al., 2013).

Over the past decades, beach nourishment has been implemented in small islands either to reduce beach erosion (e.g., in tourist areas), or to protect critical human assets (e.g., roads) that are highly exposed to storm waves. It has been increasingly used to maintain beaches in the islands of the Maldives (Shaig, 2011), and in Barbados (Mycoo, 2014b). However, islands have limited sand stocks and sediment extraction can aggravate risks and/or accelerate ecosystem degradation if implemented without the necessary precautions.

In designing and implementing EbA, IKLK have high relevance especially amongst Pacific small islands as many communities are remote and still rely on ecosystems for their livelihoods (Nalau et al., 2018b; Narayan et al., 2020). In Fiji, IKLK have informed EbA projects by identifying native species suitable to strengthen the coastal environment to reduce coastal erosion and flooding in the villages (Nalau et al., 2018b). Whole-of-island approaches, like Lomanu Gau in the Gau Island in Fiji, try to foster integrated management practices in small islands that are based on shared governance of resources, and understanding the interlinkages between sectors and ecosystems (Remling and Veitayaki, 2016). In the Caribbean, EbA approaches are somewhat absent in national and regional programmes and plans, yet at the local scale EbA strategies are used increasingly with implementation mostly led by NGOs (Mercer et al., 2012).

EbA approaches have many benefits but also face several challenges and limits. Biophysical limits can make some EbA and Nature-based Solutions ineffective: coral reefs are *unlikely* to withstand increased temperatures, reducing the effectiveness of coral reef based EbA options under higher temperature scenarios (Barkdull and Harris, 2018; Cornwall et al., 2021). Likewise, many other coastal and marine ecosystems, such as mangroves, face severe limitations with increasing sea levels and other climate impacts (Morris et al., 2018; Thomas et al., 2021).

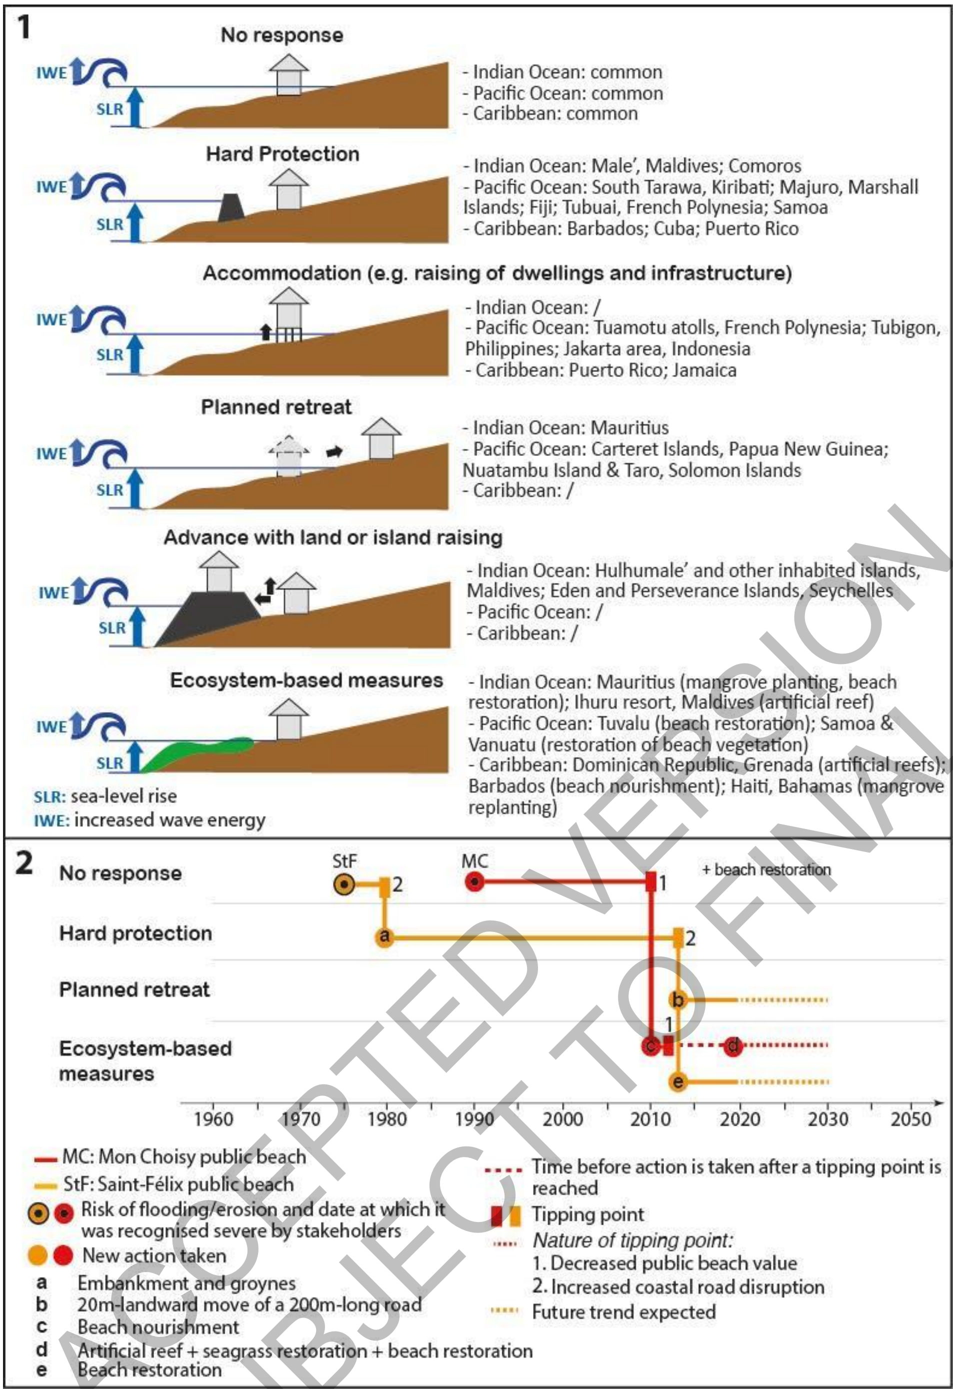

Figure 15.7: Adaptation measures implemented to reduce coastal risks in small islands. Panel 1 provides examples of implementation of different types of measures aimed at reducing coastal erosion and flooding. The measures include no response (no intervention, widespread in small islands), hard protection through the construction of engineering-based structures, accommodation through dwelling and infrastructure raising, planned retreat, advance (i.e. especially island raising) and ecosystem-based measures, in three small island regions, the Indian and Pacific Oceans and Caribbean. It highlights the prevalence of no response, hard protection and the increasing use of ecosystem-based measures. Based on the example of two beach sites in Mauritius (Mon Choisy in the north and Saint-Félix in the south), panel 2 shows that the measures used at a given coastal site evolve over time (e.g., from no response to hard protection, and then planned retreat and ecosystem-based measures) and that recent DRR (Saint-Félix) and adaptation (Mon Choisy) projects often combine several types of measures, including retreat and ecosystem-based measures (Duvat et al., 2020a). Together, panels 1 and 2 emphasize the diversity and increasing complexity of the measures implemented in small islands.

15.5.5 Community-based Adaptation

Community-based Adaptation (CBA) is best described as a "community-led process based on meaningful engagement and proactive involvement of local individuals and organisations" (Remling and Veitayaki, 2016)(p. 380). Enabling CBA projects to succeed relies on gaining a good understanding of the socio-political context within which the communities operate, including such key issues as land tenure arrangements and ownerships, gender, and decision-making processes that operate on the ground (Nunn, 2013; Buggy and McNamara, 2016; Crichton and Esteban, 2018; Delevaux et al., 2018; Nalau et al., 2018b; Parsons et al., 2018; McNamara et al., 2020; Piggott-McKellar et al., 2020).This also includes the broader and often more urgent development issues that impact on communities' wellbeing (Piggott-McKellar et al., 2020). Community-based projects demonstrate in the Pacific that communities' vulnerabilities, priorities and needs might be a better and more effective entry point for climate adaptation than framing projects solely around climate change (Remling and Veitayaki, 2016; Weir, 2020).This is supported by a recent review of 32 CBA initiatives in the Pacific where initiatives that were locally funded and implemented were more successful than those with external international funding (McNamara et al., 2020). Initiatives that integrated EbA and climate awareness raising also performed better (McNamara et al., 2020).

While CBA approaches to adaptation projects can increase community ownership and commitment to project implementation, these can also face challenges. In Pele Island, Vanuatu, implementation of CBA projects has experienced significant failures due to elite capture of project management, internal power dynamics within communities, and different priorities of communities living across the island that were supposed to be all responsible for implementing whole-of-island projects (Buggy and McNamara, 2016). Similarly, in Samoa, consultations with community leaders led to the misplacement of a revetment wall that increased flooding in the area against engineering advice (McGinn, 2020). Also, community-scale might not be always the best fit if the best scale to leverage adaptation is across catchment or whole-of-island scale (Buggy and McNamara, 2016; Remling and Veitayaki, 2016).

15.5.6 Livelihood Responses

Communities across small islands are adapting to the impacts of climate change across a range of livelihood activities. Coastal fishers have adapted by employing several activities ranging from diversification of livelihoods to changing fishing grounds and considering weather insurance (Blair and Momtaz, 2018; Lemahieu et al., 2018; Karlsson and McLean, 2020; Turner et al., 2020). In Antigua and Vanuatu, fishers have undertaken adaptation in response to increases in air and ocean temperature, increases in wind and changes in rainfall. In Antigua, adaptation strategies amongst coastal fishers have included investments in improved technologies and equipment, changing fishing grounds, and seeking better training and education (Blair and Momtaz, 2018). In Efate (Vanuatu) the majority (87%) of the fishermen used livelihood diversification as an adaptation strategy whereas 53% also searched for new fishing areas as a result of the changing conditions (Blair and Momtaz, 2018). In Southwest Madagascar, due to deteriorated reef conditions, coastal fishermen now go further offshore to catch fish or have adapted their fishing techniques, while others closer to the tourism markets, have opted for livelihood diversification (Lemahieu et al., 2018). Coastal fishers in the Dominican Republic have also diversified their livelihoods and use local knowledge in changing fishing practices and locations depending on environmental conditions (Karlsson and McLean, 2020). In the future, increased inland rainfall could for example provide new areas for inland aquaculture in the Solomon Islands as an adaptation strategy and also reduce pressure from coastal fishing (Dey et al., 2016).

In the agricultural sector in Jamaica, adaptation strategies include varying expenditure on inputs (e.g., fertilizers, chemicals, labour), diversifying cropping patterns, expanding or prioritising other cash crops (e.g., fruits and vegetables), engaging in small-scale livestock husbandry (Guido et al., 2018), and investing in irrigation technologies due to increased drought and infrequent rainfall (Popke et al., 2016). In many higher elevation islands within the Pacific, including Vanuatu and Fiji, communities continue to use to varying degrees traditional adaptive strategies designed to reduce their vulnerability to tropical cyclones. These include planting a diversity of different crops within household and communal gardens, locating gardens in different areas within their customary lands to ensure that not all crops are destroyed due to an extreme event, and the storage, and preservation of certain foodstuffs (so-called famine foods) (Campbell, 2014b; McMillen et al., 2014; Le Dé et al., 2018; Moncada and Bambrick, 2019).

Given changes in climatic conditions, in Puerto Rico women in the coffee industry are now forming their own "micro-clusters" of complementary activities, such as rebuilding of public spaces, running environmental education programmes for children, and opening new commercial enterprises (e.g., coffee shops, and food products) that do not rely on traditional coffee supply chains or government assistance (Borges-Méndez and Caron, 2019). Such alternative livelihood strategies parallel those undertaken by Pacific women working on various local-level climate change adaptation and environmental projects throughout small island nations of the Pacific. Women report testing and using adaptive strategies informed by IKLK, but which are being modified to suit the changing environmental conditions they are encountering and those projected in the future. This includes harvesting rainwater during droughts, planting native plants along coastlines to prevent erosion and flooding, developing plant nurseries, experimenting with growing salt-tolerant (taro) crops, and relocating crop cultivation inland (McLeod et al., 2018).

The tourism sector is increasingly a major source of cash-based livelihoods across small islands. Despite the high vulnerability and sensitivity of island tourism to climate change at a national scale (Scott et al., 2019), there is evidence from the South Pacific that local tourism operators' adaptive capacity is high due to socio-cultural factors. In Samoa, adaptive capacity consists of accommodation providers' social networks, resources, past experiences and understanding of environmental conditions, and remittances as a form of informal insurance (Parsons et al., 2017). The adaptive capacity of Tongan tour operators is strengthened by high climate change awareness, strong social networks and remittances as well as perceived high resilience against climate change (van der Veeken et al., 2016).

Evidence from Vanuatu shows that climate risk to tourism destinations is influenced by multiple, interconnected economic, socio-cultural, political, and environmental factors suggesting that holistic approaches are needed to reduce risk and avoid negative knock-on effects (Loehr, 2019). Tourism can strengthen mechanisms that reduce vulnerability and increase adaptive capacity of the wider destination, such as providing adaptation finance, investing in education and capacity building, and working with nature (Loehr, 2019).Examples include numerous EBA initiatives in the Caribbean including Marine Protected Areas in St. Lucia and Jamaica (Mycoo, 2018a). In Vanuatu, tourism businesses are engaged in establishing Marine Protected Areas to address multiple risks from climate change, population growth and development (Loehr et al., 2020). In the Seychelles, coral restoration programmes and mangrove reforestation are promoted through public-private partnerships, generating new opportunities for wetland-tourism livelihoods (Khan and Amelie, 2015).

The willingness of tourism businesses to finance adaptation measures varies. Islands have developed building codes which consider impacts from sea level rise but these are often not enforced enforced (Hess and Kelman, 2017). In cases where tourist resorts have been part of climate adaptation projects, such as funding for hard coastal protection infrastructure, the resort owners find that these diminish the aesthetics of the beach destination (Crichton and Esteban, 2018). Adaptation taxes and levies imposed on tourism can provide funding (Mycoo, 2018a) as The Environmental Protection and Tourism Improvement Fund Act, 2017 of British Virgin Islands shows (Smith, 2017). A lack of interaction between tourism and climate change decision makers is a commonly identified issue (Becken, 2019; Mahadew and Appadoo, 2019; Scott et al., 2019). A number of adaptation measures are recommended in the literature such as increasing climate change research, education and institutional capacities; product and market diversification away from coastal tourism to include terrestrial-based experiences and heritage tourism, and mainstreaming adaptation in tourism policies and vice versa (e.g., to include appropriate planning guidelines for tourism development, coastal setbacks and environmental impact assessments (Mycoo, 2018a; Becken et al., 2020) Thomas et al., 2020; van der Veeken et al., 2016).

15.5.7 Disaster Risk Management, Early Warning Systems and Climate Services

Disaster risk management (DRM) investments in small islands are commonly framed as reducing climate change-driven risk and contributing to sustainable development (Johnston, 2014; Mercer et al., 2014a; Kuruppu and Willie, 2015). Examples include strengthening the capacity of National Meteorological and Hydrological Services (NMHS) to deliver effective (WMO et al., 2018); nurturing community-based DRM to build social capital (Blackburn, 2014; McNaught et al., 2014; Gero et al., 2015; Handmer and Iveson, 2017; Chacowry et al., 2018; De Souza and Clarke, 2018; Currenti et al., 2019; Cvitanovic et al., 2019;

Hagedoorn et al., 2019), as well as processes that integrate IKLK with science (Hiwasaki et al., 2014; Carby, 2015; Bryant-Tokalau, 2018a; CANARI, 2019).

Many small islands, especially those with the highest risks and the least resources, remain highly challenged in building and sustaining integrated, people-centred, end-to-end early warning systems that are fully functional across the four interrelated components of EWS. Warning dissemination and communication, and disaster preparedness and response capacities are particular components of EWS requiring strengthening in SIDS (WMO, 2020). More recent assessments of early warning capabilities in the Caribbean highlight improvements in EWS for weather, water and climate over time (WMO et al., 2018; Mahon et al., 2019). However, progress has been uneven across hazards, governance levels and spatial and temporal scales, with more advanced development of some sub-systems and EWS pillars than others. Significant progress has been made in the area of detection, monitoring, analysis and forecasting of severe weather systems but there is a need to strengthen this area for other climate-related hazards such as wildfires, localised intense rainfall, floods, as well as heatwaves and droughts which become more important in a changing climate. Assessments also point to specific deficiencies including significant gaps in the area of disaster risk knowledge - particularly the development of risk assessments, the variable capacity for interpreting scientific warning products across states, as well as effective communication of warning messages to populations at risk (Lumbroso et al., 2016; WMO et al., 2018).

There is increasing recognition and commitment at global (Section 3.6.3.2.4; WMO, 2014; UN, 2015c; UN, 2015b; UN, 2015a), regional (CCCCC, 2012; CDEMA, 2014; SPC, 2016; SPREP, 2017; CIMH et al., 2019) and national levels (SPREP, 2016a; WMO, 2016a) of the importance of climate services in supporting adaptation decision making in small islands (*medium evidence, high agreement*). A number of SIDS-focused climate service programmes have emerged, especially in the Caribbean and Pacific (Group, 2015; Martin et al., 2015; SPREP, 2016b; WMO, 2016b; WMO, 2018a; WMO, 2018b) and at least one SIDS – Dominica - has been prioritised as a pilot implementation country under the Global Framework for Climate Services (WMO, 2016a). As is the case globally, climate services focused on decision-making at seasonal (3–6 month) timescales has thus far been the focus of investment in small islands. Less attention has been given to investments in and assessments of climate services for decision making at longer timescales (Vaughan et al., 2018).

Studies from the Caribbean (Dookie et al., 2019; Mahon et al., 2019) and Indian Ocean (Hermes et al., 2019), have found that NMHSs and regional intergovernmental bodies face capacity challenges in translation, transfer, and facilitation of the use of climate information to various end user groups. In many small island contexts a gap remains between investments in data quality and information services and uptake and use in risk reduction by policy and decision makers (Dookie et al., 2019). Bringing policy makers and users together to guide investments in climate information services is recommended, as is provision of dedicated resources to develop applicable tools and products that turn data and information services into risk reduction measures (Dookie et al., 2019; Haines, 2019).

Many of the outlined Key Risks (Section 15.3.4.9) can be addressed through the variety of adaptation options outlined in the previous sections in the context of small islands (Table 15.6, Supplementary Material 15.1). Whereas some of these adaptation options are widespread (e.g., hard protection, reforestation or the creation of MPAs), others (e.g. accommodation, health awareness raising and training) have been little experimented with to date in small island contexts. Although most of these adaptation options provide diversified co-benefits to small island communities, there is still *limited evidence* with regard to their effectiveness in reducing climate change impacts. While some of them respond directly to a Key Risk or a number of Key Risks (Table 15.6), others can be understood as overarching options that, for example, build adaptive capacity of communities and organizations and enable these actors to respond to a variety of Key Risks in an effective manner (see Supplementary Material 15.1).

Table 15.6: Adaptation options per Key Risk in small islands. This table summarizes risk-oriented adaptation options, their level of implementation, enablers and effectiveness in reducing exposure and vulnerability, co-benefits and disbenefits in small islands. For Key Risk 2 (submergence of reef islands), not included, adaptation options are the same as for Key Risk 5.

[INSERT TABLE 15.6 HERE]

15.6 Enablers, Limits and Barriers to Adaptation

Since AR5, more literature has emerged on barriers, limits and enablers to climate change adaptation across small islands. Here, we cover barriers, limits and enablers as they relate to key themes across small islands and adaptation.

15.6.1 Governance

Specific governance-related barriers for effective adaptation include: lack of coordination between government departments and sectors and limited policy integration (Scobie, 2016; Robinson, 2018b), lack of ownership of adaptation implementation in cases where communities or national governments have not been part of the adaptation decision process (Conway and Mustelin, 2014; Kuruppu and Willie, 2015; Prance, 2015; Nunn and Kumar, 2018; Parsons and Nalau, 2019), and difficulties in integrating IKLK in adaptation initiatives. Specific barriers to effective sustained adaptation in the Pacific include variable climate change awareness among decision-makers, and the preference for short-term responses rather than longer-term transformative ones (Nunn et al., 2014). These barriers also stem from donors' preferencing their own priorities that do not necessarily fit the country priorities or context (Conway and Mustelin, 2014; Kuruppu and Willie, 2015; Prance, 2015), which has led to increasing calls for effective community/cultural engagement in adaptation, especially through CBA and EbA (Nalau et al., 2018b). In cases where recovery efforts are framed as purely a matter of infrastructure other important aspects, such as livelihoods and gender, are more easily overlooked in adaptation (Turner et al., 2020).

In the Caribbean small islands such as Jamaica and St. Lucia, and also in the Pacific, barriers to mainstreaming adaptation include competing development priorities, the absence of planning frameworks or 'undetected' overlaps in existing frameworks, serious governance flaws linked to the prevalence of corruption and corrupt people in political and public life, and insufficient manpower and human resources, linked to countries' financial capacity (Robinson, 2018b). In addition, the lack of strong governance mechanisms for urban planning have contributed to urban sprawl and expansion that has increased the number of informal settlements, which together with population growth are driving Caribbean small islands to their limits (Enríquez-de-Salamanca, 2018; Mycoo, 2018a; Mycoo, 2018b). In the Pacific, only a few countries have embedded climate change adaptation in existing legislation despite the overall regional agreement to *A New Song for Coastal Fisheries - Pathways to Change: the Noumea Strategy*' to improve coastal fisheries management in a changing climate (Gourlie et al., 2018). Many climate change specific initiatives across small islands have a unidirectional focus on climate risks and shift limited resources away from other important development objectives (Baldacchino, 2018). Local level plans are often overlooked: for example, in Mauritius, local level climate adaptation plans are currently nearly non-existent while district councils have rarely been successful in even accessing international adaptation finance (Williams et al., 2020). In Samoa, several national level programs on adaptation have had difficulties in engaging with the local level even if the decision-making powers on actual land management sit within the communities (McGinn and Solofa, 2020).

Adaptation governance is also complicated further by the multitude of stakeholders involved, with differing agendas and priorities. In the Bahamas, private properties have significant say in how and what adaptation measures they decide to pursue and are not well regulated, with the tourism sector in particular dominated mainly by external investors (Petzold et al., 2018). Social organisations, such as the churches, that have significant influence in many Oceanic countries, are engaging in climate change discussions and governance. Many churches report, however, being constrained to act on climate adaptation due to lack of financial resources, low levels of professional knowledge on adaptation, and their members not perceiving climate change as an urgent risk (Rubow and Bird, 2016). Actors such as military services in the Indian and Pacific Oceans also control a high number of assets in vulnerable locations and will need to integrate climate information into adaptive planning in the future (Finucane and Keener, 2015).

Low technical capacity, and poor data availability and quality are reported as limiting adaptation in Caribbean small islands such as Dominica, and St. Vincent and the Grenadines (Smith and Rhiney, 2016; Robinson, 2018a) and Trinidad and Tobago (Mycoo, 2020). These factors are, however, secondary to the lack of finances, which is seen as a fundamental limit (Charan et al., 2017; Robinson, 2018a; Williams et al., 2020). This was also reported in the Seychelles, despite its success with innovative financing streams and being a leader in the Indian Ocean in this regard (Robinson, 2018a).

Limited regional cooperation across sub-national island jurisdictions (jurisdictions with semi-autonomous status) along with limited regional-scale climate information are also stymying action (Petzold and Magnan, 2019). This is a concern given the need for pooled governance in response to capacity constraints across small jurisdictions (Dornan, 2014; Kelman, 2018). There is also an insufficient understanding of the role of regional and international actors such as the Caribbean Community Climate Change Centre and the Global Environment Facility, respectively (Middelbeek et al., 2014). Sometimes external pressure and, for example, trans regional trade agreements are "useful for reducing unsustainable local socio-political arrangements" as seen in the Solomon Islands regarding fisheries management within the concept of Blue Economy (Keen et al., 2018, p. 338). Similarly, in Samoa, the World Bank's Pilot Program for Climate Resilience (PPCR) and Adaptation Fund's Enhancing Resilience of Samoa's Coastal Communities to Climate Change, illustrate successful examples of multi-level governance due to their programmatic and pragmatic approaches versus project-based approaches (McGinn and Solofa, 2020). Enabling factors in these programmes relate to strategic placements of funds and responsibilities in the relevant ministries, alignment with national priorities and pre-existing plans, pooling funding to fill existing finance gaps, and increased awareness across scales and departments of synergies and gaps between different initiatives (McGinn and Solofa, 2020). Initiatives such as the Pacific Adaptive Capacity Framework (Warrick et al., 2017) and regional strategies such as the Framework for the Disaster and Climate Resilient Development in the Pacific (FRDP) enable the localising of climate adaptation into cultural contexts in an integrated manner (SPC, 2016).

Countries including the Seychelles and Maldives have developed national climate change plans that recognize linkages to food security, health and disaster risk reduction, although these-face significant resourcing issues when it comes to implementation (Techera, 2018). National level plans, such as National Adaptation Plans of Action (NAPAs), increasingly could include local government engagement and have a stronger focus on urban centres and adaptation (Mycoo, 2018a). Building codes act as supportive enablers for adaptation governance: requiring more hurricane-resistant housing in the Caribbean, including incentives for informal settlements to build in a more resilient manner, can achieve multiple development and adaptation outcomes (Mycoo, 2018a). In Dominica, a Climate Resilience Executing Agency of Dominica (CREAD) established in 2019, aims to enable stronger climate resilience by bringing all sectors and services together for more effective coordination (Turner et al., 2020). Improvements in cross sectoral and cross agency coordination are creating opportunities for improved disaster preparedness and resilience measures in Vanuatu (Webb et al., 2015). A range of mechanisms also exists in the tourism industry: adaptation taxes and improved building regulations could reduce risk drastically for example in the Caribbean region (Mycoo, 2018a).

15.6.2 Health-Related Adaptation Strategies

The term 'health systems' refers to the organisation of people, institutions, and resources that work to protect and promote population health. The two components of health systems are public health and health care; adaptation is needed in both to develop climate-resilient health systems (WHO, 2015). Adaptation measures focus on each of the building blocks of health systems, including leadership and governance; a knowledgeable health workforce; health information systems; essential medical products and technologies; health service delivery; and financing. Many small island states have policies to manage climate-sensitive health risks, although Ministries of Health are largely unprepared to adapt to a changing climate because few programmes take climate change into account (McIver et al., 2016). Particularly vulnerable groups, such as Indigenous peoples, are often inadequately represented in adaptation planning processes and implementation, resulting in less effective interventions (Jones, 2019).

A range of climate-sensitive diseases pose threats to island communities. A vulnerability and adaptation assessment conducted in Dominica identified vector-, water- and food-borne diseases and food security as priority threats from climate change (Schnitter et al., 2019). Short-term adaptation options include strengthening solid waste management and enforcing current legislation; increasing public awareness; training health sector staff; improving the reliability and safety of water storage practices; improving climate change and health data collection methods and enhancing environmental monitoring; enhancing the integration of climate services into health decision-making; strengthening the organisational structure of emergency response; and ensuring sufficient resources and surge capacity. Longer-term adaptation options include developing early warning and response systems for climate-sensitive health risks; enhancing data collection and information flow; increasing the capacity of laboratory facilities; and developing emergency plans. For example, rainfall is the best environmental predictor of malaria in North Guadalcanal, Solomon Islands, leading to the development of an early warning tool that could increase resilience to climate change (Smith et al., 2017; Jeanne et al., 2018).

In small island states, water, sanitation, and hygiene infrastructure are particularly vulnerable to climate change, with impacts on the burden of diarrheal diseases. The resilience of types of sanitation infrastructure in urban and rural households in the Solomon Islands differ under scenarios of increased rainfall and flooding versus decreased rainfall and drought, reinforcing the centrality of taking the local context into account during adaptation decision-making (Fleming et al., 2019). Healthcare facilities, including hospitals, clinics, and community care centres, are vulnerable to extreme weather and climate events, such as flooding and TCs, and to climate-related outbreaks of infectious diseases that overwhelm their capacity to provide critical services (WHO, 2020). These facilities may lack functioning infrastructure and trained health workforce, and be predisposed to inadequate energy supplies, and water, sanitation, and waste management services. Adaptation is needed to build resilience and contribute to environmental sustainability.

Many major health care facilities in small island states are in exposed coastal areas and have limited ability to provide health services during disasters when services are most needed (WHO, 2018). For example, in Vanuatu, TC Pam in 2015 severely damaged two hospitals, 19 health care centres, and 50 healthcare dispensaries in 22 affected islands (Kim et al., 2015). A Smart Hospital Initiative in the Caribbean focuses on improving hospital resilience, strengthening structures and operations, and installing green technologies to reduce energy consumption and provide energy autonomy during extreme events and disasters (https://www.paho.org/en/health-emergencies/smart-hospitals).

15.6.3 Adaptation Finance and Risk Transfer Mechanisms

In the majority of small island developing states there is a high dependence on international financing to support adaptation to slow and rapid onset events (Robinson and Dornan, 2017; Petzold and Magnan, 2019). However, funds tend to be geared towards supporting sectoral-level adaptation initiatives for vulnerable natural resource sectors such as water, biodiversity and coastal zones (Kuruppu and Willie, 2015). Considering low income small islands such as Comoros, Haiti, and São Tomé and Príncipe, international modalities do little to address the root causes of vulnerability or to support system-wide transformations (Kuruppu and Willie, 2015). Although countries like Trinidad and Tobago have amassed oil wealth, the profits are not invested in a way that benefits environmental goals (Middelbeek et al., 2014). In Mauritius, a lack of financial resources for climate change adaptation has been recognised as a specific impediment in district council level (Williams et al., 2020).

Although small island jurisdictions have seen increased flows of adaptation finance through mostly top-town arrangements, they face large implementation difficulties (*medium evidence, high agreement*) (Weir and Pittock, 2017; Magnan and Duvat, 2018). There are growing concerns among policy- and decision-makers in small islands about the current levels and forms of adaptation finance, and about countries' experience with accessing it (Robinson and Dornan, 2017). In the Caribbean, 38% of flows were concessional loans and 62% were grants (Atteridge et al., 2017); the situation in the Atlantic and Indian Oceans is starkly different—nearly 75% of the flows were in the form of concessional loans and grants accounted for the remaining 25% (Canales et al., 2017). This raises questions about fairness and justice for small islands having to finance adaptation to climate impacts to which they have made a negligible contribution. In the Pacific, 86% of aid was delivered as project-based support (Atteridge and Canales, 2017), that can undermine the long-term sustainability of adaptation interventions (Conway and Mustelin, 2014; Remling and Veitayaki, 2016; Atteridge and Canales, 2017). Direct budget support was rare (Atteridge and Canales, 2017), signalling the importance of works such as Rambarran (2018) that support cross-regional lesson-learning by, for example, showcasing the experience of Seychelles with successfully devising innovative financing mechanisms for supporting adaptation and conservation goals, and reducing its public debt. Regional catastrophe risk insurance schemes however, such as Pacific Catastrophe Risk Insurance Company under the World Bank's Pacific Catastrophe Risk Assessment and Financing Initiative (PCRAFI) Program are trying to enable a regional effort in increasing accessibility to insurance (PCRAFI, 2017) as does the Caribbean Catastrophe Risk Insurance Facility, although these funds are still rather small compared to the needs across the countries (Handmer and Nalau, 2019).

Microfinance is increasingly viewed as a positive mechanism to improve access to climate adaptation funding (Di Falco and Sharma, 2018). In the Caribbean, a significant barrier in accessing climate finance relates to bureaucratic structures, which means that money intended for communities does not reach them (Mycoo, 2018a). Many adaptation projects even at the community level have upfront costs that need to be supported, especially in communities where there is little hard cash in use (Remling and Veitayaki, 2016). Despite such challenges, communities in the Pacific region have used "cashless adaptation" for a long time that involves trading of services and items as a form of Indigenous microfinance (Nunn and Kumar, 2019b). Social networks also function as a source of informal microfinance where extended family members send back remittances from overseas to their families and communities especially after disasters. In Samoa Indigenous tourism operators receive remittances from overseas family members (Crichton and Esteban, 2018; Parsons et al., 2018), with similar processes observed among atoll communities in the Solomon Islands (Birk and Rasmussen, 2014), Vanuatu (Handmer and Nalau, 2019) and Jamaica (Carby, 2017). However, the role of migration and remittances is still poorly understood; it is difficult to quantify the informal flows and understand the extent they support effective adaptation (*limited evidence, high agreement)* (Campbell, 2014a; Parsons et al., 2018; Handmer and Nalau, 2019).

In Old Harbour Bay, Jamaica's largest fishing village, a high number of community members engaged in the fishing industry, particularly vendors and scalers, do not own the material assets needed to fully benefit from these livelihood activities (Baptiste and Kinlocke, 2016). Developing a broader asset portfolio by increasing access to such assets via adaptation finance investments could reduce vulnerability across the community. This could function as an effective livelihood-based adaptation strategy for the most vulnerable such as women, who are part-time employed and in peripheral roles in the fishing industry (Baptiste and Kinlocke, 2016). In Belize and the Dominican Republic, many coastal fishers for example use informal credit from food stores or captains to enable them to withstand financial losses that are often incurred during bad weather and extreme events (Karlsson and McLean, 2020).

In Vanuatu, discussions are ongoing on increasing insurance availability for TCs and droughts, but standardisation of housing designs to get insurance can become difficult where the costs make it prohibitive and run counter to traditional building designs and materials (Baarsch and Kelman, 2016). Empirical evidence from Belize, Grenada, Jamaica and St. Lucia indicates that there are also other factors why people do not take insurance, including "the cost of premiums (44 %), lack of trust in insurance companies (27 %), having never considered insurance (26 %), a lack of need for insurance (25 %) and a lack of knowledge of insurance (22 %)" (Lashley and Warner, 2013, p. 108). Increasing trust could be addressed by seeking out domestic banks or credit unions with whom people are already engaging with, while also using social marketing campaigns to raise awareness of weather-related insurance to address knowledge gaps and lack of awareness of these tools (Lashley and Warner, 2013). In Dominica, many coastal fishers are suspicious of insurance schemes given past experiences of not being paid out on time or having to disclose catch data (Turner et al., 2020). Yet, insurance is not capable of addressing all kinds of loss and damage accruing from climate impacts and should be used as an adaptation strategy in combination with other strategies (Lashley and Warner, 2013).

Insurance cover is a critical question in small islands. For example, in Vanuatu, some companies do not "cover storm damage from the sea or high tides…which is not helpful for properties damaged by a tropical cyclone's storm surge" (Baarsch and Kelman, 2016)(p. 6). There is also limited access to insurance schemes due to lower demand in small markets (Petzold and Magnan, 2019) especially when many people do not have high cash-based incomes and likely cannot pay insurance premiums (Baarsch and Kelman, 2016). In Saint Lucia and Grenada (via the Caribbean Oceans and Aquaculture Sustainability Facility), discussions are ongoing with regard to national level parametric insurance, underpinned by financing from the US State Department, to help fishing communities recover more quickly following the passage of TCs in the future (Sainsbury et al., 2019; Turner et al., 2020). Likewise, (Reguero et al., 2020) have suggested a resilience insurance mechanism that could in theory reduce climate related losses and damages through investments in nature-based adaptation projects (e.g. coral reef restoration and potentially mangrove restoration).

15.6.4 Education and Awareness-Raising

A significant barrier to effective climate adaptation is the lack of education and awareness around climate change both among the general public, for example in the Bahamas (Petzold et al., 2018) and among decision-makers in the more remote rural communities (Nunn, 2013; Mycoo, 2015). Increasing knowledge on adaptation options and needs can increase adaptive capacity that is underpinned by "the ability of individuals to access, understand and apply the knowledge needed to inform their decision-making processes" (Cvitanovic et al., 2016 p. 54). This should however also be seen as a collective effort (Hayward et al., 2019).

Workshops and training are seen as crucial at the local scale to build communities' capacity to take action and to integrate climate change considerations to the broader development processes (Remling and Veitayaki, 2016), although purely workshop-based short-term capacity building in adaptation has been questioned (Conway and Mustelin, 2014; Lubell and Niles, 2019). More interactive community engagement strategies could include "participatory three-Dimensional modelling (P3DM), participatory video, development of photo journals, and civil society plans" (Beckford, 2018, p. 46) that enables broader engagement. In Fiji, Laje Rotuma youth EcoCamps have been used to engage younger Fijians to understand adaptation and increasing environmental stewardship with good outcomes (McNaught et al., 2014). In Palau, Camp Ebiil provides a culturally-based platform for younger generations to learn about nature and culture in an interactive camp (Singeo, 2011). Vanuatu's Volunteer Rainfall Observer Network in turn engages volunteers to record their rainfall observations, demonstrating the use of IKLK that can be integrated with contemporary weather forecasting (Chand et al., 2014). Likewise, initiatives such as ePOP Petites Ondes Participatives aim to develop a citizen network to share environmental information (e.g., via minivideos on smartphones). Across the Pacific, projects such as the European Union Pacific Technical Vocational Education and Training on Sustainable Energy and Climate Change Adaptation Project (EU PacTVET), have sought to increase capacity of Pacific islanders in disaster risk management and climate adaptation (Hemstock et al., 2018).

In Fiji, a study on adaptive behaviour and intention to invest in more adaptive portfolios found that the intent for adaptive behaviour increased with the supply of climate information (Di Falco and Sharma, 2018). In the Pacific, high performing CBA initiatives included climate awareness raising that equipped people with knowledge to understand occurring environmental changes and what to do (McNamara et al., 2020). Lack of information can increase community vulnerability. Remote Indigenous farming communities in St Vincent, in the Caribbean, for example have already observed decreased rainfall and increases in temperatures, but they have been largely excluded from agricultural training that includes information in how to improve agricultural strategies in times of climatic shocks and how to prepare for changing climatic conditions (Smith and Rhiney, 2016). In the Bahamas, cultural background, income and education levels impact the extent that people are aware of climate risks (Petzold et al., 2018) . In Dominica, access to information critical to fisheries is noted as a significant challenge, including data collection, its management and human resources in building capacity to process and use this information for evidence-based decision making (Turner et al., 2020).

The Caribbean Climate Online Risk and Adaptation tool has been developed to assist the tourism industry in producing "climate-sensitive developments" (Mackay and Spencer, 2017,p. 55). Though some authors conclude on the low climate awareness/understanding among small islanders (Middelbeek et al., 2014; Betzold, 2015; Petzold et al., 2018), others indicate that many Caribbean islanders are acutely aware of past storm events (i.e., social memory) and have a certain degree of self-reliance, which creates the capability to multi-task and cope with limited resources (Petzold and Magnan, 2019). There is, however, a disconnect between knowledge, attitudes and practices—knowledge sharing and learning need to be improved along with the take-up of an evidence-based decision-making approach (Lashley and Warner, 2013; Petzold et al., 2018; Saxena et al., 2018).

15.6.5 Culture

Culture can be defined as "material and non-material symbols that express collective meaning" (Adger et al., 2014, p. 762) and includes worldviews and values, how individuals and communities relate to their environment, and what they perceive to be at risk and in need of adaptation (McNaught et al., 2014; Nunn et al., 2014; Remling and Veitayaki, 2016; Nunn et al., 2017bGranderson, 2017; Neef et al., 2018; Oakes, 2019). In small islands, culture plays an important role in individual and community decision-making on adaptation both as an enabling factor and as a barrier (*robust evidence, high agreement*) (Nunn et al., 2017b; Parsons et al., 2017; Neef et al., 2018; Piggott-McKellar et al., 2020). The concept of *Vai Nui* as the interconnectedness of Pacific Islanders continues to support the collective agency to plan and undertake adaptation efforts in the region (Hayward et al., 2019). In Samoa, the principles of *Fa'asamoa* (the Samoan way of life) impacts on how decisions are made, including the role of the *aiga* (extended family) that is a web of local, national and transnational kinship networks (Parsons et al., 2018). Traditional village council structures and land stewardship enables an expanded range of coastal adaptation options in Samoa, including potential relocation, but at the same time may limit participation of all social groups in adaptation decision making (Crichton et al., 2020). In Dominica, in the aftermath of Hurricane Maria (2017), social capital in the form of transboundary nearby island networks enabled some communities to recover faster from the disaster including access to more livelihood opportunities and assets (Turner et al., 2020).

Yet, culture is often overlooked in adaptation policies and plans. For example, in the National Communications of 16 SIDS, only one country (Cook Islands) reported adaptation actions that addressed social issues, culture, and heritage (Robinson, 2018b). Externally-driven adaptation efforts in rural small-island communities that exclude community priorities, ignore or undervalue IKLK, and are based on secular western/global worldviews (Donner and Webber, 2014; Prance, 2015; McNamara et al., 2016; Nunn et al., 2017b; Schwebel, 2017; Mallin, 2018; Nunn and McNamara, 2019; Piggott-McKellar et al., 2019b) are often less successful (*high agreement, medium evidence*). The World Bank Kiribati Adaptation Program (KAP) for example builds mainly on western knowledge and science despite consultations with the Kiribati communities (Prance, 2015). Yet, in many contexts most land and knowledge is embedded in traditional governance and culture while adaptation plans and decisions are made elsewhere on how that land should be used and what knowledge is used (*high agreement*) (Nunn, 2013; Prance, 2015; Charan et al., 2017; Nalau et al., 2018a; Parsons et al., 2018; McGinn and Solofa, 2020).

In Kiribati, communities often use different timescales to evaluate the need for adaptation. I-Kiribati culture's core concept of time is short- and medium term (Prance, 2015), which should be considered in adaptation policy and planning processes especially at the household and community level (Donner and Webber, 2014). Key stakeholders, especially community leaders, should be included and empowered to help design and sustain adaptation (Baldacchino, 2018; Weiler et al., 2018). Focusing on values-as-relations (e.g., island communities' relationship with the environment and each other) could diversify the values considered in adaptation decision-making processes (Parsons and Nalau, 2019). Indeed, those Pacific islands with a more island-centric approach to climate adaptation tend to have overall more successful adaptation policies in place (Schwebel, 2017).

The cultural context and sources of knowledge are myriad and diverse in small islands. Community members often use both IKLK as well as western scientific-based weather forecasts to take actions to prepare for extreme weather events (Chand et al., 2014; Johnston, 2015; Janif et al., 2016; Granderson, 2017; Kelman et al., 2017), with specific examples from Niue, Tonga, Vanuatu and the Solomon Islands *(high agreement, high evidence)* (Chand et al., 2014; Chambers et al., 2017; Chambers et al., 2019). In Samoa, people keep particular areas reserved for disaster times such as TC seasons (Kuruppu and Willie, 2015) while in Vanuatu IKLK indicators for tropical cyclones include mango trees flowering early and turtles going further inland to lay their eggs (Chand et al., 2014). IKLK are however not evenly distributed within communities due to IKLK being traditional intellectual property of particular roles in the villages (e.g., weathermen in Vanuatu), and not available to other community members or external actors directly (Chand et al., 2014; Prance, 2015). In Tongoa Island, Vanuatu, communities are finding however that their IKLK-based seasonal calendars are out of sync given the changes in climatic conditions (Granderson, 2017) while erosion of IKLK remains a concern across most small island nations (Kuruppu and Willie, 2015; Granderson, 2017; Beckford, 2018).

Not all IKLK and other knowledge are necessarily helpful and IKLK can lead to maladaptation (Mercer et al., 2012; Beckford, 2018). Elders from the Chuuk State (Federated States of Micronesia, (Elders from Atafu Atoll, 2012), for instance, assign blame for changeable weather patterns, destructive typhoons, and loss of biodiversity to people's failure to maintain and employ their IKLK. Fatalism (belief that disasters are God's will) is still reported as a major cultural barrier to adaptation. In Maldives fatalism decreases direct adaptation action and influences perceptions of climate risks (Shakeela and Becken, 2015) while Indigenous communities in St Vincent do not prepare for hurricanes or climatic shocks for the same reason (Smith and Rhiney, 2016). In Oceania, Christianity and the church play an important role in how issues, such as climate change, are communicated and thought about (Rubow and Bird, 2016; Nunn et al., 2017b), including the Noah and flood story used as a justification that there is no need to worry about sea level rise (Rubow and Bird, 2016). New emerging forms of eco-theology (theology that connects humans with land, sea and sky) however situate climate change as part of environmental stewardship (Rubow and Bird, 2016) making churches active partners in caring for the environment.

Many studies also now demonstrate the value in considering multiple systems of knowledge through collaborative and co-production projects and strategies, which allow for culturally-situated knowledge, values, and practices to be positioned at the heart of sustainable climate change adaptation *(high agreement)* (Chambers et al., 2017; Plotz et al., 2017; Beckford, 2018; Malsale et al., 2018; Parsons et al., 2018; Suliman et al., 2019). In the Caribbean context, Beckford (2018) suggests the establishment of Caribbean Local and Traditional Knowledge Network, a shared regional platform makes IKLK more available for climate adaptation and community resilience projects where appropriate. Likewise, Indigenous research methodologies are emerging that introduce more culturally grounded concepts and methods into how research is conducted and decolonise mainstream research in the Pacific Islands (Suaalii-Sauni and Fulu-Aiolupotea, 2014).

Despite widespread international evidence that the impacts of climate change and disaster events often negatively affect women (and gender minorities) more than men (McSherry et al., 2014; Aipira et al., 2017; Gaillard et al., 2017), attention to gender equality as a concept is still only "embryonic in climate change adaptation in the Pacific" and although recognised in some policies and project designs, it is not well supported by on-the-ground actions or well monitored (Aipira et al., 2017, p. 237). Many Pacific small island climate change adaptation policies do not mainstream gender across the activities (Aipira et al., 2017), with women's groups being excluded from climate grants due to patriarchal formal and informal governance structures, lack of resources, lower access to educational and training schemes, and no track record (or receiving grants or meeting grant milestones) (McLeod et al., 2018). However, Pacific women identify several strategies that enable them to adapt to climate change more effectively. These include the recognition and support of women's IKLK by governments, researchers, and NGOs; increasing women's access to climate change funding and support from organisations to allow them to meet the requirements of international climate change grants; and specific education and training to women's groups to allow them to develop strategic action plans, mission statements, learn financial reporting requirements, as well as general leadership and institutional training (McLeod et al., 2018). Such and other measures could enable a broader representation and participation in adaptation processes despite cultural constraints (Table 15.7 on Enabling Conditions).

Table 15.7: Enabling Conditions and Factors for Adaptation in Small Islands
[INSERT TABLE 15.7 HERE]

15.7 Climate Resilient Development Pathways and Future Solutions in Small Islands

Synergies exist between climate resilient development pathways and implementation of SDGs in small islands because development decisions and outcomes are strengthened by consideration of climate and disaster risk (Robinson, 2017b; Hay et al., 2019a). However, monitoring progress of SDGs is challenging for small islands, in part due to large numbers of indicators and inadequate data. Literature on SDG implementation is generally lacking for small islands as is the integration of climate risk into infrastructure decisions.

Decisions that are optimal for adaptation may not be acceptable in the wider development context within which they operate. In the Pacific region, where 67% of infrastructure is located within 500 metres of coastline and commercial, public and industrial infrastructure are particularly vulnerable due to the location of urban centres (Kumar and Taylor, 2015). Yet the Parliamentary Complex in Samoa was redeveloped at the original site due to cultural and historical factors despite strong evidence of the need to relocate (Hay et al., 2019b).

Energy transitions in the Pacific islands demonstrate development synergies such as reduced dependency on volatile fossil fuel markets, increased resilience to weather related disasters and less need for investment in large scale centralised energy systems (Dornan, 2014; Cole and Banks, 2017; Weir, 2018; Weir and Kumar, 2020). However, high and rapid energy transition ambitions can lead to trade offs for rural electrification (Box 18.4; Dornan, 2014; Cole and Banks, 2017; Hills et al., 2018).

Tourism system transitions can enable the sector to contribute to climate resilient development pathways through managing climate risks and improving ecological, economic and social outcomes for small islands (*medium evidence, high agreement*) (Loehr, 2019; Mahadew and Appadoo, 2019; Loehr et al., 2020; Sheller, 2020).

There is a clear role for local governments to work closely with the informal private sector to achieve a 'trifecta' of climate change adaptation, economic development and disaster risk reduction, especially for women (McNamara et al., 2020). Yet, many cities and local governments in the Pacific region are severely resource constrained (Kelman, 2014; Kiddle et al., 2017; Keen and Connell, 2019; Nunn and McNamara, 2019).

Broader innovation in climate resilient development policy making has taken place in the Pacific (Hay et al., 2019a) and Caribbean (Mycoo, 2018a). The Pacific region is bringing together disaster risk management, low carbon growth and climate change adaptation with broader development efforts for the first time (SPC, 2016). Improvements in cross sectoral and cross agency coordination are creating opportunities for improved disaster preparedness and resilience measures in small islands (Webb et al., 2015; Nalau et al., 2016). Further integration between development priorities and risk management in national budgetary and development processes is necessary, as is continued investment in coordination mechanisms (Hay et al., 2019a).

Early research on the response to COVID-19 indicates that existing disaster response mechanisms in the Caribbean islands have assisted in rapid responses to COVID-19 (Hambleton et al., 2020). Many small islands are highly dependent on tourism for their economies and are facing worsening crises associated with climate-related disasters and more recently COVID-19 disruptions of travel (Sheller, 2020). The adaptive capacity and innovations demonstrated by SIDS during COVID-19, moving beyond dependence on ‘extractive’ international tourism, demonstrate the potential benefits of diversified and sustainable economies (and ecologies) for the enhanced resilience of both human and ecological communities (Sheller, 2020).

In the context of small islands, climate justice research is expanding beyond initial debates about nation-states responsibilities for the causes and responses to climate change, to demonstrate complex and dynamic intergenerational and multiscalar dilemmas of climate justice (Ferdinand, 2018; Sheller, 2018; Baptiste and Devonish, 2019; Look et al., 2019; Douglass and Cooper, 2020; Kotsinas, 2020; Sheller, 2020). In Caribbean SIDS, research highlights how intersecting external and internal socio-economic and political processes are allowing marginalised populations to become increasingly socially and economically disadvantaged and politically marginalised, which in turn heightens climate vulnerability and impedes sustainable development efforts (Baptiste and Devonish, 2019) (Moulton and Machado, 2019; Gahman and Thongs, 2020; Rhiney, 2020; Duvat et al., 2021b). Inequity extends to how development and disaster aid were coordinated and distributed within various nations after Hurricanes Irma, Maria and Harvey in 2017.

15.8 Research Gaps

Despite intensive study many knowledge gaps remain due to the complexity of biophysical and social interactions, and the local and regional diversity of small islands. Research and data gaps exist in four areas: island-scale data availability; ecosystem services data; vulnerability and resilience, and adaptation (Table 15.8).

Table 15.8: Research Gaps in Small Islands
[INSERT TABLE 15.8 HERE]

[START FAQ15.1 HERE]

FAQ 15.1: How is climate change affecting nature and human life on small islands, and will further climate change result in some small islands becoming uninhabitable for humans in the near future?

Climate change has already affected and will increasingly affect biodiversity, nature's benefits for people, settlements, infrastructure, livelihoods and economies on small islands. In the absence of ambitious human intervention to reduce emissions, climate change impacts are likely to make some small islands uninhabitable in the second part of the 21st century. By protecting and restoring nature in and around small islands as well as implementing anticipatory adaptation responses, humans can help reduce future risks to ecosystems and human lives on most small islands.

Observed changes – including increases in air and ocean temperatures, increases in storm surges, heavy rainfall events, and possibly more intense tropical cyclones - are already reducing the number and quality of ecosystem services, thereby causing the disruption of human livelihoods, damage to buildings and infrastructure, and loss of economic activities and cultural heritage on small islands. Widespread observed impacts include severe coral reef bleaching events, such as that associated with the 2015–16 El Niño season, the most damaging on record worldwide. Additionally, the 2017 Atlantic hurricane season was unusually characterised by sequential severe tropical cyclones that resulted in widespread cyclone-induced damage to ecosystems from the very interior of small islands to those of the ocean waters that surround them as well as damage to human settlements and economic activities within the whole Caribbean region. Although knowledge is limited regarding long term increases in tropical cyclone intensity, studies have shown that heavy rainfall and intense wind speed of individual tropical cyclones were increased by climate change. The combination of various climate events, such as tropical cyclones, extreme ocean waves, and El Niño or La Niña phases, with sea-level rise causes increased coastal flooding, especially on low-lying atoll islands of the Indian and Pacific Oceans.

The expected increased risk of such impacts under further climate change is significant. For example, some low-lying islands and areas may be extensively flooded at every high tide or during storms. As a result, their freshwater supplies and soils would be repeatedly contaminated by saltwater, with adverse cascading consequences for freshwater and terrestrial food supplies, biodiversity and ecosystems, and economic activities. It is unlikely that these locations would remain habitable unless such impacts are mitigated through reduction of heat-trapping greenhouse gas emissions or adaptation solutions that are acceptable for the populations of these islands. Acceptable adaptation options may be limited in these locations. Additionally, drought intensity may challenge freshwater security in some regions such as the Caribbean. Likewise, remote atoll islands where inhabitants rely on reef-derived food and other resources and that are at high risk of widespread coral reef degradation may become uninhabitable. Strategies to reduce risk may include substituting the consumption of vulnerable inshore reef resources by developing onshore aquaculture (fish farming), or promoting access to tuna and other pelagic fish, and/or importing food to meet nutritional needs. However, adoption of these strategies will depend on the acceptance of their local populations.

The intensity and timing of such impacts will be more severe under high warming futures compared to low warming futures accompanied by ambitious adaptation. Tailored, desirable and locally owned adaptation responses that incorporate both short- and long-term time horizons would certainly help to reduce future risks to nature and human life in small islands. Among the short-term measures frequently employed to address sea-level rise and flooding are seawalls. Long-term measures include ecosystem-based adaptation such as mangrove replanting, relocation of coastal villages to upland sites, creation of elevated land through reclamation, revised building codes as part of a broader disaster risk reduction strategy, shifting to alternative livelihoods and changes in farming and fishing practices.

[START FAQ15.2 HERE]

FAQ 15.2: How have some small-island communities already adapted to climate change?

Faced with rising sea levels and storm surges along their coastal areas which have significantly threatened people's safety, buildings, infrastructure and livelihoods, Small Island communities have already embarked on the use of different adaptation strategies. These include reactive adaptation, which deals with short-term measures, and anticipatory adaptation, which takes action in advance to lessen climate change impacts in the long run. Reactive measures have proven not always to be effective. In contrast, anticipatory measures hold much promise for future adaptation.

The majority of people living on small islands occupy coasts, so the most widespread threats to people's livelihoods are those from sea-level rise, shoreline erosion, increased lowland flooding, and salinization of groundwater and soil. Humans can either adapt reactively or anticipate coming changes and prepare for them. Given the diversity of small islands across the world, and their capacities to adapt, there is no single solution that fits all contexts.

Coastal livelihoods in particular are already impacted by climate impacts. Coastal fishers have adapted to these changes in environmental conditions by diversifying livelihoods, expanding aquaculture production, considering weather insurance, building social networks to cope with reduced catches and availability during extreme storms, switching fishing grounds, and changing target species. Similarly, farmers have diversified livelihoods to more cash- and service-based activities such as tourism, changed plant species that thrive better in altered conditions, and shifted planting seasons according to changes in climate.

A typical reactive adaptation along small-island coasts involves the construction of hard impermeable structures such as seawalls to stop the encroachment of the sea. Yet such structures, especially along rural island coasts, often fail to prevent flooding during extreme sea levels or extreme-wave impacts, and can inadvertently damage nearshore ecosystems such as mangroves and beaches. In the Caribbean, Indian Ocean islands and some Pacific islands, there are numerous examples of coastal engineering structures that have been destroyed already or are in grave danger from the encroaching sea. In many instances, citizens and governments are unable to access external advice or funding, communities have built such structures without assistance or knowledge of expected future sea level rise.

In contrast, anticipatory adaptation, which anticipates expected future impacts and acts in advance, requires a longer-term view as well as some understanding of future climate-change impacts in particular contexts. Along small-island coasts, anticipatory adaptation typically involves recognising that sea level will continue rising and that problems currently experienced will be amplified in the future. One strategy for anticipatory adaptation in response to sea level rise and flooding is relocation, which is the movement of coastal communities away from vulnerable (coastal-fringe) locations to sites that are further inland. . Coastal setback policies have been applied to hotels in some islands such as Barbados. In coastal locations where the risks of rising sea level, flooding and erosion are very high and cannot effectively be reduced, 'retreat' from the shoreline is the only way to eliminate or reduce such risks.

Where relocation is successful, it is most commonly driven and funded by governments and non-government organisations, often within a specially designed policy framework. The Government of Fiji, for example, has introduced a relocation framework that specifically develops guidance on relocation processes, with several villages already having relocated. Evaluations to date recommend thorough cost-benefit analyses of relocation be undertaken before this strategy is pursued. Relocation is often viewed as a 'last resort' adaptation option because of high cost and because some socio-cultural aspects of life cannot be maintained in locations separated from customary land. The Bahamas relocated a community on Family Island from the shoreline to an inland location and the community of Boca de Cachón in the Dominican Republic was relocated to higher ground. The Navunievu community (Bua, Fiji) has mandated that every young adult building their family home in the village should do so upslope rather than on the regularly flooded coastal flat where the existing village is located. Over the next few decades, this will result in the gradual upslope migration of the community, an example of autonomous adaptation. Such creative community-grounded solutions hold great promise for future adaptation on small islands, where they are undertaken inclusively.

Anticipatory adaptation has been aligned with disaster risk reduction in some small islands. For example, Jamaica adopted such an approach in relocating three communities. Recognising that a proactive approach is needed, Jamaica developed a Resettlement Policy Framework aligned with the National Development Plan and based on vulnerability assessments of communities at risk of climate change and disaster risk. A resettlement action plan was developed for the Harbour Heights community using community engagement to design successful planned relocation. In some islands revised building codes are implemented as an anticipatory adaptation measure. As part of the build-back-better strategy hurricane resistant roofs are being built to cope with strong winds associated with tropical cyclones.

Ecosystem-based adaptation can be a low-cost anticipatory adaptation measure that is often used in small islands. It is referred to as a 'no-regret' or 'low-regret' strategy because it is low-costing, brings co-benefits and requires less maintenance in contrast to hard engineering structures. Ecosystem-based adaptation is used at different scales and in different sectors such as to protect fisheries, farming and tourism assets, and integrates various stakeholders from national to local governments and non-governmental agencies. Many islands have implemented ecosystem-based adaptation such as watershed management, mangrove replanting and other nature-based solutions to strengthen coastal foreshore areas that are subjected to coastal erosion and flooding caused by sea level rise and changing rainfall patterns. For example, mangroves have been planted on several cays in Belize and pandanus trees have been planted near the coastlines of the Marshall Islands. Agroforestry is another example of ecosystem-based adaptation. Planting trees and shrubs in combination with crops has been used to increase resilience of crops to droughts or excessive rainfall run-off. Case studies show that people living on islands benefit even further from using ecosystem-based adaptation. Their health improves as well as their food and water supply, while risks of disasters caused by extreme events are reduced.

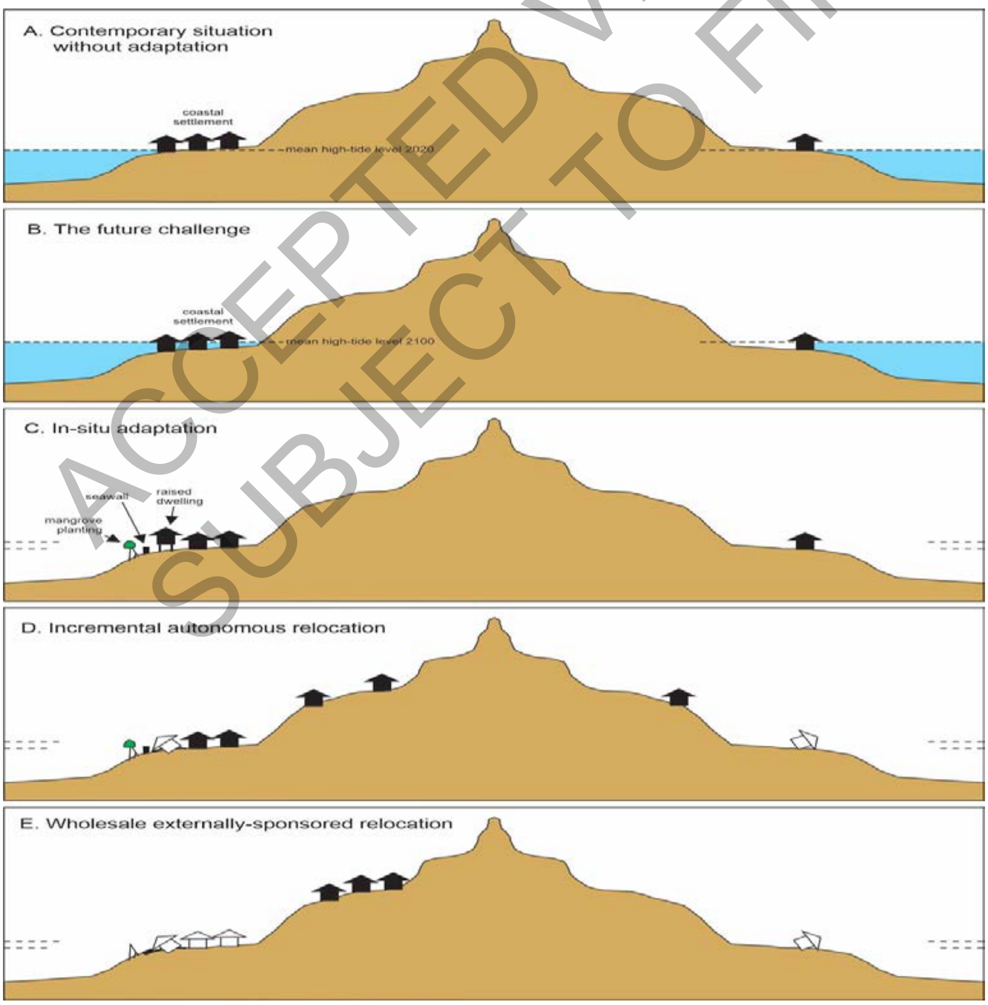

Figure FAQ15.2.1: Adaptation options for rural coastal communities in small islands
A – In many places today, coastal communities which have been established for hundreds of years are being more regularly inundated than ever before as a result of rising sea level. B – By the end of this century, sea level in such places may have risen one meter or more, making many such settlements (largely) uninhabitable, underscoring the need for effective (anticipatory) adaptation. C – One option is in-situ adaptation, popular because it is cheaper and less disruptive than other options; it is typically characterised by mangrove replanting, seawall construction and raising of dwellings. D – A second option is for communities to incrementally relocate upslope by building all new houses further inland. E – A third option is complete relocation of a vulnerable coastal community with external support upslope and inland.

[START FAQ15.3 HERE]

FAQ 15.3: How will climate related changes affect the contributions of agriculture and fisheries to food security in small islands?

Agriculture and fisheries are heavily influenced by climate, which means a change in occurrence of tropical cyclones, air temperature, ocean temperature and/or rainfall can have considerable impacts on the production and availability of crops and seafood and therefore the health and welfare of island inhabitants. Projected impacts of climate change on agriculture and fisheries in some cases will enhance productivity, but in many cases could undermine food production, greatly exacerbating food insecurity challenges for human populations in small islands (also see Cross-Chapter Box MOVING PLATE in Chapter 5).

Small islands mostly depend on rain-fed agriculture, which is likely to be affected in various ways by climate change, including loss of agricultural land through floods and droughts, and contamination of freshwater and soil through salt-water intrusion, warming temperatures leading to stresses of crops, and extreme events such as cyclones. In some islands, crops that have been traditionally part of people's diet can no longer be cultivated due to such changes. For example, severe rainfall during planting seasons can damage seedlings, reduce growth and provide conditions that promote plant pests and diseases.

Changes in the frequency and severity of tropical cyclones or droughts will pose challenges for many islands. For example, more pronounced dry seasons, warmer temperatures, greater evaporation could cause plant stress reducing productivity and harvests. The impacts of drought may hinder insects and animals from pollinating crops, trees and other vegetative food sources on tropical islands. For instance, many agroforestry crops are completely dependent on insect pollination, and it is, therefore, important to monitor and recognize how climate change is affecting the number and productivity of these insects. Coastal agroforest systems in small islands are important to national food security but rely on biodiversity (e.g., insects for pollination services). Biodiversity loss from traditional agroecosystems has been identified as one of the most serious threats to food and livelihood security in islands. Ecosystem-based adaptation practices and diversification of crop varieties are possible solutions.

The continuous reduction of soil fertility as well as increasing incidences of pests, diseases, and invasive species contribute to the growing vulnerability of the agricultural systems on small islands. Higher temperatures could increase the presence of food or water borne diseases and the challenge of managing food safety. Changes in weather patterns can also disrupt food transportation and distribution systems on islands where indigenous communities are often located in remote areas.

Impacts of climate change on fisheries in small islands result from ocean temperature change, sea-level rise, extreme weather patterns such as cyclones, reducing ocean oxygen concentrations and ocean acidification. These combined pressures are leading to the widespread loss or damage to marine habitats such as coral reefs but also mangroves and seagrass beds and consequently of important fish species that depend on these habitats and are crucial both to the food security (a high proportion of dietary protein is derived from seafood) and incomes of island communities. Shifting ocean currents and warming waters are also changing the distribution of pelagic fish stocks, especially of open-water tuna, with further consequences for both local food security and national economies, where they are often highly dependent on income from fishing licenses (e.g., 98% of Gross Domestic Product in Tokelau, 66% of national income in Kiribati).

Climate change is projected to have profound effects on the future status and distribution of coastal and oceanic habitats, and consequently of the fish and invertebrates they support. High water temperature causes changes in the growth rate of fish species as well as the timing of spawning and migration patterns, with consequences for fisheries catch potential. Some small island countries and territories are projected to experience more than 50% declines in fishery catches by 2100. Other small islands such as Easter Island (Chile), Pitcairn Islands (UK), Bermuda, and Cabo Verde may actually witness increases in catch potential under certain climate scenarios. Food shortages are often apparent in small islands, following the passage of catastrophic tropical cyclones. Access to pelagic fisheries can help to alleviate immediate food insecurity pressures in some circumstances, whereas aquaculture (fish farming) is being viewed as a longer term means of diversifying incomes and enhancing resilience in many Caribbean and Pacific islands.

Large Tables

Table 15.2: A small subset of projected changes in basic climate metric. Med=Mediterranean; NC=no change

Phenomenon	Location	General Trend	Metric	Specific projections 2040-2060		Specific projections 2080-2100		Comments	Reference
				RCP 4.5	RCP 8.5	RCP 4.5	RCP 8.5		
Air Temperature	Caribbean	Hotter, especially in the East	Monthly mean temperature compared to 1971-2000	NA	1.2C rise	1.6C rise	3.0C rise	Specific to Lesser Antilles	Bowden et al. (2020) Cantet et al. (2014)
	East Atlantic	Hotter	Average annual temperature compared to 1971-2000	1.5-2C rise	2.5C rise	NA	NA	Low-confidence, specific to Sao Tome and Principe	Chou et al. (2020)
	Med	Hotter, especially in summer	Average maximum daily temperature during summer compared to 1970-2000	1.6-1.9C rise	2-2.5C rise	NA	NA	Specific to Sicily, Crete and Cyprus	Varotsos et al. (2021)
	Pacific	Hotter	Average temperature compared to 1986-2005	0.5-1.5C rise	1.0-2.0C rise	1.0-2.0C rise	2.0-4.0C rise	Consistent in tropical lattitudes	Lough et al. (2016)
	Global small islands	Hotter	Heat index compared to 1986-2005	1C rise	1.5C rise	1.3C rise	2.8C rise	Equatorial, coastal and continental islands hotter than oceanic	Harter et al. (2015)
ENSO	Pacific	More frequent extreme events	Frequency compared to ~1900-1999	NA	NA	NA	100% more El Ninos, 73-100% more La Ninas	High natural variability limits statistical significance in related patterns	Cai et al., (2014); Cai et al. (2015b)
		Inconclusive change in variability	Amplitude change compared to 1979-2005	0.02C drop	0.01C rise	0.04C drop	0.04C rise	Specific projections are not statistically significant	Cai et al., (2018); Beobide-Arsuaga et al. (2021)
Precipitation	East Caribbean	Slightly wetter, more extreme seasonality	Total rainfall compared to wet/dry season compared to 1971-2001	NA	NA	5% rise/ 10% drop	8% rise/ 15% drop	Significant local variability	Cantet et al. (2014)
	West/ North Caribbean	Drier	Annual rainfall compared to 1986-2005; consecutive dry days compared to 1961-1990	NA	9% less rain	NA	Up to 327% more dry days	Specific to Puerto Rico and US Virgin Islands	Stennett-Brown et al. (2017); Bowden et al. (2020)

	East Atlantic	Inconclusive change	Monthly rainfall compared to 1971-2000	10-25mm rise	10-25mm drop	NA	NA	Low-confidence, specific to Sao Tome and Principe	Chou et al. (2020)
	West Pacific	Wetter, especially after mid-century	Annual average rainfall compared to 1971-2005	2% rise	6% rise	3% rise	8% rise	Low-confidence, specific to Borneo	Sa'adi et al. (2017)
	Central Pacific	Drier, more extreme seasonality	Total rainfall compared to 1975-2005	15% drop	20% drop	17% drop	30% drop	Low-confidence, specific to Hawaii	Timm et al. (2015)
	Southwest Indian Ocean	Drier during the wet season, especially south of 10S	Average change in daily rainfall compared to 1971-2000	NA	NA	NA	0.2 mm per day drop	Low confidence	Lazenby et al. (2018)
	Med	Drier, but highly varied	Annual mean precipitation compared to 1960-1990	70-100 mm drop	60-150 mm drop	NA	NA	Specific to Malta; no significant change in Sicily, Crete and Cyprus	Varotsos et al. (2021)
	Global small islands	Slightly wetter, highly variable	Mean annual precipitation compared to 1986-2005	<1% rise	<1% rise	1.8% rise	3.2% rise	Confidence limited by high standard deviation	Harter et al. (2015)
Tropical Cyclones	North Indian Ocean	More storms in the west, fewer in the east	Frequency compared to 1990-2013	NA	NA	NA	30-60% rise/ 20-40% drop	Specific to Arabian sea/ Bay of Bengal	Bell et al. (2020)
	South Indian Ocean	Fewer storms, fewer strong storms in east	Storm/category 4-5 frequency compared to 1979-2010	NA	NA	NA	20-40% drop/ 0-20% drop		Bell et al. (2019a)
	Northwest Pacific	Slightly more and stronger storms at increasingly high latitudes	Storm density compared to 1970-2000; poleward shift in annual mean of location of maximum intensity compared to 1980-2005	NA	NA	NA	15-40% rise; 0.2°	10-40N, 140-170E	Kossin et al. (2016); Chand et al. (2019)
	Southwest and low-latitude Pacific	Less frequent storms	Storm density compared to 1970-2000	NA	NA	NA	0-20% drop/ 20-30% drop	South/North Pacific up to 20N, 100-140E	Bell et al. (2019a) Chand et al. (2019)
	Northeast Pacific	Less frequent storms	Storm frequency compared to 1970-2016	NA	NA	NA	2-13% drop	No data for Southern Hemisphere	Bell et al. (2019b)
	Central North Pacific	More and stronger storms	Mean annual TC/category 4-5 composition	NA	NA	NA	31%/ 88% rise	Specific to Hawaii	Yoshida et al. (2017)

			compared to 1979-2010						
	Caribbean	Slightly fewer storms	Minor/major cyclones compared to 1984-2013	NA	12% drop/ NC	NA	NA	Specific to lesser Antilles	Cantet et al. (2021)
	East Atlantic	More storms and slightly more frequent intense storms	Storms per decade compared to 1979-2010	NA	NA	NA	0-3 rise	Specific to latitude >15N	Yoshida et al. (2017)
Extratropical cyclone	Med	Decreased frequency but increased intensity	Frequency of storms compared to 1986-2005	NC	NA	12% drop	NA		González-Alemán et al. (2019)

Table 15.3: Percentage of selected islands classified as refugia for biodiversity at increasing levels of warming. While protected land is still 'protected' this table demonstrates the difficulty of protecting lands which might be 'more resilient' to climate change under increasing levels of warming and current land use practices. Derived from current and future projected distributions of ~130,000 terrestrial fungi, plants, invertebrates and vertebrates (Warren et al., 2018a). Refugia =areas remaining climatically suitable for >75% of the species modelled (Warren et al., 2018b). **Projections:** based on mean impacts from 21 CMIP5 climate model patterns (no dispersal) and elevationally downscaled to 1km under interpolated warming levels derived from RCP 2.6, 4.5, 6.0 and 8.0 (Warren et al., 2018a). First column-set = % island/island chain classified as a refugia based on ***climate alone*** ; second column-set = % natural land projected to be climate refugia — illustrating potential refugia 'space' already lost to habitat conversion. **Colour Key**: white > 50%; yellow = 30%-50%; red = 17%-30% and dark red <17% of land classified as refugia.

Table 15.5: Summary of inter- and intra-regional transboundary risks and impacts on small islands

Transboundary Risks/Issues	**Small Island examples**	**Reference**
Large ocean waves from distant sources	Unusually large deep ocean swells generated from sources in the mid and high latitudes by extratropical cyclones (ETCs) cause considerable damage on the coasts of small islands thousands of kilometres away in the tropics. Impacts include inundation of settlements, infrastructure, and tourism facilities as well as coastal erosion. These waves can propagate to and influence reef islands in equatorial areas not usually exposed to high energy waves.	Hoeke et al. (2013); Smithers and Hoeke (2014); Shope et al. (2016); Canavesio (2019); Wandres et al. (2020) Jury (2018)

	Examples of extratropical swell waves causing flooding and inundation have been reported throughout the Pacific (French Polynesia, Fiji, Micronesia, the Marshall Islands, Kiribati, Papua New Guinea and the Solomon Islands). Modelling of future wave climates has been carried out for 25 tropical Pacific islands, and results suggests that December–February extreme wave heights will decrease for most islands by 2100 under both an RCP4.5 and RCP 8.5 scenario, although the frequency of the large winter wave events may increase around the Hawaiian Islands. In the Caribbean, northerly swells affecting the islands have been recognised as a significant coastal hazard. They cause considerable seasonal damage to beaches, marine ecosystems, and coastal infrastructure throughout the region.	
Transcontinental dust clouds and their impacts	The transport of airborne Saharan dust across the Atlantic into the Caribbean has been intensively studied. In the West African Sahel, where drought has been persistent since the mid-1960s, analysis has shown that there have been remarkable changes in dust emissions since the late 1940s. Variability in Sahel dust emissions may be related not only to droughts, but also to changes in the North Atlantic Oscillation (NAO), North Atlantic sea surface temperatures and the Atlantic Multidecadal Oscillation (AMO). The frequency of dust storms has been on the rise during the last decade. Forecasts suggest that their incidence will increase further. Transboundary movement of Saharan dust into the island regions of the Caribbean and the Mediterranean has been associated with human health problems including asthma cases in the Caribbean, cardiovascular morbidity in Cyprus, and pulmonary disease in the Cape Verde islands.	Prospero and Lamb (2003); Goudie (2014); Schweitzer et al. (2018); Goudie (2020) Middleton et al. (2008); Martins et al. (2009); Akpinar-Elci et al. (2015); Sakhamuri and Cummings (2019)
Influx of Sargassum from distant sources	Since 2011, the Caribbean region has witnessed unprecedented influxes of the pelagic seaweed Sargassum. These extraordinary sargassum 'blooms' have resulted in mass deposition of seaweed on beaches throughout the Lesser Antilles, with damage to coastal habitats, mortality of seagrass beds and associated corals, as well as consequences for fisheries and tourism. This recent phenomenon has been linked to climate change as well as the possible influence of nutrients from Amazon River floods and/or Sahara dust.	van Tussenbroek et al. (2017); Oviatt et al. (2019) Franks et al. (2016); Putman et al. (2018)
Large-scale changes in the distribution of fisheries resources	Ocean warming and other climatic phenomena (e.g., El Niño Southern Oscillation events and Indian Ocean Dipole) have been linked to observed oceanic shifts in tuna distribution with significant impacts on revenue for vulnerable small island states that depend on fisheries licences (e.g., 98% of national income in Tokelau, 66% of national income in Kiribati). The projected eastward redistribution of skipjack and yellowfin tuna due to climate change is expected to reduce the total tuna catch within the combined EEZs of the 10 Pacific Island Countries and territories (PICTs) where most purse-seine activity occurs by approximately 10% by 2050. Projected increases in tuna biomass have been anticipated for Ascension Island and Saint Helena in the South Atlantic.	Bell et al. (2018); SPC (2019); Oremus et al. (2020); Bell et al. (2021); Townhill et al. (2021)

Movement and impact of introduced and invasive species across boundaries	The spread of invasive alien species (IAS) is regarded as a significant transboundary threat to the health of biodiversity and ecosystems worldwide. The extent to which IAS (both animals and plants) successfully establish themselves at new locations in a changing climate will be dependent on many variables, but non-climate factors such as transmission pathways, suitability of the destination, ability to compete and adapt to new environments, and susceptibility to invasion of host ecosystems are deemed to be critical. Modelling studies have been used to project the future 'invisibility' of small island ecosystems subject to climate change and therefore to anticipate marine and terrestrial habitat degradation in the future. Evidence suggests that hurricanes may have hastened the spread of highly invasive Indo-Pacific lionfish (Pterois volitans) throughout the Caribbean in recent years. Two IAS, the Common Green Iguana (*Iguana iguana*) and Cuban Treefrog (*Osteopilus septentrionalis*) were reported in the Caribbean island of Dominica, following the passage of TC Maria in 2017. Observations 7 months after the hurricane, within close proximity to ports, suggest that these animals were stowaways on ships or within relief containers.	Russell et al., 2017) Vorsino et al. (2014); Taylor and Kumar (2016b) Johnston and Purkis (2015); van den Burg et al. (2020)
Spread of pests and pathogens within and between island regions	Increased climate instability has contributed to the emergence and spread of serious diseases carried by mosquitoes such as dengue, chikungunya and zika. The incidence and severity of mosquito-borne diseases have increased significantly in Pacific, Indian Ocean and Caribbean islands during the past 10 years, which calls for a better understanding of how climate change is shaping disease prevalence and transmission. Rising sea temperatures are thought to increase the frequency of disease outbreaks affecting reef-buildings. Of the range of bacterial, fungal and protozoan diseases known to affect stony corals, many have explicit links to temperature. Global projections suggest that disease is as likely to cause coral mortality as bleaching in the coming decades at many localities, with effects occurring earlier at sites in the Caribbean compared to the Pacific and Indian oceans. Model hindcasts suggest that climate-driven changes in sea surface temperature, as well as extreme heatwave events have all played a significant role in the spread of white-band disease throughout the Caribbean. Global food security is threatened by climate-related increases in crop pests and diseases. Black Sigatoka disease of bananas has recently completed its invasion of Latin American and Caribbean banana-growing areas. Infection risk has increased by a median of 44.2% across the Caribbean since the 1960s, due to increasing canopy wetness and improving temperature conditions for the pathogen.	Cao-Lormeau and Musso (2014); Caminade et al. (2017); Pecl et al. (2017); Filho et al. (2019) Maynard et al. (2015); Randall and van Woesik (2015) Bebber (2019)

Human migration and displacement	Currently there is limited empirical evidence that long-term climate change is driving transboundary human migration from islands, however following Hurricane Maria, Puerto Rico witnessed "depopulation" of 14% in only 2 years as a result of emigration to the US mainland.	Campbell (2014a); Melendez and Hinojosa (2017)
Transboundary risks to island food security. COVID-19 caused disruptions to food supply and disaster risk management operations	While SIDS are a diverse group of nations, most share such characteristics as limited land availability, insularity, susceptibility to natural hazards that make them particularly vulnerable to global environmental and economic change processes leading to regional food insecurity. The Pacific Islands Forum Secretariat (PIFS) has established a transboundary Framework for Action on Food Security, that promotes cooperation, investments, research and development, capacity-building, and adaptation to mitigate climate change threats.	Connell (2013) Islam and Kieu (2020); Sheller (2020)

Table 15.6: Adaptation options aimed at reducing Key Risks in small islands.

Key Risks	Risk-oriented adaptation options		Evidence and agreement	Implementation	Key enablers	Reduction of exposure and vulnerability	Co-benefits	Disbenefits
KR1. Loss of marine and coastal biodiversity and ecosystem services	EbA measures (15.4.4)	MPAs; paired terrestrial and MPAs	Medium evidence, low agreement with regard to climate change adaptation and benefits	Widespread across small islands, with climate resilience being a target of some MPAs	Strong governance and sufficient financial resources	Reduces the ecosystem exposure to human disturbances, increasing their resistance and resilience to climate events	For biodiversity, food supply, economics, human health and well-being	
		Active restoration of coastal and marine ecosystems	Limited evidence, low agreement with regard to long-term success	Mostly small-scale: replanting of mangroves, seagrasses and beach vegetation; transplantation of corals; beach nourishment	Funding: adaptation taxes and levies imposed on tourism; blue bonds; public-private partnerships	Reduces the vulnerability of natural ecosystems by increasing their resilience	Improved water quality; reduction in coastal erosion and flood risks; economic benefits	
	Hard protection (15.5.1)	Hard structures designed to enhance marine biodiversity	Medium evidence, medium agreement	Artificial reefs	Funding: adaptation and environmental taxes and levies, with limited evidence of direct reinvestment in conservation and management	Uncertainty on reduction of exposure and vulnerability of marine ecosystems; reduces the exposure of population and infrastructure to coastal risks	For food supply, economies (tourism), human health and well-being	
	Diversifying livelihoods (15.5.6)	Diversifying fisheries livelihoods (e.g. to aquaculture and tourism),	Limited to medium evidence,	Examples in the Caribbean region and in the	Improved governance and cooperation (e.g. through regional	Reduces exposure and vulnerability	Sustainably managed fisheries, improved food and	

		changing fishing grounds and/or target species	medium agreement	Pacific and Indian Oceans	strategies); weather insurance to enhance resilience	of livelihoods through the diversification of income and spreading of risks; targeting less offshore pelagic species reduces exposure of coastal habitats to overfishing	income security, greater economic and social resilience	
	Reef-to-ridge ecosystem management (Figure 15.4)	Improved land use as a driver of marine ecosystem health, including better management of forests, nutrients and waster water upland catchments	Limited evidence, medium agreement	Mostly in the Caribbean region and Pacific	Improved governance	Reduces the exposure of coral reefs to human degradation, increasing their resilience	Improved ecosystem protection services (e.g. against flooding, landslides and mudflows), biodiversity, human health and livelihoods	
KR3. Loss of terrestrial biodiversity and ecosystem services	Decreased deforestation (15.5.4)		Limited to medium evidence, high agreement	Mostly in the Caribbean region and Pacific	NDC, external and long-term funding, engagement of local landowners and resolution of land ownership issues, gender sensitive participation	For example, increase in forest extent, reduction in human exposure to natural disasters (hurricanes, landslides), improvement in vulnerability assessment scores	Increased connectivity between forest fragments, reduced erosion, improved water supply and quality, improved human health and sanitation, improved livelihoods and soil health; decreased poverty; supports global mitigation	

	Increased reforestation (native species) (15.5.4)	Towards habitat connectivity, heterogeneity and diversity	Medium evidence, high agreement	Relatively widespread, with examples in the Caribbean region and Pacific	NDC, funding, technical assistance, supply materials, provision of land, awareness raising, enforcement of policies, sense of shared responsibility, inclusion of Indigenous knowledge and local knowledge, social capital	Generally limited evidence, lack of long-term monitoring	Increased DRR; fewer floods and landslides; reduced erosion; increased human health and well-being; increased quality of ecosystem services; increased adaptive capacity; supports global mitigation	
	EbA (15.5.4)	Agroforestry and other silvicultural/agroecological practices (e.g. climate-smart agriculture)	Medium evidence, high agreement	Widespread in the Caribbean region and Pacific Ocean	NDC, shared access and benefit, local knowledge and training, farmers, private sector for developing technology, financing, data availability; political, institutional and socioeconomic conditions	Limited examples, some increases in adaptive capacity	Improved climate change awareness, increased well-being, improved gender equity, improved productivity and livelihoods	
	Watershed management/conservation (15.5.4)	Reforestation, slope revegetation	Medium evidence, high agreement	Widespread (e.g. in the Caribbean region and Pacific Ocean)	Less socially and politically acceptable than engineering solutions; communication and trust between stakeholders; sustainable financing mechanisms; island remoteness barrier to logistical implementation	Yes, through improved water security, reduced adaptation costs, reduced vulnerability to drought	DRD, improved climate change awareness, increased water security and quality, reduced run-off and sedimentation, increased well-being and financial stability	
	Ridge-to-reef ecosystem management (Figure 15.4)	Improved land use as a driver of terrestrial ecosystem health	Medium evidence, high agreement	See above	See above	Limited but slowly increasing evidence to date		

	Increasing the connectivity of Protected Areas (Pas) across elevation/climatic gradients to facilitate climate-driven redistribution of species (Figure 15.4)	Establishment of new PAs, forested migration corridors across elevation/climatic gradients, improving landscape connectivity by permanent protection of stepping stones	Very limited evidence, high agreement	Low degree of new implementations due to terrain limitations combined with competition from human land use needs; large variation in PA coverage among islands	Conservation of larger areas of forest habitat surrounding PAs, reforestation of degraded areas, increasing and enforcement of forest cover within PAs, policies towards the coordination of conservation actions/partnerships, incorporation of 'Other Effective area-based Conservation Measures' (OECMs)	Yes, especially if landscape connectivity is improved (migration corridors)	Improved water security, improved coastal ecosystem health, greater resiliency and recovery from wildfires, reduced pollution, DRR	May facilitate movement of Invasive Alien Species
	Eradication of Invasive Alien Species (IAS) (15.3.3.3)		Robust evidence, high agreement	Widespread (>700 islands)	Integration of changing climate conditions within ongoing prevention, control and eradication strategies, prevention via ongoing vigilance and biosecurity via quarantine, control and monitoring of incoming cargo and goods into islands	Yes, positive demographic and distributional responses of native species following eradication of IAS	Food security, protection of ecosystem health and services, increased livelihood security	A few native species harmed by eradication process
KR4. Water insecurity	Rainwater harvesting (15.3.4.3)		Robust h evidence, high agreement	Widespread across small islands (e.g. Jamaica, Barbuda, Solomon Islands)	Socio-cultural and financial	Yes	Biodiversity (watershed protection); health; economic (reduced dependence on public supply); food security	Dependent on mode of implementation. Nothing mentioned in the chapter.
	Desalination (15.6.1)		Limited evidence, high agreement	Relatively limited (e.g. Maldives)	Financial	Yes	Health; economic (reduced dependence on public supply)	Energy intensive (carbon footprint)

	Reforestation (15.5.4)		Medium evidence, high agreement	Examples reported in the Caribbean and Pacific (e.g. Fiji, Papua New Guinea)	Governance - whole-of-island approaches foster integrated management practices in small islands	Yes, through supporting wetland-oriented tourism	Economic (agroforestry); biodiversity (watershed restoration); food security; disaster risk reduction	Dependent on mode of implementation. Nothing mentioned in the chapter.
	Protected Area Management (terrestrial) (15.5.4)		Medium evidence, high agreement	Widespread across small islands (e.g. Samoa, Jamaica, Haiti, Grenada)	Financial/governance	Yes, through soil stabilization and sequestration of pollutants	Biodiversity (forest conservation); disaster risk reduction	
KR5. Destruction of settlements and infrastructure	Hard protection (15.5.1)		Medium agreement, limited evidence with regard to climate change adaptation and success	Widespread in both urban and rural areas of the Caribbean, Pacific and Indian Oceans	External funding; socio-cultural (meets the preference of the population); political-institutional (e.g. supported by business-as-usual approach of coastal risks); technical (requires materials and skills)	Reduces exposure in some places but not in others; increases vulnerability	Limited evidence of co-benefits	Beach loss; erosion acceleration; ecosystem degradation through material extraction; increased SLR impacts
	Accommodation (15.5.2)		Limited evidence with regard to climate change adaptation and success	Relatively limited	Technological, financial, institutional, sociocultural	Limited evidence to date	Maintains the functionalities of coastal systems and allows their maintenance through landward migration, under SLR	
	Advance with land raising and/or through the creation of artificial islands (15.5.2)		Limited evidence with regard to climate change adaptation (driven by population	Limited (e.g. Hulhumale', Maldives)	Technological, financial, institutional, sociocultural, high potential in urban (compared to rural) areas	Reduces population exposure where high standard as in Hulhumale', Maldives	Offers new land for economic development, generates revenues through sale or lease of land in urban areas	Widespread ecosystem destruction, increased negative impacts of SLR

			growth in the Maldives)					
	Migration including planned resettlement (15.5.3)		Limited evidence, low agreement with regard to climate change adaptation	Village-scale planned resettlement supported by government policy/legislation in the Pacific	Participatory inclusion of all social groups; financial (for small and remote communities); social-cultural connections; strong governance frameworks; enabling legislation; land availability or ownership; conditions in receiving locations; technical support	Reduced exposure locally; has created new vulnerabilities at some locations by bearing significant economic cost, impacting social capital and reducing access to services	New livelihood opportunities	Loss of cultural heritage, impacts on receiving communities
	EbA measures (15.4.4)		Medium agreement, medium evidence	Increasingly experienced; includes artificial reefs, beach nourishment and vegetation (including mangrove) restoration	Environmental/physical conditions; social acceptability; technical capacities (enhanced by external support); funding; inclusion in national adaptation policies	Limited evidence to date	Biodiversity strengthening; increased food supply; increased human health and well-being	
KR6. Health degradation	Increasing public awareness of health risks associated with climate change; providing training to health sector staff; improving reliability and safety of water storage practices (15.6.2)		Limited evidence	Few examples	Financial and human resources to implement options; early warning and response systems; integrating climate services into health decision-making systems; public uptake and buy in; improving health data collection systems	Primarily reduces vulnerability	Increased water security	

KR7. Economic decline and livelihood failure	Circular migration (15.5.3)		Limited evidence with regard to climate change adaptation (mostly driven by economic or social factors)	Examples in Tuvalu from outer to capital atoll and locations overseas	Labour and education opportunities in Funafuti, Tuvalu, and overseas	Yes on Namumea Atoll, Tuvalu	Job and education for migrants	
	Diversifying livelihoods (15.5.6)		Limited to medium evidence, low agreement	Observed in the Caribbean region and Pacific	Use of ndigenous knowledge and local knowledge and changing fishing areas; investment in technology and education	Yes in documented places (e.g. Antigua, Vanuatu, Madagascar, Dominican Republic)	Reduction of pressure on previous fishing areas	Greater catch putting increasing pressure on fish stock
	Improved technology & equipment/training (15.5.6)		Limited evidence, medium agreement	Examples in the Caribbean region and Pacific	Investments in technologies and education (e.g. irrigation technologies, growing salt-tolerant crops and relocating crop cultivation in Jamaica)	Yes in documented places	New technologies and education strengthening	
	Livestock husbandry (15.5.6)		Limited evidence	Limited (e.g. small-scale livestock husbandry in Jamaica)	Farm inputs and investments in technologies and education	No evidence to date. Limited examples of successful livestock husbandry only in Jamaica	Investments in farm inputs	
	Adaptive finance/education (15.5.6)		Limited evidence, medium agreement	Limited (e.g. in Puerto Rico, women engage in new	Tourism income; investment in education and capacity building;	Yes, reduces risk and avoids negative	Generates opportunities (e.g. for wetland tourism)	

				commercial enterprises that do not rely on traditional coffee supply chains or government assistance)	working with nature and EbA	knock-on effects		
	Product/Market diversification (15.5.6)	Diversity of crops, gardening in different areas, storage and preservation of foodstuffs, engagement of women in new commercial enterprises	Medium evidence, high agreement	Examples in the Caribbean region and Pacific	Availability of crops and land, new markets	Reduces vulnerability to tropical cyclones in Fiji and Vanuatu; new markets in Puerto Rico	Increases food security and improves nutrition; increases income security	
	Adaptation in tourism policies (15.5.6)		Limited evidence, high agreement	Limited (e.g. in the British Virgin Islands, policies like adaptation taxes and levies imposed on tourism can provide funding for adaptation measures)	Tourism regulations and policies that mainstream climate change adaptations; taxes and levies imposed on tourism	Limited evidence in reducing vulnerability		
KR8. Loss of cultural resources and heritage	Integrating Indigenous Knowledge and local knowledge (IKLK) with western science to provide integrated approaches to climate change (15.6.5)		Medium evidence, high agreement	Reported in the Pacific and Caribbean	Use of IKLK for preparing for disasters and understanding environmental change; social networks in sharing information and helping others; ecotheology increasing people's awareness of the environment	Yes, can reduce vulnerability when IK LK supports robust adaptation; No, can increase vulnerability if IKLK no longer provides	Can increase climate change information and its understanding in communities, and increase culturally appropriate climate adaptation	Reports from Vanuatu indicates that IK LK are at times inaccurate (eg seasonal calendars, biophysical weather indicators) due to climate change

						accurate information		
	Hard protection (15.5.5.1)		Medium agreement, limited evidence with regard to climate change adaptation and success	Widespread in protecting cultural sites and villages in both urban and rural areas of the Caribbean, Pacific and Indian Oceans	External funding; socio-cultural (generally meets the preference of the population); political-institutional (e.g. supported by business-as-usual approach of coastal risks); technical (requires materials and skills)	Reduces exposure in some places but not in others; increases vulnerability	Limited evidence of co-benefits	Beach loss; erosion acceleration; ecosystem degradation through material extraction; increased SLR impacts

Table 15.7: Enabling Conditions and Factors for Adaptation in Small Islands

Enabling Conditions and Factors for Adaptation		
Enabler	Example	Reference
Knowledge (Indigenous, Local, External)		
IKLK in developing adaptation strategies (soft protective structures; disaster preparedness)	Using IKLK in identifying Indigenous vegetation (e.g., ecosystem-based adaptation) to reduce erosion (Samoa, Vanuatu)	Crichton and Esteban (2018); Nalau et al. (2018b)
	Pacific storm prediction, disaster preparedness	Chand et al. (2014); Kuruppu and Willie (2015); Granderson (2017)
	Shared resource governance and understanding of linkages between sectors and ecosystems based on IKLK (e.g., Lomanu Gau village initiative (Fiji)	Remling and Veitayaki (2016)
Increased access to climate information	Increased access to climate information increasing individuals will and capacity to support/take adaptive actions (Fiji)	Di Falco and Sharma-Khushal (2019)
	Dissemination of adaptation skills and significance to youth (e.g., Ecocamps in Fiji)	McNaught et al. (2014)
Increased access to climate information (continued)	Pacific women's improved participation in adaptation processes via training, access to information and decision-making	McLeod et al. (2018)
	Improved climate data quality, management and associated observation, modelling and information services	Martin et al. (2015); Hermes et al. (2019)
	Caribbean: Improved climate data quality, management and associated observation, modelling and information services	Trotman et al. (2018)
	Provision of user-tailored products and services through knowledge co-production processes	SPREP (2016a)
Economy and Finance		
Economic diversification and shifting to CRDPs	Tourism system transitions/cooperation from tourism sector	Loehr (2019); Mahadew and Appadoo (2019); Loehr et al. (2020); Sheller (2020)
Finance models for adaptation	Innovative financing models that enable adaptation (e.g., Seychelles)	Rambarran (2018)
	Parametric fisheries insurance products to increase fishery resilience funded by Caribbean Catastrophe Risk Insurance Facility (Grenada and Saint Lucia)	CCRIF (2019)
Transregional trade agreements/associated pressure	Revised socio-political arrangements for better fisheries management (Solomon Islands)	Keen et al. (2018)
Economic viability via revenue from sale of new land	Maldives land raising on Hulhumale	Bisaro et al. (2019)
	"Safe island development programme" after 2004 Indian Ocean Tsunami in the Maldives	Shaig (2008)
Government subsidies	Tuamotu's government subsidy of raised houses	Magnan et al. (2018)
Co-investments and cooperation between agencies (donors, governments)	Tuvalu use of beach nourishment in collaboration with JICA	Onaka et al. (2017)
Diversification of livelihoods as basis for economic activity	Coastal fishers' diversification of livelihoods into the tourism sector (Vanuatu and Madagascar)	Blair and Momtaz (2018)

	Fishermen varying fishing practices and locations depending on environmental conditions (e.g., Dominican Republic)	Karlsson and McLean (2020)
Governance		
Changed governance arrangements resulting in improved coordination	Improved governance arrangements: Cross-sectoral and cross-agency coordination (e. g. Vanuatu)	Webb et al. (2015); Nalau et al. (2016)
Changed governance arrangements resulting in improved coordination (continued)	Agency explicitly tasked with coordinating sectors and services for climate resilience across government (Dominica)	Turner et al. (2020)
	Efficient and coordinated distribution of climate adaptation support across national projects and departments (e.g., Samoa)	McGinn and Solofa (2020)
New strict/explicit building codes	Caribbean infrastructure (esp. housing and hotels) now must be built to withstand strong hurricanes	Mycoo (2018a)
Localising climate adaptation plans, frameworks and policies	Pacific Adaptive Capacity Framework Framework for the Disaster and Climate Resilient Development in the Pacific (FRDP) Island-centric adaptation policy and planning	Warrick et al. (2017) SPC (2016) Schwebel (2017)
Social and cultural		
Social networks and capacity in disaster recovery	Support of social networks in hurricane recovery, access to livelihood opportunities (e.g., Dominica)	Turner et al. (2020)
	Increased Indigenous resilience and adaptive capacity via social networks and capital (e.g., Samoa)	Petzold and Ratter (2015); Parsons et al. (2018)
	Informal credit for fishermen at food stores during and after disasters (e.g., Belize and Dominican Republic)	Karlsson and McLean (2020)
Social networks and traditional familiarity with barter/microfinance	Community-level fundraising (e.g., Samoa, Solomons, Jamaica)	Birk and Rasmussen (2014); Carby (2017); Crichton and Esteban (2018); Parsons et al. (2018); Nunn and Kumar (2019a)
Maintenance of home community	Circular migration between Tuvalu and overseas	Marino and Lazrus (2015)
Empowerment of the migrating individuals	Relocations of villages (Fiji)	Marino and Lazrus 2015)

Table 15.8: Research Gaps in Small Islands

Research Gap	Elaboration
Unavailability of adequately downscaled climate data	There is a lack of oceanographic (e.g. tidal), meteorological, high resolution topographic and bathymetric data, as well as future sea-level and wave climate projections for most islands, which severely constrain modelling studies and therefore improved understanding of future coastal flooding, erosion, and rates of saline intrusion into aquifers (Giardino et al., 2018; Lal and Datta, 2019)
	There is a need for further developing context-specific numerical models, especially through the inclusion of sediment transport, production and delivery (Shope and Storlazzi, 2019), coastal and marine ecosystems' responses (Beetham et al., 2017), and various societal responses (e.g., engineering and ecosystem-based solutions (Giardino et al., 2018)) under different climate change and SLR scenarios.
	The complexity and specificities of small island environments and unavailability of robust baseline data considerably challenge modelling studies in small islands contexts, as reflected by the serious limitations of global modelling impact studies for these (Mentaschi et al., 2018; Vousdoukas et al., 2020).

	Data and model developments are therefore urgently needed to assess the future habitability or exploitability of the islands that are the most critical to small island countries and territories, and to help identify and promote appropriate (especially in technical terms) solutions.
	Adequately downscaled Regional Climate Model (RCM) data (sub-5 km^2) is also required to conduct modelling assessments for small island terrestrial ecosystems. This is particularly needed for islands with complex topography which could be important in providing much-needed climate refugia for the survival of narrow range species such as endemics (Balzan et al., 2018). Such spatial data could be used to maximize the potential of islands to deliver critical ecosystem services (Katovai et al., 2015; Balzan et al., 2018).
	Widely used WorldClim data may not be suitable when applied to the small island context (Box CCP1.1) Without such data, robust ecosystem based adaptation strategies such as climate-smart protected area planning and management under changing climate conditions cannot be developed.
	Thomas and Benjamin (2017) highlighted the lack of data as an area of concern related to assessing loss and damage at 1.5°C. Understanding loss and damage also requires more detail on island-specific losses and damages accruing from anthropogenic climate change impacts. At the moment, such assessments are limited, and most of the small islands have not yet documented these factors in their national adaptation plans or policies (Handmer and Nalau, 2019). There is a need for specific studies also on biophysical variables and species (e.g. impact of temperature rise on mangroves); long term impacts of ocean acidification on species, including relationship to disease outbreaks, and changing breeding grounds of marine species and impacts on fisheries and marine-based livelihoods; incorporating biophysical feedback and interconnectivity of environments into models; and more detailed datasets (e.g. bathymetry, coastal assets) (World Bank, 2016; McField, 2017; Wilson, 2017).
Vulnerability and Resilience	There is need for new research that investigates the variability of vulnerability within and between islands and states, typologies of best practice (Oculi and Stephenson, 2018), frequency of knowledge sharing among islands and regions (Foley, 2018), identification of regional framework mechanisms, and mapping the complex impact and hazard interactions at a regional scale (Duvat et al., 2017b; Neef et al., 2018; Scandurra et al., 2018; Thiault et al., 2018). Research needs to also examine resilience-building efforts within the four domains of islandness (boundedness, smallness, isolation, and littorality) to effectively capture subjective nuances associated with climate development efforts on islands (Kelman, 2018).
	Research gaps in place-based assessments of social service bundles coupled with policy actions (Balzan et al., 2018) highlight the need for new knowledge to strengthen communication, collaboration and networks between academia, donors, the private sector, community and government (Allahar and Brathwaite, 2016; Schipper et al., 2016) so as to improve understanding of vulnerability and resilience in small islands.
	A paucity of research exists currently on the vulnerability of island ecosystem services to climate change (Balzan et al., 2018). While there is rich scientific evidence on the pressures of habitat loss and degradation, impacts of natural hazards and invasive species, far less is known about the interactions of these factors with adaptive capacity and livelihood conditions on islands. In small island contexts, there is a specific need for assessing the effectiveness and cost of ecosystem - and community-based solutions where the latter have been implemented (Filho et al., 2020). The design of generic assessment methods and tools is required to allow for comparative analyses that will, in turn, provide useful guidance for the promotion of context-specific adaptation strategies (Blair and Momtaz, 2018). For many of the small islands, especially SIDS, the economic valuation of marine and coastal ecosystem services – coastal protection, fisheries, tourism - is of great importance, as well as the subsequent losses in these sectors and related livelihoods due to climate change impacts (Waite et al., 2014; Schuhmann and Mahon, 2015; World Bank, 2016; Layne, 2017; Duijndam et al., 2020). There are few integrated modelling studies to inform future habitability of differentiated small island types and how these models can inform decision support processes for ridge to reef stewardship (Povak et al., 2020). Existing studies (Rasmussen et al., 2018) have progressed knowledge since AR5, but island-specific analyses are required to robustly estimate the future ability of land to support life and livelihoods, taking into account multiple climate-drivers, future population exposure, and adaptation responses.
	More research is also needed in understanding how ecosystem benefits are modified under changing climate conditions and how these benefits can be quantified (Doswald et al., 2014). For example, many small islands lack comprehensive (and disaggregated) data related to food security which makes it challenging to attribute climate impacts on local food systems (Taylor et

	al., 2019). Balzan et al. (2018) highlight the importance of quantifying the role of biodiversity in delivering key ecosystem services and demonstrate how such data could provide insights on the interrelatedness of island ecosystems and transboundary service benefits.
Adaptation	In the last decade or so, there has been a significant increase in climate-related financing for small island states. However, monitoring and tracking of funding and metrics to evaluate overall impact are lacking (Boyd et al., 2017; Mallin, 2018). Research into adaptation costs could benefit from the inclusion of indirect effects of climate change such as psychological costs (Vincent and Cull, 2014; Gibson et al., 2019) but to date this research is missing. Greater effort could also be placed on quantifying the relationship between adaptation costs and adverse events (Adelman, 2016). There is also a need for overall land use planning guidelines in small coastal communities, including small islands (Major and Juhola, 2016). The usefulness and utility of insurance mechanisms for building resilience to climate hazards require up to date information on assets at risk (Tietze and van Anrooy, 2018) and further exploration of adaptation measures in small island contexts (Baarsch and Kelman, 2016). Additionally, the differences between theoretical adaptation practices and observed results from actual implementation, along with the integration of IKLK and external knowledge are currently not well understood (Mercer et al., 2014b; Kelman, 2015b; Saint Ville et al., 2015; Robinson and Gilfillan, 2016; Robinson, 2017b). Documenting experience-based knowledge of adaptation projects and programme implementation could fill important data gaps. At the project design stage, paucity of climate finance data is a barrier to accessing climate finance (Bhandary et al., 2021).
	Although studies examining the association between climate and weather extremes, events and conditions and mobility in small islands have increased since AR5 (Birk and Rasmussen, 2014; Kelman, 2015a; Connell, 2016; Stojanov et al., 2017; Barnett and McMichael, 2018), few studies robustly examine attribution of migration of small island populations, communities and individuals to anthropogenic climate change and other non-climate migration drivers. Biophysical, socio-economic and in-situ adaptation threshold that force small island populations to migrate remains under-explored (Barnett, 2017; Handmer and Nalau, 2019). The implications of forced and voluntary immobility (Allgood and McNamara, 2017; Farbotko, 2018; Suliman et al., 2019), the socio-economic, health, psychological and cultural outcomes of climate migrants, and gender dimensions of climate migration all remain under-researched.
	Limits to adaptation is still a largely under-researched topic globally (Nalau and Filho, 2018) and specifically in small island contexts, as are the linkages between adaptation limits, loss and damage and transformative adaptation (Thomas et al., 2020). In terms of projected risks and adaptation responses, further work is needed to improve knowledge of commonalities, differences, successes, and failures of natural and human adaptation responses (Kuruppu and Willie, 2015). One of the failings of current literature on limits to adaptation revolves largely on the use of barriers for sector-specific or small-scale scenarios, that provide an understanding only for that particular scenario and does not identify common constraints (Kuruppu and Willie, 2015). Research gaps on loss and damage include: how to assess the economic costs of loss and damage; mechanisms to develop robust policies in small island contexts; specific data on experienced loss and damage across socio-economic groups and demographics; monitoring and tracking of slow onset events (Thomas and Benjamin, 2017; Thomas et al., 2020) and the non-economic aspects including sense of place, health and community cohesion (Thomas and Benjamin, 2019).
	More studies are needed on the role that organisations (international, national and regional) play in adaptation efforts – their effectiveness at achieving desired outcomes, roles and accountability (Robinson and Gilfillan, 2016; Scobie, 2016; Mallin, 2018). It is also important that the impacts of socio-political relations inter-state are researched (Belmar et al., 2015) and more focus on climate justice (Baptiste and Devonish, 2019; Moulton and Machado, 2019; Gahman and Thongs, 2020) and gender are similarly needed (Mcleod et al., 2018). Given the high number of place-specific case studies in adaptation literature, more reviews are needed that synthesise key lessons and principles of adaptations in small island contexts from this knowledge. Further research is also needed to capture the lessons from COVID-19 response in small islands and how these could enable more robust adaptation and climate resilient development transitions as has been suggested at a broader scale by Schipper et al. (2020). There is also little to no information on impacts upon terrestrial and freshwater biodiversity from the relocation of coastal human populations inland due to SLR.

Executive Summary

Introduction and framing

This chapter synthesizes observed climate change impacts (16.2), adaptation-related responses (16.3), limits to adaptation (16.4), and the key risks identified across sectors and regions (16.5). We consider how these risks accrue with increasing global average temperature; how they depend on future development and adaptation efforts; and what this implies for the Sustainable Development Goals and the five main Reasons for Concern about climate change (16.6).

Observed impacts

The impacts of changes in climate-related systems have been identified in a wide range of natural, human, and managed systems (*very high confidence*[1]). Compared to the last IPCC AR5 there is more evidence for impacts of long-term changes in climate-related systems (including the atmosphere, ocean and cryosphere) on socio-economic indicators and *high confidence* in the sensitivity of societies to weather conditions. There is also stronger evidence for impacts of long-term climate change on ecosystems, including the observed widespread mortality of warm water corals, far reaching shifts in phenology in marine and terrestrial ecosystems and the expansion of tropical species into the ranges of temperate species, and boreal species moving into Arctic regions (*high confidence*). {16.2.3, 16.2.3.1}

Increased rainfall intensity associated with tropical cyclones and rising sea levels have contributed to observed damages in local coastal systems (*medium confidence*). However, while the impact is expected to be widespread, formal attribution of damages to long term changes in the climate-related systems is still limited by restricted knowledge about changes in exposure and vulnerability and the missing quantification of the contribution of sea level rise to the extent of flooded areas. {16.2.3.3}

Due to complex interactions with socio-economic conditions, evidence on the impact of long-term climate change on crop prices and malnutrition is largely lacking while the sensitivity of malnutrition to weather conditions has become more evident in some regions, particularly Africa (*medium to high confidence*). A negative impact of long-term climate change on crop yields has been identified in some regions (e.g., wheat yields in Europe) (*medium confidence*) while studies are still inconsistent in other regions. {16.2.3.4}

Climate change has increased observed heat-related mortality (*medium confidence*) and contributed to the observed latitudinal or altitudinal range expansion of vector- borne diseases into previously colder areas (*medium to high confidence*) while evidence on the impact of long-term climate change on water-borne diseases is largely lacking. Overall, there is extensive observational evidence that extreme ambient temperatures increase human mortality (*high confidence*) and that the occurrence of water- and vector-borne diseases is sensitive to weather conditions (*high confidence*). {16.2.3.5, 16.2.3.6, 16.2.3.7}

Extreme weather events not only cause substantial direct economic damage (*high confidence*), but also reduce economic growth in the short-term (year of, and year after event) (*high confidence*) as well as in the long-term (up to 15 years after the event) (*medium confidence*), with more severe impacts in developing than in industrialized economies (*high confidence*). Evidence has increased for all of these conclusions; however, evidence for impacts of long-term climate change is still limited. {16.2.3.7}

Climate variability and extremes are associated with increased prevalence of conflict, with more consistent evidence for low-intensity organized violence than for major armed conflict (*medium confidence*). Compared to other socio-economic drivers, the link is relatively weak (*medium confidence*) and conditional on high population size, low socioeconomic development, high political marginalization, and high agricultural dependence (*medium confidence*). Literature also suggests a larger climate-related influence

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

on the dynamics of conflict than on the likelihood of initial conflict outbreak (*low confidence*). There is insufficient evidence at present to attribute armed conflict to climate change. {16.2.3.8}

There is high confidence that anthropogenic climate forcing has had an impact on internal displacement, given the observed impact of anthropogenic climate forcing on the occurrence of weather extremes (*high confidence*, Table SM16.21) and the strong contribution of weather extremes to observed displacement (*high confidence*). However, the link between long-term changes in the climate-related systems has not been demonstrated systematically and so far there is no attribution of observed trends in displacement to long-term changes in the climate-related systems. Links between weather fluctuations (including extreme events) and human mobility are complex and conditional on socio-economic situations; e.g., poor populations may more often be involuntarily displaced or 'trapped' and not be able to migrate. {16.2.3.9}

Observed adaptation in ecosystems

While species are increasingly responding to climate change, these responses may not be adaptive or sufficient to cope with the rate of climate changes (*high confidence*). Responses have been documented in a range of species, including for example changes in the timing of breeding and migration. It is unclear whether these responses reflect long-term evolutionary adaptation or short-term coping mechanisms. Existing assessments indicate that some species' responses will be insufficient to avert extinction. {16.3.1}

Observed adaptation-related responses in human systems

Responses across all sectors and regions reported in the scientific literature are dominated by minor modifications to usual practices or measures for dealing with extreme weather events, whilst evidence of transformative adaptation in human systems is low (*high confidence*). Responses have accelerated in both developed and developing regions since AR5, with some examples of regression. Despite this, there is negligible evidence in the scientific literature documenting responses that are simultaneously widespread, rapid, and that challenge norms and adaptation limits. {16.3.2.3}

There is negligible evidence that existing responses are adequate to reduce climate risk (*high confidence*). There is some evidence of global vulnerability reduction, particularly for mortality and economic losses due to flood risk and extreme heat. (16.3.2.4) Evidence on the effectiveness of specific adaptations remains limited. There is negligible robust evidence to assess the overall adequacy of the global adaptation response to address the scale of climate risk. No studies have systematically assessed the adequacy and effectiveness of adaptation at a global scale, across nations or sectors, or for different levels of warming. {16.3.2.3}

Adaptation responses are showing co-benefits, for mitigation and other societal goals (*high confidence*). There is increasing evidence of co-benefits of adaptation responses. Co-benefits are most frequently linked to changes in agricultural practices (e.g., conservation agriculture), land use management (e.g., agroforestry), building technologies (e.g., building efficiency standards), and urban design (e.g., walkable neighbourhoods). {16.3.2.3}

Evidence of maladaptation is increasing (*high confidence*), i.e. adaptation that increases climate risk or creates new risks in other systems or for other actors. Globally, maladaptation has been reported most frequently in the context of agriculture and migration in the global south. {16.3.2.6}

Limits to adaptation across natural and human systems

There is increasing evidence on limits to adaptation which result from the interaction of adaptation constraints and can be differentiated into soft and hard limits (*high confidence*). Soft limits may change over time as additional adaptation options become available. Hard limits will not change over time as no additional adaptive actions are possible. Evidence focuses on constraints that may lead to limits at some point of the adaptation process, with less information on how limits may be related to different levels of socio-economic or climatic change (*high confidence*). {16.4.1, 16.4.2, 16.4.3}

Limits to adaptation have been identified for terrestrial and aquatic species and ecosystems, coastal communities, water security, agricultural production, and human health and heat (*high confidence*). Beginning at 1.5°C, autonomous and evolutionary adaptation responses by terrestrial and aquatic species and ecosystems face hard limits, resulting in biodiversity decline, species extinction and loss of related livelihoods (*high confidence*). Beginning at 3°C, hard limits are projected for water management measures, leading to decreased water quality and availability, negative impacts on health and wellbeing, economic losses in water and energy dependent sectors and potential migration of communities (*medium confidence*). Adaptation to address risks of heat stress, heat mortality and reduced capacities for outdoor work for humans face soft and hard limits across regions beginning at 1.5°C, and are particularly relevant for regions with warm climates (*high confidence*). {16.4.2, 16.4.3}

Soft limits are currently being experienced by individuals and households along the coast and by small-scale farmers (*medium confidence*). As sea levels rise and extreme events intensify, coastal communities face soft limits due to financial, institutional and socio-economic constraints reducing the efficacy of coastal protection and accommodation approaches and resulting in loss of life and economic damages (*medium confidence*). {16.4.2, 16.4.3}

Hard limits for coastal communities reliant on nature-based coastal protection will be experienced beginning at 1.5°C (*medium confidence*). Soft and hard limits for agricultural production are related to water availability and the uptake and effectiveness of climate-resilient crops which are constrained by socio-economic and political challenges (*medium confidence*). {16.4.2, 16.4.3}

Across regions and sectors, the most significant determinants of soft limits are financial, governance, institutional and policy constraints (*high confidence*). The ability of actors to overcome these socio-economic constraints largely influence whether additional adaptation is able to be implemented and prevent soft limits from becoming hard. While the rate, extent and timing of climate hazards largely determine hard limits of biophysical systems, these factors appear to be less influential in determining soft limits for human systems (*medium confidence*). {16.4.2, 16.4.3}

Financial constraints are important determinants of limits to adaptation, particularly in low-to-middle income countries (*high confidence*). Impacts of climate change may increase financial constraints (*high confidence*) and contribute to soft limits to adaptation being reached (*medium confidence*). Global and regional evidence shows that climate impacts may limit the availability of financial resources, stunt national economic growth, result in higher levels of losses and damages and thereby increase financial constraints. {16.4.3.2, 16.4.3.3}

Key risks across climate and development pathways

Regional and sectoral chapters of this report identified over 130 Key Risks (KRs) that could become severe under particular conditions of climate hazards, exposure, and vulnerability. These key risk are represented in eight so-called Representative Key Risks (RKRs) clusters of key risks relating to low-lying coastal systems; terrestrial and ocean ecosystems; critical physical infrastructure, networks and services; living standards; human health; food security; water security; and peace and mobility (*high confidence*). A key risk is defined as a potentially 'severe' risk, i.e. that is relevant to the interpretation of dangerous anthropogenic interference (DAI) with the climate system. Key risks cover scales from the local to the global, are especially prominent in particular regions or systems, and are particularly large for vulnerable subgroups, especially low-income populations, and already at-risk ecosystems (*high confidence*). The conditions under which RKRs would become severe have been assessed along levels for warming, exposure/vulnerability, and adaptation: for warming, high refers to climate outcomes consistent with RCP8.5 or higher, low refers to climate outcomes consistent with RCP2.6 or lower, and medium refers to intermediary climate scenarios; exposure/vulnerability levels are relative to the range of future conditions considered in the literature; for adaptation, high refers to near maximum potential and low refers to the continuation of today's trends. (6.5.2.1, 16.5.2.2, Table SM16.4).

For most Representative Key Risks (RKRs), potentially global and systemically pervasive risks become severe in the case of high warming, combined with high exposure/vulnerability, low adaptation, or both (*high confidence*). Under these conditions there would be severe and pervasive risks to

critical infrastructure and to human health from heat-related mortality (*high confidence*), to low-lying coastal areas, aggregate economic output, and livelihoods (all *medium confidence*), of armed conflict (*low confidence),* and to various aspects of food security (with different levels of confidence). Severe risks interact through cascading effects, potentially causing amplification of RKRs over the course of this century (*low evidence, high agreement*). {16.5.2.3, 16.5.2.4, 16.5.4, Figure 16.10}
For some RKRs, potentially global and systemically pervasive risks would become severe even with medium to low warming (i.e. 1.5-2°C) if exposure/vulnerability is high and/or adaptation is low (*medium to high confidence*). Under these conditions there would be severe and pervasive risks associated with water scarcity and water-related disasters (*high confidence*), poverty, involuntary mobility, and insular ecosystems and biodiversity hotspots (all *medium confidence*). {16.5.2.3, 16.5.2.4}

All potentially severe risks that apply to particular sectors or groups of people at more specific regional and local levels require high exposure/vulnerability or low adaptation (or both), but do not necessarily require high warming (*high confidence*). Under these conditions there would be severe, specific risks to low-lying coastal systems, to people and economies from critical infrastructure disruption, economic output in developing countries, livelihoods in climate-sensitive sectors, waterborne diseases especially in children in low- and middle-income countries, water-related impacts on traditional ways of life, and involuntary mobility for example in small islands and low-lying coastal areas (*medium to high confidence*). {16.5.2.3, 16.5.2.4}

Some severe impacts are already occurring (*high confidence*) and will occur in many more systems before mid-century (*medium confidence*). Tropical and polar low-lying coastal human communities are experiencing severe impacts today (*high confidence*), and abrupt ecological changes resulting from mass population-level mortality are already observed following climate extreme events. Some systems will experience severe risks before the end of the century (*medium confidence*), for example critical infrastructure affected by extreme events (*medium confidence*). Food security for millions of people, particularly low-income populations, also faces significant risks with moderate to high warming or high vulnerability, with a growing challenge by 2050 in terms of providing nutritious and affordable diets (*high confidence*). {16.5.2.3, 16.5.3}

In specific systems already marked by high exposure and vulnerability, high adaptation efforts will not be sufficient to prevent severe risks from occurring under high warming (*low evidence, medium agreement*). This is particularly the case for some ecosystems and water-related risks (from water scarcity and to indigenous and traditional cultures and ways of life). {16.5.2.3, 16.5.2.4, 16.5.3}

Interconnectedness and globalization establish pathways for the transmission of climate-related risks across sectors and borders, for instance through trade, finance, food, and ecosystems (*high confidence*). Examples include semiconductors, global investments, major food crops like wheat, maize and soybean, and transboundary fish stocks. There are knowledge gaps on the need for, effectiveness of, and limits to adaptation to such interregional risks {Cross-Chapter Box INTERREG in this Chapter}

Key risks increase the challenges in achieving global sustainability goals (*high confidence*). The greatest challenges will be from risks to water (RKR-G), living standards (RKR-D), coastal socio-ecological systems (RKR-A) and peace and human mobility (RKR-H). The most relevant goals are Zero hunger (SDG2), Sustainable cities and communities (SDG11), Life below water (SDG14), Decent work and economic growth (SDG8), and No poverty (SDG1). Priority areas for regions are indicated by the intersection of hazards, risks and challenges, where, in the near term, challenges to SDGs indicate probable systemic vulnerabilities and issues in responding to climatic hazards. (*high confidence*) {16.6.1}

The scale and nature of climate risks is partly determined by the responses to climate change, not only in how they reduce risk, but also how they may create other risks (sometimes inadvertently, and sometimes to others than those who implement the response, in other places, or later in time).

Solar Radiation Modification (SRM) approaches have potential to offset warming and ameliorate other climate hazards, but their potential to reduce risk or introduce novel risks to people and ecosystems is not well understood (*high confidence*). SRM effects on climate hazards are highly dependent on deployment scenarios and substantial residual climate change or overcompensating change would occur at regional scales and seasonal timescales (*high confidence*). Due in part to limited research, there is low confidence in projected benefits or risks to crop yields, economies, human health, or ecosystems. Large negative impacts are projected from rapid warming for a sudden and sustained termination of SRM in a high-CO2 scenario. SRM would not stop CO2 from increasing in the atmosphere or reduce resulting ocean acidification under continued anthropogenic emissions (*high confidence*). There is high agreement in the literature that for addressing climate change risks SRM is, at best, a supplement to achieving sustained net zero or net negative CO2 emission levels globally. Co-evolution of SRM governance and research provides a chance for responsibly developing SRM technologies with broader public participation and political legitimacy, guarding against potential risks and harms relevant across a full range of scenarios. [Cross-Working Group Box SRM}

Recent global estimates of the economic cost of climate impacts exhibit significant spread and generally increase with global average temperature, as well as vary by other drivers, such as income, population and composition of the economy (*high confidence*). The wide variation across disparate methodologies does not allow a robust range of damage estimates to be identified with confidence, though the spread of estimates increases with warming in all methodologies, indicating higher risk (in terms of economic costs) at higher temperatures (*high confidence*). Reconciling methodological variance is a priority for facilitating use of different lines of evidence; however, that some new estimates are higher than the AR5 range indicates that global aggregate economic impacts could be higher than previously assessed (low confidence due to the lack of robustness and comparability across methodologies). {Cross-Working Group Box ECONOMIC in Chapter 16}

Reasons for Concern across scales

The five major Reasons for Concern (RFCs), describing risks associated with (1) unique and threatened systems, (2) extreme weather events, (3) distribution of impacts, (4) global aggregate impacts, and (5) large-scale singular events, were updated using expert elicitation. RFC risk levels were assessed with no or low adaptation, but limits to adaptation are a factor in the identification of very high risk levels.

Compared to AR5 and SR15, risks increase to high and very high levels at lower global warming levels for all five RFCs (*high confidence*), and transition ranges are assigned with greater confidence. Transitions from high to very high risk emerge in all five RFCs, compared to just two RFCs in AR5 (*high confidence*). {16.6.3, Figure 16.15}

- For unique and threatened systems (RFC1), as before, levels of risk at a given level of warming are higher than for the other RFCs. Risks are already (at current warming of 1.1ºC) in the transition from moderate to high (*very high confidence*), compared to moderate in AR5 and SR15, based on observed and modelled impacts. The transition to very high risk occurs between 1.2ºC and 2.0ºC warming *(high confidence)*. {16.6.3.1}

- For risks from extremes (RFC2), the transition to high risk is between 1.0ºC and 1.5ºC (high confidence) and to very high risk (new in AR6) between 1.8 and 2.5ºC (*medium confidence*). {16.6.3.2}

- For risks disproportionately affecting particularly vulnerable societies and socio-ecological systems, including disadvantaged people and communities in countries at all levels of development (RFC3), current risk is moderate (*high confidence*) and the transition to high risk is between 1.5–2.0ºC warming (*medium confidence)*. The transition to very high risk occurs at between 2.0–3.5ºC warming (*medium confidence*). {16.6.3.3}

- The risk of global aggregate impacts, including monetary damages, lives affected, species lost or ecosystem degradation at a global scale (RFC4), has begun to transition to moderate risk (*medium confidence*), with a transition to high risk between 1.5–2.5ºC (*medium confidence*) and to very high risk (new in AR6) at between 2.5 and 4.5ºC (*low confidence*). {16.6.3.4}

- Present-day risks associated with large-scale singular events (sometimes called tipping points or critical thresholds) (RFC5) are already moderate (*high confidence*), with a transition to high risk between

1.5–2.5ºC (*medium confidence*) and to very high risk (new in AR6) between 2.5–4ºC (*low confidence*). {16.6.3.5}

Limiting global warming to 1.5ºC would ensure risk levels remain moderate for RFC3, RFC4 and RFC5 (*medium confidence*) but risk for RFC2 would have transitioned to a high risk at 1.5ºC and RFC1 would be well into the transition to very high risk (*high confidence*). Remaining below 2ºC warming (but above 1.5ºC) would imply that risk for RFC3 through 5 would be transitioning to high, and risk for RFC1 and RFC2 would be transitioning to very high (*high confidence*). By 2.5ºC warming, RFC1 will be in very high risk (*high confidence*) and all other RFCs will have begun their transitions to very high risk (medium confidence for RFC2 and RFC3, low confidence for RFC4 and RFC5).

RFC1, RFC2 and RFC5 include risks that are irreversible, such as species extinction, coral reef degradation, loss of cultural heritage, or loss of a small island due to sea level rise. Once such risks materialise, as is expected at very high risk levels, the impacts would persist even if global temperatures would subsequently decline to levels associated with lower levels of risk in an 'overshooting' scenario (*high confidence*). {16.6.3}

16.1 Introduction and Framing

16.1.1 Objective of the Chapter

Anthropogenic climate change poses risks to many human and ecological systems. These risks are increasingly visible in our day-to-day lives, including a growing number of disasters that already bear a fingerprint of climate change. There is increasing concern about how these risks will shape the future of our planet – our ecosystems, our well-being and development opportunities. Policy makers are asking what is known about the risks, and what can be done about them. Many people and especially youth around the world are calling for urgency, ambition and action. Companies are wondering how to manage new threats to their bottom line, or how to grasp new opportunities. On top of this growing concern about climate change, the COVID-19 pandemic has exposed vulnerabilities to shocks, significantly aggravated climate-related risks, and posed new questions about how to achieve a green, resilient and inclusive recovery (see Cross-Chapter Box COVID in Chapter 7).

The three synthesis chapters of this report (16, 17 and 18) aim to address these concerns. They synthesize information from across all thematic and regional Chapters of the Working Group (WGII) Sixth Assessment Report (AR6) and the recent IPCC Special Reports on Global Warming of 1.5ºC, on Climate Change and Land, and on Ocean and Cryosphere in a Changing Climate (SR15, SRCCL and SROCC), but also include an independent assessment of the literature, especially literature that cuts across sectors and regions.

Chapter 16 lays the groundwork by synthesizing the state of knowledge on the observed impacts of climate change (Section 16.2) and ongoing adaptation responses (Section 16.3), the limits to adaptation (Section 16.4), and the key risks we should be concerned about, how these risks evolve with global temperature change, and also how they depend on future development and adaptation efforts (Sections 16.5 and 16.6). It thus brings together elements that were assessed in different chapters in previous assessments, especially the Third, Fourth and Fifth Assessment Reports (TAR, AR4, and AR5, respectively). Background on specific methodological aspects of this chapter is provided in Supplementary Material..

The strong link between risks, adaptation and development connects this chapter closely to Chapters 17 and 18. Chapter 17 assesses decision-making: what do we know about the ways to manage risks in a warming climate (including in the context of the key risks and limits to adaptation identified in this chapter)? Chapter 18 puts all of this information into the perspective of climate-resilient development pathways: how can we achieve sustainable development given the additional challenges posed by climate change?

16.1.2 Risk Framing

In the IPCC AR6, 'risk' is defined as the potential for adverse consequences for human or ecological systems, recognizing the diversity of values and objectives associated with such systems. Relevant adverse consequences include those on lives, livelihoods, health and well-being, economic, social and cultural assets and investments, infrastructure, services (including ecosystem services), ecosystems and species (Chapter 1 this volume, SR15). The AR6 definition explicitly notes that 'risks can arise from potential impacts of climate change as well as human responses to climate change.'

The main risks assessed here relate to the potential *impacts* of climate change. In recent years, the growing visibility of current climate impacts has resulted in a stronger focus on understanding and managing such risk across timescales, rather than just for the longer-term future. Examples include the rapid growth in attribution of specific extreme weather events, the use of scientific evidence of climate change impacts in legal cases, the context of the Paris Agreement's Article 8 on 'averting, minimizing and addressing loss and damage' associated with climate change, but also the stronger links between adaptation and disaster risk reduction, including early warning systems, wider discussions on how to build resilience in the face of a more volatile climate, and attention for limits to adaptation that are already being reached.

Of course the scale of these risks is also determined by the *responses* to climate change, mainly in how they reduce risk, but also how they may create risks (sometimes inadvertently, and sometimes to others than those who implement the response, in other places, or later in time). Our focus is on adaptation responses, given that mitigation is covered in WGIII AR6, but we acknowledge certain important interactions, such as biomass-production as an alternative to fossil fuels which can compete with food production and thus aggravate adaptation challenges. Given that solar radiation modification (SRM) could also be considered a response with significant implications for climate risks across scales, this chapter also includes Cross-Working Group Box SRM.

This assessment focuses primarily on *adverse* consequences of climate change. However, climate change also has *positive* implications (benefits and opportunities) for certain people and systems, although there are gaps in the literature on these positive effects. Some risks assessed in this chapter are actually about a balance between positive and negative effects of climate change (and of response options, especially adaptation). In those contexts, we assess the combined effect of both, aiming to identify not only the aggregate impacts (the balance between positive and negative effects) but also the distributional aspects (winners and losers). A more comprehensive discussion of the decision-making related to such trade-offs in relation to adaptation is provided in Chapter 17.

This chapter's assessment takes a global perspective, although many risks and responses materialise at the local or national scale. We use case studies to illustrate the ways these risks aggregate across scales, again with particular concern for distributional aspects.

16.1.3 Storyline of the Chapter, and What's New Compared to Previous Assessments

Figure 16.1 illustrates the elements covered by the chapter, which can be summarised as four key questions.

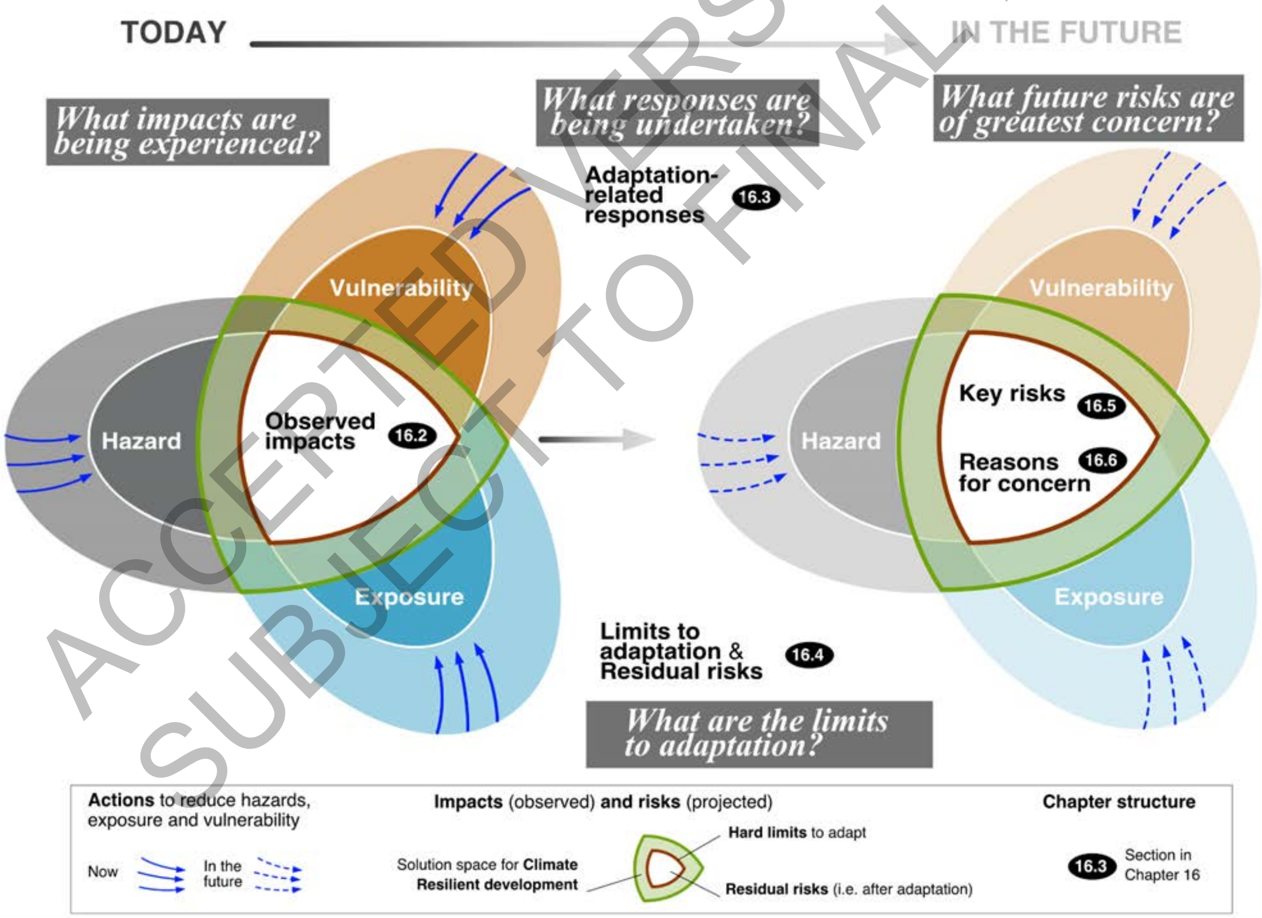

Figure 16.1. Illustrative storyline of the chapter highlighting the central questions addressed in the various sections, going from realized risks (observed impacts) to future risks (key risks and reasons for concern), informed by adaptation-related responses and the limits to adaptation. The pink arrows illustrate actions to reduce hazard, exposure and vulnerability, which shape risks over time. Accordingly, the green areas at the centre of the propeller diagrams indicate the ability for such solutions to reduce risk, up to certain adaptation limits, leaving the white residual risk (or observed impacts) in the centre. The shading of the right-hand side propeller diagram compared to the non-shaded one on the left reflects some degree of uncertainty about future risks. The figure builds on the conceptual framework of risk-adaptation-relationships used in SROCC (Garschagen et al., 2019).

16.1.3.1 What Impacts are Being Experienced?

This assessment of climate related impacts that are already taking place is covered in Section 16.2, which aims to differentiate between observed changes in climate hazards (also called 'climate impact drivers' in IPCC Working Group I) and the exposure and vulnerability of human and ecological systems.

Observed impacts of climate change were synthesized in the TAR, AR4 and AR5. The TAR found that recent regional climate changes had already affected many physical and biological systems, with preliminary indications that some human systems had been affected, primarily through floods and droughts. AR4 found *likely*[2] discernible impacts on many physical and biological systems, and more limited evidence for impacts on human environments. AR5 devoted a separate chapter to observed impacts, which found growing evidence of impacts on human and ecological systems on all continents and across oceans (Cramer et al., 2014).

Section 16.2 reports on the expanded literature since then, generally reflecting a growing and more certain impact of climate change on humans and ecological systems.

16.1.3.2 What Responses are Being Undertaken?

Section 16.3 provides, for the first time, a comprehensive synthesis of observed adaptation-related responses to the rising risks.

Such adaptation responses were first covered in the TAR, and further developed in the AR4 and AR5. For instance, AR5 Chapter 15 notes that adaptation to climate change was transitioning from a phase of awareness to the construction of actual strategies and plans in societies (Mimura et al., 2014) but did not include a comprehensive mapping of responses.

Based on such a comprehensive mapping, Section 16.3 finds growing evidence of adaptation-related responses, although these are dominated by minor modifications to usual practices or measures for dealing with extreme weather events, and there is limited evidence for the extent to which they reduce climate risk.

16.1.3.3 What are the Limits to Adaptation?

The literature on limits to adaptation, which is covered in Section 16.4, has strongly evolved since AR5, including links to discussions on Loss and Damage in the UNFCCC. While the SPM of AR4 noted that there was no clear picture of the limits to adaptation, or the cost, AR5 Chapter 16 (Klein et al., 2014) reported increasing insights emerging from the interactions between climate change and biophysical and socioeconomic constraints, and highlighted the fact that limits could be both hard and soft. It also noted that residual losses and damages will occur from climate change despite adaptation and mitigation action. However, AR5 Chapter 16 still found that the empirical evidence needed to identify limits to adaptation of specific sectors, regions, ecosystems, or species that can be avoided with different GHG mitigation pathways was lacking.

Section 16.4 provides a more comprehensive assessment of limits to adaptation, highlighting again that limits to adaptation are not fixed, but are properties of dynamic socio-ecological systems. They are shaped not only by the magnitude of the climate hazards (e.g., the amount of sea level rise in low lying coasts and islands), and the exposure and vulnerability to those hazards (e.g., people and assets in those areas), but also by physical, infrastructural and social tolerance thresholds and adaptation choices of actors in societies (e.g., the decision to migrate from locations strongly impacted by climate change). The evolution of such socio-

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

economic systems over time, including their interaction with the changing physical climate, determines the evolution of limits to adaptation.

16.1.3.4 What Future Risks are of Greatest Concern?

The fourth and final element of the chapter is the question about the risks we face, and which ones we should be most concerned about. This is addressed in Section 16.5 and 16.6.

Section 16.5.1 presents a full discussion of 'key risks', synthesized from across all chapters, defined as those risks that are potentially severe and therefore especially relevant to the interpretation of 'dangerous anthropogenic interference with the climate system' in the terminology of UNFCCC Article 2.

In 2015 the Paris Agreement established the goal of 'holding the increase in the global average temperature to well below 2°C above pre-industrial levels and pursuing efforts to limit the temperature increase to 1.5°C above pre-industrial levels'. However, assessment of key risks across a range of future warming levels remains a high priority for several reasons: (1) understanding risks at higher levels of warming can help prepare for them, should efforts to limit warming be unsuccessful (UNEP, 2017); (2) understanding risks at higher levels can inform the benefits of limiting warming to lower levels; (3) in addition, there is continued debate about whether warming limits should be at or rather somewhere below 2ºC (in particular at 1.5ºC); and (4) there is a more explicit recognition that key risks can result not only from increased warming, but also from changes in the exposure and vulnerability of society, and from a lack of ambitious adaptation efforts. So relatively limited warming does not automatically imply that key risks will not occur. In assessing key risks, we have applied four criteria: magnitude of adverse consequences, likelihood of adverse consequences, temporal characteristics of the risk, and ability to respond. Of course, this is an aggregated approach to what is dangerous; it should be noted that in practice, 'dangerous' will occur at a myriad of temperature levels depending on who or what is at risk (and their circumstances), geographic scale and time scale.

A new element is that we particularly look at a set of eight 'representative key risks' that exemplify the underlying set of key risks identified in the earlier chapters: risk to the integrity of low-lying coastal socio-ecological systems, risk to terrestrial and ocean ecosystems, risk to critical physical infrastructure and networks, risk to living standards (including economic impacts, poverty and inequality), risk to human health, risk to food security, risk to water security, and risk to peace and mobility (Section 16.5.2.3). Another increased focus relates to the issue of compound risks. This includes risks associated with compound hazards (WGI AR6 Chapter 11, Seneviratne et al., 2021), but also implications for future risk when repeated impacts erode vulnerability, as well as through transboundary effects (including effects both from one system to a neighbouring one, as well as from one system to a distant one), also discussed in the cross-chapter box on interregional risks and adaptation (Cross-Chapter Box INTEREG in this Chapter).

Section 16.6 maps the representative key risks in Section 16.5 to the Sustainable Development Goals, noting both direct and indirect implications for Climate Resilient Development as assessed in Chapter 18.

Finally, section 16.6 presents an updated assessment of the so-called 'Reasons for Concern' (RFC): risks related to unique and threatened systems, extreme events, distribution of impacts, aggregate impacts (including the cross-chapter box on the global economic impacts of climate change and the social cost of carbon, Cross-Working Group Box ECONOMIC) and the risk of irreversible and abrupt transitions.

The AR4 and AR5 each also evaluated the most important climate risks, framed firstly in terms of the state of knowledge relevant to Article 2 of the UNFCCC. The TAR first synthesized this knowledge in five RFCs. AR4 identified a set of 'key vulnerabilities', and provided an update of the RFCs. AR5 further refined a new risk framework developed in SREX, and used it to assess 'key risks' and provide another update of the overarching Reasons for Concern, drawing as well on Cramer et al. (2014) assessment of observed changes.

Our risk assessment also further builds on risk assessments from the Special Reports that are part of the AR6 cycle, i.e. SR15; SRCCL, and SROCC. While since AR4 the RFC assessment framework has remained largely consistent, refinements in methodology have included the consideration of different risks, the role of adaptation, use of confidence statements, more formalized protocols and standardized metrics (Zommers et al., 2020). In subsequent assessment cycles, the risk level at a given temperature has generally increased, reflecting accumulating scientific evidence (Zommers et al., 2020).

16.1.4 Drivers of Exposure and Vulnerability

While this chapter focuses on climate-related impacts, risks and responses, these all take place against a backdrop of trends in exposure and vulnerability driven by demographics, socio-economic development (including inequalities) and ecosystem degradation. Other global trends that are shaping climate risks include technological innovation, shifts in global power relations, and resource scarcity (Retief et al., 2016). Note that these global trends may *increase* but also *reduce* exposure and/or vulnerability, for instance when growing incomes, savings and social protection systems increase resilience in the face of shocks and stresses. Drivers and future trends in vulnerability and exposure – next to climate-induced changes in natural hazards – therefore need to be considered in comprehensive risk assessments and eventually adaptation solutions, but empirical research suggests that they remain to be underemphasized in current national adaptation planning (Garschagen et al., 2021a).

While these risk drivers are often listed separately, they are often closely interconnected, including between human and ecological systems, and increasingly also through climate risks and responses (e.g., Simpson et al., 2021). Climate impacts increasingly affect these drivers, and may compete with financial resources that could otherwise be applied for development, mitigation, adaptation and resilience building, also affecting inequalities (e.g., Taconet et al., 2020).

16.1.4.1 Demographics

Population growth (or decline) can result in increasing (or decreasing) pressure on natural resources (e.g., soils, water and fish stocks) (IPBES, 2019), and can result in the expansion of densely populated areas (Cardona et al., 2012; Day et al., 2016). A majority of the population in the coming decades will be in urban areas. While urbanization can have many benefits that reduce vulnerability, such as employment opportunities and increased income, better access to healthcare and education, and improved infrastructure, unsustainable urbanisation patterns can create challenges for resource availability, exacerbate pollution levels (Rode et al., 2015), and increase exposure to some risks. For example, ~10% of the global population live in Low Elevation Coastal Zones (in 2000; areas <10 m of elevation) (McGranahan et al., 2007; Neumann et al., 2015), which is expected to increase by 5% to 13.6% by 2100 depending on the population scenario (Neumann et al., 2015; Jones and O’Neill, 2016). Building assets and infrastructure in naturally risk-prone areas are also projected to increase (Magnan et al., 2019), which may also lead to environmental degradation that can further aggravate risk, e.g., destruction of wetlands that buffer against floods (Schuerch et al., 2018; Oppenheimer et al., 2019). Demographic trends, coupled with changes in income, can also result in increasing demands for land, food, water and energy, and therefore to major changes in land use and cover change (Arneth, 2019). The observed and projected population decline in some rural areas also has implications for vulnerability and exposure. In addition, demographic changes such as aging may increase vulnerability to some climate hazards, including heat stress (Byers et al., 2018; Rohat et al., 2019a; Rohat et al., 2019b).

16.1.4.2 Biodiversity and Ecosystems

Rapidly accelerating trends in human impacts on global ecosystems and biodiversity, especially in the past 5 decades, have resulted precipitous declines in the numbers of many wild species on land and in the ocean, transformation of the terrestrial land surface for agricultural production, and the pervasive spread of alien and invasive species (IPBES, 2019). As a result, the capacity of ecosystems to support human society is thought to be coming under threat. For instance, the fraction of all primary production being appropriated for human use has doubled over the course of the 20th Century (to about 25% in 2005), although it has grown at a slower rate than human population (Krausmann et al., 2013). Future projections significantly depend on bioenergy production, signalling one of the feedbacks between responses to climate change and climate risks.

16.1.4.3 Poverty Trends and Socioeconomic Inequalities Within and Across Societies

Poverty contributes to exposure and vulnerability by limiting access of individuals, households and communities to economic resources and restraining adaptive capacities (e.g., for food and energy supply, or for financing adaptation responses) (Hallegatte and Rozenberg, 2017). Over the past decades, until the COVID-19 pandemic, global poverty rates have declined rapidly. Between 1981 and 2015, the share of global population living in extreme poverty (under the international poverty line of US$1.90 per day) declined from 42% to 10%, leaving 736 million people in extreme poverty, concentrated in South Asia and Sub-Saharan Africa (World Bank, 2018). This general reduction in poverty across the world is accompanied by a decrease in vulnerability to many types of climate change impacts (*medium confidence*). However, the COVID-19 pandemic has significantly increased extreme poverty by about 100 million people in 2020, with disproportionate economic impacts on the poorest, most fragile and smaller countries (World Bank, 2021) and significant implications for vulnerability to climate change (see also Cross-Chapter Box COVID in Chapter 7).

The majority of the population in poverty are smallholder farmers and pastoralists, whose livelihoods critically depend on climate-sensitive natural ecosystems, e.g., through semi-subsistence agriculture where food consumption is primarily dependent on households' own food production (Mbow et al., 2019). A significant share of this population is affected by armed conflict, which deters economic development and growth and increases local dependence on subsistence agriculture (Serneels and Verpoorten, 2015; Braithwaite et al., 2016; Tollefsen, 2017), and aggravating humanitarian challenges (e.g., ICRC, 2020). Extreme weather events, particularly droughts, can result in poverty traps keeping people poor or making them poorer, resulting in widening inequalities within and across countries.

Climate risks are also strongly related to other inequalities, often but not always intersecting with poverty. AR5 found with very high confidence that differences in vulnerability and exposure arise from multidimensional inequalities, often produced by uneven development processes. These inequalities relate to geographic location, as well as economic, political and socio-cultural aspects, such as wealth, education, race/ethnicity, religion, gender, age, class/caste, disability, and health status (Oppenheimer et al., 2014). Since AR5, a number of studies have confirmed and refined this assessment, especially also regarding socio-economic inequality and poverty (Hallegatte et al., 2016; Hallegatte and Rozenberg, 2017; Pelling and Garschagen, 2019; Hallegatte et al., 2020). Poor people more often live in exposed areas such as wastelands or riverbanks (Garschagen and Romero-Lankao, 2015; Winsemius et al., 2018). Also, poor people lose more of their total wealth to climatic hazards, receive less post-shock support from their often-times equally poor social networks, and are often not covered by social protection schemes (Leichenko and Silva, 2014; Hallegatte et al., 2016). Countries with high inequality tend to have above-average levels of exposure and vulnerability to climate hazards (BEH UNU-EHS, 2016). Many socio-economic models used in climate research have been found to have a limited ability to capture and represent the poor at a larger scale (Rao et al., 2019; Rufat et al., 2019). However, an analysis of 92 countries found that relative income losses and other climate change impacts were disproportionately high among the poorest (Hallegatte and Rozenberg, 2017, see Section 16.2.6). There have also been advances in detecting and attributing the impacts of climate change and vulnerability at household scale and specifically on women's agency and adaptive capacity (Rao et al., 2019). The distribution of impacts and responses (adaptation and mitigation) affects inequality, not just between countries, but also within countries (e.g., Tol, 2020) and between different people within societies. Distribution has so far largely been thought of in a geographical sense, but identifying those most at risk requires an additional focus on the social distribution of impacts, responses, as well as of resilience, as influenced for instance by differential social protection coverage (Tenzing, 2020).

Many climate responses interact with all of these global risk drivers. Some raise additional equity concerns about marginalising those most vulnerable and exacerbating social conflicts (Oppenheimer et al., 2019), leading to wider questions about the governance of climate risks (and impacts) across scales. Hence, our assessment of impacts, responses, and risks is complemented by the assessment of governance and the enabling environment for risk management in Chapter 17, and of climate-resilient development in Chapter 18.

16.2 Synthesis of Observed Impacts

This section synthesizes the observed impacts of changes in climate-related systems (see Section 16.2.1) on different natural, human, and managed systems (outlined in Chapters 2-8) and regions (outlined in Chapters 9-15). To stay as specific as possible given the required level of aggregation, we decided in favour of a summary along specific prominent indicators such as 'crop yields' or 'areas burned by wildfires' instead of an assessment across broad categories such as 'food production' which could include a broad range of measures ranging from climate induced changes in growing seasons to growing seasons to impacts on livestock and fisheries etc. or 'wildfires' which could also cover impacts on the frequency, intensity, timing, or emissions and health impacts of wildfires. However, this decision for specificity certainly implies a decision against comprehensiveness. In addition, the level of specificity has to be adjusted given the literature basis which is quite broad regarding crop yields but still limited and less harmonized regarding indicators when it comes to e.g., conflicts. A broader discussion can be found in the sectoral or regional chapters that all cover 'observed impacts' individually. Section 16.2.1 provides key definitions, followed by recent advances in available methods and data for climate impact attribution (Section 16.2.2), and the assessment of observed impacts (Section 16.2.3). It is important to note that the assessment is primarily based on peer-reviewed literature, i.e. it is limited to the regions and phenomena for which such studies are available. So 'no assessment' in a certain region does not apply the considered type of impact did not occur in this region.

16.2.1 Definitions

The section adopts the general definition of **detection** as 'demonstration that a considered system has changed without providing reasons for the change' and **attribution** as identifying the causes of the observed change or a specific event (see Glossary).

Based on these general definitions and following the approach applied in WGII AR5 Chapter 18 (Cramer et al., 2014), we define an **observed impact** as the difference between the observed state of a **natural, human, or managed system** and a counterfactual baseline that characterizes the system's state in the absence of changes in the **climate-related systems** defined here as climate system including the ocean and the cryosphere as physical or chemical systems.

The difference between the observed and the counterfactual baseline state is considered the change in the natural, human, or managed system that is attributed to the changes in the climate-related systems (**impact attribution**).The counterfactual baseline may be stationary or may change over time, for example due to direct human influences such as changes in land use patterns, agricultural or water management affecting exposure and vulnerability to climate related hazards (see Section 16.2.3 for methods on how to construct the counterfactual).

In line with the AR5 definition, 'changes in climate-related systems' here refer to any long-term trend, irrespective of the underlying causes; thus, an observed impact is not necessarily an observed impact of anthropogenic climate forcing. For example, in this section sea level rise is defined as relative sea level rise measured against a land-based reference frame (tide gauge measurements), meaning that it is driven not only by thermal expansion and loss of land ice influenced by anthropogenic climate forcing, but also by vertical land movements. As attribution of coastal damages to sea level rise does not distinguish between these components it does not imply attribution to anthropogenic forcing. Where the literature does allow attribution of changes in natural, human or managed systems to anthropogenic climate forcing ('joint attribution', Rosenzweig et al., 2007), this is highlighted in the assessment. Often the attribution of changes in the natural, human or managed systems to anthropogenic forcing can be done in a two-step approach where i) an observed change in a climate-related system is attributed to anthropogenic climate forcing ('climate attribution') and ii) changes in natural, human, or managed systems are attributed to this change in the climate-related system ('impact attribution').

For climate attribution the main challenge is the separation of externally human forced changes in the climate-related systems from their internal variability while for impact attribution it often is the separation of the effects of other external forcings (i.e., direct human influences or natural disturbances) from the impacts of the changes in the climate-related systems. Direct influences not related to changes in the climate-related systems could e.g., be pollution and land use changes amplifying biodiversity losses, intensification of fishing reducing fish stocks, and increasing protection reducing losses due to river floods. The direct human or natural influences may counter the impacts of climate change (e.g., climate change may have reduced flood hazards but exposure may have increased as people have moved to flood-prone areas, resulting in no change in observed damages). Given the definition of impact attribution, that means that there may be an observed impact of climate change without the detection of a change in the natural, human or managed system. This is different from 'climate attribution' where detection and attribution are consecutive steps.

Changes in climate related systems can certainly also affect natural, human and managed systems through indirect effects on land use, pollution or exposure. However, these indirect effects are barely addressed in existing studies.

In addition to impact attribution, there is research on the identification of natural, human, or managed systems' response to short-term (typically daily, monthly or annual) weather fluctuations or individual *extreme weather events*. As different from impact attribution we separately define:

'Identification of weather sensitivity' refers to the attribution of the response of a system to fluctuations in weather and short-term changes in the climate-related systems including individual *extreme weather events* (e.g., a heatwave or storm surge).

Typical questions addressed include: 'How much of the observed variability of crop yields is due to variations in weather conditions compared to contributions from management changes?' (e.g., Ray et al., 2015; Müller et al., 2017) and 'Can weather fluctuations explain part of the observed variability in annual national economic growth rates?' (e.g., Burke et al., 2015). Identification of weather sensitivity may also address the effects of individual *climate extremes*, for example asking, 'Was the observed outbreak of cholera triggered by an associated flood event?' (e.g., Rinaldo et al., 2012; Moore et al., 2017b). It is important to note that sensitivity could be described in diverse ways and that for example the fraction of the observed variability in a system explained by weather variability differs from the strength of the systems' response to a specific change in a weather variable. Nevertheless, all these different measures are integrated in the 'identification of weather sensitivity' assessment where 'sensitivity' should not be considered a quantitative one dimensional mathematical measure.

In this chapter we explicitly distinguish between assessment statements related to 'climate attribution' (listed in Table SM16.21), 'impact attribution' (listed in Table SM16.22), and 'identification of weather sensitivity' (listed in Table SM16.23). The identification of 'weather sensitivity' does not necessarily imply that there also is an impact of long-term climate change on the considered system. However, if the probability or intensity of an *extreme weather event* has increased due to anthropogenic forcing ('climate attribution') (NASEM, 2016; WGI AR6 Chapter 11 Seneviratne et al., 2021) and the event is also identified as an important driver of an observed fluctuation in a natural, human or managed system ('identification of weather sensitivity'), then the observed fluctuation is considered (partly) attributed to long-term climate change ('impact attribution') and even to anthropogenic forcing.

16.2.2 Methods and Data for Impact Attribution Including Recent Advances

By definition the counterfactual baseline required for impact attribution cannot be observed. However, it may be approximated by impact model simulations forced by a stationary climate e.g. derived by de-trending the observed climate (Diffenbaugh et al., 2017; Mengel et al., 2021) while other relevant drivers (e.g., land use changes or application of pesticides) of changes in the system of interest (e.g., a bird population) evolve according to historical conditions. To attribute to anthropogenic climate forcing, the anthropogenic trends in climate are estimated from a range of different climate models and subtracted from the observed climate e.g., Abatzoglou and Williams (2016) for changes in the extent of forest fires or Diffenbaugh and Burke (2019) for effects on economic inequality) or the 'no anthropogenic climate forcing' baseline is directly derived from a large ensemble of climate model simulations not accounting for anthropogenic forcings e.g., Kirchmeier-Young et al. (2019b) for the extent of forest fires). In any case it has to be demonstrated that the applied impact models are able to explain the observed changes in natural, human or managed systems by e.g., reproducing the observations when forced by observed changes in climate-related systems and other relevant drivers.

In a situation where an influence of other direct human drivers can be excluded (e.g., by restriction to remote areas not affected by direct human interventions), the 'no climate-change' baseline can also be approximated by data from early observational periods with no or minor levels of climate change. In particular, the contribution of climate change to the observed changes in ecosystems is often also determined by a 'multiple lines of evidence' approach where the baseline is not formally quantified but the observed changes are identified as a signal of climate change compared to a no-climate change situation based on process understanding from e.g. paleo data and laboratory or field experiments in combination with individual long term observational records and the large scale spatial or temporal pattern of observed changes that can hardly be explained by alternative drivers (Parmesan et al., 2013).

To date, explicit accounting for direct human or natural influences is often hampered by an incomplete understanding of the processes and limited observational data. There are, however, first studies demonstrating the potential of detailed process-based or empirical modelling that explicitly account for known variations in direct human or natural drivers and separate their effects from the ones induced by changes in the climate-related systems. Examples are Butler et al. (2018) for the separation of growing season adjustments from within growing season climate effects on US crop yields; Wang and Hijmans (2019), separating effects of shifts in land use from climate effects; Jongman et al. (2015); Formetta and Feyen (2019), and Tanoue et al. (2016) for the separation of changes in exposure and vulnerability from climate effects on river floods; Kirchmeier-Young et al. (2019b) for wildfire attribution; Venter et al. (2018) for the attribution of ecosystem structural changes to climate change versus other disturbances.

There also has been significant progress in the compilation of fragmented and distributed observational data (e.g., Cohen et al. (2018) for phenological ecosystem changes, Poloczanska et al. (2013) for distributional shifts in marine ecosystems, the new global fire atlas (Andela et al., 2019) including information about individual fire size, duration, speed and direction), as well as regional downscaling (e.g., Ray et al. (2015)) allowing for the identification of an overall picture of the impacts of progressing climate change. Given the ever increasing body of literature on observed changes in natural, human, and managed systems there also is a first machine learning approach for an automated identification for relevant literature that could complement or support expert assessments as the one provided here (Callaghan et al., 2021).

16.2.3 Observed Impacts

In this section we synthesize observed impacts across a range of ecosystems, sectors, and regions. Figure 16.2 summarizes the attribution of observed (regional) changes in natural, human or managed systems (orange symbols and confidence ratings), the quantification of weather sensitivity of those systems (blue symbols and confidence ratings), and the attribution of underlying changes in the climate-related systems to anthropogenic forcing (grey symbols and confidence ratings). The Figure can be read as a summary and Table of content for the underlying Tables 16.B.1 on climate attribution, 16.B.2 on impact attribution, and 16.B.3 on identification of weather sensitivity that provide the more detailed explanations behind each regional or global assessment, including all references. The synthesis was generated in collaboration with 'detection and attribution contact persons' from the individual chapters that each includes its own assessment of observed impacts, and contributing authors on individual topics. The synthesis of 'climate attribution' studies in Table SM16.21 was particularly informed by the WGI assessment.

If Figure 16.2 only provides an assessment of attributed impacts on a given system (e.g., Phenology shifts in terrestrial ecosystems) but does not include an associated 'identification of weather sensitivity' that does not mean that the system is not sensitive to weather fluctuations. The focus of our assessment was on 'impacts attribution' and we only provide an assessment of 'weather sensitivities' if the literature has turned out to provide only limited evidence on impacts of long-term climate change but rather addressed the system's responses to short term weather fluctuations.

16.2.3.1 Ecosystems

The collapse or transformation of ecosystems is one of the most abrupt potential tipping points associated with climate change. Climate change has started to induce such tipping points with the first examples including mass mortality in coral reef ecosystems (e.g., Donner et al., 2017; Hughes et al., 2018; Hughes et al., 2019) (*high confidence*), and changes in vegetation cover triggered by wildfires with climate change suppressing the recovery of the former cover (Tepley et al., 2017; Davis et al., 2019) (*low confidence* because of the still limited number of studies). Another example of an abrupt change in an ecosystem triggered by a climate extreme is the shift from kelp- to urchin-dominated communities along parts of the Western North America coast due a marine heatwave (Rogers-Bennett and Catton, 2019; McPherson et al., 2021, see 'Marine ecosystems - Kelp forest', Table SM16.22) where anthropogenic climate forcing has been shown to have increased the probability for an event of that duration by at least a factor of 33 (Laufkötter et al., 2020). Many terrestrial ecosystems on all continents show evidence of significant structural transformation, including woody thickening and 'greening' in more water-limited ecosystems, with a significant role played by rising atmospheric CO2 fertilization in these trends (*high confidence*) (Fang et al., 2017; Stevens et al., 2017; Burrell et al., 2020). Climate change is identified as a major driver of increases in burned areas in the Western US (*high confidence,* see 'Terrestrial ecosystems - Burned areas', Table SM16.22).

There is also a clear footprint of climate change on species distribution, with appreciable proportions of tropical species expanding into the ranges of temperate species, and boreal species moving into Arctic regions (*high confidence*, see 'Marine ecosystems - Range reduction and shift' and 'Terrestrial ecosystems - Range reduction and shift', Table SM16.22). Climate change has also shifted the phenology of animals and plants on land and in the ocean (*high confidence*, see 'Marine ecosystems - Phenology shift' and 'Terrestrial ecosystems - Phenology shifts', Table SM16.22). Both processes have led to emerging hybridisation, competition, temporal or spatial mismatches in predator-prey, guest-host relationships, and invasion of alien plant pests or pathogens (Edwards and Richardson, 2004; Bebber et al., 2013; Parmesan et al., 2013; Millon et al., 2014; Thackeray et al., 2016).

16.2.3.2 Water Distribution - River Flooding and Reduction in Water Availability

Observed trends in high river flows strongly vary across regions but also with the considered time period (Gudmundsson et al., 2019; Gudmundsson et al., 2021) as influenced by climate oscillations such as the El Niño–Southern Oscillation (Ward et al., 2014). On global scale the spatial pattern of observed trends is largely explained by observed changes in climate conditions as demonstrated by multi-model hydrological simulations forced by observed weather while the considered direct human influences only play a minor role on global scale (Gudmundsson et al., 2021, see 'Water distribution - Flood hazards', Table SM16.22). The annual total number of reported fatalities from flooding shows a positive trend (1.5% per year from 1960-2013, Tanoue et al., 2016) which appears to be primarily driven by changes in exposure dampened by a reduction in vulnerability while climate induced increases in affected areas only show a weak positive trend on global scale (see 'Water distribution - Flood induced fatalities', Table SM16.22). However, the signal of climate change in flood induced fatalities may be lost in the regional aggregation where effects of increasing and decreasing hazards may cancel out. Thus, a climate driven increase in flood induced damages becomes detectable in continental subregions with increasing discharge while the signal of climate change may not be detectable without disaggregation (Sauer et al., 2021, see 'Water distribution: Flood-induced economic damages', Table 16.2), see 'Water distribution: Flood-induced economic damages', Table 16.2). Compared to river floods the analysis of impacts of long-term changes in the climate related systems on the reduction in water availability is much more fragmented and reduced to individual case studies regarding associated societal impacts (see 'Water distribution - Reductions in water availability + induced damages and fatalities', Table SM16.22). At the same time weather fluctuations have led to reductions in water availability with severe societal consequences and high numbers of drought-induced fatalities and damages in particular in Africa and Asia (see 'Water distribution - Reductions in water availability + induced damages and fatalities, Table SM16.23) and impacts on malnutrition (see 'Food system - Malnutrition, Table SM16.23). Although anthropogenic climate forcing has increased droughts' intensity or probability in many regions of the world (*medium confidence*), ('Atmosphere - Droughts, Table SM16.21), the existing knowledge has not yet been systematically linked to attribute long-term trends in malnutrition, fatalities, and damages induced by reduced water availability to anthropogenic climate forcing or long-term climate change. For impacts of individual attributable drought events see Table 4.5 of Chapter 4 and 'Water distribution - Reductions in water availability + induced damages and fatalities, Table SM16.23.

16.2.3.3 Coastal Systems

With their enormous destructive power tropical cyclones represent a major risk for coastal systems (see 'Coastal systems - Damages', Table SM16.23). Despite its relevance, confidence in the influence of anthropogenic climate forcing on the strength and occurrence probability of tropical storms themselves is still low (see 'Coastal systems: Tropical cyclones', Table SM16.21). However, anthropogenic climate forcing has become the dominant driver of sea level rise (*high confidence*) (see 'Coastal systems - Mean and extreme sea levels', Table SM16.21) and has increased the risk of coastal flooding, including inundation induced by tropical cyclones. In addition, anthropogenic climate forcing has increased the amount of rainfall associated with tropical cyclones (*high confidence)* (Risser and Wehner, 2017; Van Oldenborgh et al., 2017; Wang et al., 2018) for hurricane Harvey in 2017 (Patricola and Wehner, 2018) and for hurricanes Katrina in 2005, Irma in 2017, and Maria in 2017 (see 'Atmosphere - Heavy precipitation', Table SM16.21). Assuming that the extreme rainfall is a major driver of the total damages induced by the tropical cyclone, the contribution of anthropogenic climate forcing to the occurrence probability of the observed rainfall (fraction of attributable risk) can also be considered the fraction of attributable risk of the hurricane-induced damages or fatalities (Frame et al., 2020; Clarke et al., 2021, see 'Coastal systems - Damages', Table SM16.22). However, first studies do not only quantify the change in occurrence probabilities but translate the actual change in climate-related systems into the additional area affected by flooding in a process-based way (Strauss et al. (2021), contribution of anthropogenic SLR to damages induced by hurricane Sandy; Wehner and Sampson (2021), contribution increased precipitation to damages induced by hurricane Harvey) and attribute a considerable part of the observed damage to anthropogenic climate forcing. In addition, disruption of local economic activity in Annapolis, Maryland and loss of areas and settlements in Micronesia and Solomon Islands have been attributed to relative sea level rise (Nunn et al., 2017; Albert et al., 2018; Hino et al., 2019) while permafrost thawing and sea ice retreat are additional drivers of observed coastal damages in Alaska (Albert et al., 2016; Smith and Sattineni, 2016; Fang et al., 2017).

16.2.3.4 Food System

Crop yields respond to weather variations but also to increasing atmospheric CO_2, changes in management (e.g., fertilizer input, changes in varieties), diseases, and pests. However, the weather signal is clearly detectable in national and subnational annual yield statistics in main production regions (see 'Food system - Crop yields', Table SM16.23). Over the last decades crop yields have increased nearly everywhere mainly due to technological progress (e.g., Lobell and Field, 2007 (global); Butler et al., 2018 (US); Hoffman et al., 2018 (Sub-Saharan Africa); Agnolucci and De Lipsis, 2019 (Europe)) with only minor areas not experiencing improvements in maize, wheat, rice, and soy yields. However meanwhile, stagnation or decline in yields is also observed on parts of the harvested areas (*high confidence*) (~20% to 40% of harvested areas of maize, wheat, rice and soy with wheat being most affected) (Ray et al., 2012; Iizumi et al., 2018). Evidence on the contribution of climate change to recent trends is still limited (see 'Food system - Crop yields', Table SM16.22). Current global-scale process-based simulations forced by simulated historical and pre-industrial climate miss an evaluation to what degree simulations reproduce observed yields (Iizumi et al., 2018). Global scale empirical approaches do not explicitly account for extreme weather events but growing season average temperatures and precipitation (e.g., Lobell et al., 2011; Ray et al., 2019). In addition, studies are constrained by only fragmented information about changes in agricultural management such as growing season adjustments. Some of these limitations have be overcome in regional studies indicating a climate induced increase (28% of observed trend since 1981) in maize yields in the US (Butler et al., 2018 based on a detailed accounting of impacts of extreme temperatures and growing season adjustments) and a climate induced decrease in millet and sorghum yields (10–20% for millet and 5–15% for sorghum in 2000-2009 compared to pre-industrial conditions) in Africa and a negative effect of historical climate change on potential wheat yields (27% reduction from 1990 to 2015) in Australia (Hochman et al., 2017; Sultan et al., 2019) based on detailed process-based modelling including a dedicated evaluation against observed yield fluctuations). However, these findings need additional support by independent studies while results are relatively convergent that climate change has been an important driver of the recent declines in wheat yields in Europe (*medium confidence*) (Moore and Lobell, 2015; Agnolucci and De Lipsis, 2019; Ray et al., 2019).

Due to complex interactions with socio-economic conditions, climate-induced trends in crop yields and production do not directly transmit to crop prices, availability of food, or nutrition status. This complexity, in addition to the limited availability of long-term data, has so far impeded the detection and attribution of a long-term impact of climate change on associated food security indicators. However, in a few cases, observed crop prices (e.g., domestic grain price in Russia and Africa, Götz et al., 2016; Mawejje, 2016;

Baffes et al., 2019) are shown to be sensitive to fluctuations in local weather through its impact on production (see 'Food system - Food prices', Table SM16.23). In addition, there is growing evidence that *climate extremes* (in particular droughts) have led to malnutrition (in particular stunting of children) in the historical period (*medium confidence*, see 'Food system - Malnutrition', Table SM16.23) but without an attribution of changes to long-term climate change.

16.2.3.5 Temperature-related Mortality

There is nearly universal evidence that non-optimal ambient temperatures increase mortality (*high confidence)*, with notable heterogeneity only in the shape of the temperature-mortality relationship across geographical regions but often sharply growing relative risks at the outer 5% of the local historical temperature distributions (Gasparrini et al., 2015; Guo et al., 2018; Carleton et al., 2020; Zhao et al., 2021, see 'Other societal impacts - Heat-related mortality', Table SM16.23). Significant advances have been made since AR5 regarding the study of temperature-related excess mortality in previously under-researched regions, such as developing countries and (sub-)tropical climates e.g. Africa (South-East Asia: Dang et al., 2016; Ingole et al., 2017; Mazdiyasni et al., 2017; Wichmann, 2017; e.g., Scovronick et al., 2018; Alahmad et al., 2019; the Middle East: Gholampour et al., 2019; and Latin America: Péres et al., 2020). Progress has also been made with regard to temporal changes in temperature-related excess mortality and underlying population vulnerability over time. Heat-attributable mortality fractions have declined over time in most countries due to general improvements in health care systems, increasing prevalence of residential air conditioning, and behavioural changes. These factors, which determine the susceptibility of the population to heat, have predominated over the influence of temperature change (see 'Other societal impacts - Heat-related mortality', Table SM16.22, De'Donato et al., 2015; Arbuthnott et al., 2016; Vicedo-Cabrera et al., 2018a). Important exceptions exist, e.g., where unprecedented heat waves have occurred recently. No conclusive evidence emerges regarding recent temporal trends in excess mortality attributable to cold exposure (Vicedo-Cabrera et al., 2018b). Quantitative detection and attribution studies of temperature-related mortality are still rare. One study (Vicedo-Cabrera et al.), using data from 43 countries, found that 37% (range 20.5–76.3%) of average warm-season heat-related mortality during recent decades can be attributed to anthropogenic climate change (*medium confidence*, see 'Other societal impacts - Heat-related mortality', Table SM16.22). Studying excess mortality associated with past heat waves, such as the 2003 or 2018 events in Europe, even higher proportions of deaths attributable to anthropogenic climate change have been reported for France and the UK (Mitchell et al., 2016; Clarke et al., 2021). Formal attribution studies encompassing cold-related mortality are quasi non-existent. The very few studies from Europe and Australia (Christidis et al., 2010; Åström et al., 2013; Bennett et al., 2014) find weak impacts of climate change on cold-associated excess mortality, with contradictory outcomes both towards higher and lower risks (*low confidence*, see 'Other societal impacts - Heat-related mortality', Table SM16.22).

16.2.3.6 Water-borne Diseases

Infectious diseases with water-associated transmission pathways constitute a large burden of disease globally. Since AR5 the evidence has strengthened that waterborne diseases, and especially gastrointestinal infections, are highly to moderately sensitive to weather variability (*medium confidence*, see 'Water distribution - Water-borne diseases', Table SM16.23). Increased temperature and high precipitation, with associated flooding events, have been shown to generally increase the risk of diarrhoeal diseases. There are however a number of studies that describe important exceptions and modifications to this general observation. While high temperatures favour bacterial diarrhoeal diseases, virally transmitted diarrhoea is on the contrary mostly associated with low temperatures (Carlton et al., 2016; Chua et al., 2021). Socio-economic determinants, such as the existence of single household water supplies (Herrador et al., 2015) or combined sewer overflows (Jagai et al., 2017), have been shown to critically increase the risk of gastrointestinal infections linked to heavy rainfall in high-income countries. Also, for both low- and high-income countries it has been found that gastrointestinal diseases increase following a heavy rainfall event only if preceded by a dry period (Carlton et al., 2014; Setty et al., 2018). Yet, so far there is no consistent evidence on the role of droughts in favouring waterborne disease transmission (Levy et al., 2016). As exemplified by the large cholera outbreak following the 2010 earthquake in Haiti, the existence of functioning sanitation systems is critical for preventing waterborne disease outbreaks, while climatic factors (especially rainfall) are important in driving the transmission dynamics once the outbreak has started (Rinaldo et al., 2012). Other socio-economic factors, such as human mobility and water management project (e.g., dam constructions) also modify the strength of the association between climatic factors and waterborne diseases, as shown by recent studies in Africa (Perez-Saez et al., 2015; Finger et al., 2016).

Whereas the weather sensitivity of waterborne diseases is well-established for all world regions (see 'Water distribution - Water-borne diseases', Table SM16.23), studies attempting to attribute recent trends in waterborne disease to climate change are non-existent, except for investigations on the distribution of marine *Vibrio* bacteria and associated disease outbreaks in the coastal North Atlantic and the Baltic Sea regions (Baker-Austin et al., 2013; Baker-Austin et al., 2016; Vezzulli et al., 2016; Ebi et al., 2017). These investigations provide evidence that increases in sea surface temperatures over recent decades as well as during recent summer heat waves are linked to increased concentrations of *Vibrio* bacteria in coastal waters and an associated rise in environmentally acquired *Vibrio* infections in humans.

16.2.3.7 Vector-borne Diseases

Vector-borne diseases constitute a large burden of infectious diseases worldwide and are highly sensitive to fluctuations of weather conditions including extreme events. Thus, both extreme rainfall and droughts have increased infections (*high confidence,* see documentation of cases in 'Other societal impacts - Vector-borne diseases', Table SM16.23). For example, in Sudan, anomalous high rainfall increased *Anopheles* mosquito breeding sites, leading to malaria outbreaks (Elsanousi et al., 2018) while in Barbados and Brazil, drought conditions in urban areas have enhanced dengue incidence due to changes in water storage behaviour creating breeding sites for *Aedes* mosquitoes around human dwellings (Lowe et al., 2018; Lowe et al., 2021)). In the Caribbean and Pacific island nations, weather extremes, such as storms and flooding have led to outbreaks of dengue due to disruption to water and sanitation services, leading to increased exposure to *Aedes* mosquito breeding sites (Descloux et al., 2012; Sharp et al., 2014; Uwishema et al., 2021). In South and Central America, and Asia, dengue incidence has been shown to sensitive to variations in temperature and the monsoon season in addition to variations induced by urbanization and population mobility (*high confidence* (South and Central America)*; medium confidence* (Asia); see 'Other societal impacts - Vector-borne diseases', Table SM16.23).

The attribution of changes in disease incidence to long-term climate change is often limited by relatively short reporting periods often only covering 10-15 years. Most studies then attribute trends in the occurrence of vector-borne diseases to the trends in climate across the same observational period and do not refer to an early 'no climate change' baseline climate. This means that they also capture trends induced by longer term climate oscillations. Nevertheless, we list them in Table SM16.22 on 'impact attribution' to clearly distinguish them from the analysis of interannual fluctuations. The overall consistency of their findings across regions and time windows indicates that climate change is an important driver of the observed latitudinal or altitudinal range expansions of vector-borne diseases into previously colder areas (*medium to high confidence,* see 'Other societal impacts - Vector-borne diseases', Table SM16.22). In highland areas of Africa and South America, epidemic outbreaks of malaria have become more frequent due to warming trends that allow *Anopheles* mosquitoes to persist at higher elevations (Pascual et al., 2006; Siraj et al., 2014). In the US, ticks that transmit Lyme disease have expanded their range northwards due to warmer temperatures (*high confidence*, (Kugeler et al., 2015; McPherson et al., 2017; Lin et al., 2019; Couper et al., 2020, see 'Other societal impacts - Vector-borne diseases', Table SM16.22). In Southern Europe, climate suitability for *Aedes* mosquitoes, which transmit dengue and chikungunya, and *Culex* mosquitoes, which transmit West Nile virus, has also increased and contributed to unprecedented outbreaks including the 2018 West Nile fever outbreak (*medium confidence*) (Medlock et al., 2013; Paz et al., 2013; Roiz et al., 2015; ECDC, 2018, see 'Other societal impacts - Vector-borne diseases', Table SM16.22).

16.2.3.8 Economic Impacts

Since the AR5, there has been significant progress regarding the identification of economic responses to weather fluctuations: Evidence has increased that *extreme weather events* such as tropical cyclones, droughts, and severe fluvial floods have not only caused substantial immediate direct economic damage (*high confidence*, see 'Coastal Systems - Damages, Table SM16.23, 'Water distribution - Reductions in water availability + induced damages and fatalities, Table SM16.23, and 'Water distribution - Flood-induced economic damages, Table SM16.22), but have also reduced economic growth in the short-term (year of, and year after event) (Strobl, 2011; Strobl, 2012; Fomby et al., 2013; Felbermayr and Gröschl, 2014, Loyaza et al. 2012) (*high confidence*) as well as long-term (up to 10-15 years after event) (*medium confidence*) (Hsiang and Jina, 2014; Berlemann and Wenzel, 2016; Berlemann and Wenzel, 2018; Krichene et al., 2020; Tanoue et al., 2020, see 'Other societal impacts - Macroeconomic output', Table SM16.23). Short- and long-term reductions of economic growth by *extreme weather events* affect both, developing and industrialized countries, but have been shown to be more severe in developing than in industrialized economies thereby increasing inequality between countries (*high confidence*, see 'Other societal impacts - Between country inequality', Table SM16.23). Further, *extreme weather events* have increased within-country inequality since poorer people are more exposed and suffer relatively higher well-being losses than richer parts of the population (*medium confidence*, see 'Other societal impacts - Between country inequality', Table SM16.23). Going beyond *extreme weather events*, economic production depends non-linearly on temperature fluctuations: below a certain threshold temperature, economic production increases with temperature whereas it decreases above a certain threshold temperature (*high confidence*) (Burke et al., 2015; Pretis et al., 2018; Kalkuhl and Wenz, 2020; Kotz et al., 2021).

So far, there are few individual studies attributing observed economic damages to long term climate change except for damages induced by river flooding, droughts, and tropical cyclones (see 'Coastal systems - Damages', 'Water distribution - Flood induced damages', and 'Water distribution - Reduction in water availability + induced damages and fatalities', Table SM16.22) *extremes* to anthropogenic forcing. In addition, the empirical findings on the sensitivity of macroeconomic development to weather fluctuations and *extreme weather events* have been used to estimate the cumulative effect of historical warming on long term economic development (see 'Other societal impacts - Macroeconomic output', Table SM16.22): anthropogenic climate change is estimated to have reduced GDP growth over the last 50 years with substantially larger negative effects on developing countries and in some cases positive effects on colder industrialized countries (*low confidence*) (Diffenbaugh and Burke, 2019). Globally, between-country inequality has decreased over the last 50 years. Climate change is estimated to have substantially slowed down this trend, i.e., increased inequality compared to a counterfactual no climate change baseline (*low confidence*) (Diffenbaugh and Burke, 2019). On a regional level, decreasing rainfall trends in Sub-Saharan Africa (SSA) may have increased the GDP per capita gap between SSA and other developing countries (*low confidence*) (Barrios et al., 2010). Overall, more research is needed on the impact channels through which *extreme weather events* and weather variability can hinder economic development, especially in the long-term.

16.2.3.9 Social Conflict

There are few studies directly attributing changes in conflict risk to climate change in the modern era (van Weezel, 2020), preventing a confident assessment of the effect of long-term changes in the climate-related systems on armed conflict (see 'Other societal impacts - Social conflict', Table SM16.22). However, a sizeable literature links the prevalence of armed conflict within countries to within- and between-year variations in rainfall, temperature or drought exposure; often via reduced-form econometric analysis or statistical models that control for important non-climatic factors, such as agricultural dependence, level of economic development, state capacity, and ethnopolitical marginalization (see 'Other societal impacts - Social conflict' in Table SM16.23). Overall, there is more consistent evidence that climate variability has influenced low-intensity organized violence than major civil wars (Detges, 2017; Nordkvelle et al., 2017; Linke et al., 2018). Likewise, there is more consistent evidence that climate variability has affected dynamics of conflict, such as continuation, severity, and frequency of violent conflict events, than the likelihood of initial conflict outbreak (Yeeles, 2015; Eastin, 2016; Von Uexkull et al., 2016, Section 7.2.7). Moreover, research suggests with *medium confidence* (*medium evidence*, *medium agreement*) that weather effects on armed conflict have been most prominent in contexts marked by a large population, low socioeconomic development, high political marginalization, and high agricultural dependence (Theisen, 2017; Koubi, 2019; Buhaug et al., 2020; Ide et al., 2020).

Some studies also seek to evaluate potential indirect links between climate and weather anomalies and prevalence of armed conflict via food price shocks or forced migration. While there is *robust evidence* that the likelihood of social unrest in the developing world generally increases in response to rapid growth in food prices (Bellemare, 2015; Rudolfsen, 2018), the magnitude of the climate effect on unrest via food prices is less well established (Martin-Shields and Stojetz, 2019). Similarly, research shows with *high confidence* that climate variability and extremes have affected human mobility (see 'Other societal impacts -

Displacement and migration', Table SM16.23), but there is low agreement and limited evidence that weather-induced migration has increased the likelihood of armed conflict (Section 7.2, Brzoska and Fröhlich, 2016; Kelley et al., 2017; Selby et al., 2017; Abel, 2019). Research on weather-related effects on interstate security generally conclude that periods of transboundary water scarcity are more likely to facilitate increased international cooperation than conflict (Bernauer and Böhmelt, 2020).

In general, the historical influence of climate on conflict is judged to be small when compared to dominant conflict drivers (Mach et al., 2019). Much of this research is limited to (parts of) Sub-Saharan Africa, which raises some concerns about selection bias and generalizability of results (Adams et al., 2018).

16.2.3.10 Displacement and Migration

Given the complexity of human migration processes and decisions (e.g., Boas et al., 2019, Cattaneo et al., 2019) and the paucity of long-term, reliable and internally consistent observational data on displacement (IDMC, 2019; IDMC, 2020) and migration (Laczko, 2016) the contribution of long-term changes in climate related systems to observed human displacement or migration patterns has not been quantified so far, except for individual examples for displacement induced by inland flooding where the heavy precipitation has been attributed to anthropogenic climate forcing and coastal flooding (see 'Other societal impacts - Displacement and migration', Table SM16.22; CCP2).

However, new evidence has emerged since the AR5 that further documents widespread effects of weather fluctuations and extreme events on migration (see 'Other societal impacts- Displacement and migration' in Table SM16.23). Numerous studies find significant links between temperature or precipitation anomalies, or *extreme weather events* such as storms or floods, and internal as well as international migration (Coniglio and Pesce, 2015; Cattaneo and Peri, 2016; Nawrotzki and DeWaard, 2016; Beine and Parsons, 2017for international migration; and IDMC, 2019 for internal displacement). Internal displacement of millions of people every year is triggered by natural hazards, mainly floods and storms (IDMC, 2019). The effects of weather fluctuations and extremes on migration are considered more important for temporary mobility and displacement than permanent migration, and more influential on short-distance movement, including urbanization, than international migration (McLeman, 2014; Hauer et al., 2020; Hoffmann et al., 2020, Section 7.2.6). Importantly, these links are conditional on the socio-economic situation in the origin; e.g., poor populations may be 'trapped' and not be able to migrate in the face of adverse climate or weather conditions (Black et al., 2013; Adams, 2016). Many studies have also explored the channels through which climate or weather influence migration, and have identified incomes in the agricultural sector as one of the main channels (Nawrotzki et al., 2015; Viswanathan and Kavi Kumar, 2015; Cai et al., 2016a). In particular, declines in agricultural incomes and employment due to changed weather variability may foster increased rural-urban movement; and the resulting pressures on urban wages in turn fosters international migration (Marchiori et al., 2012; Maurel and Tuccio, 2016). Another possible but controversial channel is violent conflict, which may be fostered (though not exclusively caused) by adverse climate conditions such as drought, and in turn lead to people seeking refugee status, although evidence of such an indirect effect is weak (Brzoska and Fröhlich, 2016; Abel et al., 2019; Schutte et al., 2021).

16.2.3.11 Case study on climate change and the outbreak of the Syrian civil war

Separating between climatic and non-climatic factors in impact attribution is often challenging, as highlighted by the debate surrounding the causes of the Syrian civil war. During the years 2006–2010, the Fertile Crescent region in Eastern Mediterranean and Western Asia was hit by the worst drought on meteorological record, compounding a consistent drying of the region over the past half century (Trigo et al., 2010; Hoerling et al., 2012; Mathbout et al., 2018, SR15 BOX 3.2). The magnitude of the multiyear drought is estimated to have become two to three times more likely as a result of increased CO_2 forcing (Kelley et al., 2015). The drought had a devastating impact on agricultural production in the northeast of Syria. In 2007–2008 alone, average crop yields dropped by 32% in irrigated areas and as much as 79% in rain-fed areas (De Châtel, 2014), and herders in the northeast lost around 85% of their livestock (Werrell et al., 2015). Successive years with little or no income eventually forced people to leave their farms in great numbers and seek employment in less affected parts of the country, adding to existing pressures on housing, labour market, and public goods provision (Gleick, 2014; Kelley et al., 2015). In March 2011, by which time the

'Arab Spring' uprisings had gained momentum and spread across much of the region, anti-regime protests broke out in Syria, first in the southern city of Dara'a and then in Damascus and throughout the country.

Yet, the attribution of the Syrian civil war to climate change has triggered a heated debate. A number of studies argue that the principal drivers of the drought-induced economic collapse were political rather than environmental in nature, shaped by adverse economic reforms and unsustainable agricultural policies, promoting water-intensive irrigation schemes for cotton cultivation and implementing abrupt subsidy cuts at the peak of the drought, implying that many poor farmers no longer could afford fertilizers or fuel to power irrigation pumps (Barnes, 2009; De Châtel, 2014; Eklund and Thompson, 2017; Selby et al., 2017). Thus, the 2006–10 drought did not precipitate similar devastating socioeconomic impacts on agrarian communities across the borders in Turkey, Iraq or Jordan, although environmental conditions were comparable (Trigo et al., 2010; Eklund and Thompson, 2017; Feitelson and Tubi, 2017).

However, the relevant attribution question is not whether the same drought would produce the same consequences under different political and socio-economic conditions but rather, given the same political and socio-economic context, how would the outcomes have differed in the absence of the climate event? Research still provides very limited insights into whether and how the escalation process would have evolved differently in a counterfactual no-climate change world.

Thus, the role of the drought in augmenting pre-existing internal migration, and the role of the distress migration in accentuating demographic, economic, and social pressures in receiving areas, remain contested. Estimates of the number of people who abandoned their farms in response to the drought range from less than 40–60,000 families (Selby et al., 2017) to more than 1.5 million displaced (Gleick, 2014). However, the numbers have to be seen in the context of prevailing population growth, significant rural-urban migration, and the preceding inflow of around 1.5 million refugees from neighbouring Iraq (De Châtel, 2014; Hoffmann, 2016). In addition, research suggests that the migrants played a peripheral role in the initial social mobilization in March 2011 (Fröhlich, 2016).

While it is undisputed that the drought caused direct economic losses, its overall additional impact on the Syrian economy, relative to other prevalent drivers of economic misery, including rampant unemployment, increasing inequalities, declining rural productivity, and loss of oil revenues (Aïta, 2009; Landis, 2012; De Châtel, 2014; Selby, 2019) has not been quantified.

In addition, the protesters' demands centred around contentious political rather than economic issues, including release of political prisoners, ending of torture and indiscriminate violence by security forces, and abolishment of the near 50-year old state of emergency (Selby et al., 2017; Ash and Obradovich, 2020). The mobilization in Syria in the spring of 2011 also made explicit references to events across the Middle East and North African region. Analyses of regional and social media and networks show high level of interaction across the Arab world, and the initial Syrian uprising adopted a mobilization model and rhetorical frames similar to those developed in Tunisia and Egypt (Leenders, 2013; 2014). However, the Syrian uprising stands out in how it was met with overwhelming violent force by the police and security forces, which changed the character of the resistance and opened up for militarization of non-state actors that further escalated the conflict (Heydemann, 2013; Leenders, 2013; Bramsen, 2020).

In summary, the drought itself is shown to be attributable to greenhouse gas emissions. The agricultural losses and internal migration from rural to urban areas can be directly linked to the drought and in this way are partly attributable to greenhouse gas emissions, although there are no studies comparing the observed losses and number of people displaced to a counterfactual situation of a weaker drought in a 'no climate change' situation. Current research does not provide enough evidence to attribute the civil war to climate change. In contrast, it is likely that social uprisings would have occurred even without the drought.

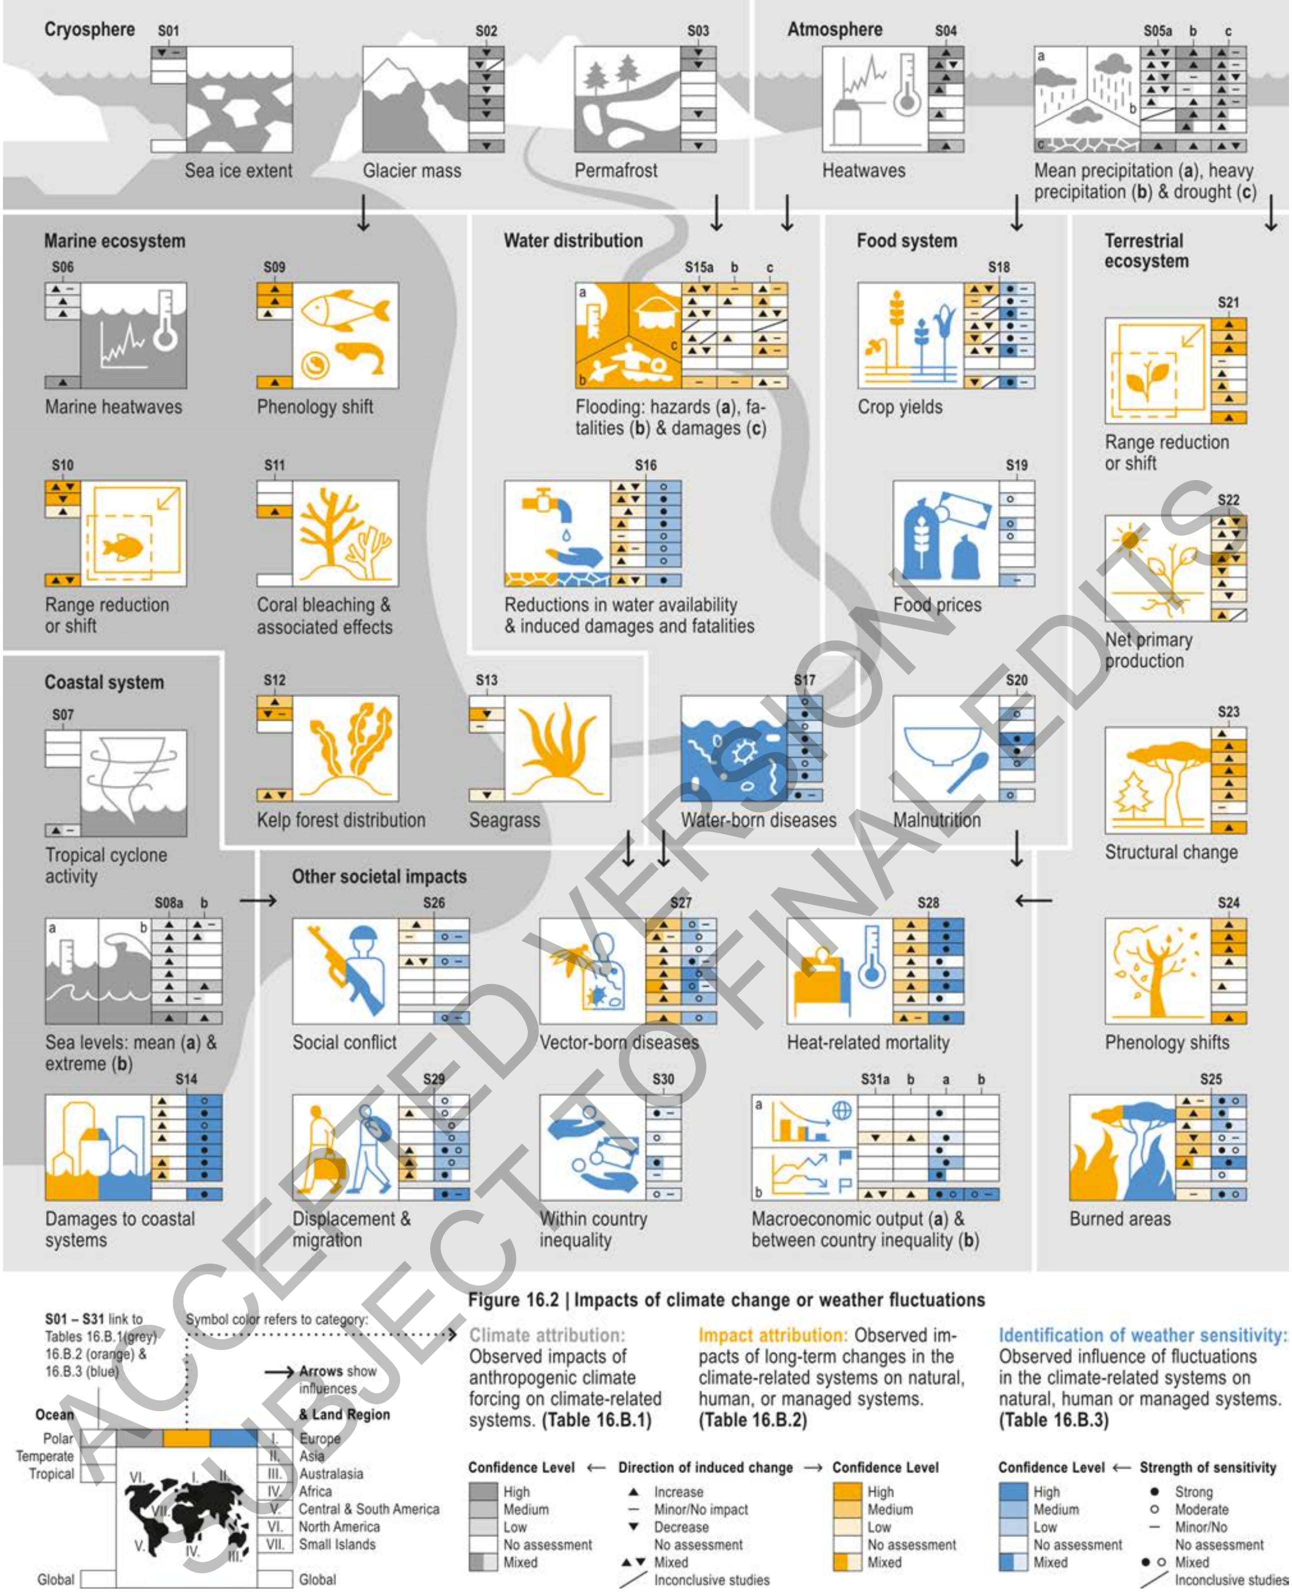

Figure 16.2: Impact of Climate Change or Weather Fluctuations.

16.3 Synthesis of Observed Adaptation-related Responses

A new development since AR5, is there is now growing evidence assessing progress on adaptation across sectors, geographies and spatial scales. Uncertainty persists around what defines adaptation and how to measure it (Cross-Chapter Box FEASIB in Chapter 18, UNEP, 2021). As a result, most literature synthesizing responses are based on documented or reported adaptations only, and are thus subject to substantial reporting bias.

We document implemented adaptation-related responses that could directly reduce risk. Adaptation *as a process* is more broadly covered in Chapter 17 (Section 17.4.2), including risk management, decision-making, planning, feasibility (see Cross-Chapter Box FEASIB in Chapter 18), legislation and learning. Here, we focus on a subset of adaptation activities: adaptation-related responses of species, ecosystems, and human societies that have been implemented, observed, and could directly reduce risk. We consider all adaptation-related responses to assumed, perceived, or expected climate risk, regardless of whether or not impacts or risks have been formally attributed to climate change.

We use the term 'adaptation-related responses', recognising that not all responses reduce risk. While 'adaptation' implies risk reduction, we use the broader term 'responses' to reflect that responses may decrease risk, but in some cases may increase risk.

It is not currently possible to conduct a comprehensive global assessment of effectiveness, adequacy, or the contribution of adaptation-related responses to changing risk due to an absence of robust empirical literature. This constrains assessment of adaptation progress and gaps in the context of over-shoot scenarios. Given limited evidence to inform comprehensive global assessment of effectiveness and adequacy, we assess evidence that adaptation responses in human systems indicate transformational change. Chapter 17 considers adaptation planning and governance, including adaptation solutions, success, and feasibility assessment (Cross-Chapter Box FEASIB in Chapter 18), discussed further in Box 16.1 (also see Cross-Chapter Box PROGRESS in Chapter 17).

In natural ecosystems or species, detectable changes can be considered as 'impact' or 'response'. The distinction between 'observed impacts' (16.2) and 'observed responses' (16.3) is not always clear. For example, autonomous distributional shifts in wild species induced by increasing temperatures (an observed impact) may reduce risk to the species (an autonomous adaptation response), but this process can be enhanced or supported by human intervention such as intentional changes in land use. Observed autonomous changes in natural ecosystems or species unsupported by human intervention are treated as impacts (see Section 16.2).

Adaptation-related responses are frequently motivated by a combination of climatic and non-climatic drivers, and interact with other transitions to affect risk. For societal responses, it is difficult to say whether they are triggered by observed or anticipated changes in climate, by non-climatic drivers, or a combination of all three. In the case of observed impacts, assessment typically focuses on detection and attribution *vis à vis* a counterfactual of no climate change. While there has been some effort to attribute reduced climate risk to adaptation-related responses (Toloo et al., 2013a; Toloo et al., 2013b; Hess et al., 2018; Weinberger et al., 2018), in many cases this has not been feasible given difficulties in defining adaptation and empirically disentangling the contribution of intersecting social transitions and changing risks. Literature on adaptation-related response frequently draws on theories-of-change to assess the likely contribution of adaptations to changes in risk, including maladaptation and co-benefits.

16.3.1 Adaptation-related Responses by Natural Systems

There is growing evidence of shifts in species distributions and ecosystem structure and functioning in response to climate change (Chapter 2). While many species are increasingly responding to climate change, there is limited evidence that these responses will be fully adaptive, and for many species the rate of response appears insufficient to keep pace with the rate of climate change under mid- and high-range emissions scenarios (*medium confidence*). There is relatively limited, but growing, empirical data to document adaptation of natural systems in the absence of human interventions. For example, Scheffers et al. (2016) reviewed climate responses across diverse species, reporting widespread and extensive observed changes in organisms (genetics, physiology, morphology), populations (phenology, abundance and dynamics), species (distributions), and ecosystems. A systematic review by Franks et al. (2014) synthesized evidence from 38 empirical studies of changes in terrestrial plant populations, finding evidence to support a mix of plastic and evolutionary responses. Boutin and Lane (2014) similarly reviewed adaptive responses in mammals, finding most species' responses due to phenotypic plasticity. Charmantier and Gienapp (2014) reviewed responses to climate change among birds, finding emerging evidence that birds from a range of taxa show advancement in their timing of migration and breeding in response to warming. Aragão et al.

(2018) reviewed adaptation responses in marine systems, including 12 studies of live marine mammals. They observed widespread evidence of shifting distributions and timing of biological events (Chapter 2, Chapter 3, and Cross-Chapter Paper 1 on Biodiversity Hotspots).

Some ecosystems and species' responses may be insufficient to keep pace with rates of climate change. It is difficult to distinguish whether adaptations are due to genotypic change or to phenotypic plasticity. Long-term natural adaptations will require the former, but the latter may provide short-term coping mechanisms to 'buy time' to respond to climate changes or lay foundations for evolutionary adaptation. There is mixed evidence regarding evolutionary versus plastic responses, with relatively limited evidence of longer-term evolutionary responses of species that can be associated with climate change. Similarly, it is difficult to assess whether responses are indeed potentially adaptive (e.g., coping, shifting, migrating) or simply reflective of impacts (e.g., stress, damage). Among mammal responses reviewed by Boutin and Lane (2014), for example, only 4 of 12 studies found some evidence that responses were adaptive. Even where adaptive responses are occurring, they may not be sufficient to keep pace with the rate of climate change. found, for example, that among the twelve studies in their review that directly assessed the sufficiency of responses to keep pace with the rate of climate change, eight concluded that responses would be insufficient to avert extinction.

16.3.2 Adaptation-related Responses by Human Systems

The literature that seeks to assess adaptation progress is growing at the global (Berrang-Ford et al., 2021a), regional (Bowen and Ebi, 2015; England et al., 2018; Robinson, 2018a; Wirehn, 2018; Olazabal et al., 2019; Thomas et al., 2019a; Biesbroek et al., 2020; Canosa et al., 2020; Robinson, 2020b), national (Hegger et al., 2017; Lesnikowski et al., 2019a; Lesnikowski et al., 2019b), and municipal (Araos et al., 2016; Reckien et al., 2018; Reckien et al., 2019; Lesnikowski et al., 2020; Singh et al., 2021) levels, using National Communications (Gagnon-Lebrun and Agrawala, 2007; Lesnikowski et al., 2015; Muchuru and Nhamo, 2017), local climate change action plans (Regmi et al., 2016b; Regmi et al., 2016a; Reckien et al., 2018; Reckien et al., 2019), adaptation project proposals, and reported adaptations in the peer reviewed literature. There remains persistent publication bias in the evidence base on adaptation given the difficulty of integrating diverse knowledge sources (see Section 16.3.3). To better assess how adaptation is occurring in human systems, we draw on this literature base and characterize evidence of adaptation across regions and sectors in terms of five key questions (Table 16.4, Ford et al., 2013; Biagini et al., 2014; Ford et al., 2015a; Bednar and Henstra, 2018; Reckien et al., 2018; Tompkins et al., 2018): What types of hazards are motivating adaptation-related responses? Who is responding? What types of responses are being documented? What evidence is available on adaptation effectiveness, adequacy, and risk reduction? To characterize evidence that adaptation responses indicate transformation, we use a typology based on four dimensions of climate adaptation: scope, depth, and speed, and consideration of limits to adaptation (Section 16.4, Termeer et al., 2017; Berrang-Ford et al., 2021a).

16.3.2.1 What Hazards are Motivating Adaptation-related Responses?

Drought and precipitation variability are the most prevalent hazards in the adaptation literature, particularly in the context of food and livelihood security. Adaptation frequently occurs in response to specific rapid or slow-onset physical events that can have adverse impacts on people. In some cases, people adapt in anticipation of climate change in general or to take advantage of new opportunities created by hazards (e.g., increased navigability due to melting sea ice). There is evidence that prior experience with hazards increases adaptation response (Barreca et al., 2015). Following drought and precipitation variability, the next specific hazards that are most frequently documented in the global adaptation literature are heat and flooding. Heat, while less salient, appears to be a driver of adaptation across all regions and sectors (Stone Jr et al., 2014; Hintz et al., 2018; Nunfam et al., 2018). Drought, extreme precipitation, and inland flooding are commonly reported in the context of water and sanitation (Bauer and Steurer, 2015; Lindsay, 2018; Kirchhoff and Watson, 2019; Hunter et al., 2020; Simpson et al., 2020). Flooding is frequently reported as a key hazard for adaptation in cities, followed by drought, precipitation variability, heat, and sea level rise (Broto and Bulkeley, 2013; Araos et al., 2016; Georgeson et al., 2016; Mees, 2017; Reckien et al., 2018; Hunter et al., 2020).

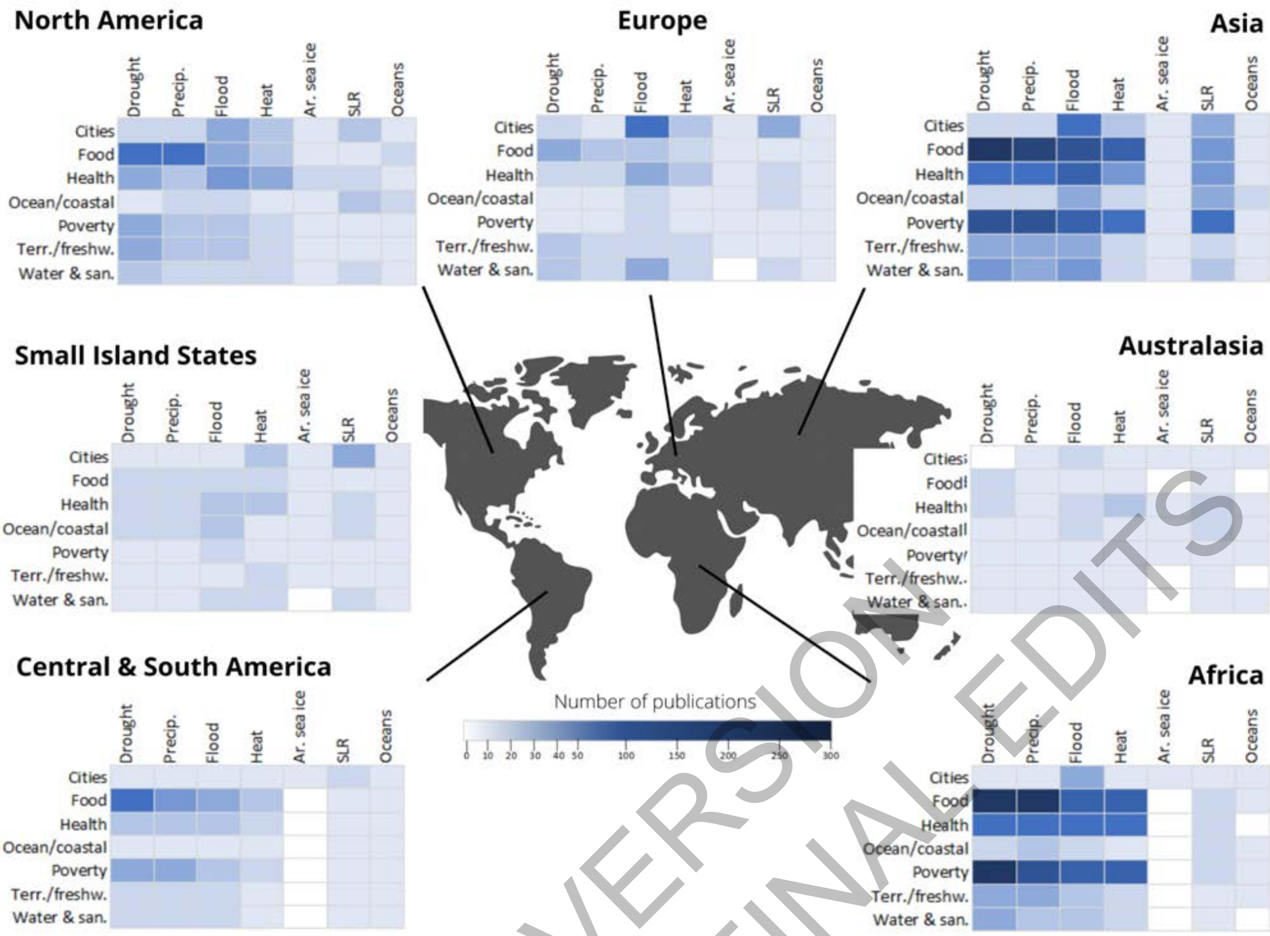

Figure 16.3: Salience of different types of hazards in the scientific literature on adaptation-related responses (i.e., responses that people undertake to reduce risk from climate change and associated hazards). Updated from a systematic review of 1,682 scientific publications (2013-2019) reporting on adaptation-related responses in human systems (Berrang-Ford et al., 2021a). Numbers in table reflect the number of publications reporting. Darker colours denote more extensive reporting on a hazard as a motivating factor for the response. Publications are counted in all relevant regions or sectors.

16.3.2.2 Who is Responding?

Individuals and households play a central role in adaptation globally. The most frequently reported actors engaged in adaptation-related responses in the scientific literature are individuals and households, particularly in the global south (Fig. 16.4). Regionally, household- and individual-level adaptation is documented most extensively in Africa and Asia, and to a lesser but still substantial extent in North America (Fig. 16.4).

National and local governments are also frequently engaged in reported adaptation across most regions. In Africa and Asia, reported adaptations have been primarily associated with individuals, households, national governments, NGOs, and international institutions, with more limited reporting of involvement from sub-national governments or the private sector (Ford et al., 2015a; Ford and King, 2015; Hunter et al., 2020). Engagement by sub-national governments in adaptation is more frequently documented in Europe and North America (Craft and Howlett, 2013; Craft et al., 2013; Bauer and Steurer, 2014; Lesnikowski et al., 2015; Shi et al., 2015; Austin et al., 2016). Reporting of private sector engagement is generally low. Civil society participation in adaptations is reported across all regions. Consistent with this, local governments are also widely reported in documented adaptation responses, particularly where municipal jurisdiction is high, including cities, infrastructure, water, and sanitation.

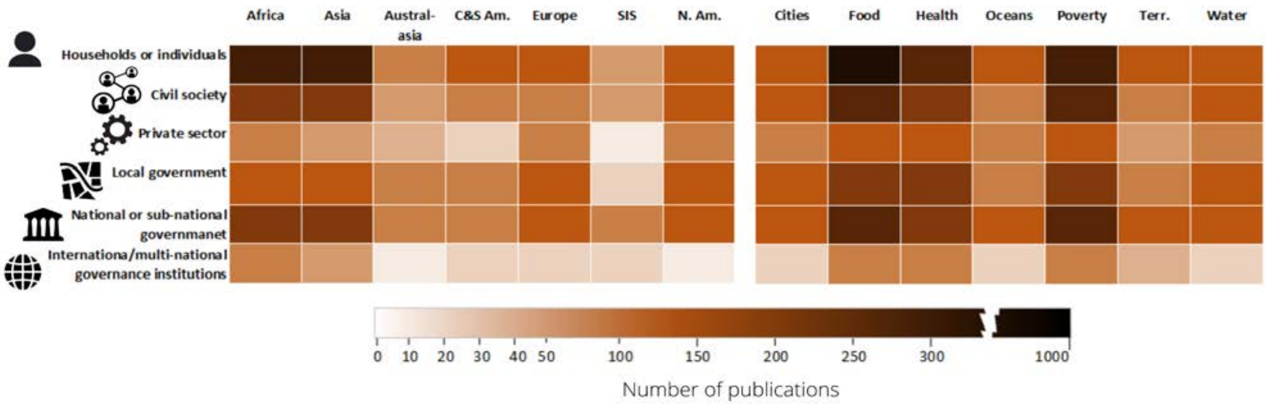

Figure 16.4: Who is responding, by geographic region and sector? Cell contents indicate the number of publications reporting engagement of each actor in adaptation-related responses. Darker colours denote a high number of publications. Based on a systematic review of 1,682 scientific publications (2013-2019) reporting on adaptation-related responses in human systems (Berrang-Ford et al., 2021a). SIS: Small Island States; Terr: Terrestrial and freshwater ecosystems.

16.3.2.3 What Types of Responses are Documented?

Behavioural change is the most common form of adaptation. The scientific literature presents extensive evidence of behavioural adaptation -- change in the strategies, practices, and actions that people, particularly individuals and households, undertake to reduce risk (Figure 16.5). This includes, for example, household measures to protect homes from flooding, protect crops from drought, relocation out of hazard zones, and shifting livelihood strategies (Porter et al., 2014). This is followed by adaptation via technological innovation and infrastructural development, nature-based adaptation (enhancing, protecting, or promoting ecosystem services), and institutional adaptation (enhancing multilevel governance or institutional capabilities). Behavioural adaptation is most frequently documented in Asia, Africa, and Small Island States, and in the agriculture, health, and development sectors. In the agricultural sector, households are adopting or changing to crops and livestock that are more adapted to drought, heat, moisture, pests, and salinity (Arku, 2013; Kattumuri et al., 2017; Wheeler and Marning, 2019). Studies in Africa and Asia have documented shifts in farming and animal husbandry practice (Arku, 2013; Garcia de Jalon et al., 2016; Gautier et al., 2016; Chengappa et al., 2017; Epule et al., 2017; Kattumuri et al., 2017; Abu and Reed, 2018; Asadu et al., 2018; Haeffner et al., 2018; Shaffril et al., 2018; Wiederkehr et al., 2018; Zinia and McShane, 2018; Currenti et al., 2019; Fischer, 2019a; Fischer, 2019b; Schofield and Gubbels, 2019; Sereenonchai and Arunrat, 2019; Wheeler and Marning, 2019; Mayanja et al., 2020). In Small Island Nations, studies have documented household flood protections measures such as raising elevation of homes and yards, creating flood barriers, improving drainage, moving belongings, and in some cases, relocating (Middelbeek et al., 2014; Currenti et al., 2019; Klock and Nunn, 2019).

The mix of adaptation response types differs across regions and sectors. Technological and infrastructural responses are widely reported in Europe, and globally in the context of cities and water and sanitation (Mees, 2017; Hintz et al., 2018). Responses to flood risk in Europe include the use of flood and climate resistant building materials, large scale flood management, and water storage and irrigation systems (van Hooff et al., 2015; Mees, 2017). Technological and infrastructural responses are also documented to some extent in agriculture, including for example breeding more climate resilient crops, precision farming and other high-tech solutions such as genetic modification (Makhado et al., 2014; Fisher et al., 2015; Costantini et al., 2020; Fraga et al., 2021; Grusson et al., 2021; Naulleau et al., 2021). While less common, institutional responses are more prominent in North America and Australasia as compared to other regions, and include zoning regulations, new building codes, new insurance schemes, and coordination mechanisms (Craft and Howlett, 2013; Craft et al., 2013; Parry, 2014; Ford et al., 2015b; Beiler et al., 2016; Lesnikowski et al., 2016; Labbe et al., 2017; Sterle and Singletary, 2017; Hu et al., 2018; Conevska et al., 2019). Institutional adaptations are more frequently reported in cites than other sectors. Institutional adaptation may be particularly subject to reporting bias, however, with many institutional responses likely to be reported in the grey literature (see Chapter 17). Nature-based solutions are less frequently reported, except in Africa, where they are relatively well-documented, and in the content of terrestrial systems where reports included species regeneration projects, wind breaks, erosion control, reforestation, and riparian zone management (Munji et al., 2014; Partey et al., 2017; Muthee et al., 2018).

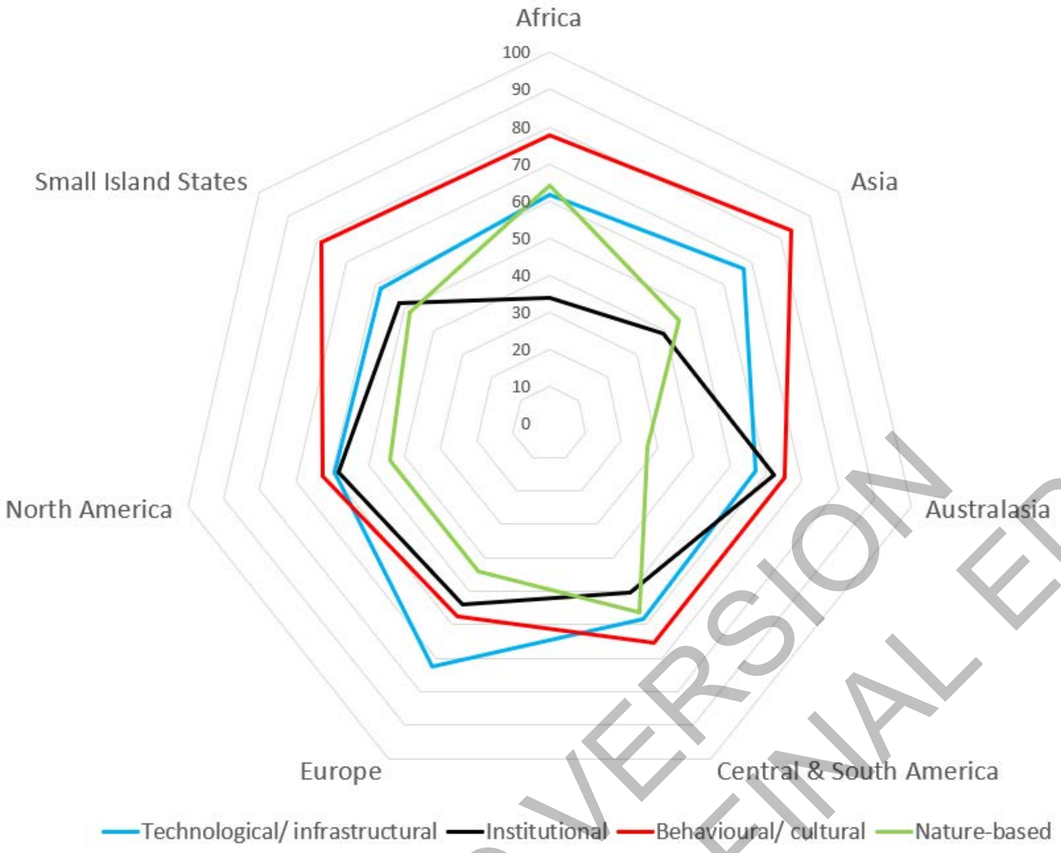

Figure 16.5: Type of adaptation responses by global region. Percentages reflect the number of articles mentioning each type of adaptation over the total number of articles for that region. Radar values do not total 100% per region since publications frequently report multiple types of adaptation; for example, construction of drainage systems (infrastructural), changing food storage practices by households (behavioural), and planting of tree cover in flood prone areas (nature-based) in response to flood risk to agricultural crops. Data updated and adapted from Berrang-Ford et al. (2021a), based on 1682 scientific publications reporting on adaptation-related responses in human systems.

Some but not all adaptation-related responses are engaging vulnerable populations in planning or implementation (*high confidence)* (Araos et al., 2021). Consideration of vulnerable populations is most frequently focused on low-income populations and women through the inclusion of informal or formal institutions or representatives in adaptation planning, or through targeted adaptations to reduce risk in these populations (*high confidence*). Consideration of vulnerable groups in adaptation responses are more frequently reported in the global south (*medium confidence*). Engagement in adaptation planning of vulnerable elderly, migrants, and ethnic minorities remains low across all global regions *(medium confidence)*. There is negligible literature on consideration of disabled peoples in planning and implementation of adaptation-related responses *(medium confidence)*.

16.3.2.4 Adaptation Effectiveness, Adequacy, and Risk Reduction

Despite a lack of systematic methods for assessing general adaptation effectiveness, there is some evidence of risk reduction for particular places and hazards, especially flood and heat vulnerability. There is some evidence of a reduction in global vulnerability, particularly for flood risk (Jongman et al., 2015; Tanoue et al., 2016; Miao, 2019) and extreme heat (Bobb et al., 2014; Boeckmann and Rohn, 2014; Gasparrini et al., 2015; Arbuthnott et al., 2016; Chung et al., 2017; Sheridan and Allen, 2018; Folkerts et al., 2020). Investment in flood protection, including building design and monitoring and forecasting, have reduced flood-related mortality over time and are cost-effective (Bouwer & Jonkman 2018; Ward et al. 2017).

Declining heat sensitivity, primarily reported in developed nations, has also been observed, and has been linked to air conditioning, reduced social vulnerability, and improved population health (Boeckmann and Rohn, 2014; Chung et al., 2017; Kinney, 2018; Sheridan and Allen, 2018). Formetta and Feyen (2019) demonstrate declining global all-cause mortality and economic loss due to extreme weather events over the past four decades, with the greatest reductions in low income countries, and with reductions correlated with wealth. Studies that correlate changes in mortality or economic losses with wealth indicators, to infer changes in vulnerability or exposure, lack direct empirical measures of vulnerability or exposure and are limited in their ability to assess how indirect effects of extreme events (e.g., morbidity, relocation, social disruption) may have changed or how changes may redistribute risk across populations.

There remain persistent difficulties in defining and measuring adaptation effectiveness and adequacy for many climate risks. No studies have systematically assessed the adequacy and effectiveness of adaptation at a global scale, across nations or sectors, or for different levels of warming. There has, however, been progress in operationalizing assessment of adaptation feasibility (Cross-Chapter Box FEASIB in Chapter 18). Effectiveness of adaptation-related responses reflects whether a particular response actually reduces climate risk, typically through reductions in vulnerability and exposure (Fig 1.7 in Section 1.4). Some adaptation-related responses may increase risk or create new risks (maladaptation) or have no or negligible impact on risk. Adequacy of adaptation-related responses refers to the extent to which responses are collectively sufficient to reduce the risks or impacts of climate change (Fig 1.7 in Section 1.4). A set of adaptation-related responses may, for example, result in reduced climate risk (effectiveness), but these reductions may be insufficient to offset the level of risk and avoid loss and damages. Feasibility reflects the degree to which climate responses are possible or desirable, and integrates consideration of potential effectiveness. A feasibility assessment drawing on these methods is presented in (Cross-Chapter Box FEASIB in Chapter 18).

Global adaptation is predominantly slow, siloed, and incremental with little evidence of transformative adaptation (*high confidence*). In the absence of a general method to assess the adequacy of adaptation actions, we assessed evidence for transformational adaptation documented in peer-reviewed publications identified by a global stock-taking initiative (Berrang-Ford et al., 2021b) and in other AR6 chapters (2-15) (see Supplemental Material, SM16.1 for details). 'Transformational adaptation' refers to the degree to which adaptations have been implemented widely (scope), reflect major shifts (depth), occur rapidly (speed), and challenge limits to adaptation (limits, Pelling et al., 2015; Few et al., 2017; Termeer et al., 2017, Table 16.1).

Table 16.1: Evidence of transformational adaptation assessed across four components (depth, scope, speed, and limits). Transformational adaptation does not imply adequacy or effectiveness of adaptation (low transformation may be sufficient for some climate risks, and high transformation may be insufficient to offset others). Nevertheless, these components provide a systematic framework for tracking adaptation progress and assessing the state of adaptation-related responses. The 'high' categories across each component reflect more transformative scenarios. Methods are described in Supplementary Material (SM16.1).

	Transformative potential of adaptation		
Dimensions	Low	Medium	High
Overall	Adaptation is largely sporadic and consists of small adjustments to business-as-usual. Coordination and mainstreaming are limited and fragmented.	Adaptation is expanding and increasingly coordinated, including wider implementation and multi-level coordination.	Adaptation is widespread and implemented at or very near its full potential across multiple dimensions.

Depth	Adaptations are largely expansions of existing practices, with minimal change in underlying values, assumptions, or norms.	Adaptations reflect a shift away from existing practices, norms, or structures to some extent.	Adaptations reflect entirely new practices involving deep structural reform, complete change in mindset, major shifts in perceptions or values, and changing institutional or behavioral norms.
Scope	Adaptations are largely localized and fragmented, with limited evidence of coordination or mainstreaming across sectors, jurisdictions, or levels of governance.	Adaptations affect wider geographic areas, multiple areas and sectors, or are mainstreamed and coordinated across multiple dimensions.	Adaptations are widespread and substantial, including most possible sectors, levels of governance, and actors.
Speed	Adaptations are implemented slowly.	Adaptations are implemented moderately quickly.	Change is considered rapid for a given context
Limits	Adaptations may approach but do not exceed or substantively challenge soft limits.	Adaptations may overcome some soft limits but do not challenge or approach hard limits.	Adaptations exceed many soft limits and approach or challenge hard limits.

Based on the literature, the overall transformative nature of adaptation across most global regions and sectors is low (*high confidence)* (Figure 16.6). Documented adaptations tend to involve minor modifications to usual practices taken to address extreme weather conditions (*high confidence*). For example, changing crop variety or timing of crop planting to address floods or droughts, new types of irrigation, pursuing supplementary livelihoods, and home elevations are widely reported but typically do not reflect radical or novel shifts in practice or values and are therefore considered low-depth (*high confidence*) (see Supplementary Material, SM16.1 for more examples). Adaptations documented in the literature are also frequently focused on a single sector or small geographic area (*high confidence*). Actions taken by individuals or households are generally small in scope (Hintz et al., 2018; Hlahla and Hill, 2018) unless they are widely adopted (e.g., by farmers across a region) or address numerous aspects of life. National policies are more likely to be broad in scope (Puthucherril et al., 2014), although they frequently focus on a single sector and are therefore still limited. The speed of adaptation is rarely noted explicitly, but the average speed documented in the literature is slow (*medium confidence*) (Cross-Chapter Box FEASIB in Chapter 18). Adaptation efforts frequently encounter either soft or hard limits (see Section 16.4), but there is limited evidence to suggest these limits are being challenged or overcome (*medium confidence*).

Few documented responses are simultaneously widespread, rapid, and novel (*high confidence*). Some examples exist, such as village relocations or creation of new multi-stakeholder resource governance systems (Schwan and Yu, 2018; McMichael and Katonivualiku, 2020), but these are rare. In general, adaptations that are broad in scope tend to be slow (*medium confidence*), suggesting that achieving high transformation in all four categories (depth, scope, speed, and limits) may be particularly challenging or even involve trade-offs.

Figure 16.6. Evidence of transformative adaptation by sector and region. Evidence of transformational adaptation does not imply effectiveness, equity, or adequacy. Evidence of transformative adaptation is assessed based on the scope, speed, depth, and ability to challenge limits of responses reported in the scientific literature (see Supplementary Material for methods). Studies relevant to multiple regions or sectors are included in assessment for each relevant sector/region.

16.3.2.5 Observed Maladaptation and Co-benefits

There is increasing reporting of maladaptation globally (Table 16.2, Section 17.5.1) (*high confidence*). Maladaptation has been particularly reported in the context of agricultural, forestry, and fisheries practices, migration in the global south, and some infrastructure based-interventions. Urban heat adaptations have been linked to maladaptation that increase health risks and/or energy consumption. Heat poses significant risks to the evolutionary tolerance levels of humans, animals, and crops (Asseng et al., 2021), and current adaptation interventions for reducing urban heat like cool or evaporation roofs and street trees may be insufficient to reduce heat-related vulnerabilities in some urban areas at higher levels of warming (Krayenhoff et al., 2018) (see also Section 16.4 on adaptation limits). There is evidence that autonomous adaptation by individuals and households can shift risk to others, with net increases in vulnerability. Intensification of pasture use as a coping response to climate-induced drought has been observed to increase risks to livestock reproduction and human life expectancy due to overgrazing, suggesting responses to pastoral vulnerability can cross tolerance limits for animals, humans, and food available for foraging (Suvdantsetseg et al., 2017).

Evidence on *realized* co-benefits of implemented adaptation responses with other priorities in the sustainable development goals is emerging among the areas of poverty reduction, food security, health and well-being, terrestrial and freshwater ecosystem services, sustainable cities and communities, energy security, work and economic growth, and mitigation (Table 16.2) (*high confidence*). Evidence on co-benefits of adaptation for mitigation is particularly strong, and is observed in various agricultural, forestry and land use management practices like agroforestry, climate smart agriculture and afforestation (Kremen and Miles, 2012; Christen and Dalgaard, 2013; Mbow et al., 2014; Locatelli et al., 2015; Suckall et al., 2015; Wichelns, 2016;

Kongsager, 2018; Debray et al., 2019; Loboguerrero et al., 2019; Morecroft et al., 2019; Chausson et al., 2020) as well as in the urban built environment (Perrotti and Stremke, 2020; Sharifi, 2020). Evidence on co-benefits of implemented responses for other SDG priority areas is less developed, however, in the areas of education, gender inequality and reduced inequalities, clean water and sanitation, industry, innovation and infrastructure, consumption and production, marine and coastal ecosystem protection, and peace, justice, and strong institutions. This indicates a gap between some assumed likely co-benefits of adaptation and empirical evidence on the realization of these co-benefits within the context of implemented adaptation responses (Berga, 2016; Froehlich et al., 2018; Gattuso et al., 2018; Morris et al., 2018; Chausson et al., 2020; Karlsson et al., 2020; Krauss and Osland, 2020).

Table 16.2: Observed examples of maladaptation and co-benefits from adaptation-related responses in human systems

Implemented adaptations	Observed maladaptation	References
Agricultural & forestry practices		
Intensified cultivation of marginal lands: clearing of virgin forests for farmland; frequent weeding; poorly-managed irrigation schemes; dependence on rainfed agriculture	Increased competition for resources such as water and nutrients; reduced soil fertility; invasive species; degraded environment; increased greenhouse gas emissions; reduced crops diversity and reduced harvest, thus increasing food insecurity in rural areas; accelerated illegal logging practices; increased vulnerability of herders and translated into poor health and working conditions (Mongolia)	Bele et al. (2014); D'haen et al. (2014); Chapman et al. (2016); Ifeanyi-obi et al. (2017); Suvdantsetseg et al. (2017); Villamayor-Tomas and Garcia-Lopez (2017); Afriyie et al. (2018); Ticehurst and Curtis (2018); Tran et al. (2018); Neset et al. (2019); Work et al. (2019); Yamba et al. (2019); Singh and Basu (2020)
Agroforestry systems	Higher water demand where trees were combined with crops and livestock; replaced native trees with non-indigenous trees; Reduced resilience of certain plants (e.g., cocoa); degraded soil and water quality and accelerated environmental degradation in Africa and Asia (Pakistan, Nepal, India, China, Philippines)	Nordhagen and Pascual (2013); D'haen et al. (2014); Hoang et al. (2014); Ruiz-Mallen et al. (2015); Kibet et al. (2016); Chengappa et al. (2017); Haji and Legesse (2017); Abdulai et al. (2018); Antwi-Agyei et al. (2018); Mersha and van Laerhoven (2018); Ullah et al. (2018); Krishnamurthy et al. (2019)
Agricultural transitions: Commercialization of common property; market-integration and sedentarisation of pastoralists; adoption and expansion of commercial crops	Soil degradation and high dependency on external inputs in South and Central America (El-Salvador, Guatemala, Honduras, Nicaragua, and Peru); dependency on foreign corporation seed systems; land enclosures. Adaptation that forced local farmers in Costa Rica to switch crops to commercially viable products (e.g., from rice to sugar cane) impoverished the land by removing nutrients and affecting food security for smallholder farmers.	Nordhagen and Pascual (2013); D'haen et al. (2014); Warner et al. (2015); Kibet et al. (2016); (Warner and Kuzdas, 2016); Haji and Legesse (2017); Antwi-Agyei et al. (2018); Mersha and van Laerhoven (2018); Krishnamurthy et al. (2019); Neset et al. (2019)
Proper, improper, and increased use of agrochemicals, pesticides, and fertilizers	Fertilizer and agrochemicals negatively affected soil quality and accelerated environmental degradation in several parts of Africa (Ghana, Nigeria) and Asia (Pakistan, Nepal, India, China, Philippines). In Europe (Sweden and Finland) there are concerns about the risk of pests and weeds developing immunity to pesticides, and drainage systems and rain transferred chemicals to other fields, thereby affecting arable land. In South and Central America (El-Salvador, Guatemala, Honduras, Nicaragua, and Peru) agrochemicals led to soil degradation, and high dependency on external input was reported. Loss of soil nutrients, increased GHG emissions (Sweden, Finland); high nitrate and phosphate concentration (Great Britain)	Postigo (2014); Rodriguez-Solorzano (2014); Fezzi et al. (2015); Sujakhu et al. (2016); Begum and Mahanta (2017); de Sousa et al. (2018); Tang et al. (2018); Yamba et al. (2019)

Tree planting	The lack of shaded trees increased vulnerability to landslides in areas where Robusta coffee was grown (Mexico); new tree species to cope with climate change increased sensitivity and displaced non-indigenous trees (India; Tanzania and Kenya); Cocoa planted under shade trees had higher mortality rate and more stress (Ghana); Eucalyptus trees planted to reduce soil erosion had high water demand (Pakistan); In certain urban areas, trees planted to provide shade damaged buildings during heavy storms.	Benito-Garzon et al. (2013); Hoang et al. (2014); Ruiz Meza (2015); Chengappa et al. (2017); Abdulai et al. (2018); Ullah et al. (2018)
Fisheries & water management		
Increased fishing activity	Fishery depletion and exacerbated negative trends in the ecosystem that threatened fishermen's subsistence	Goulden et al. (2013); Mazur et al. (2013); Rodriguez-Solorzano (2014); Pershing et al. (2016); Kanda et al. (2017); Kihila (2018); Pinsky et al. (2018)
Shrimp farming	A driver of deforestation of mangroves in Bangladesh; imposes external cost on paddy farmers; salinity levels are relatively higher in paddy plots closer to shrimp ponds. Coral mining increased vulnerability to flooding (in small islands in the Philippines)	Johnson et al. (2016); Jamero et al. (2017); Paprocki and Huq (2018); Sovacool (2018); Morshed et al. (2020)
Water irrigation infrastructure for agriculture; water desalination in response to water shortages	Increased land loss; redistributed risk among agrarian stakeholders; affected the rural poor (Cambodia; Costa Rica); uneven distribution of cost and benefits (US-Mexico border); Desalination plants to led disproportionately high cost for low income water users.	Barnett and O'Neill (2013); Olmstead (2014); Warner and Kuzdas (2016); Work et al. (2019)
Storage of large quantities of water in the home	Water rendered unsafe for drinking due contamination by fecal coliforms in Zimbabwe; drought-induced changes in water harvesting and storage increased breeding sites for mosquitoes (Australia); Water storage facilities and tanks provided ideal breeding conditions for mosquitoes and flies bringing both vectors and diseases closer to people (Ethiopia).	Boelee et al. (2013); Trewin et al. (2013); Kanda et al. (2017)
Increased number of farm dams for water storage; groundwater extraction and interbasin water transfers	Reduced river and ground water flow downstream; water grabs from shared surface or groundwater resources with poorly defined property rights shifted vulnerability to other groups and ecosystems (Cambodia; California): water extractions increased risks for the environment and food security, while transfers reduced hydropower generation and resulted in higher costs paid by electricity consumers and health impacts from air pollution caused by more electricity generation from natural gas (California); increase the concentration in hands of the more powerful large farmers (Argentina)	Mazur et al. (2013); Christian-Smith et al. (2015); (Hurlbert and Mussetta, 2016); Work et al.)
Built environment		

Seawalls and infrastructural development along coastlines	Coastal erosion, beach losses, changes in water current, and destruction of natural ecosystems in Asia, Australasia, Europe, and North America; increased or shifted erosion from protected to unprotected areas in Fiji, Marshall Islands, Nuie, Kiribati, Norway; failed or sped up flood waters and worsened conditions for riparian habitat and downstream residents; harmed nearby reefs and impeded autonomous adaptation practise that could be effective (Bangladesh).	Macintosh (2013); Maldonado et al. (2014); Porio (2014); Betzold (2015); Renaud et al. (2015); Gundersen et al. (2016); Sayers et al. (2018); Craig (2019); Javeline and Kijewski-Correa (2019); Loughran and Elliott (2019); Rahman and Hickey (2019); Piggott-McKellar et al. (2020); Simon et al. (2020) Dahl et al. (2017)
Smart or green luxury real estate development designed to reduce impacts from storm surges and erosion along coastal area; artificial islands.	Redistributed risk and vulnerability; displaced and diminished adaptive capacity of vulnerable groups, created new population of landless peasants; negatively affected neighbouring coastal areas and local ecology (Lagos, Miami, Hanoi, Jakarta, Manila; Maldives)	Caprotti et al. (2015); Magnan et al. (2016); Atteridge and Remling (2018); Ajibade (2019); Salim et al. (2019); Thomas and Warner (2019)
Subsidized insurance premiums for properties located in flood-prone areas, levees, dykes	Rebuilding in risky areas	Shearer et al. (2014); O'Hare et al. (2016); Craig (2019); Loughran and Elliott (2019)
Autonomous flood strategies such as sand bags, digging channels and sand walls around homes.	Sand bags used to reduce coastal erosion released plastics into the sea and led to loss of recreational value of beaches; sand walls shifted the flood impacts across space and time and were more detrimental to poor informal urban settlers (Dakar); caused erosion and degraded coastal lands (South Africa).	Schaer (2015); Wamsler and Brink (2015); (Chapman et al., 2016); Magnan et al. (2016); Mycoo (2018); Rahman and Hickey (2019)
Top-down technocratic adaptation with no consideration for ecosystem biodiversity, local adaptive capacity, and gender issues	Ignored the complexities of the landscapes and socio-ecological systems; constrained autonomous adaptation due to time and labour demands of public work; increased gender vulnerability; hamper women's water rights (South Africa); altered local gender norms (Ethiopia); led to a mismatch that undermine local-level processes that are vital to local adaptive capacity (Rwanda)	Cartwright et al. (2013); Goulden et al. (2013); Nordhagen and Pascual (2013); Carr and Thompson (2014); Nyamadzawo et al. (2015); Ruiz-Mallen et al. (2015); Djoudi et al. (2016); Gautier et al. (2016); Gundersen et al. (2016); Barnett and McMichael (2018); Kihila (2018); Mersha and van Laerhoven (2018); Clay and King (2019); Currenti et al. (2019); Yang et al. (2019)
Migration & relocation		
Out-migration or rural to urban migration in response to food insecurity and agricultural livelihood depreciation	Migration mostly undertaken by poorer household weakened local subsistence production capacity; disrupted family structures; reduced labour available for agricultural work; increased burden of responsibilities on women; fostered loss of solidarity within communities; increased divorce rates; exacerbated conflicts among different groups; increased pressure on urban housing and social services; expanded slum settlements around riparian and coastal areas including flood plains and swamplands (Ethiopia, Namibia, Benin, Botswana, Nigeria, Ghana, Kenya, Niger, Mail, Tanzania, Zimbabwe, South Africa, Morocco, Nepal, Pakistan, Bangladesh China, India, Australia, Nicaragua). Out-migration from small communities had devastating consequences on their fragile economies, thereby reducing community resilience in the long term (Australia).	Su et al. (2017);Aziz and Sadok (2015);Bhatta and Aggarwal (2016);Clay and King (2019); Elagib et al. (2017);Gao and Mills (2018); Kattumuri et al. (2017); Magnan et al. (2016); Ofoegbu et al. (2016); Rademacher-Schulz et al. (2014);Rademacher-Schulz et al. (2014);Wiederkehr et al. (2018); Yegbemey et al. (2017); Yila and Resurreccion (2013); Nizami et al. (2019); Mersha and Van Laerhoven (2016); Ojha et al. (2014); Radel et al. (2018); Gioli et al. (2014); Hooli (2016); Koubi et al. (2016)

Certain autonomous, forced, and planned relocation Temporary resettlement (India)	Expansion of informal settlements in cities (Solomon Islands); relocation to areas prone to landslide and soil erosion or insufficient housing (Fiji); disproportionate burden on vulnerable communities (China); temporary relocation created gender inequality associated with minimal privacy; poor access to private toilets; sexual harassment; reduced sleep; insufficient or food rationing; exploitation and abuse of children (India); inadequate funding and governance mechanism for community-based relocation caused loss of culture, economic decline and health concerns (Alaska); relocation of supply chain to reduce exposure to climate change resulted in adverse outcomes for communities along the supply chain.	Monnereau and Abraham (2013); Maldonado et al. (2014); Pritchard and Thielemans (2014); Averchenkova et al. (2016); Lei et al. (2017); Barnett and McMichael (2018); Currenti et al. (2019)
Implemented adaptations	Observed co-benefits	References
Agricultural practices		
Integrated agricultural practices (e.g., climate smart agriculture, urban and peri-urban agriculture and forestry; agroecology; silvopasture; soil desalinization; drainage improvement; integrated soil-crop system management; no tillage farming; rainwater harvesting; check dams)	Mitigation, especially carbon sequestration (but see (Sommer et al., 2018)); improved household equity regarding farming decisions, particularly inclusion of women; food security	Furman et al. (2014); Lwasa et al. (2014); Kibue et al. (2015); Nyasimi et al. (2017); Aryal et al. (2018); Han et al. (2018); Kakumanu et al. (2018); Sikka et al. (2018); Debray et al. (2019); Kerr et al. (2019); (Teklewold et al., 2019a); Teklewold et al. (2019b); Wang et al. (2020) Sommer et al. (2018)
Improved irrigation systems	Mitigation, especially avoided emissions; improved crop yields	Islam et al. (2020)
Conservation agriculture (e.g.crop diversification; soil conservation; cover cropping)	Mitigation, especially carbon sequestration; increased crop yields; food security; reduced heat and water stress; increased food security	Helling et al. (2015); Sapkota et al. (2015); Kimaro et al. (2016); Mainardi (2018); Asmare et al. (2019); Gonzalez-Sanchez et al. (2019)
Return to traditional farming practices	Mitigation, especially carbon sequestration	Pienkowski and Zbaraszewski (2019)
Place-specific practices & innovations: animal cross-breeding; direct crop seeding; site-specific nutrient management; irrigation innovations; use of riparian buffer strips;	Mitigation, especially carbon sequestration; improved crop yields; food security	Sushant (2013); Balaji et al. (2015); Helling et al. (2015); Jorgensen and Termansen (2016); Sen and Bond (2017); Wilkes et al. (2017); Kakumanu et al. (2018); Mainardi (2018); Sikka et al. (2018) Yadav et al. (2020)

use of green winter land; rice-rice system		
Land and water management		
Agroforestry	Mitigation, especially carbon sequestration; biodiversity and ecosystem conservation; improved food security; plant species diversification; diversification of household livelihoods; improved household incomes; improved access to forage material; energy access and reduced fuel wood gathering time and distance for women; soil and water conservation; aesthetic improvements in landscapes	Holler (2014); Suckall et al. (2015); Sharma et al. (2016); Nyasimi et al. (2017); Pandey et al. (2017); Schembergue et al. (2017); Ticktin et al. (2018); Debray et al. (2019); Jezeer et al. (2019); Krishnamurthy et al. (2019); Nyantakyi-Frimpong et al. (2019); Tschora and Cherubini (2020)
Afforestation and reforestation programs; Forest management practices (e.g., tree thinning)	Mitigation, especially carbon sequestration; biodiversity and ecosystem conservation; new employment opportunities; diversification of household livelihoods; increased household incomes; improved access to fuel wood; harvesting opportunities from enclosures	Holler (2014); Etongo et al. (2015); Diederichs and Roberts (2016); Acevedo-Osorio et al. (2017); Nyasimi et al. (2017); Krishnamurthy et al. (2019); Rahman et al. (2019) Wolde et al. (2016)
Ecosystem-based adaptations like mangrove restoration and natural coastal defences	Mitigation, especially carbon sequestration; habitat enhancement and protection for marine species; prevention of floor-related deaths, injuries, and damage; improved nutrition and income generation for local communities, improved water quality	Fedele et al. (2018) Roberts et al. (2012); Morris et al. (2019); (Jones et al., 2020)
Sustainable water management	Mitigation, especially avoided emissions; reduced water demand; increased awareness about impacts of water consumption; decreased incidence of fecaloral disease transmission; decreased use of drinking water for irrigation; reduced soil loss; increased groundwater retention; increased vegetation cover; increased food security and health and well-being; increased forage for livestock and amount of cultivated area; enhanced recreational areas	Spencer et al. (2017); Siraw et al. (2018); Stanczuk-Galwiaczek et al. (2018)
Return to traditional land management practices (e.g., the Ngitili system)	Mitigation, especially carbon sequestration; increased water availability for household and livestock use; increase in presence of edible and medicinal plants; regional economic growth; reduced land management conflicts; increased household income and access to education for children; improved access to wood fuel and reduced collection time for women; improved wildlife habitat.	Duguma et al. (2014)
REDD+ participation to maintain intact forest ecosystems	Mitigation, especially carbon sequestration; improved air quality; water and soil conservation; slowed rate of vector-borne disease; improved mental well-being associated with cultural continuity; clean water; nutritional and spiritual value of forest-derived foods; protection from violence related to natural resource extraction	McElwee et al. (2017); Spencer et al. (2017)
Urban planning and design		

Spatial planning – walkable neighbourhood design; strategic densification.	Mitigation, particularly avoided emissions; public health – increases in physical activity, reductions in air pollution and urban heat island effect	Beiler et al. (2016); Belanger et al. (2016)
Urban greening (e.g tree planting; construction of stormwater retention areas; construction of green roofs and cool roofs; provision of rainwater barrels; pervious pavement materials)	Mitigation, particularly avoided emissions; public health improvements – increases in physical activity, reductions in air and noise pollution, reduced urban heat island effect, improved mental health; urban flood risk management; water savings; energy savings	Samora-Arvela et al. (2017); Vahmani and Jones (2017); Newell et al. (2018); Alves et al. (2019); De la Sota et al. (2019)
Improved building efficiency standards	Mitigation, particularly avoided emissions; improved air quality; reduced urban heat island; improved natural indoor lighting	Barbosa et al. (2015); Koski and Siulagi (2016); Balaban and Puppim de Oliveira (2017); Landauer et al. (2019)
Use of local building materials	Mitigation, particularly avoided emissions	Lundgren-Kownacki et al. (2018)

16.3.3 Knowledge Gaps in Observed Responses

Many adaptation responses are not documented, and reporting bias is a key challenge for assessment of observed responses. Evidence of absence (i.e., where no adaptations are occurring) is different from absence of evidence (where responses are occurring but are not documented), with implications for understanding trends in global responses.

Adaptation is being reported differently across different sources of knowledge. The peer-reviewed literature, for example, has been primarily reporting reactive adaptation at the individual, household, and community levels, while the grey literature has been more mixed, reporting adaptation across governmental levels and civil society, with less focus on individuals and households (Ford et al., 2015a; Ford and King, 2015). Synthesis of impacts and responses within the private sector is particularly limited (Averchenkova et al., 2016; Minx et al., 2017), further suggesting that knowledge accumulation on climate responses has been particularly slow, and that more robust evidence synthesis is required to fill key knowledge gaps.

The potential for under-reporting is most acute in the context of minorities, remote and marginalized groups, who are often also be the most affected by the impacts of climate change and least able to respond to, or benefit from, the responses to, climate change (Araos et al., 2021). Deficits in reporting on impacts and responses are well-recognized in the global south, among vulnerable populations (e.g., women, socio-economically disadvantaged, indigenous, people living with disabilities), and within civil society (ibid.).

There is growing support for more comprehensive and systematic approaches to assess adaptation progress (Berrang-Ford et al., 2015; Ford et al., 2015a; Ford and King, 2015; Ford and Berrang-Ford, 2016; Biesbroek et al., 2018). Since AR5, there is increased recognition of the value of integrating diverse knowledge sources to fill knowledge gaps in observation of impacts and responses (Chapter 17; Cross-Chapter Box PROGRESS in Chapter 17). Van Bavel, for example, found that the involvement of local and diverse knowledge can improve the detection (*medium confidence*) and attribution (*medium confidence*) of health impacts, and improve the action (*high confidence*) (Van Bavel et al., 2020).

Cross-Chapter Box INTEREG: Inter-regional Flows of Risks and Responses to Risk

Authors: Birgit Bednar-Friedl (Austria, Chapter 13), Christopher Trisos (South Africa, Chapter 9), Laura Astigarraga (Uruguay, Chapter 12), Magnus Benzie (Sweden/United Kingdom), Aditi Mukherji (India, Chapter 4), Maarten Van Aalst (The Netherlands, Chapter 16)

Introduction

Our world today is characterized by a high degree of interconnectedness and globalization which establish pathways for the transmission of climate-related risks across sectors and borders (*high confidence*) (Challinor et al., 2018; Hedlund et al., 2018). While AR5 has pointed to this connection of risks across regions as 'cross-regional phenomena' (Hewitson et al., 2014), only a few countries so far have integrated interregional aspects into their climate change risks assessments (Liverman, 2016; Surminski et al., 2016; Adams et al., 2020) and adaptation is still framed as a predominantly national or local issue (Dzebo and Stripple, 2015; Benzie and Persson, 2019).

Interregional risks from climate change - also called cross-border, transboundary, transnational or indirect risks - are risks that are transmitted across borders (e.g., transboundary water use) and/or via teleconnections (e.g., supply chains, global food markets) (Moser and Hart, 2015). The risks can result from impacts, including compound or concurrent impacts, that cascade across several tiers, in ways that either diminish or escalate risk within international systems (Carter et al., 2021). Risk transmission may occur through trade and finance networks, flows of people (Cross-Chapter Box MIGRATE in Chapter 7), biophysical flows (natural resources such as water) and ecosystem connections. But not only risks are transmitted across borders and systems, but also the adaptation response may reduce risks at the origin of the risk, along the transmission channel or at the recipient of the risk (Carter et al., 2021). This Cross-Chapter Box discusses four interregional risk channels (trade, finance, food, and ecosystems) and how adaptation can govern these risks.

Figure Cross-Chapter Box INTEREG.1: Interregional climate risks: the example of the trade transmission channel, illustrated for the Thailand flood 2011 (Abe and Ye, 2013; Haraguchi and Lall, 2015; Carter et al., 2021)

Trade

Most commodities are traded on global markets and supply chains have become increasingly globalized. For instance, specialized industrial commodities like semi-conductors are geographically concentrated in a few countries (Challinor et al., 2017) (Liverman, 2016). When climatic events like flooding or heat affect the location of these extraction and production activities, economies are not only disrupted locally but also across borders and in distant countries (*high confidence*), as exemplified by the Thailand flood 2011 that led to a shortage of key inputs to the automotive and electronics industry not only in Thailand but also in Japan, Europe, and the USA (Figure Cross-Chapter Box INTEREG.1). For many industrialized countries like the United Kingdom, Japan, the USA and the European Union, there is increasing evidence that the trade impacts of climate change are significant and can have substantial domestic impacts (*medium confidence*) (Nakano, 2017; Willner et al., 2018, Section 13.9.1; Benzie and Persson, 2019; Knittel et al., 2020). Enhanced trade can transmit risks across borders and thereby amplify damages (Wenz and Levermann, 2016), but it can also increase resilience (Lim-Camacho et al., 2017; Willner et al., 2018).

Finance

Climate risks can also spread through global financial markets (Mandel et al., 2021). For the case of coastal and riverine flooding with low adaptation 2080 (RCP 8.5-SSP5), the financial system is projected to amplify direct losses by a factor of 2 (global average), but reach up to a factor of 10 for countries that are central financial hubs (Mandel et al., 2021, Figure 13.28). Indirect impacts may also arise through indirect effects on foreign direct investment, remittance flows, and official development assistance (Hedlund et al., 2018).

Food

The global supply of agricultural products is concentrated to a few main breadbaskets (Bren d'Amour et al., 2016; Gaupp et al., 2020, Chapter 5). For instance, Central and South America is one of the regions with the highest potential to increase food supplies to more densely populated regions in Asia, Middle East and Europe (Chapter 12). The exports of agricultural commodities (coffee, bananas, sugar, soybean, corn, sugarcane, beef livestock) have gained importance in the past two decades as international trade and globalization of markets have shaped the global agri-food system (Chapter 5).

The export of major food crops like wheat, maize and soybeans from many of the world's water scarce areas – Middle East, North Africa, parts of South Asia, North China Plains, south-west USA, Australia – to relatively water abundant parts of the world carries a high virtual water content (the net volume of water embedded in trade) (*high confidence*) (Hoekstra and Mekonnen, 2012; Dalin et al., 2017; Zhao et al., 2019, Chapter 4). Both importing and exporting countries are exposed to transboundary risk transmission through climate change impacts on distant water resources (Sartori et al., 2017; Zhao et al., 2019; Ercin et al., 2021). Climate change is projected to exacerbate risk and add new vulnerabilities for risk transmission (*medium confidence*). Rising atmospheric CO_2 concentration is projected to decrease water efficiency of growing maize and temperate cereal crops in parts of USA, East and Mediterranean Europe, South Africa, Argentina, Australia and South East Asia with important implications for future trade in food grains (Fader et al., 2010). By 2050 (SRES B2 scenario) virtual water importing countries in Africa and the Middle East may be exposed to imported water stress as they rely on imports of food grains from countries which have unsustainable water use (Sartori et al., 2017). Until 2100, virtual trade in irrigation water is projected to almost triple (for SSP2-RCP6.5 scenarios) and the direction of virtual water flows is projected to reverse with the currently exporting regions like South Asia becoming importers of virtual water (Graham et al., 2020). An additional 10-120% trade flow from water abundant regions to water scarce regions will be needed to sustain environmental flow requirements on a global scale by end of the century (Pastor et al., 2019). Exports of agricultural commodities contribute to deforestation, over-exploitation of natural resources and pollution, affecting the natural capital base and ecosystem services (Agarwala and Coyle, 2020; Rabin et al., 2020, Section 12.5.4).

Species and ecosystems

The spatial distributions of species on land and in the oceans are shifting due to climate change, with these changes projected to accelerate at higher levels of global warming (Pecl et al., 2017). These 'species on the move' have large effects on ecosystems and human well-being, and present challenges for governance (Pecl et al., 2017). For example, the number of transboundary fish stocks are projected to increase as key fisheries species are displaced by ocean warming (Pinsky et al., 2018). Conflict over shifting mackerel fisheries has already occurred between European countries (Spijkers and Boonstra, 2017), because few regulatory bodies have clear policies on shifting stocks; this leaves species open to unsustainable exploitation in new waters in the absence of regularly updated catch allocations to reflect changing stock distributions (Caddell, 2018).

Human health will also be affected as vector-borne diseases such as malaria and dengue shift geographic distributions (Caminade et al., 2014). There is also evidence that many warm-adapted invasive species, such as invasive freshwater cyanobacterium, have spread to higher latitudes due to climate change (Chapter 2).

Adaptation to interregional climate risks

Adaptation responses to reduce interregional risks can be implemented at a range of scales: at the point of the initial climate change impact (e.g. assistance for recovery after an extreme event, development of resilient infrastructure, climate-smart technologies for agriculture); at or along the pathway via which impacts are transmitted to the eventual recipient (e.g. trade diversification, re-routing of transport); in the recipient country (e.g. increasing storage to buffer supply disruptions), or by third parties (e.g. adaptation finance, technology transfer) (Bren d'Amour et al., 2016; Carter et al., 2021; Talebian et al., 2021). A knowledge gap exits on the need for, effectiveness of, and limits to adaptation under different socio-economic and land-use futures.

Due to regional and global interdependencies, climate resilience has a global, multi-level public good character (Banda, 2018). The benefits of adaptation are therefore shared beyond the places where adaptation is initially implemented. Conversely, adaptation may be successful at a local level whilst redistributing vulnerability elsewhere or even driving or exacerbating risks in other places (Atteridge and Remling, 2018). International cooperation is therefore needed to ensure that inter-regional effects are considered in adaptation and that adaptation efforts are coordinated to avoid maladaptation. However, regional and global scale governance of adaptation is only just beginning to emerge (Persson, 2019).

The UNFCCC Paris Agreement frames adaptation as a 'global challenge' (Article 7.2) and establishes the global goal on adaptation (Article 7.1), which provides space for dialogue between Parties on the global scale challenge of adaptation and the need for renewed political and financial investment in adaptation, including to address interregional effects (Benzie et al., 2018).

National Adaptation Plans (NAPs) can evolve to consider inter-regional effects as well as domestic ones (Liverman, 2016; Surminski et al., 2016; European Environment, 2020). Regional and international coordination of NAPs, coupled with building capacities and addressing existing knowledge gaps at the country level, can help to ensure that resources are oriented towards reducing interregional risks and building systemic resilience to climate change globally (Booth et al., 2020; Wijenayake et al., 2020).

Given the important role of private actors in managing interregional climate risks (Goldstein et al., 2019; Tenggren et al., 2019), efforts will be needed to align public and private strategies for managing interregional climate risks to avoid maladaptation and ensure just and equitable adaptation at different scales (Talebian et al., 2021).

[END CROSS-CHAPTER BOX INTEREG HERE]

A new development since AR5, there is now growing evidence assessing progress on adaptation across sectors, geographies and spatial scales. Uncertainty persists around what defines adaptation and how to measure it (Cross-Chapter Box FEASIB in Chapter 18, UNEP, 2021). As a result, most literature synthesizing responses are based on documented or reported adaptations only, and are thus subject to substantial reporting bias.

We document implemented adaptation-related responses that could directly reduce risk. Adaptation *as a process* is more broadly covered in Chapter 17 (Section 17.4.2), including risk management, decision-making, planning, feasibility (see Cross-Chapter Box FEASIB in Chapter 18), legislation and learning. Here, we focus on a subset of adaptation activities: adaptation-related responses of species, ecosystems, and human societies that have been implemented, observed, and could directly reduce risk. We consider all adaptation-related responses to assumed, perceived, or expected climate risk, regardless of whether or not impacts or risks have been formally attributed to climate change.

We use the term 'adaptation-related responses', recognising that not all responses reduce risk. While 'adaptation' implies risk reduction, we use the broader term 'responses' to reflect that responses may decrease risk, but in some cases may increase risk.

Given limited evidence to inform comprehensive global assessment of effectiveness and adequacy, we assess evidence that adaptation responses in human systems indicate transformational change. Chapter 17 considers adaptation planning and governance, including adaptation solutions, success, and feasibility assessment

(Cross-Chapter Box FEASIB in Chapter 18). It is not currently possible to conduct a comprehensive global assessment of effectiveness, adequacy, or the contribution of adaptation-related responses to changing risk due to an absence of robust empirical literature (discussed further in Cross-Chapter Box PROGRESS in Chapter 17).

In natural ecosystems or species, detectable changes can be considered as 'impact' or 'response'. The distinction between 'observed impacts' (16.2) and 'observed responses' (16.3) is not always clear. For example, autonomous distributional shifts in wild species induced by increasing temperatures (an observed impact) may reduce risk to the species (an autonomous adaptation response), but this process can be enhanced or supported by human intervention such as intentional changes in land use. Observed autonomous changes in natural ecosystems or species unsupported by human intervention are treated as impacts (see Section 16.2).

Adaptation-related responses are frequently motivated by a combination of climatic and non-climatic drivers, and interact with other transitions to affect risk. For societal responses, it is difficult to say whether they are triggered by observed or anticipated changes in climate, by non-climatic drivers, or as is the case in many societal responses, a combination of all three. In the case of impacts, assessment typically focuses on detection and attribution vis a vis a counterfactual of no climate change. While there has been some effort to attribute reduced climate risk to adaptation-related responses (Toloo et al., 2013a; Toloo et al., 2013b; Hess et al., 2018; Weinberger et al., 2018), in many cases this has not been feasible given difficulties in defining adaptation and empirically disentangling the contribution of intersecting social transitions and changing risks. Literature on adaptation-related response frequently draws on theories-of-change to assess the likely contribution of adaptations to changes in risk, including maladaptation and co-benefits.

16.4 Synthesis of Limits to Adaptation Across Natural and Human Systems

This section builds on previous IPCC Reports (i.e., AR5, SR15, SROCC, SRCCL) to advance concepts and emphasize remaining gaps in understanding about limits to adaptation. We provide case studies to illustrate these concepts and synthesize regional and sectoral limits to adaptation across natural and human systems that informs key risks (Section 16.5) and Reasons for Concern (Section 16.6). We also identify residual risks - risks that remain after efforts to reduce hazards, vulnerability, and/or exposure - associated with limits to adaptation.

16.4.1 Definitions and Conceptual Advances Since AR5

16.4.1.1 Limits to Adaptation since AR5

AR5 introduced the concept of limits to adaptation and provided a functional definition that has been used in subsequent Special Reports (SR15, SROCC, SRCCL) and is also used for AR6 (see also Chapter 1).

A limit is defined as the point at which an actor's objectives or system's needs cannot be secured from intolerable risks through adaptive actions (Klein et al., 2014). Tolerable risks are those where adaptation needed to keep risk within reasonable levels is possible, while intolerable risks are those where practicable or affordable adaptation options to avoid unreasonable risks are unavailable. This highlights that limits to adaptation are socially constructed and based on values that determine levels of reasonable or unreasonable risk as well as on available adaptation options, which vary greatly across and within societies.

Limits are categorized as being either 'soft' or 'hard'. Soft limits may change over time as additional adaptation options that are practicable or affordable become available. Hard limits will not change over time as no additional adaptive actions are possible. When a limit is exceeded, then intolerable risk may materialize and the actor's objectives or system's needs may be either abandoned or transformed (Figure Box16.1.1).

For human systems, soft and hard limits are largely distinguished by whether or not constraints to adaptation are able to be overcome. Constraints to adaptation (also called barriers) are factors that make it harder to plan and implement adaptation actions – such as limited financial resources, ineffective institutional arrangements or insufficient human capacity. Soft limits are mostly associated with human systems, due in part to the role of human agency in addressing constraints. For natural systems, the magnitude and rate of climate change and capacity of adaptation to such change largely determine the type of limit. Hard limits are largely associated with natural systems and are mostly due to inability to adapt to biophysical changes.

Using this understanding of limits, subsequent Special Reports have assessed relevant literature (Mechler et al., 2020). SR15 identifies several regions, sectors and ecosystems – including coral reefs, biodiversity, human health, coastal livelihoods, small island developing states, and the Arctic – that are projected to experience limits at either 1.5ºC or 2ºC. SRCCL states that land degradation due to climate change may result in limits to adaptation being reached in coastal regions and areas affected by thawing permafrost. SROCC details that risks of climate-related changes in the ocean and cryosphere may result in limits for ecosystems and vulnerable communities in coral reef environments, urban atoll islands and low-lying Arctic locations before the end of this century in case of high emissions scenarios.

A key area of advancement since AR5 is how incremental and transformational adaptation relate to limits to adaptation. Incremental adaptation maintains 'the essence and integrity of a system or process at a given scale' while transformational adaptation 'changes the fundamental attributes of a social-ecological system' (Matthews, 2018). Both incremental and transformational adaptation may expand the adaptive possibilities for a system, providing additional adaptation options after a system reaches a soft limit (Felgenhauer, 2015; Pelling et al., 2015; Termeer et al., 2017, see also Chapter 1 and 17; Alston et al., 2018; Panda, 2018; Mechler and Deubelli, 2021). However, it is critical to note that adaptation, whether incremental or transformational, must support securing an actor's objectives or system's needs from intolerable risks. Once objectives or needs have been abandoned or transformed, a limit to adaptation has occurred. However, objectives or needs may change over time as values of a society change (Taebi et al., 2020), thus adding further complexity to assessing limits to adaptation.

16.4.1.2 Residual risk since AR5

The term 'residual risk' was not assessed in detail in AR5 and was used interchangeably with other terms including 'residual impacts', 'residual loss and damage' and 'residual damage'. SR15 includes discussion of residual risks without an explicit definition and relates these to loss and damage and limits to adaptation, concluding that residual risks rise as global temperatures increase from 1.5°C to 2°C. SRCCL refers to residual risks arising from limits to adaptation related to land management. Such residual risk can emerge from irreversible forms of land degradation, such as coastal erosion when land completely disappears, collapse of infrastructure due to thawing of permafrost, and extreme forms of soil erosion. SROCC advanced the conceptualization of residual risk and integrated it within the risk framework, defining residual risk as the risk that remains after actions have been taken to reduce hazards, exposure and/or vulnerability. Residual risk is therefore generally higher where adaptation failure, insufficient adaptation or limits to adaptation occur. We use the SROCC definition of residual risk for our assessment in the following sections and identify residual risks that are associated with limits to adaptation.

[START BOX 16.1 HERE]

Box 16.1: Linking Adaptation Constraints, Soft and Hard Limits

McNamara et al. (2017) provides an example of community-scaled adaptation that highlights how constraints affect limits, the relationship between soft and hard limits, and the potential need to abandon or transform objectives. In Boigu Island, Australia, community members are already adapting to perceived climate change hazards - including sea level rise and coastal erosion - to secure their objective of sustaining livelihoods and way of life in their current location. Existing seawall and drainage systems provide inadequate protection from flooding during high tides, leading residents to elevate their houses to prevent damages. However, these adaptation measures have proved to be insufficient. Standing saltwater for extended periods of time after floods has resulted in losses and damages – including erosion of infrastructure, increased soil salinity, and heightened public health concerns. Additional adaptation efforts are constrained by scarcity of elevated land which inhibits movement of infrastructure within the community and lack of financial, technical and human assets to improve coastal protection measures.

These constraints are leading to a soft limit to adaptation – where risks would become unreasonable as sea levels continue to rise and practicable and affordable adaptation options are limited to currently available approaches. This soft limit could be overcome through addressing constraints and allowing further adaptation to take place, such as providing financial, technical and human resources for more effective coastal protection and drainage systems that would reduce flooding. However, if the effectiveness of these new adaptation measures decreases as sea levels rise further and if constraints are not able to be overcome, another soft limit may be reached. Eventually, if constraints are not addressed, no further adaptation measures are implemented and climate hazards intensify, the area could become uninhabitable. This would then be a hard limit for adaptation – there would be no adaptation options available that would allow the community to sustain livelihoods and way of life in its present location. This hard limit to adaptation may necessitate abandoning the objective of remaining in the community. The objective of the community may then transform to sustaining their livelihoods in a less vulnerable location which would necessitate relocation. However, such transformation of the community's objectives may be hindered by the expressed resistance of residents to migrate, due to their strong sense of place.

[END BOX 16.1 HERE]

16.4.2 Insights from Regions and Sectors about Limits to Adaptation

Here we provide example case studies to highlight constraints that may lead to soft limits, potential incremental and transformational adaptation options that may overcome soft limits, evidence of hard limits and residual risks.

16.4.2.1 Small Island Developing States (SIDS)

An expanding volume of empirical research highlights existing adaptation constraints that may lead to soft limits in SIDS. Investigation of national communications among 19 SIDS found that financial constraints, institutional challenges and poor resource endowments were the most-frequently reported as inhibiting adaptation for a range of climate impacts (Robinson, 2018b). Governance, financial and information constraints such as unclear property rights and lack of donor flexibility have led to hasty implementation of adaptation projects in Kiribati, whereas in Vanuatu and the Solomon Islands, limited awareness of rural adaptation needs and weak linkages between central governance and local communities have resulted in an urban bias in resource allocation (Kuruppu and Willie, 2015). Limited availability and use of information and technology also present constraints to adaptation – many SIDS suffer from lack of data and established routines to identify loss and damage, and the combination of poor monitoring of slow-onset changes and influence of non-climatic determinants of observed impacts challenges attribution (Thomas and Benjamin, 2018). The fact that climate information is often available only in the English language represents another common constraint for island communities (Betzold, 2015). Although indigenous and local knowledge systems can provide important experience-based input to adaptation policies (Miyan et al., 2017), socio-cultural values and traditions such as attachment to place, religious beliefs and traditions can also constrain adaptation in island communities, particularly for more transformational forms of adaptation (Ha'apio et al., 2018; Oakes, 2019).

Soft limits to adaptation for coastal flooding and erosion are already being experienced in Samoa due largely to financial, physical and technological constraints (Crichton and Esteban, 2018). While sea walls have been erected to minimize coastal erosion, these defences need regular upgrading and replacement as high swells, tropical cyclones and constant wave action erode their effectiveness. The high costs of installing, upgrading and enlarging such infrastructure has led to sea walls only being used in specific locations, leaving communities that are beyond the extent of these measures exposed to inundation and erosion. Native tree replanting has also been implemented but coastal flooding and erosion persist as large swells lead to high failure rates of replanting efforts. Across SIDS, adaptation to coastal flooding and erosion in particular is increasingly facing soft limits due to high costs, unavailability of technological options and limited physical space or environmental suitability for hard engineering or ecosystem-based approaches (Mackey and Ware, 2018; Nalau et al., 2018).

Retreat and relocation constitute transformative adaptation options, although evidence of permanent community-scale relocation in response to climate change remains limited at present (Kelman, 2015; McNamara and Des Combes, 2015). Material and emotional cost of emigration as well as loss of homeland, nationhood, and other intangible assets and values imply that relocation is generally considered a last resort (Jamero et al., 2017) and may mean abandoning objectives of remaining in existing locations, hence exceeding adaptation limits.

Hard limits in SIDS are mostly due to adaptation being unable to prevent intolerable risks from escalating climate hazards such as sea-level rise and related risks of flooding and surges, severe tropical cyclones, and contamination of groundwater. Emerging evidence suggests that shortage of water and land degradation have already contributed to migration of multiple island communities in the Pacific (Handmer and Nalau, 2019).

Residual risks for SIDS include loss of marine and terrestrial biodiversity and ecosystem services, increased food and water insecurity, destruction of settlements and infrastructure, loss of cultural resources and heritage, collapse of economies and livelihoods and reduced habitability of islands (Section 3.5.1, Section 15.3).

16.4.2.2 Agriculture in Asia

Lack of financial resources is found to be a significant constraint that contributes to soft limits to adaptation in agriculture across Asia. Although smallholder farmers are currently adapting to climate impacts, lack of finance and access to credit prevents upscaling of adaptive responses and has led to losses (Bauer, 2013; Patnaik and Narayanan, 2015; Bhatta and Aggarwal, 2016; Loria, 2016). Other constraints further contribute to soft limits including governance and associated institutional factors such as ineffective agricultural policies and organizational capacities (Tun Oo et al., 2017), information and technology challenges such as limited availability and access to technologies on the ground (Singh et al., 2018), socio-cultural factors such as the social acceptability of adaptation measures that are affected by gender (Huyer, 2016; Ravera et al., 2016), and limited human capacity (Masud et al., 2017). A wide range of pests and pathogens are predicted to become problematic to regional food crop production as average global temperatures rise (Deutsch et al., 2018) increasing crop loss across Asia for which farmers are already experiencing a variety of adaptation constraints including financial, economic and technological challenges (Sada et al., 2014; Tun Oo et al., 2017; Fahad and Wang, 2018). Extreme heat waves are projected in the densely populated agricultural regions of South Asia leading to increased risk of heat stress for farmers and resultant constraints on their ability to implement adaptive actions (Im et al., 2017). However, socio-economic constraints appear to have a higher influence on soft limits to adaptation in agriculture than biophysical constraints (Thomas et al., 2021). For example, an examination of farmers' adaptation to climate change in Turkey found that constraints related to access to climate information and access to credit will likely limit the yield benefits of incremental adaptation (Karapinar and Özertan, 2020). In Nepal, conservation policies restrict traditional grazing inside national parks, which promotes intensive agriculture and limits other cropping systems that have been implemented as climate change adaptation (Aryal et al., 2014).

In Bangladesh, small and landless farm households are already approaching soft limits in adapting to riverbank erosion (Alam et al., 2018). While wealthier farming households can implement a range of adaptation responses including changing planting times and cultivating different crops, poorer households have limited access to financial institutions and credit to implement such measures. Their adaptation responses of shifting to homestead gardening and animal rearing are insufficient to maintain their livelihoods and these households are more likely to engage in off-farm work or migrate.

(Palao et al., 2019) identify the possible need for transformational adaptation in Asian-Pacific agricultural practices due to changes in biophysical parameters as global average temperatures rise. In this context, transformational adaptation would consist of changing farming locations to different provinces or different elevations for the production of specific crops or introducing new farming systems. Nearly 50% of maize in the region along with 18% of potato and 8% of rice crops would need to either be shifted in location or use new cropping systems, with the most significant transformation being needed in China, India, Myanmar and the Philippines. For maize suitability by 2030, seven provinces in the east and northeast of China are projected to experience over 50% reduction in suitability and two northern states in India may experience

70% reduction in suitability. Cassava and sweet potato may play a critical role in food resilience in these areas, as these crops are more resilient to climate change (Prain and Naziri, 2019).

In terms of hard limits, the rate and extent of climate change is critical as agriculture is climate-dependent and sensitive to changes in climate parameters. Poudel and Duex (2017) document that over 70% of the springs used as water sources in Nepalese mountain agricultural communities had a decreased flow and approximately 12% had dried up over the past decade. While there are some adaptation measures to address reduced water availability – e.g., the introduction of water-saving irrigation technology among Beijing farmers to alleviate water scarcity in metropolitan suburbs (Zhang et al., 2019) – these actions still depend on some level of water availability. If climate hazards intensify to the point where water supply cannot meet agricultural demands, hard limits to adaptation will occur.

Residual risks associated with agriculture in Asia include declines in fisheries, aquaculture and crop production, particularly in South and Southeast Asia (Section 10.3.5), increased food insecurity (Section 10.4.5), reductions of farmers' incomes by up to 25% (Section 10.4.5), loss of production areas (Section 10.4.5) and reduced physical work capacity for farmers - between 5-15% decline in south-southwest Asia and China under RCP8.5 (Section 5.12.4).

16.4.2.3 Livelihoods in Africa

For livelihoods dependent on small-scale rain-fed agriculture in Africa, climate hazards include floods and droughts. However, governance, financial and information/awareness/technology challenges are identified as the most significant constraints leading to soft limits, followed by social and human capacity constraints (Thomas et al., 2021). Finance and land tenure constraints restrict Ghanaian farmers when considering adaptation responses due to climate variability (Guodaar et al., 2017). Similarly, in East Africa, farmers with small pieces of land have limited economic profitability, making it difficult to invest in drought and/or flood management measures (Gbegbelegbe et al., 2018).

Increasing droughts and floods require costlier adaptation responses to reduce risks, such as using drought-tolerant species (Berhanu and Beyene, 2015) and coping strategies for flood-prone households (Schaer, 2015; Musyoki et al., 2016), resulting in soft limits for poorer households who cannot afford these responses. In Namibia weak governance and poor integration of information, such as disregarding knowledge of urban and rural residents in flood management strategies, has resulted in soft limits to adaptation, leading to temporary or permanent relocation of communities (Hooli, 2016). Shortage of land – namely high population pressure and small per capita land holding – leads to continuous cultivation and results in poor soil fertility. This low productivity is further aggravated by erratic rainfall causing soft limits as farmers cannot produce enough and must depend on food aid (Asfaw et al., 2019).

Relocation due to flooding is discussed as a transformation adaptation action taken in Botswana where the government decided to permanently relocate hundreds of residents to a nearby dryland area (Shinn et al., 2014). Some residents permanently relocated whereas others only temporarily relocated against the government's instructions. Such relocation processes must attend to micro-politics and risks of existing systemic issues of inequality and vulnerability.

In terms of hard limits, land scarcity poses a hard limit when implementing organic cotton production, an adaptation response supporting sustainable livelihoods (Kloos and Renaud, 2014).

Residual risks associated with livelihoods in Africa include poorer households becoming trapped in cycles of poverty (Section 9.9.3), increased rates of rural-urban migration (Section 9.8.4), decline of traditional livelihoods such as in agriculture (Section 9.9.3, Section 9.11.3.1) and fisheries (Section 9.11.1.2) and loss of traditional practices and cultural heritage (Section 9.9.2).

16.4.3 Regional and Sectoral Synthesis of Limits to Adaptation

16.4.3.1 Evidence on Limits to Adaptation

There is *high agreement* and *medium evidence* that there are limits to adaptation across regions and sectors. However, much of the available evidence focuses on constraints that may lead to limits at some point with little detailed information on how limits may be related to different levels of socio-economic or environmental change (*high confidence)*. Figure 16.7 assesses evidence on constraints and limits for broad categories of region and sector. Small Islands and Central and South America show most evidence of constraints being linked to adaptation limits across sectors while ocean and coastal ecosystems and health, wellbeing and communities show most evidence of constraints being linked to limits across regions (*medium confidence)*.

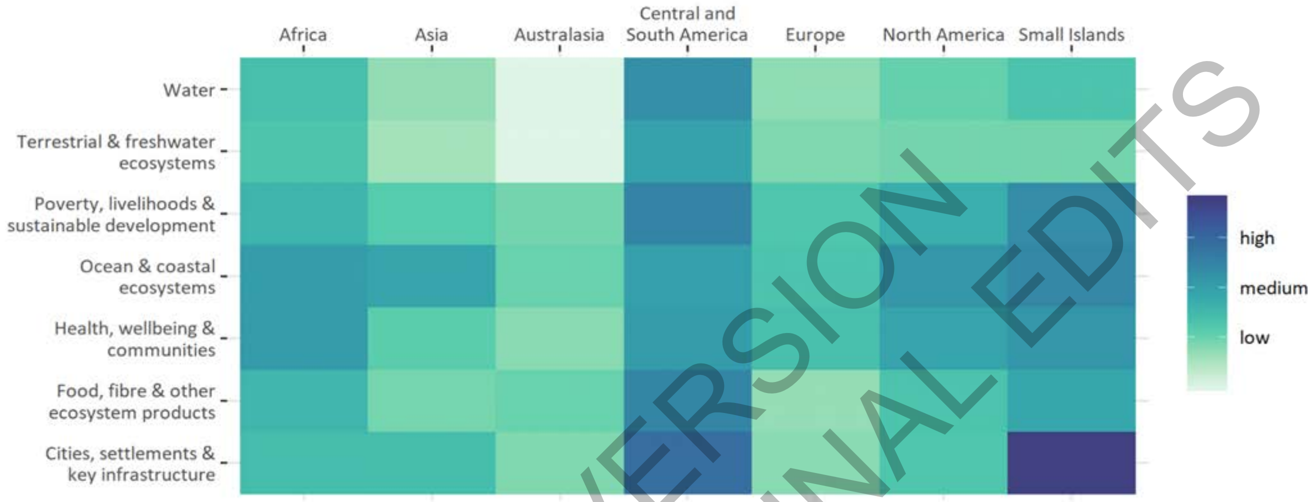

Figure 16.7 Evidence on constraints and limits to adaptation by region and sector. Data from (Thomas et al. 2021), based on 1682 scientific publications reporting on adaptation-related responses in human systems. See SM16.1 for methods. **Low evidence:** <20% of assessed literature has information on limits, literature mostly focuses on constraints to adaptation **Medium evidence:** between 20-40% of assessed literature has information on limits, literature provides some evidence of constraints being linked to limits **High evidence:** > 40% of assessed literature has information on limits, literature provides broad evidence of constraints being linked to limits

There are clusters of evidence with additional details on limits to adaptation, as detailed in Table 16.3. Evidence on limits to adaptation is largely focused on terrestrial and aquatic species and ecosystems, coastal communities, water security, agricultural production, and human health and heat *(high confidence)*.

Beginning at 1.5°C, autonomous and evolutionary adaptation responses by terrestrial and aquatic species and ecosystems face hard limits, resulting in biodiversity decline, species extinction and loss of related livelihoods *(high confidence)*. Interventionist adaptation strategies to reduce risks for species and ecosystems face soft limits due to governance, financial and knowledge constraints *(medium confidence).*

As sea levels rise and extreme events intensify, coastal communities face soft limits due to financial, institutional and socio-economic constraints reducing the efficacy of coastal protection and accommodation approaches and resulting in loss of life and economic damages (*medium confidence).* Hard limits for coastal communities reliant on nature based coastal protection will be experienced beginning at 1.5°C (*medium confidence)*.

Beginning at 3°C, hard limits are projected for water management measures, leading to decreased water quality and availability, negative impacts on health and wellbeing, economic losses in water and energy dependent sectors and potential migration of communities (*medium confidence*).

Soft and hard limits for agricultural production are related to water availability and the uptake and effectiveness of climate-resilient crops which is constrained by socio-economic and political challenges (*medium confidence).*

Adaptation measures to address risks of heat stress, heat mortality and reduced capacities for outdoor work for humans face soft and hard limits across regions beginning at 1.5°C and are particularly relevant for regions with warm climates *(high confidence)*.

Table 16.3: Adaptation limits and residual risks for select actors and systems. Asterisks indicate confidence level *=l*ow confidence*, **=*medium confidence*, ***=*high confidence, ****=very high confidence.*

Actor/system at risk	Adaptation limits	Residual risks
Terrestrial species in islands at risk to loss of habitat	**Hard:** autonomous adaptation unable to overcome loss of habitat and lack of physical space (***) (Box CCP1.1)	Biodiversity decline, local extinctions, half of all species currently considered to be at risk of extinction occur on islands (Box CCP 1.1)
Terrestrial species across Africa at risk to habitat changes	**Hard:** beyond 2°C many species will lack suitable climate conditions by 2100 despite migration and dispersal (***) (9.6.4.1)	9% of species face complete range loss (*) mountain-top endemics and species at poleward boundaries of African continent at risk of range loss due to disappearing cold climates (***) (9.6.4.1)
African aquatic organisms at risk to habitat changes	**Hard:** thermal changes above optimal physiological limits will reduce available habitats (9.6.2.4)	Greater risks of loss of endemic fish species than generalist fish species (9.6.2.4)
African coastal and marine ecosystems at risk to habitat changes	**Hard:** at 2°C bleaching of east African coral reefs (***) (9.6.2.3)	Over 90% of east African coral reefs destroyed at 2C (***) (9.6.2.3)
Coral reefs at risk to oceanic changes	**Hard:** coral restoration and management no longer effective after 2°C (***), enhanced coal and reef shading no longer effective after 3°C (**) (Figure 3.23)	Loss of more than 80% of healthy coral cover, loss of livelihoods dependent on coral reefs (***) (Figure 3.23, Table 8.7)
Cold-adapted species whose habitats are restricted to polar and high mountaintop areas at risk to loss of climate space	**Hard:** evolutionary responses unable to keep pace with the rate of climate change and degraded state of ecosystems (2.6.1, CCP 1.2.4.2)	Species extinctions in the case of species losing its climate space entirely on a regional or global scale (2.6.1, CCP 1.2.4.2)
Ecosystems in North America at risk to multiple climate hazards	**Soft:** governance constraints hinder implementation of adaptation strategies **Hard**: some species unable to adapt (Table 14.8)	-
Ecosystems and species at risk to multiple climate hazards	**Soft:** financial and knowledge constraints lead to limits for interventionist approaches such as translocation of species or ecosystem restoration **Hard:** some habitats unable to be effectively restored (2.6.6)	Species extinctions and changes, irreversible major biome shifts (2.6.6)
Coastal settlements in Australia and New Zealand at risk to sea level rise	**Soft and hard**: limits in the efficacy of coastal protection and accommodation approaches as sea levels rise and extreme events intensify (Box 11.5)	With 1-1.1m of sea level rise, value of coastal urban infrastructure at risk in Australia is A$164 to >226 billion while in NZ it is NZ$43 billion. Sea level rise will also result in significant cultural and archaeological sites disturbed and increasing flood risk and water insecurity with health and well-being impacts on Australia's small northern islands (Box 11.5)

Human settlements in coastal areas in the 1 in 100 year floodplain at risk to coastal flooding	**Soft**: socio-economic, institutional and financial constraints may lead to soft limits well in advance of technical limits of hard engineering measures (CCP 2.3.2, 2.3.4) **Hard:** Nature based measures (e.g. restoration of coral reefs, mangroves, marshes) reach hard limits beginning at 1.5°C of global warming. Retreat strategies reach hard limits as availability and affordability of land decreases (CCP 2.3.2.3, CCP 2.3.5)	at 3°C, globally up to 510 million people and up to US$12,739 billion in assets at risk by 2100 (CCP 2.2.1)
Communities in small islands at risk to freshwater shortages	**Hard**: domestic freshwater resources unable to recover from increased drought, sea level rise and decreased precipitation by 2030 (RCP8.5+ ice-sheet collapse), 2040 (RCP8.5) or 2060 (RCP4.5) (Box 4.2, 4.7.2)	Migration of communities due to water shortages with impacts on well-being, community cohesion, livelihoods and people-land relationships (Box 4.2)
Communities in North America at risk to poor water quality	**Soft**: financial and technological constraints lead to limits in ability to treat water for harmful algal blooms. (Table 14.8)	
Communities in Western and Central Europe at risk to water shortages	**Hard**: at 3°C, geophysical and technological limits reached in Southern Europe (13.10.3.3)	At 3°C, two thirds of the population of Southern Europe at risk to water security with significant economic losses in water and energy dependent sectors (**) (13.2.2, 13.6, 13.10.2.3)
Communities in Central and South America at risk to water shortages	**Soft**: improved water management as an adaptation strategy unable to overcome lack of trust and stakeholder flexibility, unequal power relations and reduced social learning. (12.5.3.4)	Increasing competition and conflict associated with high economic losses (**); glacier shrinkage leading to loss of related livelihoods and cultural values (12.5.3.1, Table 8.7)
Agricultural production in Europe at risk to heat and drought	**Soft**: above 3°C, unavailability of water will limit irrigation as an adaptation response (***) (13.5.1, 13.10.2.2)	At 3-4°C, yield losses for maize may reach up to 50% (**) (13.5.1, 13.10.2.2)
Crops at risk to temperature increase	**Soft**: socio-economic and political constraints limit uptake of climate-resilient crops (5.4.4.3) **Hard**: after 2°C, cultivar changes unable to offset global production losses (5.4.4.1)	Costs of adaptation and residual damages are US$63 billion at 1.5°C. US$80 billion at 2°C and US$128 billion at 3°C, with greater risks and damages in tropical and arid regions (5.4.4.1)
Human health in Europe at risk to heat	**Soft**: many adaptation measures will not be able to fully mitigate overheating in buildings with high levels of global warming (***) (13.6.2.3) **Hard:** above 3°C, people and health systems unable to adapt (***) (13.6.2.3, 13.7.2, 13.7.4, 13.10.2.1, 13.8)	At 1.5°C, 30,000 annual deaths due to extreme heat with up to 90,000 annual deaths at 3C in 2100 (***) (13.7.1) At 3°C, thermal comfort hours during summer will decrease by as much as 74% in locations in southern Europe (***) (13.6.1.5)
Human health at risk to heat	**Soft**: socio-economic constraints limit adaptation responses to extreme heat (7.4.2.6, Table 8.7)	Globally the impact of projected climate change on temperature-related mortality is expected to be a net increase under RCP4.5 to RCP8.5, even with adaptation, particularly for regions with warm climates (****) (7.3.1, Table 8.7)
South Asian settlements at risk to coastal flooding, drought, sea level rise and heatwaves	**Soft and hard**: At 4.5ºC, maximum temperature is expected to exceed survivability threshold across most of South Asia, particularly relevant for outdoor work (*) (Table 10.6)	At RCP4.5, 25-50% of population affected; at RCP8.5 more than 50% of population affected. At 4.5ºC of warming, increase in heat-related deaths of 12.7% in South Asia (*) (Table 10.6)

Tourism in Europe reliant on snow at risk to higher levels of warming	**Soft**: at 3°C, snowmaking as an adaptation measure limited by biophysical and financial constraints (***) (13.6.1.4, 13.6.2.3)	Damages in European tourism with larger losses in Southern Europe (***) (13.6.1.4)
Rapidly growing towns/cities and smaller cities at risk to range of climate hazards	**Soft**: governance and financial constraints lead to limits in ability to adapt (6.3, 6.4)	-

16.4.3.2 Constraints Leading to Limits to Adaptation

Across regions and sectors, a range of constraints (Figure 16.8) are identified as leading to limits to adaptation, particularly financial constraints and constraints related to governance, institutions and policy (*high confidence).* While individual constraints may appear straightforward to address, the combination of constraints interacting with each other leads to soft limits that are difficult to overcome (*high confidence*). The interplay of many different constraints that lead to limits makes it difficult to categorize limits beyond being either soft or hard.

Figure 16.8 Constraints associated with limits by region and sector. Data from (Thomas et al. 2021), based on 1682 scientific publications reporting on adaptation-related responses in human systems. See SM16.1 for methods. Constraints are categorized as: (1) Economic: existing livelihoods, economic structures, and economic mobility; (2) Social/cultural: social norms, identity, place attachment, beliefs, worldviews, values, awareness, education, social justice, and social support; (3) Human capacity: individual, organizational, and societal capabilities to set and achieve adaptation objectives over time including training, education, and skill development; (4) Governance, Institutions & Policy: existing laws, regulations, procedural requirements, governance scope, effectiveness, institutional arrangements,

adaptive capacity, and absorption capacity; (5) Financial: lack of financial resources; (6) Information/Awareness/Technology: lack of awareness or access to information or technology; (7) Physical: presence of physical barriers; and (8) Biologic/climatic: temperature, precipitation, salinity, acidity, and intensity and frequency of extreme events including storms, drought, and wind. **Insufficient data:** there is not enough literature to support an assessment (less than 5 studies available); **Minor constraint:** <20% of assessed literature identifies this constraint; **Secondary constraint:** 20-50% of assessed literature identifies this constraint; **Primary constraint:** >50% of assessed literature identifies this constraint

Table 16.4: Key constraints associated with limits to adaptation for regions

Region	Key constraints associated with limits to adaptation
Africa	Financial constraints inhibit implementation of a variety of adaptation strategies including ecosystem-based adaptation (Section 9.11.4.2) and adoption of drought tolerant crops by farmers (Section 9.12.3). Information constraints (including limited climate science information), governance constraints (such as communication disconnects between national, district and community levels) and human capacity constraints (limited capacities to analyse threats and impacts) are identified as negatively affecting the implementation of adaptation policies (Section 9.13.1). Social/cultural constraints (social status, caste and gender) also affect adaptation in contexts with deep-rooted traditions (Section 9.12.4).
Asia	Governance, human capacity, financial and informational constraints commonly present barriers to urban adaptation (Section 10.4.6.5). Economic, governance, financial and informational constraints are related to both soft and hard limits to adaptation against a range of hazards in South Asia (Box 10.7), while in West Asia, physical constraints to heatwaves and drought have been associated with limits to adaptation (Box 10.7).
Australasia	A range of constraints, including governance, information and awareness, social/cultural, human capacity and financial have been identified as impeding adaptation action in the region (Section 11.7.2, Box 11.1). Evidence of limits to adaptation are primarily for ecosystems (Section 11.7.2, 11.6) although individuals and communities are also approaching soft limits due to social constraints (Chapter 11.7.2).
Central and South America	Financial, governance, knowledge, biophysical and social/cultural constraints identified as most significant for adaptation (Section 12.5, Table 12.3). Soft limits are largely related to governance constraints, while evidence of hard limits is related to biophysical constraints, such as glacier shrinking leading to loss of livelihoods and cultural values (Section 12.5.3.4).
Europe	Key constraints are identified as technical, biophysical, economic and social (Section 13.6.2.4). For cities, settlements and key infrastructure, technical socio-economic and environmental & regulatory constraints may lead to limits at a range of spatial scales (Figure 13.12) Biophysical constraints may lead to limits to the ability of water saving and water efficiency measures to prevent water insecurity under high warming scenarios (Section 13.2.2.2).
North America	Social/cultural, governance, financial, knowledge and biophysical constraints are identified as most significant for adaptation and leading to both soft and hard limits (Section 14.5.2.1, Section 14.6, Section 14.6.2.1, Table 14.8)
Small Islands	Financial, governance, information/awareness, technological, cultural and human capacity constraints are identified as affecting adaptation and leading to soft limits (Section 15.5.3, Section 15.5.4, Section 15.6.1, Section 15.6.3, Section 15.6.4). Differences between constraints and soft limits in the small island context is marginal, with policymakers in the Caribbean and Indian Oceans seeing these as synonymous (Section 15.6.1).

16.4.3.3 Climate Change Impacts, Financial Constraints and Limits to Adaptation

Across regions and sectors, financial constraints are identified as significant and contributing to limits to adaptation, particularly in low-to-middle income countries (*high confidence)* (Section 3.6.3, Section 4.7.2, Section 5.14.3, Section 6.4.5, Section 7.4.2, Section 8.4.5, Section 12.5.1, Section 12.5.2, Section 15.6.1, Section 15.6.3, Figure 16.8, Table 16.4, CCP2.4.2). Impacts of climate change may increase financial constraints (*high confidence*) and contribute to soft limits to adaptation being reached (*medium confidence*). Table 16.5 details climate impact observations that point to potentially substantial negative impacts on the availability of financial resources for different regions.

Table 16.5: Evidence of climate change impacts affecting availability of financial resources. Asterisks indicate confidence level *=*low confidence*, **=*medium confidence*, ***=*high confidence.*

Region	Evidence of climate change impacts affecting availability of financial resources
Africa	Negative consequences for economic growth and GDP growth rate from higher average temperatures and lower rainfall (***) (Section 9.9.1.1, Section 9.9.2, Section 9.9.3) Economic losses from damage to infrastructure in the energy, transport, water supply, communication services, housing, health, and education sectors (observed) (Section 9.7.2.2, Section 9.8.2)
Asia	High coastal damages due to sea level rise (China, India, Korea, Japan, Russia) (***) (Section 10.4.6.3.4) Decline in aquaculture production (Section 10.4.5.2.1) Loss of coastal ecosystem services (Bangladesh) (Section 5.9.3.2.4)
Australasia	Loss of wealth and negative impacts on GDP (Section 11.5.1.2, Section 11.5.2.2) High disaster costs (observed in Australia, NZ) (Section 11.5.2.1)
Central and South America	High costs of extreme events relative to GDP (observed in Guatemala, Belize) (Section 12.3.1.4) Decrease in growth of total GDP per capita and total income and labour income from one standard deviation in the intensity of a hurricane windstorm (Section 12.3.1.4)
Europe	Negative combined effect of multiple risks on economy for Europe in total (**) (Section 13.9.1, Section 13.10.2) Negative combined effect of multiple risks on economy for Southern Europe (***) (Section 13.9.1, Section 13.10.2) High economic costs in agriculture and construction following heat waves and flooding (Section 6.2.3.2, Section 7.4.2.2.1)
North America	Small but persistent negative economy wide effect on GDP (observed in the United States and Mexico) (**) (Box 14.5) Economic risks associated with high temperature scenarios (***) (Box 14.5) Small but persistent positive economy wide effect on GDP (observed in Canada) (**) (Box 14.5) Significant economic costs for urban, natural and ecosystem infrastructure (USA) (Section 6.2.5.9) High economic damages for a subset of sectors from high warming (southern and southeastern US) (Box 14.5) Adverse effects on municipal budgets due to costly liabilities, and disruption of financial markets (Box 14.5)
Small Islands	High economic costs relative to GDP from extreme events, particularly tropical cyclones (observed) (Section 15.3.4.1) Negative long-term implications of extreme events for state budgets (Section 8.2.1.4) Inundation of almost all port and harbour facilities (Caribbean) (Section 15.3.4.1)

At the national level, negative macroeconomic responses to climate change may limit the availability of financial resources, impede access to financial markets and stunt economic growth (*high confidence*). Economic growth has been shown to decline under higher temperatures (Burke et al., 2015; Kahn et al., 2019, Section 16.5.2.3.4) and following extreme events (Hsiang and Jina, 2014; IMF, 2017), particularly for medium- and low-income developing countries (Section 18.1). The most severe impacts of climate-related disasters on economic growth per capita have been observed in developing countries, although authors note a publication bias in the reporting of negative effects (Klomp and Valckx, 2014). Substantial immediate output losses and reduced economic growth due to extreme events have been observed both in the short- and long-term (Section 16.2.3). Estimates of the duration of negative effects of climate-related disasters differ, with some analyses suggesting that on average economies recover after two years (Klomp, 2016) and others finding negative effects of cyclones to persist 15 – 20 years following an event (Hsiang and Jina, 2014; IMF, 2017). Rising climate vulnerability has also been shown to increase the cost of debt (Kling et al., 2018). Rising climatic risks negatively affect developing countries' ability to access financial markets (Cevik and Jalles, 2020) and their disclosure may result in capital flight (Cross-Chapter Box FINANCE in Chapter 17). Overall, the direct and indirect economic effects of climate change represent a major risk to financial system stability (Section 11.5.2). These risks and effects may further limit the availability of financial resources needed to overcome constraints, in particular for developing countries.

Sectoral studies indicate that climate impacts will result in higher levels of losses and damages and decreases in income, thereby increasing financial constraints (*medium confidence)*. Yield losses for major agricultural crops are expected in nearly all world regions (Figure 5.7). Decreases in estimated marine fish catch potential and large economic impacts from ocean acidification are expected globally, leading to the risk of revenue loss (Section 5.8.3). Losses of primary productivity and farmed species of shellfish are expected in tropical and subtropical regions (Section 5.9.3.2.2). Economic losses have been observed in the power generation sector and transport infrastructure (Section 10.4.6.3.8), including economic losses from floods in urban areas (Section 4.2.4.5). However, some positive sectoral climate change impacts have been identified for the timber and forestry sector (Section 5.6.2), for primary productivity and farmed species of shellfish in high-latitude regions (Section 5.9.3.2.2) and agriculture in high-latitude regions (Section 5.4.1.1).

At the household or community level, climate impacts may increase financial constraints (*high confidence).* Impacts on agriculture and food prices could force between 3 to 16 million people into extreme poverty (Hallegatte and Rozenberg, 2017). Within-country inequality is expected to increase following extreme weather events (Section 16.2.3.6 and Chapter 8). Households affected by climate-related extreme events may be faced with continuous reconstruction efforts following extreme events (Adelekan and Fregene, 2015) or declines in critical livelihood resources in the agriculture, fisheries and tourism sectors (Forster et al., 2014, Section 3.5.1). Further erosion of livelihood security of vulnerable households creates the risk of poverty traps, particularly for rural and urban landless (Section 8.2.1, Section 8.3.3.1), for example in Malawi and Ethiopia (Section 9.9.3). Levels of labour productivity and economic outputs are projected to decrease as temperatures rise particularly in urban areas (Section 6.2.3.1). At the same time, higher utilities demand under higher urban temperatures exert additional economic stresses on urban residents and households. Substantial, negative impacts on the livelihoods of over 180 million people are expected from changes to African grassland productivity (Section 5.5.3.1). In Western Uzbekistan, farmers´ incomes are at risk of declining (Section 10.4.5.3). For Small Island Developing States, loss of livelihoods is expected due to negative climatic impacts on coastal environments and resources (Section 3.5.1). Negative effects on households from extreme events can also persist in the long-term and in multiple dimensions. Exposure to disasters during the first year of life significantly reduces the number of years of schooling, increases the chances of being unemployed as an adult and living in a multidimensionally poor household (González et al., 2021).

16.5 Key Risks Across Sectors and Regions

This section builds on the analogous chapter in AR5 (Oppenheimer et al., 2014) to refine the definition of climate-related key risks (KRs) and criteria for identifying them (16.5.1), and describe a broad range of key risks by sector and region as identified by the authors of WGII AR6 (Section 16.5.2, SM16.4). Based on this, eight clusters of key risks (i.e., Representative Key Risks, RKRs) are identified and assessed in terms of the conditions under which they would become severe. In addition, the section assesses variation in KRs and RKRs by the level of global average warming, socio-economic development pathways, and levels of adaptation, and illustrates the implications from resulting dynamics in all risk dimensions (hazard, exposure, vulnerability) along a case study of densely populated river deltas (Section 16.5.3). Last, interactions among RKRs are discussed (Section 16.5.4).

16.5.1 Defining Key Risks

A key risk is defined as a potentially severe risk and therefore especially relevant to the interpretation of dangerous anthropogenic interference (DAI) with the climate system, the prevention of which is the ultimate objective of the UNFCCC as stated in its Article 2 (Oppenheimer et al., 2014). Key risks are therefore a relevant lens for the interpretation of this policy framing. The severity of a risk is a context-specific judgment based on a number of criteria discussed below. KRs are 'potentially' severe because, while some could already reflect dangerous interference now, more typically they may become severe over time due to changes in the nature of hazards (or, more broadly, climatic impact-drivers (or, more broadly, climatic impact-drivers, IPCC, 2021a) and/or of the exposure/vulnerability of societies or ecosystems to those hazards. They also may become severe due to the adverse consequences of adaptation or mitigation responses to the risk (on the former see Section 17.5.1; the latter is not assessed separately here, except as it contributes to risks from climate hazards). Dangerous interferences in this chapter are considered over the course of the 21st century.

KRs may be defined for a wide variety of systems at a range of scales. The broadest definition is for the global human system or planetary ecological system, but KRs may also apply to regions, specific sectors or communities, or to parts of a system rather than to the system as a whole. For example, the population at the lower end of the wealth distribution is often impacted by climate change much more severely than the rest of the population (Leichenko and Silva, 2014; Hallegatte and Rozenberg, 2017; Hallegatte et al., 2017; Pelling and Garschagen, 2019).

KRs are determined not just by the nature of hazards, exposure, vulnerability, and response options, but also by values, which determine the importance of a risk. Importance is understood here as the degree of relevance to interpreting DAI at a given system's level or scale, and was an explicit criterion for identifying key vulnerabilities and risks in AR5 (Oppenheimer et al., 2014). Because values can vary across individuals, communities, or cultures, as well as over time, what constitutes a KR can vary widely from the perspective of each of these groups, or across individuals. For example, ecosystems providing indirect services and cultural assets such as historic buildings and archaeological sites may be considered very important to preserve by some people but not by others; and some types of infrastructure, such as a commuter rail, may be important to the well-being of some households but less so to others. Therefore, Chapter 16 authors do not make their own judgements about the importance of particular risks. Instead, we highlight importance as an overarching factor but identify and evaluate KRs based on four other criteria for what may be considered potentially severe.

Magnitude of adverse consequences. Magnitude measures the degree to which particular dimensions of a system are affected, should the risk materialize. Magnitude can include the size or extent of the system, the *pervasiveness of the consequences* across the system (geographically or in terms of affected population), as well as the *degree of consequences*. Consequences can be measured by a wide range of characteristics. For example, risks to food security can be measured as uncertain consequences for food consumption, access, or prices. The magnitude of these consequences would be the degree of change in these measures induced by climate change and accounting for the interaction with exposure and vulnerability. In addition to *pervasiveness* and *degree of change*, several other aspects can contribute to a judgement of magnitude, although they refer to concepts that are difficult to capture and highly context-specific:
Irreversibility of consequences. Consequences that are irreversible, at least over long timescales, would be considered a higher risk than those that are temporary. For example, changes to the prevailing ecosystem in a given location may not be reversible on the decade to century scale.
Potential for impact thresholds or tipping points. Higher risks are posed by the potential for exceeding a threshold beyond which the magnitude or rate of an impact substantially increases.
Potential for cascading effects beyond system boundaries. Higher risks are posed by those with the potential to generate downstream cascading effects to other ecosystems, sectors or population groups within the affected system and/or to another system, whether neighbouring or distant (Cross-Chapter Box INTEREG in this Chapter).

Likelihood of adverse consequences. A higher probability of high-magnitude consequences poses a larger risk a priori, whatever the scale considered. This probability may not be quantifiable, and it may be conditional on assumptions about the hazard, exposure, or vulnerability associated with the risk.

Temporal characteristics of the risk. Risks that occur sooner, or that increase more rapidly over time, present greater challenges to natural and societal adaptation. A persistent risk (due to the persistence of the hazard, exposure, and vulnerability) may also pose a higher threat than a temporary risk due, for example, to a short-term increase in the vulnerability of a population (e.g., due to conflict or an economic downturn).

Ability to respond to the risk. Risks are more severe if the affected ecosystems or societies have limited ability to reduce hazards (e.g., for human systems, through mitigation, ecosystem management and possibly solar radiation management); to reduce exposure or vulnerability through various human or ecological adaptation options; or to cope with or respond to the consequences, should they occur.

The relative influence of these different criteria is case-specific and left to author judgment in the identification of KRs (groups of authors in regional and sectoral chapters, see Supplementary Material Table SM16.10) and the assessment of representative key risks (author teams, see Supplementary Material Table SM16.10). But in general, the more criteria are met, the higher is the risk

16.5.2 Identification and Assessment of Key Risks and Representative Key Risks

16.5.2.1 Identification of Key Risks (KR)

The authors of the sectoral and regional chapters and Cross Chapter Papers of the WGII AR6 Report identified more than 130 key risks (Table SM16..4). Authors were asked to rely on the above definition and criteria to identify risks that could potentially become severe according to changes in the associated hazards, the study systems' exposure and/or vulnerability; and important adaptation strategies that could reduce these risks (see 16.B.2 for methodology). Wherever possible, identification is based on literature that includes projected future conditions for all three components of risk and adaptation. Where literature was insufficient, potential severity is based on current vulnerability and exposure to climate hazards and the expectation that hazards will increase in frequency and/or intensity in the future. This approach is more limited in that it does not consider future changes in exposure and vulnerability nor in adaptation, but has the benefit of being grounded in observed experience.

Table SM16.4 indicates that climate change presents a wide range of risks across scales, sectors and regions that could become severe under particular conditions of hazards, exposure, and vulnerability, which may or may not occur. Some illustrations of the extent and diversity of KRs are provided here, and more detailed assessment can be found in the Chapters referenced in the table.

Global scale KRs include threats to biodiversity in oceans, coastal regions, and on land, particularly in biodiversity hotspots, as well as other ecological risks such as geographic shifts in vegetation, tree mortality, reduction in populations, and reduction in growth (such as for shellfish). These ecological risks include cascading impacts on livelihoods and food security. Global-scale risks also include risks to people, property, and infrastructure from river flooding and extreme heat (particularly in urban areas), risks to fisheries (with implications for living standards and food security), and some health risks from food-borne diseases as well as psychopathologies.

Many KRs are especially prominent in particular regions or systems, or for particular subgroups of the population. For example, coastal systems and small islands are a nexus of many KRs, including those to ecosystems and their services, especially coral reefs; people (health, livelihoods); and assets, including infrastructure. Risks to socio-ecological systems in polar regions are also identified as KRs, as are ecological risks to the Amazon forest in South America and savannahs in Africa. For some regions risks from wildfire are of particular concern, including in Australasia and North America. Vector-borne diseases are a particular concern in Africa and Asia. Loss of cultural heritage is identified as a KR in Small Islands, Mountain Regions, Africa, Australasia, and North America.

For many risks, low-income populations are particularly vulnerable to KRs. Climate-related impacts on malnutrition and other forms of food insecurity will be larger for this group, along with small-holder farming households and indigenous communities reliant on agriculture, and for women, children, the elderly, and the socially isolated (Section 5.12). KRs in coastal communities are expected to affect low income populations more strongly, including through risks to livelihoods of those reliant on coastal fisheries. KRs related to health are generally higher for low income populations less likely to have adequate housing or access to infrastructure.

16.5.2.2 Identification of Representative Key Risks (RKR)

As in AR5 Oppenheimer et al. (2014), major clusters of KRs are further analysed, and here referred to as 'representative key risks' (RKRs). RKRs were defined in a three-step process (SM16.2.1). First, half of Chapter 16 authors independently mapped the KRs in Table SM16.4 to a set of candidate RKRs. Second, all Chapter 16 authors discussed the set of independent results and proposed a list of RKRs, considering scope and overlap. Third, this proposal was discussed with a consultative group of about twenty WGII AR6 authors from other chapters closely involved in the KR identification process, and a final list of 8 RKRs was identified (Table 16.6).

The RKRs are intended to capture the widest variety of KRs to human or ecological systems with a small number of categories that are easier to communicate and provide a manageable structure for further assessment. They expand the scope of some AR5 KR clusters (e.g., on coasts, health, food, and water) and add new ones (e.g., on peace and mobility). The RKRs encompass a diversity of types of systems, including an example of a geographically defined system (RKR-A on coastal regions), ecosystem well-being and integrity (RKR-B), a cross-cutting issue relevant to several outcomes of concern (RKR-C on critical infrastructure), and several topics focused directly on aspects of human well-being and security (RKR-D to RKR-H). This set of RKRs manages but does not eliminate overlap, instead providing alternative perspectives on underlying key risks that sometimes include complementary views on common risks. For example, the water security RKR highlights the many key risks mediated by water quantity or quality, which are sometimes manifested as risk to food security (RKR-F) or health (RKR-E).

Table 16.6: Climate-related representative key risks (RKRs). The scope of each RKR is further described in the assessments in Section 16.5.2.3. Relation to categories of overarching key risks identified in AR5 is provided for continuity.

Code	Representative Key Risk	Scope	Relation to AR5 overarching key risks for definitions, refer to (Oppenheimer et al., 2014)	Sub-section assessment
RKR-A	Risk to low-lying coastal socio-ecological systems	Risks to ecosystem services, people, livelihoods and key infrastructure in low-lying coastal areas, and associated with a wide range of hazards, including sea level changes, ocean warming and acidification, weather extremes (storms, cyclones), sea ice loss, etc.	Contains key risk (i), overlaps with key risks (iii) and (vii)	16.5.2.3.1
RKR-B	Risk to terrestrial and ocean ecosystems	Transformation of terrestrial and ocean/coastal ecosystems, including change in structure and/or functioning, and/or loss of biodiversity.	Contained in key risks (vii) and (viii)	16.5.2.3.2
RKR-C	Risks associated with critical physical infrastructure, networks and services	Systemic risks due to extreme events leading to the breakdown of physical infrastructure and networks providing critical goods and services.	Overlaps with key risk (iii)	16.5.2.3.3

RKR-D	Risk to living standards	Economic impacts across scales, including impacts on Gross Domestic Product (GDP), poverty, and livelihoods, as well as the exacerbating effects of impacts on socio-economic inequality between and within countries.	Broader version of key risk (ii)	16.5.2.3.4
RKR-E	Risk to human health	Human mortality and morbidity, including heat-related impacts and vector-borne and water-borne diseases.	Broader version of key risk (iv)	16.5.2.3.5
RKR-F	Risk to food security	Food insecurity and the breakdown of food systems due to climate change effects on land or ocean resources.	Overlaps with key risk (v)	16.5.2.3.6
RKR-G	Risk to water security	Risk from water related hazards (floods and droughts) and water quality deterioration. Focus on water scarcity, water-related disasters and risk to indigenous and traditional cultures and ways of life	Overlaps with key risk (iv)	16.5.2.3.7
RKR-H	Risks to peace and to human mobility	Risks to peace within and among societies from armed conflict as well as risks to low-agency human mobility within and across state borders, including the potential for involuntarily immobile populations.	New	16.5.2.3.8

16.5.2.3 Assessment of Representative Key Risks

Each RKR was assessed by a team of 4 to 9 members drawn from Chapter 16, other WGII AR6 chapters, and external contributing authors (16.B.3.1). The following subsections describe the scope of the category of risk (underlying KR considered) and the approach to defining 'severe' risks for each particular RKR. They also assess the conditions in terms of warming (more broadly, climatic impact-drivers; (Ranasinghe et al., 2021), exposure/vulnerability and adaptation under which the RKR would become severe. For each of these dimensions, RKR teams considered generic levels ranging from High to Medium and Low. For warming levels, in line with WG1 framing, High refers to climate outcomes consistent with RCP8.5 or higher, Low refers to climate outcomes consistent with RCP2.6 or lower, and Medium refers to intermediary climate scenarios. For reference, the full range of warming levels (across all climate models) associated with RCP8.5 for the 2081-2100 period is 3.0C to 6.2C; for RCP2.6 it is 0.9C to 2.3C; and for intermediate RCPs it is 1.8C to 3.6C (Cross-Chapter Box CLIMATE in Chapter 1). For Exposure-Vulnerability, levels are determined by the RKR teams relative to the range of future conditions considered in the literature, for example based on the Shared Socioeconomic Pathways (SSPs) in which future conditions based on SSPs 1 or 5 represent Low exposure or vulnerability and those based on SSPs 3 or 4 represent High exposure or vulnerability (O'Neill et al., 2014; van Vuuren and Carter, 2014). For Adaptation, two main levels have been considered: High refers to near maximum potential and Low refers to the continuation of today's trends. Despite being intertwined in reality, Exposure-Vulnerability and Adaptation conditions are distinguished to help understand their respective contributions to risk severity. Importantly, this assessment does not consider all risks, but only those that can be considered severe given the definition and criteria presented in Section 16.5.1. The assessment does not exclude the possibility that severe risks are already observed in some contexts, and considers projected risks through the end of this century.

Each RKR assessment followed a common set of guidelines (16.B.3) that included broad criteria for defining severity (Section 16.5.1), consideration of complex risks and interactions within and across RKRs, and consideration of risks across a range of scales, regions, and ecological and human development contexts. The specific definition of severity within each RKR was determined by the author teams of that assessment, applying different combinations of key risk criteria and metrics as judged appropriate in each case. Definitions are transparent and use common criteria, but are nonetheless based on the respective author team's judgment. Conclusions about severity and associated confidence statements are therefore conditional on those definitions.

Assessments are based on different types of evidence depending on the nature of the literature. In some cases, quantitative projections of potential impacts are available. In others and as for KR identification, the potential for severe risk is inferred from high levels of current vulnerability and the expectation that the relevant climate hazards (CIDs) will increase in frequency or intensity in the future.

16.5.2.3.1 Risk to the integrity of low-lying coastal socio-ecological systems (RKR-A)

RKR-A considers climate change-related risks to low-lying coasts including their physical, ecological and human components. Low-lying systems are those occupying land below 10 m of elevation that is contiguous and hydrologically connected to the sea (McGranahan et al., 2007). The assessment builds on Key Risks identified in chapters 3 and 15, Cross Chapter Paper 2 as well as in the SROCC (Magnan et al., 2019; Oppenheimer et al., 2019). It highlights risks to (i) natural coastal protection and habitats; (ii) lives, livelihoods, culture and well-being; and (iii) critical physical infrastructure; it therefore overlaps with several other RKRs (Fig. 16.10 and 16.11) but within a coastal focus. It encompasses all latitudes and considers multiple sources of climate hazards, including sea-level rise (SLR), ocean warming and acidification, permafrost thaw, and sea-ice loss and changes in weather extremes.

Severe risks to low-lying coasts involve irreversible long-term loss of land, critical ecosystem services, livelihoods, well-being or culture in relation to increasing combined drivers, including climate hazards and exposure and vulnerability conditions. The definition depends on the local context because of variation in the perception of tolerable risks and the limits to adaptation (Handmer and Nalau, 2019). Accordingly, a qualitative range of consequences is presented here, in place of a quantitative global severe risk threshold.

The literature suggests that severe risks generally occur at the nexus of high levels and rates of anthropogenic-driven change in climate hazards (16.2.3.2), concentrations of people and tangible and intangible assets, non-climate hazards such as sediment mining and ecosystem degradation (3.4.2.1), and the reaching of adaptation limits (16.4) (*medium evidence*, *high agreement*). In some Arctic communities and in communities reliant on warm-water coral reefs, even 1.5-2ºC warming will lead to severe risks from loss of ecosystem services (3.4.2.2; CCP6) (*high confidence)*. Loss of land is already underway globally due to accelerating coastal erosion and will be amplified by increased sea-level extremes and permanent flooding (*high confidence*; Oppenheimer et al. 2019, Ranasinghe et al. 2021). Observed impacts of and projected increases in high intensity extreme events (Ranasinghe et al. 2021) also provide evidence for severe risk to occur on livelihoods, infrastructure and well-being (Section 16.5.2.3.3) by mid-century (*high confidence*). Consequently, the combination of high warming, continued coastal development and low adaptation levels will challenge the habitability of many low-lying coastal communities in both developing and developed countries over the course of this century (*low evidence*, *high agreement*) (Duvat et al., 2021; Horton et al., 2021). In some contexts, climate risks are already considered severe (*medium evidence*, *medium agreement*), and in others, even lower warming will induce severe risks to habitability, which will not necessarily be offset by ambitious adaptation (*low evidence*, *medium agreement*).

(i) Natural coastal protection and habitats — Severe risks from the loss of shoreline protection from reductions in wave attenuation (Beck et al., 2018, Section 3.5.5.1; Section 3.5.4.5) and sediment delivery (3.4.2.5; 15.3.3) are already observed in some coastal systems (Section 16.2.3.1) and occur broadly even with 1.5ºC of global warming (Hoegh-Guldberg et al., 2018a; Bindoff et al., 2019, Section 3.4.2). These impacts are the consequence of warming and SLR on coastal ecosystems.

Warm-water coral reefs are at risk of widespread loss of structural complexity and reef accretion by 2050 under 1.5°C global warming (Section 3.4.2.1) (*high confidence*). Kelp forests may experience shifts in community structure (Arafeh-Dalmau et al., 2019; Rogers-Bennett and Catton, 2019; Smale, 2020; Smith et al., 2021) with >2°C of global warming especially at lower latitudes (Section 3.4.2.2) (*high confidence*). In addition, depending on the local tide and sediment conditions, SLR associated with >1.5°C of global warming (SSP1-2.6; 3.4.2.5) is sufficient to initiate shifts to alternate states in some seagrass and coastal wetland systems (van Belzen et al., 2017; El-Hacen et al., 2018, Section 3.4.2.5, Cross-Chapter Box SLR in Chapter 3), and submergence of some mangrove forests (3.4.2.5). A striking example of risks becoming severe at higher levels of warming is the one of coral islands with low elevation (Section 15.3.4, Box 15.1): the risk of loss of habitability transitions from Moderate-to-High under RCP2.6 for most island types (urban and rural) to High-to-Very High under RCP8.5 (Duvat et al., 2021), even under a high adaptation scenario

(Oppenheimer et al., 2019), partly due to declining sediment supply (Perry et al., 2018) and increased annual flooding (Giardino et al., 2018; Storlazzi et al., 2018).

More broadly, about 28,000 km2 of land have been lost globally since the 1980s due to anthropogenic factors (e.g., coastal structures, disruption of sediment fluxes) and coastal hazards (Mentaschi et al., 2018), and an additional loss of 6000-17,000 km2 is estimated by the end of the century due to coastal erosion alone associated with SLR in combination with other drivers (Hinkel et al., 2013).

(ii) Impacts to lives, livelihoods, culture and well-being — In the absence of effective adaptation, changing extreme and slow-onset hazards combined with anthropogenic drivers (e.g., increased population pressure at the coast between +5% and +13.6% by 2100 compared to today, Jones and O'Neill, 2016) will lead to loss of lives, livelihoods, health, well-being, and/or culture (McGregor et al., 2016; Pinnegar et al., 2019; Pugatch, 2019; Schneider and Asch, 2020; Thomas and Benjamin, 2020; McNamara et al., 2021) (*high confidence*). Catastrophic examples that may foreshadow the future include Hurricane Sandy in 2012 (Strauss et al., 2021)and super Typhoon Haiyan in 2013 (>6,000 deaths and inequities in access to safe housing; Trenberth et al. 2015) (6.2.2, 6.3.5.1). Although there is no unique definition of 'intolerable' loss, risks are generally expected to become severe over this century (Tschakert et al., 2017; Dannenberg et al., 2019; Tschakert et al., 2019). Globally, with High warming, 90 to 380 million more people will be exposed to annual flood levels by the mid- and end-century, respectively, compared to 250 million people today (Kulp and Strauss, 2019; Kirezci et al., 2020), with potential implications on forced displacement or migration (Oppenheimer et al., 2019; Wrathall et al., 2019; Hauer et al., 2020; Lincke and Hinkel, 2021, Section 16.5.2.3.9). Some of the largest fish-producing and fish-dependent ecoregions have already experienced losses of up to 35% in marine fisheries productivity due to warming (Free et al., 2019), and about 11% of the global population will face increasing nutritional risks if current trajectories continue (Golden et al., 2016). While difficult to measure, current climate-driven losses to (indigenous) knowledge, traditions (Tschakert et al., 2019; Pearson et al., 2021) and well-being (Ebi et al., 2017; Cunsolo and Ellis, 2018; Jaakkola et al., 2018) indicate such risk as already severe in some regions (*low evidence, medium agreement*), jeopardizing communities' realization of their rights to food, health and culture. In the Arctic, climate-driven changes to ice and weather regimes have substantially affected traditional coastal-based hunting and fishing activities (Fawcett et al., 2018; Galappaththi et al., 2019; Huntington et al., 2020; Nuttall, 2020, CCP6), and where permafrost thaw, SLR and coastal erosion are contributing to threatening cultural sites (Hollesen et al., 2018; Fenger-Nielsen et al., 2020).

(iii) Critical physical infrastructure — Severe risks are also illustrated through damages that lead to possibly long-lasting disruption of key services like transportation as well as energy generation and distribution in coastal areas (Section 16.5.2.3.3) under all RCPs (CCP2.2.3) and if no additional adaptation (*medium confidence*). Critical transport infrastructure is already suffering from structural failures in polar regions, for instance, due to permafrost thaw and increased erosion associated with ocean warming, storm surge flooding and loss of sea ice (Melvin et al., 2017; Fang et al., 2018, Section 14.5.2.8, Section 16.2.3.2, CCP6). One hundred airports are projected to be below mean sea-level in 2100 with 2°C of warming (i.e., 0.62 m SLR, Yesudian and Dawson, 2021), including in small islands (Monioudi et al., 2018; Storlazzi et al., 2018) and megacities. Projections show San Francisco International Airport, for instance, to be inundated by 2100 under the upper likely range of SLR in RCP8.5 (also considering subsidence trends, Shirzaei and Bürgmann, 2018). On the energy side, it is estimated that with 1.8m SLR, for example, four out of 13 US nuclear power plant facilities will become exposed to storm surges and three others will be surrounded or submerged by seawater (Jordaan et al., 2019; Jenkins et al., 2020).

16.5.2.3.2 Risk to terrestrial and ocean ecosystems (RKR-B)

This risk refers to transformations of terrestrial and ocean/coastal ecosystems that would include significant changes in structure and/or functioning, and/or loss of a substantial fraction of species richness (commonly used to indicate loss of biodiversity). These are sourced mainly from Chapters 2 and 3, CCP1, and reference the 1.5C report, Chapter 4 from WGII AR5, and Chapter 4 from WGII AR4 Reports.

Severe adverse impacts on biodiversity include significant risk of species extinction (e.g., loss of a substantial fraction (one tenth or more) of species from a local to global scale), mass population mortality (>50% of individuals or colonies killed), ecological disruption (order-of-magnitude increases or abrupt reductions of population numbers or biomass), shifts in ecosystem structure and function (order-of magnitude increases or abrupt decreases in cover and/or biomass of novel growth forms or functional types), and/or a socio-economically material increase in environmental risk (e.g., destruction by wildfire) or socio-economically material decline in goods and services (e.g., carbon stock losses, loss of grazing, loss of pollination). Metrics relevant to Sustainable Development Goals are also germane.

A substantial proportion of biodiversity is at risk of being lost below 2ºC of global warming (Chapter 2), due to range reductions and loss globally, with this risk amplified roughly three times in insular ecosystems and biodiversity hotspots, due to the increased vulnerability of endemic species (Manes et al., 2021). High latitude, high altitude, insular, freshwater, and coral reef ecosystems and biodiversity hotspots (Chapter 2, Cross-Chapter Paper 1 on Biodiversity Hotspots) are at appreciable risk of substantial biodiversity loss due to climate change even under Low warming (*high confidence*). These systems comprise a large fraction of unique and endemic biodiversity, with species impacts often exacerbated by multiple drivers of global change (Chapter 2, Chapter 3). Roughly one third of all known plant species are extremely rare, vulnerable to climate impacts, and clustered in areas of higher projected rates of anthropogenic climate change (Enquist et al., 2019). Much evidence shows increased risk of the loss of 10% or more of terrestrial biodiversity with increasing anthropogenic climate change (Urban, 2015; Smith et al., 2018) (*medium confidence*), *likely* with 2ºC warming above pre-industrial level (Chapter 2), with consequent degradation of terrestrial, freshwater, and ocean ecosystems (Oliver et al., 2015) and adverse impacts on ecosystem services (Pecl et al., 2017) and dependent human livelihoods (Dube et al., 2016). Adverse impacts on biodiversity may show lagged responses (Essl et al., 2015), and loss of a substantial fraction of species could occur abruptly, simultaneously across multiple taxa, below 4ºC of global warming (Trisos et al., 2020).

Mass population-level mortality (>50% of individuals or colonies killed) and resulting abrupt ecological changes can be caused by simple or compound climate extreme events, such as exceedance of upper thermal limits by vulnerable terrestrial species (Fey et al., 2015), who also note reduced mass mortality trends due to extreme low thermal events); marine heatwaves that can cause mortality, enhance invasive alien species establishment, and damage coastal ecological communities and small-scale fisheries (*high confidence*) (Section 3.4.2.7); and increased frequency and extent of wildfires that threaten populations dependent on habitat availability (like Koala Bears, Lam et al., 2020). Abrupt ecological changes are widespread and increasing in frequency (Turner et al., 2020), and include tree mortality due to insect infestation exacerbated by drought, and ecosystem transformation due to wildfire (Vogt et al., 2020). Freshwater ecosystems and their biodiversity are at high risk of biodiversity loss and turnover due to climate change (precipitation change and warming, including warming of water bodies), due to high sensitivity of processes and life histories to thermal conditions and water quality (Chapter 2) (*high confidence*). In marine systems, heatwaves cause damages in coastal systems, including extensive coral bleaching and mortality (very *high confidence*) (Section 3.4.2.1), mass mortality of invertebrate species (*low* to *high confidence*, depending on system) (Sections 3.4.2.2, Section 3.4.2.5, Section 3.4.4.1), and abrupt mortality of kelp-forest (*high confidence*) (Section 3.4.2.3) and seagrass-meadow habitat (*high confidence*) (Section 3.4.4.2). The biodiversity of polar seas shows strong impacts of climate change on phenological timing of plankton activity, Arctic fish species range contractions and species community change (Table 16.2) (*high confidence*). Extreme weather events and storm surges exacerbated by climate change have severe and sudden adverse impacts on coastal systems, including loss of seagrass meadows and mangrove forests (*high confidence*) (see Section 3.4.2.7, Section 3.4.2.8, Cross-Chapter Box EXTREMES in Chapter 2).

Ecological disruption (order-of-magnitude increases or abrupt reductions of population numbers or biomass) can occur due to unprecedented inter-species interactions with unpredictable outcomes in 'novel ecosystems' (Chapter 2) as species shift geographic ranges idiosyncratically in response to climatic drivers (Table 16.2). Idiosyncratic geographic shifts are now observed in an appreciable fraction of species studied (Chapter 2, Table 16.2). Commensal or parasitic diseases may infect immunologically naive hosts (e.g., chytrid fungus in amphibians). Atypical disturbance regimes may be enhanced, for example, with the spread of flammable plant species (e.g., du Toit et al., 2015), exacerbated by introduced species (e.g., Martin et al., 2015), thus significantly increasing risk of loss and damage to infrastructure and livelihoods, ecological degradation, and challenging existing management approaches.

Landscape- and larger-scale shifts in ecosystem structure and function (order-of magnitude increases or abrupt decreases in cover and/or biomass of novel growth forms or functional types) are occurring in non-equilibrium ecosystems (systems which exist in multiple states, often disturbance-controlled) in response to changing disturbance regime, climate and rising CO_2 (*high confidence*) Woody plant encroachment has been occurring in multiple ecosystems, including sub-tropical and tropical fire driven grassland and savanna systems, upland grassland systems, arid grasslands and shrublands (*high confidence*), leading to large scale biodiversity changes, albedo changes, and impacts on water delivery, grazing services and human livelihoods (*medium confidence*). Expansion of grasses (alien and native) into xeric shrublands is occurring causing increasing fire prevalence in previous fire free vegetation (CCP3). In tropical forests repeated droughts and recurrence of large-scale anthropogenic fires increase forest degradation, loss of biodiversity and ecosystem functioning (*high confidence*) (Anderson et al., 2018b; Longo et al., 2020). Accelerated growth rates and mortality of tropical trees is also adversely affecting tropical ecosystem functioning (McDowell et al., 2018; Aleixo et al., 2019). Projected changes in ecosystem functioning, such as via wildfire (Section 2.5.5.2), tree mortality (Section 2.5.5.3) and woody encroachment under climate change (Chapter 2) would alter hydrological processes, with adverse implications for water yields and water supplies (Sankey et al., 2017; Robinne et al., 2018; Rodrigues et al., 2019; Uzun et al., 2020).

The loss of a substantial fraction of biodiversity globally, abrupt impacts like significant local biodiversity loss and mass population mortality events, and ecological disruption due to novel species interactions have been observed or are projected at global warming levels below 2ºC (Chapter 2 Table 2.S.4, Cross Chapter Box: EXTREMES in Chapter 2, Section 2.4.4.3.1, Section 2.4.2.3.3) (*medium confidence*). Simple and compound impacts of extreme climate events are already causing significant loss and damage in vulnerable ecosystems, including through the facilitation of important global change drivers of ecological disruption and homogenisation like invasive species (*high confidence*). Severe impacts on human livelihoods and infrastructure, and valuable ecosystem services are all projected to accompany these changes. Adaptation potential for many of these risks is low due to the projected rate and magnitude of change, and to the requirement of significant amounts of land for terrestrial ecosystems (Hannah et al., 2020). Biodiversity conservation efforts may be hampered due to climate change impacts on the effectiveness of protected areas, with high sensitivity of effectiveness to forcing scenario (*medium confidence*). In addition, climate-related risks to ecosystems pose challenges to ecosystem-based adaptation responses (‘nature-based solutions’) (Section 2.1.3) (*medium confidence*).

16.5.2.3.3 Risk to critical physical infrastructure and networks (RKR-C)

RKR-C includes risks associated with the breakdown of physical infrastructure and networks which provide goods and services considered critical to the functioning of societies. It encompasses infrastructure systems for energy, water, transportation, telecommunications, health care and emergency response, as well as compound, cascading and cross-boundary risks resulting from infrastructure interdependencies (Birkmann et al., 2016; Fekete, 2019). Critical infrastructures such as transport or energy supply also play a central role in coping with climate risks, especially in acute disaster situations in which the services of transport infrastructure, communication technologies or electricity are particularly needed, despite the fact that these very systems are themselves exposed to disaster impacts (Garschagen et al., 2016; Pescaroli et al., 2018). The major hazards driving such risks are acute extreme events such as cyclones, floods, droughts or fires (*high confidence*), but cumulative and chronic hazards such as sea level rise (SLR) are also considered.

RKR-C is considered severe when the functioning of critical infrastructure cannot be secured and maintained against climate change impacts, resulting in the frequent and widespread breakdown of service delivery and eventually a significant rise of detrimental impacts on people (lives, livelihoods and well-being), the economy (including averted growth) or environment (disruption and loss of ecosystems) above historically observed levels. Severity in this RKR is assessed on two levels for (i) direct impacts of climate change on infrastructure assets and networks (e.g., amount of port infrastructure damaged or destroyed by SLR, flooding and storms) on which most of the literature focuses, as well as (ii) indirect and cascading downstream impacts to people, economy and environment (Markolf et al., 2019; Pyatkova et al., 2019; Chester et al., 2020), for which attribution is more difficult and uncertainties tend to be much higher. Overall, the literature with quantified assessments of climate change infrastructure risks remains to be less extensive than for many other risks, particularly with regards to assessments focusing on the Global South. While climate-related changes in hazards are widely considered in the literature, changes in future exposure and vulnerability conditions are often not treated explicitly. In addition, the severity of infrastructure risks also depends on future trends in the capacity to maintain, repair and rebuild infrastructure and adapt it to new hazard intensities (*medium evidence, high agreement*). These are mostly not quantified in a forward-looking manner in the literature; however, damage projections (see below) indicate a rapidly rising demand for investment, straining the financial capacity of countries (*medium evidence, high agreement*).

(i) Risks related to direct impacts on critical infrastructure would become severe with high warming, current infrastructure development regimes and minimal adaptation (*high confidence*), and in some contexts even with low warming, current vulnerability and no additional adaptation (*medium confidence*), with severity defined as infrastructure damage and required maintenance costs exceeding multiple times the current levels. Transport and energy infrastructure in coasts, polar systems and along rivers are projected to face a particularly steep rise in risk, resulting in severe risk even under medium warming (*high confidence*). Risk in relation to the increasing intensity and frequency of extreme events might become severe before the middle of the century (*medium confidence*). Damages from multiple climate hazards to transport, energy, industry and social infrastructure in Europe could increase tenfold by the 2080s, from 3.4 € billion annually to date, and 15-fold for transport infrastructure, under Medium warming (A1B, ~3°C by 2100) and with current adaptation levels, even if no further extension of the infrastructure in exposed areas is considered (Forzieri et al., 2018). Under High warming (RCP8.5) in 2100, the percent of roads in the United States that require rehabilitation due to high temperatures and precipitation is expected to increase to 23–33%, relative to 14% in 2100 when no climate change is considered (Mallick et al., 2018). Projections of climate-induced changes in exposure are an incomplete measure of risk but in the absence of other metrics can serve as a proxy for the potential for severe impacts. In the circumpolar Arctic, 14.8% of critical infrastructure assets would be affected by climate change under RCP8.5 by 2050, with lifecycle replacement costs projected to increase by 27.7% if infrastructure is to be preserved at current adaptation levels (Suter et al., 2019). Under RCP8.5, the number of ports under high risk will increase from 3.8% in the present day to 14.4% by 2100, as a result of increased coastal flooding and overtopping due to sea level rise, as well as the heat stress impacts of higher temperatures (Izaguirre et al., 2021). In the UK under High warming (4ºC), the number of clean and wastewater treatment sites located in the 1 in 75-year floodplain will increase by a third relative to today by the 2080s under current vulnerability and adaptation levels (Dawson et al., 2018). A global assessment of changing climate and water resources for electricity generation finds considerable reductions in usable hydropower and thermoelectric capacity by 2050 for a range of warming scenarios from Low to High, with absolute declines on average for most (61–74%) of the world's hydropower resources and monthly maximum reductions above 30% of usable capacity for over two-thirds of 1,427 thermoelectric power plants worldwide (Van Vliet et al., 2016). Many studies find large technical potential for coordinated adaptation-mitigation policies in the electricity sector to avoid a significant portion of projected climate change impacts (e.g., a two-thirds reduction, and in some cases fully offset) (Ciscar and Dowling, 2014; Van Vliet et al., 2016; Gerlak et al., 2018; Allen-Dumas et al., 2019).

(ii) Studies quantifying the indirect impacts of infrastructure failure on lives, livelihoods and economies are still rare but emerging, suggesting that risks would become severe in many contexts globally with high warming, current vulnerability and no additional adaptation (*medium confidence*). Severity in this context is defined as the potential to disrupt the lives, livelihoods and well-being of a significantly increased proportion of the population and to significantly forestall economic growth and development potential. Global risks to air travel from SLR, expressed in terms of expected annual route disruptions, could increase by a factor of between 17 and 69 by 2100 under the 1.5 ◦C and the 95th percentile value of the RCP8.5 SLR scenario, respectively (Yesudian and Dawson, 2021). By 2050, up to 185,000 airline passengers per year may be grounded due to extreme heat (48°C) if no additional adaptation is taken, roughly 23 times more than today (McKinsey Global Institute, 2020). In Africa, under RCP8.5 and without additional adaptation a 250% increase in disruption time of the transport network is expected by 2050 due to extreme temperatures, a 76% increase due to precipitation, and 1400% increase due to flooding (Cervigni et al., 2015). On the Dawlish railway section (UK), the number of days with line restrictions are set to increase by up to 1170%, to as many as 84–120 per year by 2100 due to 0.8m SLR with High warming (Dawson et al., 2016). Next to the limited number of projections or scenarios of indirect impacts, additional inferences from studies focusing on past and current impacts can be drawn. Already today, climate-related impacts on transport and energy infrastructure reach far beyond the direct impacts on physical infrastructure, triggering indirect impacts on, for example, health and income (*medium confidence*). A case study of future flood hazard in Europe found that the indirect impact of a power outage on the local economy is six to eight times greater than the direct flood damage and asset repair costs, due to the interruption of daily economic activity (Karagiannis et al., 2019). In low and middle-income countries, the annual costs from infrastructure disruptions reach up to 300 billion USD for firms and 90 billion USD for private households, with natural hazards such as floods being responsible for 10 to 70 % of these disruptions, depending on the sectors and regions (Hallegatte et al., 2019). Power outages triggered by floods or droughts have also been found to have substantial health implications, particularly amongst low-income populations (Klinger et al., 2014), and shown to impede disaster recovery efforts and severely disrupt local economies (Karagiannis et al., 2019; Nicolas et al., 2019). In addition, risks associated with infrastructure have the potential to become particularly severe when hazard-driven infrastructure disruptions undermine the capacity of emergency response in disaster situations (*low evidence, high agreement*). A study on the UK shows, for example, that even a small increase in minor road flooding leads to a disproportionately high disruption of the efficacy of emergency services (Yu et al., 2020). Similar risks have been found for rural areas, particularly in developing countries (Alegre et al., 2020).

16.5.2.3.4 Risk to living standards (RKR-D)

This RKR includes risks to (i) aggregate economic output at the global and national levels, (ii) poverty, and (iii) livelihoods, and their implications for economic inequality. It is informed by key risks identified by regional and sectoral chapters. Risks are potentially severe as measured by the magnitude of impacts in comparison to historical events or as inferred from the number of people currently vulnerable.

(i) Risks to aggregate economic output would become severe at the global scale with high warming and minimal adaptation (*medium confidence*), with severity defined as the potential for persistent annual economic losses due to climate change to match or exceed losses during the world's worst historical economic recessions. With historically observed levels of adaptation, warming of ~4ºC may cause a 10-23% decline in annual global GDP by 2100 relative to global GDP without warming, due to temperature impacts alone (Burke et al., 2015; Kahn et al., 2019; Kalkuhl and Wenz, 2020). These magnitudes exceed economic losses during the Great Recession (2008-2009, ~5% decline in global GDP, up to 15-18% in some countries) and the COVID-19 pandemic (2020, ~3% decline globally, up to 10% in some countries) (IMF, 2020; IMF, 2021). Unlike past recessions, climate change impacts would occur continuously in every year. However, smaller effects (1-8%) are found when using alternative methodologies (Diaz and Moore, 2017; Nordhaus and Moffat, 2017; Kompas et al., 2018; Kalkuhl and Wenz, 2020), assuming less warming (Kahn et al., 2019; Takakura et al., 2019), and assuming lower vulnerability and/or more adaptation (Diaz and Moore, 2017); this literature is comprehensively summarized in Cross-Working Group Chapter Box ECONOMIC. Impacts at high levels of warming are particularly uncertain, as all methodologies require extrapolation and insufficiently incorporate possible tipping elements in the climate system (Kopp et al., 2016).

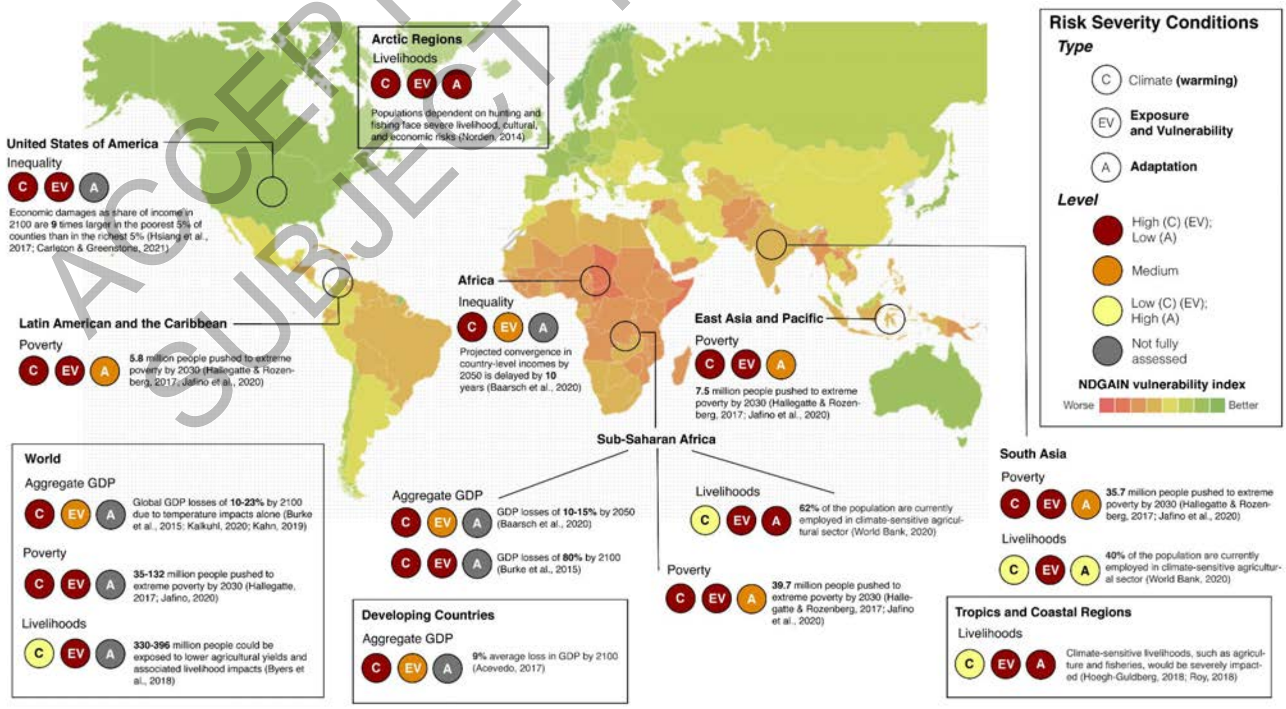

Figure 16.9. Illustrative examples from individual studies of risks to living standards and the conditions under which they could become severe. Selected studies are not representative of the literature, but provide examples of potentially

severe risks to aggregate economic output, poverty, and livelihoods. High, medium, and low levels of warming, exposure/vulnerability, and adaptation are defined as in Figure 16.10.

Annual economic output losses in developing countries could exceed the worst country-level losses during historical economic recessions (*medium confidence*). Assuming global warming of ~4ºC by 2100, historical adaptation levels, and high vulnerability, losses across sub-Saharan Africa may reach 12% of GDP by 2050 (Baarsch et al., 2020) and 80% by 2100 (Burke et al., 2015), and ~9% on average across developing countries by 2100 (Acevedo et al., 2017). The largest estimates are debated and depend on assumptions about development trends, adaptive capacity, and whether temperature impacts the level or growth rate of economic activity (Kalkuhl and Wenz, 2020). Severe risks are more likely in (typically hotter) developing countries because of nonlinearities in the relationship between economic damages and temperature (Burke et al., 2015; Acevedo et al., 2017). These risks are highest in scenarios and countries with: a large portion of the workforce employed in highly exposed industries (Acevedo et al., 2017); a high concentration of population and economic activity on coastlines (Hsiang and Jina, 2014; Acevedo et al., 2017); and an increase in the frequency or intensity of disasters triggered by natural hazards (Berlemann and Wenzel, 2018; Botzen et al., 2019). Whether baseline economic growth may help avoid severe future risks is highly uncertain (Dell et al., 2012; Burke et al., 2015; Acevedo et al., 2017; Deryugina and Hsiang, 2017).

(ii) Under medium warming pathways, climate change risks to poverty would become severe if vulnerability is high and adaptation is low (limited evidence, high agreement). We define poverty in terms of absolute consumption levels and define severity as tens to hundreds of millions of additional people in poverty relative to the number without change (globally) or an absolute increase in the number of people living in poverty compared to today (nationally or locally). This global impact is comparable to the effect of the 2007 food price shock (De Hoyos and Medvedev, 2009) and the 2020 COVID-19 pandemic (World Bank, 2020) and can be compared to about 700 million in poverty in 2017, down from 1.9 billion in 1990 (World Bank, 2020).

In a high-vulnerability development pathway, climate change in 2030 could push 35-132 million people into extreme poverty, in addition to the people already in poverty assuming climate is unchanged (disregarding impacts from natural variability; Hallegatte and Rozenberg, 2017; Jafino et al., 2020). In a low warming pathway, risks from mitigation costs could also be severe if no progressive redistribution from carbon pricing revenues is applied (Soergel et al., 2021). At the national level there is limited evidence of climate change causing an absolute increase in poverty (e.g., absolute increase of ~1-2%/yr through 2040, Montaud et al., 2017). Potentially severe risks to poverty are also supported by (1) the observed impacts of past disasters (Winsemius et al., 2018; Hallegatte et al., 2020; Rentschler and Melda, 2020) and previous crises such as food price shocks (Ivanic and Martin, 2008) or current diseases (WHO, 2018) on poor people and on poverty; (2) the expectation that these events will become more intense or frequent in some regions (WGI Chapter 12, Ranasinghe et al., 2021); and (3) population growth and the low adaptive and coping capacities of the poor (Leichenko and Silva, 2014; Huynh and Stringer, 2018; Thomas et al., 2020). This literature provides indirect evidence that climate change will keep many people poor and may cause more than tens of millions to fall into poverty (*low evidence, high agreement*).

(iii) Climate change poses severe risks to livelihoods at low levels of warming, high exposure/vulnerability, and low adaptation in climate-sensitive regions, ecosystems, and economic sectors (*high confidence*), where severity refers to the disruption of livelihoods for tens to hundreds of millions of additional people (Arnell and Lloyd-Hughes, 2014; Liu et al., 2018). More widespread severe risks would occur at high levels of warming (with high exposure/vulnerability and low adaptation) where there is additional potential for one or more social or ecological tipping points to be triggered (Cai et al., 2015; Cai et al., 2016b; Kopp et al., 2016; Steffen et al., 2018; Lenton et al., 2019), and for severe impacts on livelihoods to cascade from relatively more climate-sensitive to relatively less climate-sensitive sectors and regions (*medium confidence*) (Lawrence et al., 2020). Severity assessment is based on the current magnitude of exposure and vulnerability across multiple social and ecological systems, projected future exposure and vulnerability, and the rate at which hazard frequency or intensity is expected to increase (Otto et al., 2017; Roy et al., 2018; Li et al., 2019, Section 8.5). Without effective adaptation measures, regions with high dependence on climate-sensitive livelihoods – particularly agriculture and fisheries in the tropics and coastal regions – would be severely impacted even at low levels of warming (*high confidence*) (Hoegh-Guldberg et al., 2018b; Roy et al., 2018). For example, it is estimated that 330–396 million people could be exposed to lower agricultural yields and associated livelihood impacts at warming between 1.5 and 2ºC (Byers et al., 2018). Risks to the 200 million people with livelihoods derived from small-scale fisheries would also be severe, given sensitivity to ocean warming, acidification, and coral reef loss occurring beyond 1.5ºC (Cheung et al., 2018b; Froehlich et al., 2018; Free et al., 2019; Barnard et al., 2021). Livelihoods in highly exposed locations, such as small-island developing states, low-lying coastal areas, arid or semi-arid regions, the Arctic, and urban informal settlements or slums, are particularly vulnerable (Ford et al., 2015c; Hagenlocher et al., 2018; Ahmadalipour et al., 2019; Tamura et al., 2019). Within populations, the poor, women, children, the elderly, and indigenous populations are especially vulnerable due to a combination of factors including gendered divisions of paid and/or unpaid labour, as well as barriers in access to information, skills, services, or resources (Bose, 2017; Thomas et al., 2019b; Anderson and Singh, 2020; Adzawla and Baumüller, 2021)(*high confidence*). Future structural transformation could moderate risk severity by improving adaptive capacity, creating livelihoods in less climate-sensitive sectors, or by enabling sustainable migration to less climate-sensitive locations (Henderson et al., 2017; Roy et al., 2018). However, successful risk moderation would depend upon simultaneous avoidance of both climate change-related and mitigation-related (Doelman et al., 2019; Fujimori et al., 2019; Doelman et al., 2020) or maladaptation-related risks (Magnan et al., 2016; Benveniste et al., 2020; Schipper, 2020).

Climate change also could increase income inequality between countries (*high confidence*) as well as within them (*medium evidence, high agreement*) that result from and exacerbate impacts on aggregate economic activity, poverty, and livelihoods. Increasing inequality implies larger impacts on the least well-off, threatens their ability to respond to climate hazards, compromises basic principles of fairness and established global development goals, and potentially threatens the functioning of society and long-term progress (Roe and Siegel, 2011; Cingano, 2014; van der Weide and Milanovic, 2018). There is evidence that warming has slowed down the convergence in between-country income in recent decades (Diffenbaugh and Burke, 2019). Future impacts may halt or even reverse this trend during this century due to high sensitivity of developing economies (Burke et al., 2015; Pretis et al., 2018; Baarsch et al., 2020), although projections depend as much or more on future socioeconomic development pathways and mitigation policies as on warming levels (Takakura et al., 2019; Harding et al., 2020; Taconet et al., 2020). Within countries, studies that find adverse impacts on low-income groups imply an increase in inequality (Hallegatte and Rozenberg, 2017; Hsiang et al., 2017), although evidence for long-term climate impacts on within-country inequality at global scale remains limited.

16.5.2.3.5 Risk to human health (RKR-E)

This RKR includes (i) mortality from heat, and morbidity and mortality from (ii) vector-borne diseases and (iii) waterborne diseases. It builds on KRs identified primarily in Chapter 7 and health risks in regional chapters.

A severe risk to health is the potential for a widespread, substantial worsening of health conditions due to climate change. We measure severity in terms of the magnitude of mortality and morbidity. We consider a severe mortality impact to be a sustained increase in the crude mortality rate (CMR) of more than about 2-4 deaths per 10,000 people per year, or 2-5% over the current background rate. This range of increase is consistent with current mortality impacts with substantial global effects, including traffic fatalities (CMR of 1.6/10,000/yr, IHME) and the COVID-19 pandemic (4/10,000/yr, as of April, 2021, expressed as an annualized rate (Ritchie, Hannah et al., 2021). We use these global rates as thresholds in all cases, recognizing that they reflect substantial variation across regions and sub-populations (other points of comparison are included in Table SM16.13). Morbidity impacts are measured in numbers of disease cases or hospital admissions. We find that severe health impacts are projected to occur for particular sub-populations and regions where vulnerability is currently high and is assumed to persist into the future; we focus our assessment on these cases. In other cases, literature is either inadequate or does not support severe outcomes.

(i) Risks of heat-related mortality would become severe at global and regional scales with high levels of warming and vulnerability (*high confidence*). Under these conditions (SSP3-8.5), accounting for adaptation, heat mortality would increase the global CMR by up to 2-7/10,000/yr by 2100 (Carleton et al., 2020). For example, the US would experience a CMR increase of 2-4/10,000/yr by the end of the century (medium vulnerability without adaptation, and recent vulnerability with adaptation, respectively) (Weinberger et al., 2017; Shindell et al., 2020). Also assuming no adaptation and recent vulnerability, every population of the world would experience an increase of 2-10 percentage points in the proportion of deaths attributable to heat by the end of the century (RCP8.5). Harmful conditions for health are expected to increase in frequency and intensity over all land areas along with the rising temperatures in the coming decades (Pal and Eltahir, 2016; Russo et al., 2017; Ranasinghe et al., 2021; Saeed et al., 2021; Schwingshackl et al., 2021). Projections of exposure are an incomplete measure of risk but suggest the potential for severe impacts. For example, the percent of global population exposed to deadly heat stress would increase from today's 30% to 48-74% by the end of the century depending on level of warming and population distribution (Mora et al., 2017). Projected impacts are larger if exposure and/or vulnerability increases due to ageing of the population or increased inequality (Weinberger et al., 2017; Chen et al., 2020a; IPCC, 2021a) and with limited adaptation capacity (e.g., poor infrastructure, limited air conditioning, few medical and public health resources) (Table SM16.4) (Carleton et al., 2020). Higher risks are also expected in urban areas due to hazard amplification (i.e., urban heat island effect) and in highly dense settlements with other environmental hazards such as air pollution (Zhao et al., 2018; Sera et al., 2019).

(ii) Risks of vector-borne disease would become severe with high warming and current vulnerability, concentrated in children and in sensitive regions (*medium confidence*). Severity is defined by regionally substantial numbers of additional malaria deaths, disease cases, and episodic hospitalisation demands (for dengue).

With high warming, the CMR for malaria among children under the age of one year could increase by 5.2-10.1/10,000/yr in Africa under current vulnerability levels. This estimate assumes a net increase of 70-130 million more people exposed to potential disease transmission due to climate change in a high warming scenario (RCP8.5, end of century)(Caminade et al., 2014; Colón-González et al., 2018; Ryan et al., 2020), representing a 14-27% increase in the current population at risk (Ryan et al., 2020), and assumes children under 1 year of age are facing the same crude mortality in the future as for the African region today (Table SM16.13). The largest increase is observed in Eastern Africa, where the population exposed could nearly double by 2080 (Ryan et al., 2020) without accounting for population growth, driven mainly by changes among previously unexposed populations at higher altitude areas (Colón-González et al., 2018). Actual future disease burden of malaria will be highly sensitive to regional socio-economic development and the effectiveness of malaria intervention programs.

For dengue, with high warming and current levels of vulnerability there could be as many as a doubling of cases and hospital admissions per year globally, relative to today, driven by both warming and population growth. These estimates are derived by assuming similar relative incidence rates as today (Shepard et al., 2016) combined with projections of a more than doubling of the population exposed to potential disease transmission by the end of the century in a high warming scenario (RCP8.5), although much of this increase is driven by population growth (Colón-González et al., 2018; Monaghan et al., 2018; Messina et al., 2019). There are around 3 billion people exposed to dengue today.

(iii) Climate change would lead to severe risks of morbidity and mortality caused by waterborne diseases, particularly for diarrhoea in children in many lower- and middle-income countries (LMICs) and where vulnerability remains high (*medium confidence*). The global CMR for diarrhoea is 1.98 for all ages, but varies by region and age group, reaching as high as 53 for <1 year olds in Africa (Institute for Health Metrics and Evaluation (IHME), 2021) . In these vulnerable populations even a small percentage increase can lead to substantial additional morbidity and mortality. For example, assuming no change in vulnerability or population, an increase in diarrhoea mortality of only 5% over 2019 baseline rates would create a severe risk (CMR of 2.0) for children under the age of 1 in the WHO Africa (AFRO) region. This percent increase due to climate change is plausible since diarrhoea incidence increases of 7% (95% confidence interval 3-10%) are associated with a 1ºC increase in ambient temperature (WHO, 2014; Carlton et al., 2016), and diarrhoea is positively associated with heavy rainfall and flooding events (Levy et al., 2016), expected in some regions (WGI). Assuming vulnerability remains the same as today, mortality and morbidity rates would increase equivalently.

However, risks will be highly dependent on development trajectories, given that waterborne disease transmission is exacerbated by lack of clean drinking water and sanitation systems, inadequate food safety and hygiene conditions, lack of flood and drought protections, and interactions with other risks such as cholera outbreaks, food insecurity, and infrastructure damage. Climate change threatens the progress that has been made toward reducing the burden of diarrhea. For example, in Sub-Saharan Africa, while overall diarrhea rates are expected to continue to decline (GBD 2016 Diarrhoeal Disease Collaborators, 2018), warming in 2030 (relative to the late 20th century) is projected to lead to diarrheal deaths in children under 15 equivalent to a CMR increase of 0.56/10,000/yr (based on population projections for the region and age group (UN, 2020)) (WHO, 2014). In China, by 2030 climate change could delay progress toward reducing waterborne disease burden by 8-85 months (Hodges et al., 2014).This RKR includes (i) mortality from heat, and morbidity and mortality from (ii) vector-borne diseases and (iii) waterborne diseases. It builds on KRs identified primarily in Chapter 7 and health risks in regional chapters.

16.5.2.3.6 Risk to food security (RKR-F)

Climate change affects food security primarily through impacts on food production, including crops, livestock, and fisheries, as well as disruptions in food supply chains, linked to global warming, drought, flooding, precipitation variability and weather extremes (Myers et al., 2017; FAO et al., 2018; Mbow et al., 2019). This RKR builds on Key Risks identified primarily in the Food, Fibre, and other Ecosystem Products Chapter, some sectoral (Health), and regional (Africa, Australasia, Central and South America, North America) chapters, as well as SR15, SRCCL and SROCC.

The severity of the risk to food security is defined here using a combination of criteria including the magnitude and likelihood of adverse consequences, affecting 10s to 100s of millions of people, timing of the risk and ability to respond to the risk. In this assessment, we use the number of undernourished people as a proxy outcome of these dimensions and their multiple interactions.

Climate change will pose severe risks in terms of increasing the number of undernourished people, affecting tens to hundreds of million people under High vulnerability and High warming, particularly among low-income populations in developing countries (*high confidence*). Extreme weather events will increase risks of undernutrition even on a regional scale, via spikes in food price and reduced income (*high confidence*) (FAO et al., 2018, Hickey and Unwin, 2020; Mbow et al., 2019). The timing of these impacts and our ability to respond to them vary based on the level of GHG emissions and Shared Socioeconomic Pathways (SSP). Under a low vulnerability development pathway (SSP1), climate change starts posing a moderate risk to food security above 1ºC of global warming (i.e., impacts become detectable and attributable to climate-related factors), while beyond 2.5ºC the risk becomes high (widespread impacts on larger numbers or proportion of population or area, but with the potential to adapt or recover) (Hurlbert et al., 2019). Under high vulnerability-high warming scenario (i.e., SSP3-RCP6.0), up to 183 million additional people are projected to become undernourished in low income countries due to climate change by 2050 (Mbow et al., 2019). Climate-related changes in food availability and diet quality are estimated to result in a crude mortality rate of about 54 deaths per million people with about 2ºC warming by 2050 (SSP2, RCP8.5), most of them projected to occur in South and East Asia (67-231 deaths per million depending on the country) (Springmann et al., 2016). In a medium vulnerability-high warming scenario (SSP2, RCP6.0), Hasegawa et al. (2018) projects that the number of undernourished people increases by 24 million in 2050, compared to outcomes without climate change and accounting for the CO_2-fertilization effect. This number increases by around 78 million in a low warming scenario (RCP2.6) accounting for the impacts of both climate change and mitigation policies. Caveats to these modelling studies are that most models (crop models in particular) are designed for long-term change in climate but not suited to project the impacts of short-term extreme events. The inclusion of adaptation measures into modeling estimates remains selective and partial.

Climate change risks of micronutrient deficiency will become severe in high vulnerability development pathways and in the absence of societal adaptation, leading to hundreds of millions of additional people lacking key nutrients for atmospheric CO_2 levels above 500 ppm (*high confidence*) (Myers et al., 2017; Nelson et al., 2018; Mbow et al., 2019). For example, concentration of many micronutrients (e.g., phosphorus, potassium, calcium, sulphur, magnesium, iron, zinc, copper, and manganese) can decrease by 5-10% under atmospheric CO_2 concentrations of 690 ppm (3.5ºC warming). The decline in zinc content is projected to lead to an additional 150-220 million people affected by zinc deficiency with increases in existing deficiencies in more than 1 billion people (Myers et al., 2017). Similarly, decrease in protein and micronutrient content in rice due to a higher CO_2 concentration (568 to 590 ppm) can lead to 600 million people with rice as a staple at risk of micronutrient deficiency by 2050 (Zhu et al., 2018). Additionally, the impact on protein content of increased CO_2 concentration (> 500 ppm) can lead an additional 150 million people with protein deficiency by 2050 (within the total of 1.4 billion people with protein deficiency) in comparison to the scenario without increased CO_2 concentration (Medek et al., 2017).

16.5.2.3.7 Risk to water security (RKR-G)

Water security encompasses multiple dimensions: water for sanitation and hygiene, food production, economic activities, ecosystems, water-induced disasters, and use of water for cultural purposes (Chapter 4; Box 4.1; Section 4.6.1). Water security risks are a combination of water-related hazards such as floods, droughts, and water quality deterioration, and exposure of vulnerable groups exposed to too little, too much, or contaminated water. Reasons for these can include both environmental conditions and issues of safety and access influenced by effectiveness of water governance (Sadoff et al., 2020). These are manifest through loss of lives, property, livelihoods and culture, and impacts on human health and nutrition, ecosystems and water-related conflicts which in turn can drive forced human displacement.

This RKR focuses on three types of risks with the potential to become severe: those associated with water scarcity, those driven by water-related disasters, and those impacting indigenous and traditional cultures and ways of life. Risk to water security constitutes a potentially severe risk because climate change could impact the hydrologic cycle in ways that would lead to substantial consequences for the health, livelihoods, property, and cultures of large numbers of people. For those associated with water scarcity, 'severe' refers to magnitude (number of people in areas where water scarcity falls below recognised thresholds for adequate water supply per capita), along with the likelihood of unforeseen increases in water scarcity that outpace the ability to prepare for the increased risk by putting in place new large-scale infrastructure within the required timescale. For those associated with extreme events, 'severe' refers to magnitude (numbers of people affected, including deaths, physical health impacts including disease, mental health impacts, loss of livelihoods, loss of or damage to property) and timing (for example, events coinciding with other stresses, e.g., a pandemic occurring at a time when local infrastructures are weakened by an extreme weather event). Important water-related extreme events include river flooding caused by heavy and/or prolonged rainfall, glacial lake outburst floods, and droughts. For those impacting cultures, 'severe' refers to the loss of key aspects of traditional ways of life. This includes consequences of the above two key risks.

Risks associated with water scarcity have the potential to become severe based on projections of large numbers of people becoming exposed to low levels of water availability per person, where 'water availability' includes fresh water in the landscape, including soil moisture and streamflows, available for all uses including agriculture as a dominant sector. Approximately 1.6 billion people currently experience 'chronic' water scarcity, defined as the availability of less than 1000 m3 of renewable sources of fresh water per person per year (Gosling and Arnell, 2016). In this context, we define a severe outcome as an additional 1 billion people experiencing 'chronic' water scarcity, relating to all uses of water, representing an increase of a magnitude comparable with current levels. The global number of people experiencing chronic water scarcity is projected to increase by approximately 800 million to 3 billion for 2°C global warming, and up to approximately 4 billion for 4°C global warming, considering the effects of climate change alone, with present-day population (Gosling and Arnell, 2016). Severe outcomes are projected to occur even with no changes in exposure: present-day exposure is defined here as 'medium' since either an increase or decrease in exposure could be possible. Vulnerability is not quantified in the literature assessed here, so in this assessment it is considered that severe outcomes could occur with present-day levels of vulnerability, again defined here as 'medium'. Particularly severe outcomes (i.e., the high end of these ranges) are driven by regional patterns of climate change bringing severe reductions in precipitation and/or high levels of evapotranspiration in the most highly-populated regions, leading to very substantial reductions in water availability compared to demand. There is strong consensus across models that water scarcity is projected to increase across substantial parts of the world even though projections disagree on which specific areas would see this impact. Moreover, a projected decrease in water scarcity in some regions does not prevent the increase in water scarcity in other regions becoming severe. Hence there is *high confidence* that risks to water scarcity have the potential to become severe due to climate change. Consequences of water scarcity include potential competition and conflicts between water users (Vanham et al., 2018), damaging livelihoods, hindering socio-economic development, and reducing human well-being, for example through malnutrition resulting from inadequate water supplies leading to long-term health impacts such as child stunting (Cooper et al., 2019). The avoidance of these consequences at high levels of water scarcity would require transformational adaptations including large-scale interventions such as dams and water transfer infrastructure (Greve et al., 2018). Since these require many years or even decades for planning and construction, and are also costly and irreversible and can potentially lead to lock-in and maladaptation, the potential for inadequate policy decisions made in the context of high uncertainties in regional climate changes brings the risk of a shortfall in adaptation. Around 2050, at approximately 2°C global warming, the risk of a substantial adaptation shortfall and hence severe outcomes for water scarcity have a relatively high likelihood across large parts of the southern USA and Mexico, northern Africa, parts of the Middle-East, northern China, and southern Australia, as well as many parts of Northwest India and Pakistan (Greve et al., 2018).

Risks associated with water-related extreme events and disasters have the potential to become severe based on projections of large numbers of people or high values of assets being affected. The risks to people from disasters can often only be quantified in terms of the hazard and exposure (the number of people affected), rather than the full consequences such as number of deaths, injuries or other health outcomes, as these often depend on complex or unpredictable factors such the effectiveness of emergency and humanitarian responses or the access to healthcare. With approximately 50 million people per year currently affected by flooding (Alfieri et al., 2017), we define severe outcomes as more than 100 million people affected by flooding. At 2°C global warming, between approximately 50 million and 150 million people are projected to be affected by flooding, with figures rising to 110 million to 330 million at 4°C global warming. These projections assume present-day population and no additional adaptation, so no changes in exposure. Increased flood risk is projected by the WHO to lead to an additional 48,000 deaths of children under 5 years due to diarrhoea by 2030, with Sub-Saharan Africa impacted the most (WHO, 2014). Other consequences of floods that already occur include deaths by drowning, loss of access to fresh water, vector-borne diseases, mental health impacts, loss of livelihoods, and loss of or damage to property. Many of these consequences depend on the vulnerability of individuals, households or communities to flooding impacts, for example through the presence or absence of measures to safeguard health and livelihoods, such as through infrastructure services, insurance or community support. The risks associated with these consequences could increase if there were no local adaptations to counter the effect of increased levels of hazard by reducing exposure and/or vulnerability. Climate-related changes to extreme events that would lead to these severe outcomes: increased frequency and/or magnitude of river floods of flash floods due to heavy or long-lasting precipitation, rapid snowmelt, or catastrophic failure of glacial lake moraine dams. These climate conditions are projected to increase with global warming.

Risks to cultural uses of water can become severe if there are permanent loss of aspects of communities' cultures due to changes in water, including loss of areas of ice or snow with spiritual meanings, loss of culturally-important places of access to such places, and loss of culturally-important subsistence practices including by indigenous people (Chapter 4). This includes mountain regions where changes in the cryosphere are having profound impacts (CCP5). In these cases, severe outcomes would be defined locally rather than globally. Communities that lost a dominant environmental characteristic deeply associated with its cultural identity would be considered to be severely impacted. For example, due to the central role that travel on sea ice plays in the life of Inuit communities, providing freedom and mental wellbeing, loss of sea ice can be argued to represent environmental dispossession of these communities (Durkalec et al., 2015). Traditional ways of life are therefore threatened and resulting changes would be transformative rather than adaptive. Similarly, changes in streamflow affecting the availability of species for traditional hunting can also negatively impact indigenous communities (Norton-Smith et al.). Such changes are already being seen at current levels of warming, but studies remain somewhat limited in number, so this assessment is assigned *medium confidence* due to medium evidence and medium agreement. WG1 conclude that it is *virtually certain* that further warming will lead to further reductions in Northern Hemisphere snow cover and mass loss in individual glacier regions is projected to be between approximately 30% and 100% by 2100 under high-warming scenarios (Chapter 4). Streamflows are projected to change in most major river basins worldwide by several tens of percent at 4°C global warming (Chapter 4).

There is strong potential for increases in water scarcity, flooding, loss of snow and ice and changes in water bodies to lead to severe outcomes such as deaths from water-related diseases, drowning and starvation, long-term health impacts arising from malnutrition and diseases, loss of property, loss of existence or access to places of cultural significance, loss of livelihoods and loss of aspects of culture especially for indigenous people with traditional lifestyles. The numbers of people affected are projected to range from hundreds of millions to several billion, depending on the level of global warming and socio-economic futures. A key aspect of the risk is the high uncertainty in future regional precipitation changes in many regions of high vulnerability, including the potential for large and highly-impactful changes, for which it may not be possible to provide adaptation measures before they become needed, leading to a high likelihood of adaptation deficits.

16.5.2.3.8 Risks to peace and to human mobility (RKR-H)

This RKR includes risks to peace within and among societies from armed conflict as well as risks to human mobility, epitomized by involuntary migration and displacement within and across state borders and involuntary immobility. Breakdown of peace and the inability of people to choose to move or stay challenge core elements of human security (Adger et al., 2014). Risks to peace also inform the agency and viability of mobility decisions. However, evidence does not indicate that human mobility constitutes a general risk to peace.

Breakdown of peace, materialized as overt or covert violence across social and spatial scales, constitutes a key risk because of its potential to cause widespread loss of life, livelihood, and wellbeing. Such impacts are considered severe if they result in at least 1,000 excess battle-related deaths in a country in a year. This threshold is consistent with the conventional definition of war (Pettersson and Öberg, 2020). However, because armed conflict routinely causes significant material destruction, triggers mass displacement, threatens health and food security, and undermines economic activity and living standards (Baumann and Kuemmerle, 2016; FAO et al., 2017; de Waal, 2018), risks to peace can be considered severe also when conflict has cascading effects on other aspects of wellbeing and amplifies vulnerability to other RKRs. Beyond the magnitude of such impacts, the rapidity with which armed conflict can escalate and the challenges of ending violence once it has broken out imply potentially very limited time and ability to respond for populations at risk.

Mobility is a universal strategy for pursuing wellbeing and managing household risks (Section 7.2.6; Cross-Chapter Box MIGRATE in Chapter 7,UN, 2018) and, where it occurs in a safe and orderly fashion, can reduce social inequality and facilitate sustainable development (Franco Gavonel et al., 2021). Involuntary mobility constitutes a key risk because it implies reduced human agency with high potential for significant economic losses and non-material costs, an unequal gender burden, and amplified vulnerability to other RKRs (Schwerdtle et al., 2018; Adger et al., 2020; Maharjan et al., 2020; Piggott-McKellar et al., 2020). Climate change also may erode or overwhelm human capacity to use mobility as a coping strategy, producing involuntarily immobile populations (Adams, 2016). A severe impact is when a large share of an affected population is forcibly displaced or prevented from moving, relative to normal mobility patterns, at local to global scale. However, because mobility may be a favourable mechanism for reducing risk or an adverse outcome of risk, depending on the circumstances under which it occurs, it is not possible to specify a simple quantitative threshold for when impacts become severe.

Complex causal pathways and lack of long-term projection studies presently prevent making confident quantitative judgments about how risks to peace and human mobility will materialize in response to specific warming levels, development pathways, and adaptation scenarios. Literature concludes with medium confidence that risks to peace will increase with warming, with the largest impacts expected in weather-sensitive communities with low resilience to climate extremes and high prevalence of underlying risk factors (Theisen, 2017; Busby, 2018; Koubi, 2019; von Uexkull and Buhaug, 2021). However, climate-driven impacts on societies will depend critically on future political and socioeconomic development trajectories (limited evidence, high agreement), suggesting that risks due to climate change are relevant primarily for highly vulnerable populations and for pessimistic development scenarios. Overall risks to peace may decline despite warming if non-climatic determinants are reduced sufficiently in the future.

Regular human mobility will continue regardless of climate change but mobility-related risks will increase with warming, notably in densely populated hazard-prone regions, in small islands and low-lying coastal zones, and among populations with limited coping capacity (RKR-A; CCP2 2.2.2; Chapter 7) (*high confidence*). Such risks can become severe even with limited levels of warming for populations with low adaptive capacity and whose settlements and livelihoods are critically sensitive to environmental conditions (medium evidence, high agreement). Likewise, risk of involuntary immobility could become severe for highly vulnerable populations with limited resources, even with moderate levels of warming (limited evidence, high agreement). Critically, population growth and shifting exposure will interact with warming to shape these risks (Davis et al., 2018; Hauer et al., 2020; Robinson, 2020a). Although climate-driven human mobility generally does not increase risks to peace (*medium confidence*), armed conflict is a major driver of forced displacement (*high confidence*).

Expert elicitation estimates that 4°C warming above pre-industrial levels will have severe and widespread effects on armed conflict with 26% probability, assuming no change from present levels in non-climatic drivers (Mach et al., 2019). That judgment refers to impacts that exceed the threshold for severity considered here, suggesting that global warming of 4°C would produce severe risks to peace under present societal conditions (*low confidence*). Future risks to peace will remain strongly influenced by socioeconomic development (Hegre et al., 2016). A study of Sub-Saharan Africa that accounts for both temperature and socioeconomic changes, 2015–65, concludes that determinants other than rising temperatures, notably quality of governance, will remain most influential in shaping overall levels of violence even in the high-warming RCP8.5 scenario (Witmer et al., 2017).

A larger empirical literature offers indirect evidence that climate change may produce severe risks to peace within this century by demonstrating how climate variability and extremes affect contemporary conflict dynamics, especially in contexts marked by low economic development, high economic dependence on climate-sensitive activities, high or increasing social marginalization, and fragile governance (*medium confidence*) (Chapter 7.2.7; Chapter 16.2, Schleussner et al., 2016a; Von Uexkull et al., 2016; Busby, 2018; Harari and Ferrara, 2018; Ide et al., 2020; Scartozzi, 2020).

Climatic risks interact with economic, political, and social drivers to create risks to human mobility both directly (through the threat of physical harm and destruction of property and infrastructure) and indirectly (via adverse impacts on livelihood and wellbeing). Extreme weather events are leading causes of forced displacement (Cross-Chapter Box MIGRATE in Chapter 7, IDMC, 2020). Projected increases in the frequency and severity of extreme events (AR6 WGI Chapter 12, Ranasinghe et al., 2021) in combination with future population growth in hazard-prone regions (e.g., Merkens et al., 2016) suggest that risks to mobility will increase in response to future global warming (Robalino et al., 2015; Davis et al., 2018; Rigaud et al., 2018). For example, moving from RCP2.6 to RCP8.5 (entailing ~0.5°C additional global warming by 2050) is projected to increase internal migration by 2050 from 51 [31-72] million to 118 [92-143] million people across South Asia, Latin America, and Africa (Rigaud et al., 2018), although those estimates are principally comprised of migrants, whose decisions are also informed by non-climatic drivers, rather than involuntarily displaced people. Global levels of flood displacement are estimated to increase by 50% with each 1°C warming (Kam et al., 2021). Should future warming reduce adaptation options for vulnerable populations (Chapter 16.4), a consequence may be higher levels of involuntary migration and immobility (Grecequet et al., 2017; Otto et al., 2017). There is little evidence that climate-driven mobility negatively affects peace (Brzoska and Fröhlich, 2016; Burrows and Kinney, 2016; Freeman, 2017; Petrova, 2021).

There is high agreement that even moderate levels of future SLR will severely amplify involuntary migration and displacement in small islands and densely populated low-lying coastal areas in the absence of appropriate adaptive responses (*high confidence*) (Hauer, 2017; IPCC, 2019b; Hauer et al., 2020; McMichael et al., 2020, Section 15.3.4; Section 16.4). In some contexts climate change also may accelerate migration toward high-exposure coastal areas (Bell et al., 2021). Under a high emissions RCP8.5 scenario (global median 0.7m SLR by 2100), the number of people exposed to annual coastal flooding may more than double by 2100 compared to present numbers (Kulp and Strauss, 2019). In USA alone, SLR of 0.9 m could potentially put 4.2 million people at risk of inundation by the end of this century (Hauer, 2017). However, numbers of people exposed to SLR does not evenly translate to forcibly displaced populations (Hauer et al., 2020). Ascertaining how many people will move forcibly or as adaptive response to SLR is inherently challenging because of the complex and highly individual nature of migration decisions (Black et al., 2013; Boas et al., 2019; Piguet, 2019; Bell et al., 2021). Implications of climate change for risks to human mobility across borders are even harder to quantify and highly uncertain, due to unknown developments in legal and political conditions that govern international migration (McLeman, 2019; Wrathall et al., 2019).

16.5.2.4 Synthesis of the Assessment of Representative Key Risks

Figure 16.10 provides a synthesis of the RKRs and the conditions that lead to severe risks over the course of the 21st century, as assessed in Sections 16.5.2.3.1 to 16.5.2.3.8 (see Supplementary Table SM16.12 for further description). It identifies sets of conditions -- defined by levels of warming, exposure/vulnerability, and adaptation -- that would produce severe risk with a particular level of confidence. The risks are of two scopes: broadly applicable, meaning that the risks described by a particular KR or RKR would be severe pervasively and even globally; and specific, meaning that these risks would apply to particular areas, sectors, or groups of people.

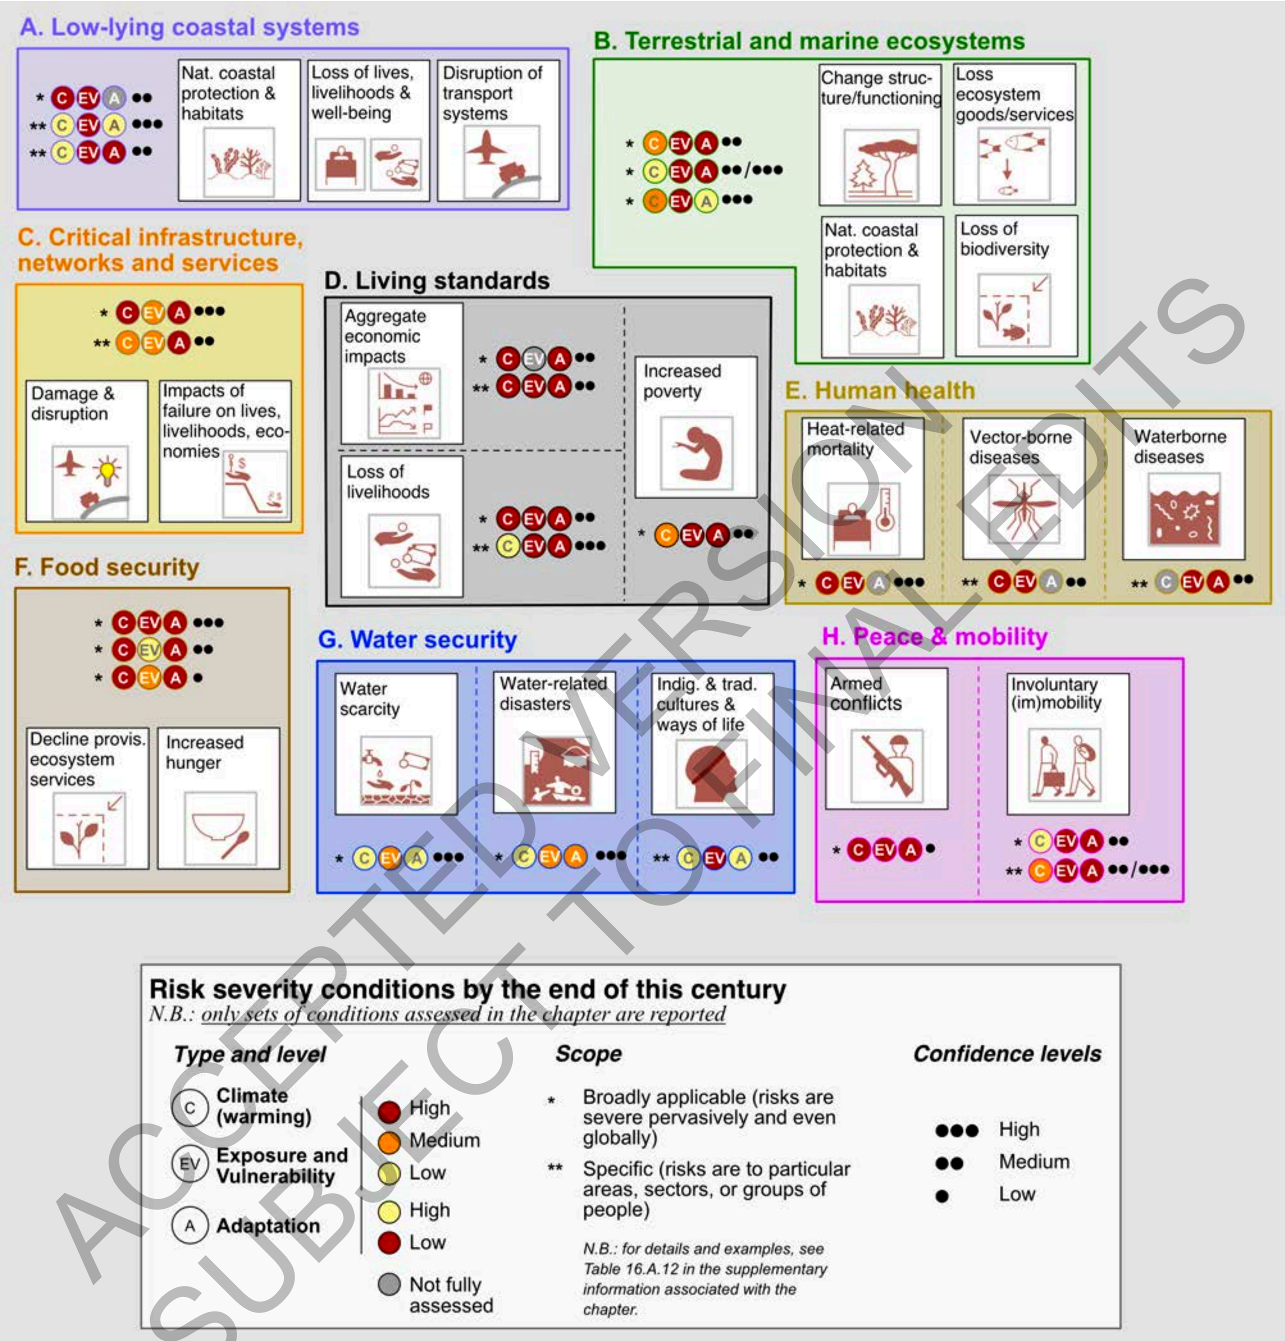

Figure 16.10: Synthesis of the severity conditions for Representative Key Risks by the end of this century. The figure does not aim to describe severity conditions exhaustively for each RKR, but rather to illustrate the risks highlighted in this report (Sections 16.5.2.3.1 to 16.5.2.3.8). Colored circles represent the levels of warming (climate), exposure/vulnerability, and adaptation that would lead to severe risks for particular key risks and RKRs. Each set of three circles represents a combination of conditions that would lead to severe risk with a particular level of confidence, indicated by the number of black dots to the right of the set, and for a particular scope, indicated by the number of stars to the left of the set. The two scopes are 'broadly applicable', meaning applicable pervasively and even globally, and 'specific', meaning applicable to particular areas, sectors, or groups of people. Details of confidence levels and scopes can be found in Section 16.5.2.3. In terms of severity condition levels (see Section 16.5.2.3), for warming levels (colored circles labeled 'C' in the figure), High refers to climate outcomes consistent with RCP8.5 or higher, Low refers to climate outcomes consistent with RCP2.6 or lower, and Medium refers to intermediary climate scenarios. Exposure-Vulnerability levels are determined by the RKR teams relative to the range of future conditions considered in the literature. For Adaptation, High refers to near maximum potential and Low refers to the continuation of today's trends.

Despite being intertwined in reality, Exposure-Vulnerability and Adaptation conditions are distinguished to help understand their respective contributions to risk severity.

Five main messages arise from this synthesis:

Severe risk is rarely driven by a single determinant (warming, exposure/vulnerability, adaptation), but rather by a combination of conditions that jointly produce the level of pervasiveness of consequences, irreversibility, thresholds, cascading effects, likelihood of consequences, temporal characteristics of risk and the systems' ability to respond (*medium* to *high confidence*). In other words, climate risk is not a matter of changing climatic impact drivers (CIDs) only, but of the confrontation between changing CIDs and changing socio-ecological conditions.

In most of the RKRs, severe risk for broadly applicable situations requires high levels of warming or exposure/vulnerability, or low adaptation. In many cases, it is associated with several of these conditions occurring simultaneously (e.g., high warming and high vulnerability). Examples include low-lying coastal areas (RKR-A; *medium confidence*), loss of livelihoods (RKR-D; *medium confidence*) or armed conflicts (RKR-H; *low confidence*).

High warming and exposure/vulnerability combined with low adaptation is however not necessarily required to lead to severe risk, and various other sets of conditions can lead to such an outcome. For example:
Without high levels of warming — This is especially the case for terrestrial and marine ecosystems (RKR-B) and water security (RKR-G) for which even medium to low levels of warming will generate severe risk, depending on the processes considered (e.g., mass population-level mortality and ecological disruption for ecosystems). This is also the case when more specific situations are considered, for example in the case of (in)voluntary mobility of vulnerable populations with limited resources (RKR-H), and for some critical infrastructure in already highly exposed and vulnerable contexts (RKR-C).
With high levels of adaptation — High levels of adaptation will not necessarily avoid severe risk, as is illustrated by the cases of coral-dependent and arctic coastal communities (RKR-A), some terrestrial and marine ecosystems (RKR-B), and water scarcity and the cultural uses of water (RKR-G).

All RKR assessments indicate that risks are higher in high vulnerability development pathways, and in some cases high vulnerability can occur in high income societies. Examples include the possibility of increasing coastal settlement and the location of critical infrastructure in highly exposed locations (RKR-A, RKR-C) including to floods (RKR-G) and risks to terrestrial and marine ecosystems (RKR-B). The assessment therefore show that depending on socioeconomic trends especially in terms of equity, social justice and income sustainability, as well as on the ability to shift towards more climate resilient economic and settlement systems (e.g., at the coast), higher income societies also are at serious risk of being substantially affected in the decades-to-century to come.

In terms of the time frames, most of the RKRs conclude that severe risks to many dimensions (ecosystems, health, etc.) are expected to occur by the end of the 21st century and across the globe. Some RKRs however highlight that severe risk could occur far earlier, e.g. as soon as a warming level of 1.5°C or 2°C is reached, which means potentially well before mid-century (IPCC, 2021a). In some cases, risks are already considered severe, for example after major climatic events such as tropical storms (RKR-A).

16.5.3 Variation of Key Risks Across Levels of Global Warming, Exposure and Vulnerability, and Adaptation

This section builds on Sections 16.5.1 and 16.5.2 as well as on additional literature to illustrate how consequences associated with KRs and RKRs are projected to vary with three types of determinants: global average warming level, as a proxy for associated changes in climate hazards (climatic impact-drivers, CIDs, Ranasinghe et al., 2021); socio-economic development pathway, as a means of capturing alternative future exposure and vulnerability conditions; and level of adaptation to reflect the extent to which successful adaptation is implemented. While these three dimensions are partly intertwined – e.g., warming and adaptation scenarios are constrained by development pathways (Chapter 18) – this section assesses the influence of each dimension separately (Section 16.5.3.2 to Section 16.5.3.4) to highlight how sensitivity varies across these dimensions for different KRs and RKRs. We then bring the dimensions together in an illustrative example (large deltas; Section 16.5.3.5).

16.5.3.1 Warming Level, Including Risks Avoided by Mitigation

Studies illustrating sensitivity to warming level typically do so by contrasting projected impacts for the same socioeconomic conditions but different climate pathways or temperature levels, often based on Representative Concentration Pathways (RCPs) (van Vuuren and Carter, 2014). We refer to future climate conditions either based on their global average warming level or as a 'high warming' scenario (based on RCP8.5), medium warming (RCP4.5 or RCP6.0), or low warming (RCP2.6 or 1.5ºC scenarios). Because some of these scenarios assume no or minimal mitigation (RCP8.5, RCP6.0) while others do (RCP4.5, RCP2.6), differences in outcomes between them reflect risks avoided by mitigation (assuming consistent socioeconomic assumptions).

Some ecological risks (Chapter 2) are particularly sensitive to warming. For example, warm-water coral reefs are already experiencing High risk levels and are expected to face Very High risks under 1.5ºC of global warming (Hoegh-Guldberg et al., 2018a; Bindoff et al., 2019). Some societal risks, such as human mortality due to extreme heat, also are sensitive to warming. A medium warming scenario (relative to high warming) reduces projected global average mortality due to heat from seven deaths per 10,000 people per year (7/10,000/yr) by 2100 to ~1/10,000/yr, assuming high vulnerability societal conditions (Carleton et al., 2020). At the national level, without considering adaptation, reductions in a broader measure of mortality are projected across a range of countries including Colombia, the Philippines, and several in Europe (Guo et al., 2018), and exposure of the US population to high mortality heatwaves is reduced by nearly half (Anderson et al., 2018a). Without considering changes in exposure or vulnerability, warming of 1.5-2ºC (compared to 4-5ºC) reduces global mortality impacts from an increase of 2.1-13.0% to 0.1-2.2% (Gasparrini et al., 2017; Vicedo-Cabrera et al., 2018a) and impacts in China from up to 4/10,000/yr (Weinberger et al., 2017) to 0.3-0.5/10,000/yr (Wang and Hijmans, 2019).

A low warming scenario (relative to high warming) reduces aggregate economic impacts from around 7% of global GDP to less than 1% (Takakura et al., 2019), and changes impacts on the number of people suffering from hunger from an increase (by 7-55 million) to a decrease (by up to 6 million) (Janssens et al., 2020). Low versus high warming also reduces the coastal population at risk of flooding due to SLR from tripling by 2100 (relative to today) to doubling (Kulp and Strauss, 2019, Section 16.5.2.3.2). The SROCC estimates that SLR risks are reduced from Moderate-to-High to Moderate for large tropical agricultural deltas and resource-rich megacities, and from High and Very high to Moderate-to-High for Arctic human communities and Urban atoll islands, respectively (Oppenheimer et al., 2019).

Higher levels of warming are projected to also generate higher income inequality between countries (e.g., Pretis et al., 2018; Takakura et al., 2019) as well as within them (Hallegatte et al., 2016) even though other drivers will be more important (Section 16.5.2.3.5). Similarly, climate and weather events are expected to play an increasing role in shaping risks to peace (*medium agreement*, *low evidence*) and migration (*high agreement*, *medium evidence*) in the future, but uncertainty is high due to complex causal pathways and non-climate factors likely dominate outcomes (Section 16.5.2.3.9). There is *high agreement* that future SLR will amplify levels of forced migration from small islands and low-lying coastal areas in the absence of appropriate adaptive responses (Oppenheimer et al., 2019).

A synthesis of risk assessments in the recent IPCC Special Reports (Magnan et al., 2021) concludes that an integrated measure of today's global climate risk level will increase by the end of this century by two- to four-fold under a low and high warming, respectively (based on aggregated scores developed in the study). An additional comparison of risk levels under +1.5 °C and +2 °C suggests that every additional 0.5 °C of global warming will increase the risk level by about a third.

16.5.3.2 Exposure and Vulnerability Trends

Development pathways describe plausible alternative futures of societal change and are critical to future risks because they affect outcomes of concern both through non-climate and climate-related channels (*very high confidence*).

Studies illustrating sensitivity to development pathways typically do so by contrasting projected impacts for the same climate pathway or temperature level but different levels of socioeconomic exposure and vulnerability, for example based on Shared Socioeconomic Pathways (SSPs) (O'Neill et al., 2014; Van Vuuren et al., 2014). Or, they infer sensitivity to future development pathways based on differences in impacts across current populations with different levels of exposure or vulnerability. We refer to future conditions based on SSPs 1 or 5 as 'low exposure' or 'low vulnerability' conditions, and those based on SSPs 3 or 4 as 'high exposure' or 'high vulnerability' conditions (O'Neill et al., 2014; van Vuuren and Carter, 2014).

A wide range of climate change impacts depend strongly on development pathway (*high confidence*), A low (relative to high) exposure future, determined by limited population growth and urbanization, results in about 30% fewer people exposed to extreme heat globally (Jones et al., 2018b) and about 50% fewer in Africa (Rohat et al., 2019a), similar to the effect of a medium vs. high level of global warming. Low exposure conditions also reduce the fraction of the population in Europe at very high risk of heat stress from 39% to 11% (Rohat et al., 2019b). Demographic differences lead to a reduction in the global population exposed to mosquitos acting as viral disease vectors by more than half (Monaghan et al., 2018) and exposure to wildfire risk by nearly half (Knorr et al., 2016).

Studies are increasingly going beyond exposure to incorporate future vulnerability, finding that it is often the dominant determinant of risk (*high confidence*). A low (relative to high) vulnerability future reduces the risk to global poverty by an order of magnitude, robustly across approaches that account for macroeconomic growth, structural change in the economy, inequality, and access to infrastructure services (Hallegatte and Rozenberg, 2017), or for the exposure of vulnerable populations to multi-sector climate-related risks (Byers et al., 2018). A low (relative to high) vulnerability future also reduces the global mean number of temperature-attributable deaths in 2080-2095 due to enteric infections by an order of magnitude (from >80,000 to <7000; (Chua et al., 2021)). Low future socioeconomic vulnerability to flooding reduces global fatalities and economic losses by 69-96% (Jongman et al., 2015). Low vulnerability as measured by indicators including per capita GDP, education, governance, water demand, and storage potential reduces water insecurity by a factor of three (Koutroulis et al., 2019). A scenario with reduced barriers to trade reduces the number of people at risk of hunger due to climate change by 64% (Janssens et al., 2020). Structural transformation of the economy (shift of the workforce from highly exposed sectors such as agriculture and fishing to less exposed sectors such as services) lowers GDP impact projections by 25-30% in today's developing countries by 2100 (Acevedo et al., 2017).

The IPCC SRCCL supports the importance of societal conditions to climate-related risk (Hurlbert et al., 2019), concluding that risks of water scarcity in drylands (i.e., desertification), land degradation and food insecurity are close to High[3] beginning at 1.5ºC under high vulnerability conditions (SSP3), but remain close to Moderate up to slightly above 2ºC for low vulnerability conditions (SSP1). Specifically, risk of water scarcity in drylands (i.e., desertification) at 1.5ºC warming is reduced in low vulnerability (relative to high vulnerability) conditions from High to Medium. Similarly, under a 2ºC warming, risk is reduced from High to Moderate for food security and High to Moderate-to-High for land degradation.

While climate change will increase risk to society and ecosystems, future exposure and vulnerability conditions will also greatly impact outcomes of concern directly. Global economic damages to coastal assets from tropical cyclones are projected to increase by more than 300% due to coastal development alone, a much larger effect than projected climate change impacts through 2100 even in RCP8.5 (Gettelman et al., 2018). Similarly, global crop prices are more than three times more sensitive to alternative assumptions about changes in production technologies and demand than to alternative climate outcomes (Ren et al., 2016). Future water scarcity is driven mainly by both demographic change and socioeconomic changes affecting water demand and management. A measure of between-country inequality (Gini coefficient) would decline by more than 50% this century in low vulnerability conditions, but would double in a high vulnerability future (Crespo Cuaresma, 2017), outweighing the effect of climate (Taconet et al., 2020).

[3] The IPCC distinguishes between four qualitative risk levels, from Undetectable (risks that are undetected), to Moderate (detectable with at least medium confidence), High (significant and widespread) and Very high (very high probability of severe risks and significant irreversibility or persistence of impacts).

Similarly, the global prevalence of armed conflict will roughly double this century in a high vulnerability future, whereas it will drop by half in a low vulnerability future (Hegre et al., 2016). In Sub-Saharan Africa, assumptions about governance and political rights are estimated to be far more important to the future risk of violent conflict than climate change (Witmer et al., 2017).

16.5.3.3 Climate Adaptation Scenarios

One approach to understand adaptation benefits for risk reduction is to contrast projected impacts for the same climate and development conditions but different levels of adaptation. For example, global-scale coastal protection studies considering both RCPs and SSPs suggest that under a given RCP, the total flooded area may be reduced by 40% by using 1-m height dykes, compared to a no-adaptation baseline (Tamura et al., 2019). The global cost of SLR over the 21st century can be lowered by factor of two to four if local cost-benefit decisions consider migration an adaptation option, in addition to hard protection (Lincke and Hinkel, 2021). Under a low warming scenario, it is estimated that adaptation (i.e. changes in crop variety and planting dates) could reduce the total number of people at risk of hunger globally by about 4%, and by about 10% in a high warming scenario Hasegawa et al. (2014). Impacts on heat-related mortality would be cut from 10 to 7 deaths per 10,000 people per year in 2100 by adaptation actions beyond those assumed to be driven by income growth (Carleton et al., 2020). In a regional example, proactive adaptation efforts on infrastructure (especially roads, runways, buildings, and airports) in Alaska, USA, could reduce damage-related expenditure by 45% under medium or high warming (Melvin et al., 2017).

Another approach infers the potential future effectiveness of adaptation based on current sensitivity of impacts to interventions. For example, the future disease burden of malaria is likely to be highly dependent on the future development of health services, deployment of malaria programs and adaptation. Investments in water and sanitation infrastructure are also recognized to have the potential to reduce severe risks of waterborne disease, although these improvements likely need to provide transformative change (Cumming et al., 2019). The potential for severe risks may also be substantially reduced through the development of vaccines for specific enteric diseases (Riddle et al., 2018), although most current vaccines target viral pathogens, incidence for which tends to be inversely correlated with ambient temperature (Carlton et al., 2016). In addition, international migration as well as forced movement of people across borders will be influenced by developments in legal and political conditions (McLeman, 2019; Wrathall et al., 2019), but the fact that these developments are unknown strongly limits any forecasts on the magnitude of adaptation benefits (Section 16.5.2.3.9).

Last, there is growing concern that even ambitious adaptation efforts will not eliminate residual risks from climate change (Section 16.4.2). A synthesis of risk assessments in the recent IPCC Special Reports (Magnan et al., 2021) concludes that high societal adaptation is expected to reduce the aggregated score –the proxy used in the study– of global risk from anthropogenic climate change by about 40% under all RCPs by the end of the century, compared to risk levels projected without adaptation. It however also shows that even for the lowest warming scenario a residual risk one-third greater than today's risk level would still remain (with a doubling of today's aggregated score under the high emission scenario).

16.5.3.4 Illustration: Risk and Adaptation Pathways in Densely Populated and Agricultural Deltas

Large deltas, which are very dynamic risk hotspots of global importance and interest (Wigginton, 2015; Hill et al., 2020; Nicholls et al., 2020), serve well to illustrate how risk pathways develop over time, determined by climatic as well as non-climatic risk drivers as well as by adaptation. Deltas occupy less than 0.5% of the global land area but host over 5% of the global population (Dunn et al., 2019) and contribute major fractions of food production in many world regions (Kuenzer et al., 2020). Future risk in these areas is heavily driven by climate change but also greatly depends on past, current and future socio-economic changes which influence future trends in exposure, vulnerability and adaptive capacity of natural and human systems (*high confidence*) (Oppenheimer et al., 2019). From a risk perspective, trends over the past decades have been unfavourable for many deltas, as most of them have experienced a simultaneous intensification of hazards, rise in exposure and stagnation or only limited reduction in vulnerability, particularly in low income countries (*high confidence*) (Day et al., 2016; Tessler et al., 2016; Loucks, 2019; Oppenheimer et al., 2019; Hill et al., 2020).

16.5.3.4.1 Hazard trends in deltas

Deltas face multiple interacting hazards, many of which over the past decades have been intensified by local and regional anthropogenic developments (e.g., the construction of dams, groundwater extraction, or agricultural irrigation practices) and most of which are expected to be exacerbated by climate change (*high confidence*) (Giosan et al., 2014; Tessler et al., 2015; Tessler et al., 2016; Arto et al., 2019; Oppenheimer et al., 2019). The most important hazards include sea level rise (SLR), inundation, salinity intrusion, cyclones, storms and erosion, many of which occur in combination. The potential for flooding and inundation depends on the relative sea level rise (RSLR) which results from global and regional SLR as well as local subsidence within the deltas. Subsidence caused by natural and human drivers (mainly compaction and groundwater extraction) is currently the most important cause for RSLR in many deltas and can exceed the rate of climate-induced SLR by an order of magnitude (Oppenheimer et al., 2019). But in higher warming scenarios the relative importance of climate-driven SLR is expected to increase over time (Oppenheimer et al., 2019). In a global study covering 47 major deltas and assessing future trends of sediment delivery across four RCPs, three SSPs (1,2,3) and a projection of future dam construction, Dunn et al. (2019) find most deltas (33 out of the 47) will experience a mean decline of 38% in sediment flux by the end of the century when considering the average of the scenarios. Nienhuis et al. (2020) find in a global assessment that some deltas have gained land through increased sediment load (e.g., through deforestation), but recent land gains are unlikely to be sustained if SLR continues to accelerate. According to the latest assessments, it is *virtually certain* that global mean sea level will continue to rise over the 21st century, with sea level rise by 2100 *likely* to reach 0.28-0.55 m in a an SSP1-1.9 and 0.63-1.01 m in an SSP5-8.5 scenario relative to 1995-2014 (IPCC, 2021a). The combined effects of local subsidence and GMSL rise result in a significant increase in the potential for inundation of low-lying deltas across all RCPs, with some variation according to regional sea level change rates, without significant further adaptation measures (*very high confidence*).

In terms of salt-water intrusion and salinization, global comparative studies are still lacking but the general processes are well understood (e.g., White and Kaplan, 2017)) and research on individual deltas is on the rise. In the Mekong Delta of Vietnam, one of the main rice producing deltas globally, salinity intrusion has been observed to extend around 15 km inland during the rainy season and around 50 km during the dry season (Gugliotta et al., 2017), resulting in rice yield losses of up to 4 tons per hectare per year (Khat et al., 2018). SLR, along with the expansion of dams and dry season irrigation upstream, is expected to further increase the salinity intrusion into the delta. This creates additional risk for food production as rice and other crops might be pushed beyond their adaptation limits in terms of salt tolerance, potentially affecting many of the 282,000 agriculture-based livelihoods in the Mekong Delta and increasing the pressure for cost-intensive adaptation (Smajgl et al., 2015). Genua-Olmedo et al. (2016) find for the Ebro that in high scenario (RCP8.5, and SLR of almost 1m by 2100), SLR-induced salinity intrusion will lead to almost a doubling of salinity levels and a decrease of mean rice productivity by over 20% in a high SLR scenario with almost 1 meter of SLR by the end of the century.

16.5.3.4.2 Exposure trends in deltas

Next to the trends in hazards, future exposure of and in deltas is shaped particularly by the increase of population and infrastructure and the intensification of land use. Over the recent years, the population has been rising in major deltas, roughly along with overall national population trends (Szabo et al., 2016). In 2017, 339 million people lived in deltas with a high exposure to flooding, cyclones and other coastal hazards (Edmonds et al., 2020). Over 40% of the global population exposed to flooding from tropical cyclones lived in deltas, more than 90% of which in developing countries and emerging economies (ibid.). Looking into the future, population in low elevation coastal zones is expected to increase by 2050 across all SSPs with diverging developments in the second half of the century, and at the end of the century will reach well over 1 billion people in SSP3 (Jones and O'Neill, 2016; Merkens et al., 2016). A major part of this population is expected to reside in deltas with large cities or mega-urban agglomerations such as the Pearl River Delta, China. One of the first studies using the SSP-RCP framework on the delta scale suggests a strong increase in intensive agricultural land by the middle of the century in three SSPs (2, 3, 5) in the Volta Delta, Ghana, whilst the Mahanadi, India, and the Ganges-Brahmaputra-Meghna do not show a significant further increase (Kebede et al., 2018). Hence, the amount of population and infrastructure as well as agricultural land is expected to rise further under certain SSPs, further increasing the exposure to future climate hazards.

16.5.3.4.3 Vulnerability trends in deltas

Deltas are characterized by multifaceted vulnerabilities of their environment and human populations. Over 200 indicators are being used in the literature to characterize and analyse vulnerability in deltas, spanning social, ecological and economic aspects (Sebesvari et al., 2016). However, only a few studies model or dynamically assess trends in vulnerability, particularly for the future, at global scale, or take a comparative approach. But overall, a global trend assessment suggests that social vulnerability to climate hazards has been improving over the past years in all world regions hosting major deltas apart from Oceania, yet with emerging economies and developing countries in Africa showing less improvement than the Americas, Asia and Europe (Feldmeyer et al., 2017). An analysis of 48 major deltas finds that vulnerability therefore is a less dominant source of future increase in risk than exposure (Haasnoot et al., 2012). However, case study research from individual deltas suggests that delta populations, particularly those with agriculture-based livelihoods, have seen more limited vulnerability reduction due in particular to the impacts of environmental hazards, stress and disasters (*high confidence*). In the Mekong Delta, for instance, the strong economic growth since the beginning of Vietnam's reform process has not led to a reduction of vulnerability across the board for all socio-economic groups (Garschagen, 2015). Rather, issues such as widespread landlessness or continued poverty have maintained and, in some respect, increased social vulnerability.

16.5.4 RKR Interactions

Multiple feedbacks between individual risks exist that have the potential to create cascades (WEF, 2018; Weyer, 2019 p. 680; Simpson et al., 2021) and then to amplify systemic risks and impacts far beyond the level of individual RKRs (*medium confidence*). Scientific research however remains limited on whether such interactions would result in increasing or decreasing the initial impact(s), and hence risk severity across systems. Given the scope of this chapter on increasing risk severity, here we focus on assessing RKR interactions that lead to increasing risk. Drawing directly on RKR assessments (16.5.2.3.2 to 16.5.2.3.9), this section cites those assessments rather than primary literature. The arrows in Figure 16.11 are derived from a qualitative analysis by three authors of Chapter 16 of the material provided by chapters on KRs and RKR assessments (Section 16.5.2.3), and do not result from any systematic and quantitative approach as done in some recent studies (e.g., WEF, 2018; Yokohata et al., 2019).

Interactions at the RKR level (Figure 16.11, Panel A) – Climate change will combine with pre-existing socioeconomic and ecological conditions (grey blocks on the left hand-side of Panel A in Figure 16.10) to generate direct and second-order effects (black plain arrows) both on the structure and/or functioning of ecosystems (RKR-B) and on some natural processes such as the hydrologic cycle (RKR-G) for example. This then translates into implications not only for biodiversity, but also for natural resources that support livelihoods, which will in turn affect food security (especially food availability; RKR-F), water security (especially access to adequate quantities of acceptable quality water; RKR-G) and the living standards of already vulnerable groups and aggregate economic outputs at the global level (RKR-D). Climatic impact drivers (CID; IPCC, 2021a) will also directly affect infrastructure that are critical to ensure some basic conditions for economies to function (RKR-C), e.g., through transportation within and outside the country, energy production and international trade. Such disturbances to socioecological systems and economies pose climate-related risks to human health (RKR-E) as well as to peace and mobility (RKR-H). Indeed, while health is concerned with direct influence of climate change, e.g., through hotter air temperatures impacting morbidity and mortality or the spatial distribution of disease vectors such as mosquitos, it is also at risk of being stressed by direct and secondary climate impacts on living standards, food security and water security (RKR-D, RKR-F, RKR-G, respectively). Increased poverty, increased hunger and limited access to drinkable water are well-known drivers of poor health conditions. The role of impact cascades is even more prominent in the case of peace and mobility (RKR-H), even though the scientific literature does not conclude on any clear and direct climate influence on armed conflict and human migration. Rather, climate-induced degradation of natural resources that are vital for subsistence agriculture and fisheries, transformational and long-term consequences on livelihoods (e.g., new risks, increasing precarious living conditions, gendered inequity, etc.), as well as erosion of social capital due to exacerbated tension within and between communities, are considered among the main drivers of armed conflicts and forced displacement, therefore highlighting links with water security (RKR-G) and living standards (RKR-D), for example.

RKR assessments also suggest that some feedback effects are at work (arrows moving from the right to the left in Panel A) that contribute to the potentially long-lasting effects of climate risks. RKR-H assessment for example states that there is robust evidence that major armed conflicts routinely trigger mass displacement, threaten health and food security, and undermine economic activity and livelihoods, often with lasting negative consequences for living standards and socioeconomic development, therefore linking back to risks to living standards (RKR-D), human health (RKR-E) and food security (RKR-F).

Interactions at the KR level (Figure 16.11, Panel B) – Panel B illustrates risk connections at the Key Risk level (Section 16.5.2.1) and as described in RKR assessments (Section 16.5.2.3). To only take one example here, risk to livelihoods and economies is influenced by the loss of ecosystem services (RKR-B) and the loss or breakdown of critical infrastructures (RKR-C), as well as it influences risks to human lives and health (RKR-E), food and water security (RKR-F, RKR-G), poverty (RKR-D) and peace and mobility (RKR-H). As a third-order sequence, RKR assessments show that increased risk to peace and mobility affects lives and health as well as food security, which in turn threaten livelihoods and economies.

The above suggests that some vicious cycle effects play a central role in explaining impact processes. Cascading effects can indeed lead to cumulative risks that partly feed various drivers of the emergence of severe risks (Section 16.5.1), such as the acceleration of ecosystem degradation, or the reaching of thresholds and irreversible states in human systems at a decade-to-century time horizon (e.g., when permanent inundation questions the habitability of some low-lying coasts; RKR-A). The extent and duration of risk cascades are however expected to substantially vary depending on warming levels and development pathways, both separately (Section 16.5.3) and when combined (Section 16.6.1 and 16.6.2) (Fig. 16.10).

In addition, RKR assessments converge to suggest that regions that are already experiencing climate change impacts will experience severe impact cascades first (e.g., RKR-F), because they are in areas (i) that face development constraints and associated challenges such as poverty, inequity and social discrimination for example, and (ii) where climate change projections are the most intense for the next decades. That is especially a concern for Africa (RKR-F, RKR-G), Asia and Latin America (Chapters 9, 10 and 12). RKR-E concludes for example that the likelihood of severe risks to human health is especially high for highly susceptible populations, particularly the poor and otherwise marginalized. RKR assessments however emphasize that middle- and high-income regions are also to be considered at serious risk because climate change is accelerating at the global level (IPCC, 2021a), and because critical dimensions are exposed to severe risks such as major transportation (e.g., international airports) and energy (e.g., nuclear power plants) infrastructure for instance (RKR-C), and because of the interconnectedness of economies.

Finally, all RKR assessments suggest that enhanced adaptation has the potential to contain such feedback effects and cascading processes more broadly, and reduce the duration of the impacts on the system as a whole. There are however knowledge gaps on such a potential, as well as on the nature of impact cascades (positive, negative, neutral, mixed).

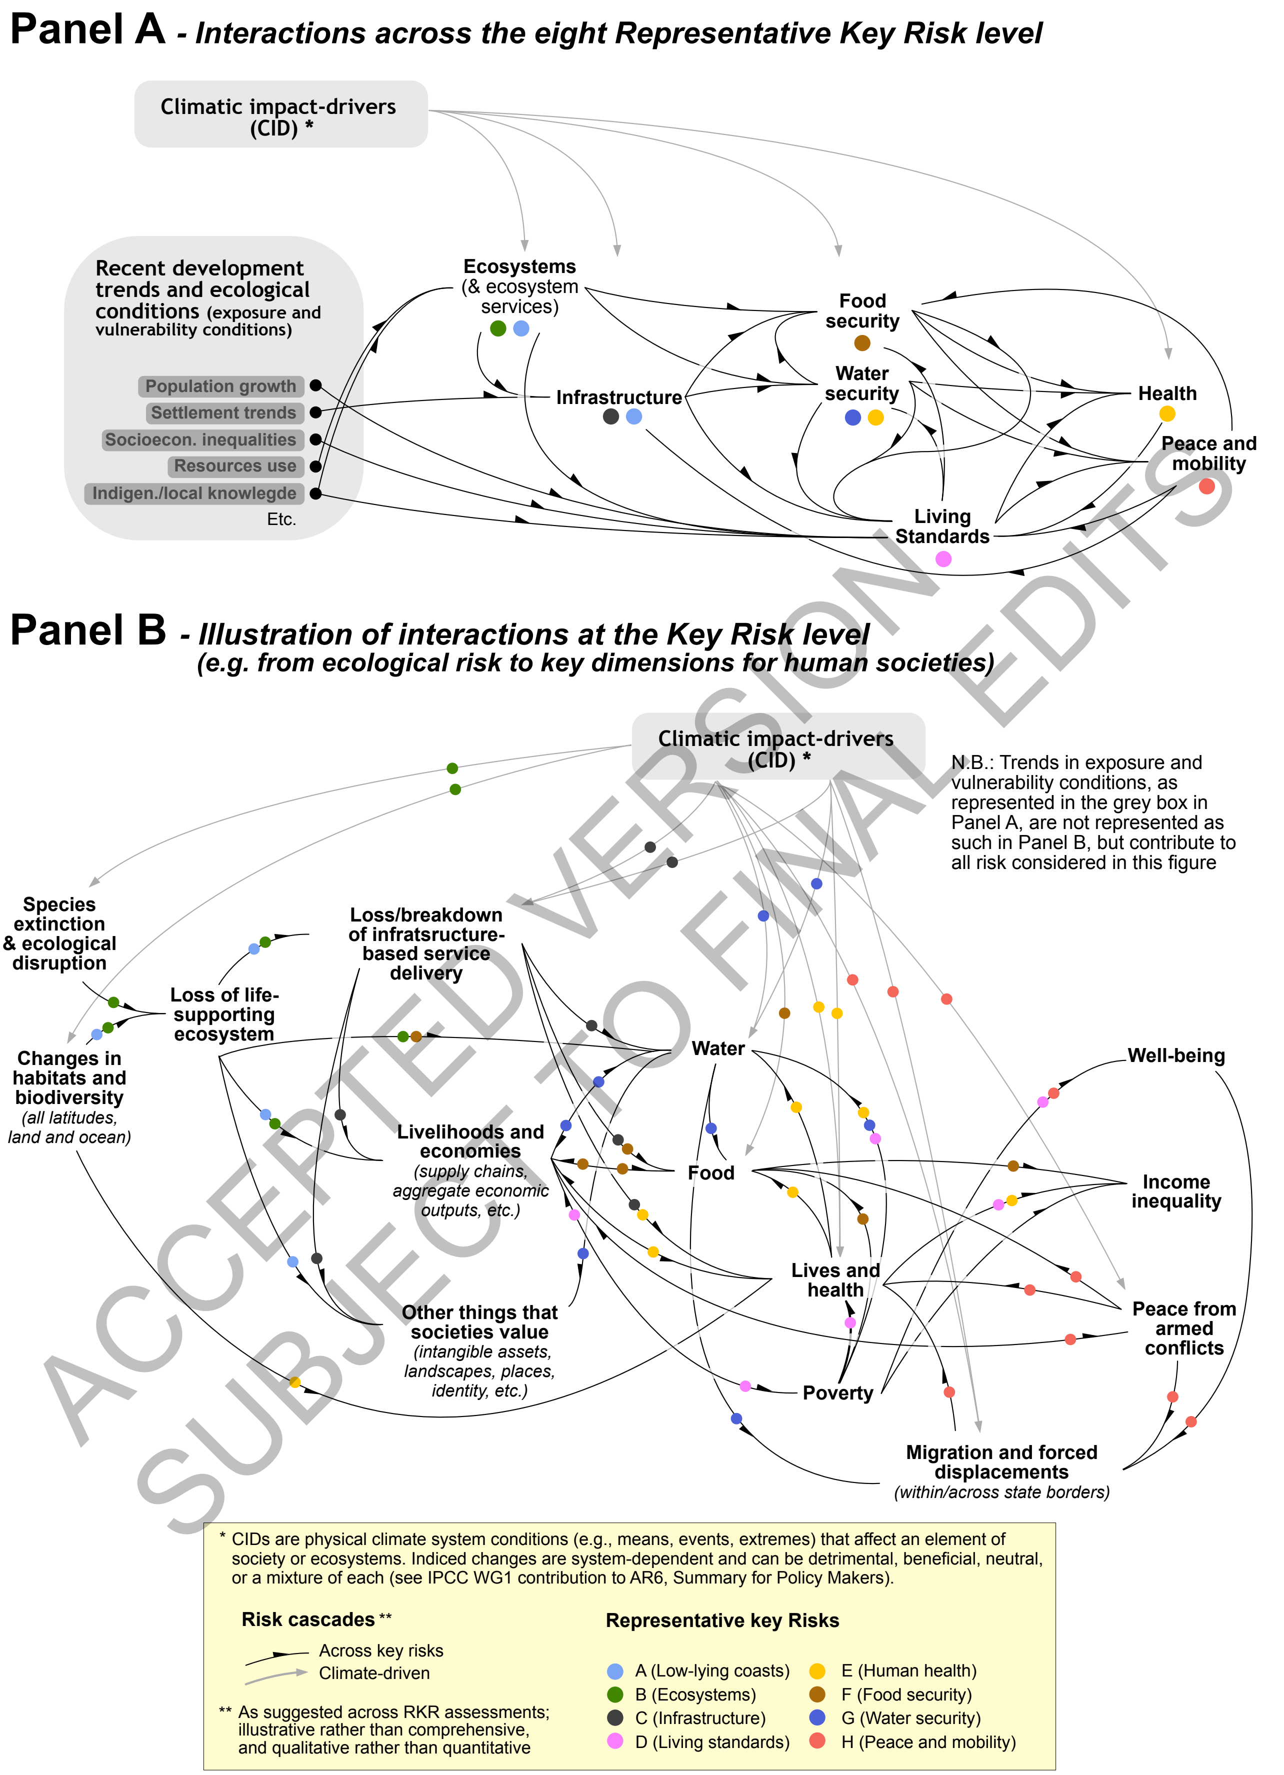

Figure 16.11: Illustration of some connections across key risks. Panel A describes all the cross-RKR risk cascades that are described in RKR assessments (Sections 16.5.2.3.2 to 16.5.2.3.9). Panel B builds on Section 16.5.2.2 and Table SM16.4 to provide an illustration of such interactions at the Key Risk level, e.g. from ecological risk to key dimensions

for human societies. The arrows are representative of interactions as qualitatively identified in this chapter; they do not result from any quantitative modelling exercise.

[START CROSS-WORKING GROUP BOX SRM HERE]

Cross-Working Group Box SRM: Solar Radiation Modification

Authors: Christopher H. Trisos (South Africa), Oliver Geden (Germany), Sonia I. Seneviratne (Switzerland), Masahiro Sugiyama (Japan), Maarten van Aalst (The Netherlands), Govindasamy Bala (India), Katharine J. Mach (USA), Veronika Ginzburg (Russia), Heleen de Coninck (The Netherlands), Anthony Patt (Switzerland)

Proposed Solar Radiation Modification Schemes

This cross-working group box assesses Solar Radiation Modification (SRM) proposals, their potential contribution to reducing or increasing climate risk, as well as other risks they may pose (categorised as risks from responses to climate change in the IPCC AR6 risk definition in 1.2.1.1), and related perception, ethics and governance questions.

SRM refers to proposals to increase the reflection of shortwave radiation (sunlight) back to space to counteract anthropogenic warming and some of its harmful impacts (de Coninck et al., 2018) (Cross-chapter Box 10; WG1 Chapter 4 and Chapter 5). A number of SRM options have been proposed, including: Stratospheric Aerosol Interventions (SAI), Marine Cloud Brightening (MCB), Ground-Based Albedo Modifications (GBAM), and Ocean Albedo Change (OAC). Although not strictly a form of SRM, Cirrus Cloud Thinning (CCT) has been proposed to cool the planet by increasing the escape of longwave thermal radiation to space and is included here for consistency with previous assessments (de Coninck et al., 2018). SAI is the most-researched proposal. Modeling studies show SRM could reduce surface temperatures and potentially ameliorate some climate change risks (with more confidence for SAI than other options), but SRM could also introduce a range of new risks.

There is high agreement in the literature that for addressing climate change risks SRM cannot be the main policy response to climate change and is, at best, a supplement to achieving sustained net zero or net negative CO_2 emission levels globally (de Coninck et al., 2018; MacMartin et al., 2018; Buck et al., 2020; National Academies of Sciences and Medicine, 2021b). SRM contrasts with climate change mitigation activities, such as emission reductions and CDR, as it introduces a 'mask' to the climate change problem by altering the Earth's radiation budget, rather than attempting to address the root cause of the problem, which is the increase in GHGs in the atmosphere. In addition, the effects of proposed SRM options would only last as long as a deployment is maintained— e.g. requiring ca. yearly injection of aerosols in the case of SAI as the lifetime of aerosols in the stratosphere is 1-3 years (Niemeier et al., 2011) or continuous spraying of sea salt in the case of MCB as the lifetime of sea salt aerosols in the atmosphere is only about 10 days—which contrasts with the long lifetime of CO_2 and its climate effects, with global warming resulting from CO_2 emissions *likely* remaining at a similar level for a hundred years or more (MacDougall et al., 2020) and long-term climate effects of emitted CO_2 remaining for several hundreds to thousands of years (Solomon et al., 2009).

Which scenarios?

The choice of SRM deployment scenarios and reference scenarios is crucial in assessment of SRM risks and its effectiveness in attenuating climate change risks (Keith and MacMartin, 2015; Honegger et al., 2021). Most climate model simulations have used scenarios with highly stylized large SRM forcing to fully counteract large amounts of warming in order to enhance the signal-to-noise ratio of climate responses to SRM (Kravitz et al., 2015; Sugiyama et al., 2018a; Tilmes et al., 2018; Krishna-Pillai et al., 2019).

The effects of SRM fundamentally depend on a variety of choices about deployment (Sugiyama et al., 2018b), including: its position in the portfolio of human responses to climate change (e.g., the magnitude of SRM used against the background radiative forcing), governance of research and potential deployment strategies, and technical details (latitude, materials, and season, among others, see WG1 Chapter 4.6.3.3). The plausibility of many SRM scenarios is highly contested and not all scenarios are equally plausible because of socio-political considerations (Talberg et al., 2018b), as with, for example, CDR (Fuss et al., 2014; Fuss et al., 2018). Development of scenarios and their selection in assessments should reflect a diverse set of societal values with public and stakeholder inputs (Sugiyama et al., 2018a; Low and Honegger, 2020), as depending on the focus of a limited climate model simulation, SRM could look grossly risky or highly beneficial(Pereira and al., 2021).

In the context of reaching the long-term global temperature goal of the Paris Agreement, there are different hypothetical scenarios of SRM deployment: early, substantial mitigation with no SRM, more limited or delayed mitigation with moderate SRM, unchecked emissions with total reliance on SRM, and regionally heterogeneous SRM. Each scenario presents different levels and distributions of SRM benefits, side effects, and risks. The more intense the SRM deployment, the larger is the likelihood for the risks of side effects and environmental risks (e.g., Heutel et al., 2018). Regional disparities in climate hazards may result from both regionally-deployed SRM options such as GBAM, and more globally uniform SRM such as SAI (Jones et al., 2018a; Seneviratne et al., 2018b). There is an emerging literature on smaller forcings of SAI to reduce global average warming, for instance, to hold global warming to 1.5°C or 2°C alongside ambitious conventional mitigation (Jones et al., 2018a; MacMartin et al., 2018), or bring down temperature after an overshoot (Tilmes et al., 2020). If emissions reductions and CDR are deemed insufficient, SRM may be seen by some as the only option left to ensure the achievement of the Paris Agreement's temperature goal by 2100.

Table Cross-Working Group Box SRM.1: SRM options and their potential climate and non-climate impacts
Description, potential climate impacts, potential impacts on human and natural systems, and termination effects of a number of SRM options: Stratospheric Aerosol Interventions (SAI), Marine Cloud Brightening (MCB), Ocean Albedo Change (OAC), Ground-Based Albedo Modifications (GBAM), and Cirrus Cloud Thinning (CCT).

SRM option	SAI	MCB	OAC	GBAM	CCT
Description	Injection of reflective aerosol particles directly into the stratosphere or a gas which then converts to aerosols that reflect sunlight	Spraying sea salt or other particles in marine clouds, making them more reflective	Increase surface albedo of the ocean (e.g., by creating microbubbles or placing reflective foam on the surface)	Whitening roofs, changes in land use management (e.g., no-till farming, bioengineering to make crop leaves more reflective), desert albedo enhancement, covering glaciers with reflective sheeting	Seeding to promote nucleation of cirrus clouds, reducing optical thickness and cloud lifetime to allow more outgoing longwave radiation to escape to space
Potential climate impacts *other than reduced warming*	Change precipitation and runoff pattern; reduced temperature and precipitation extremes; precipitation reduction in some monsoon regions; decrease in direct and increase in diffuse sunlight at surface; changes to stratospheric	Change in land-sea contrast in temperature and precipitation, regional precipitation and runoff changes	Change in land-sea contrast in temperature and precipitation, regional , precipitation and runoff changes.	Changes in regional precipitation pattern, regional extremes and regional circulation	Changes in temperature and precipitation pattern, altered regional water cycle, increase in sunlight reaching the surface

	dynamics and chemistry; potential delay in ozone hole recovery; changes in surface ozone and UV radiation				
Potential impacts on human and natural systems	Changes in crop yields, changes in land and ocean ecosystem productivity, acid rain (if using sulphate), reduced risk of heat stress to corals	Changes in regional ocean productivity, changes in crop yields, reduced heat stress for corals, changes in ecosystem productivity on land, sea salt deposition over land	Unresearched	Altered photosynthesis, carbon uptake and side effects on biodiversity	Altered photosynthesis and carbon uptake
Termination effects	Sudden and sustained termination would result in rapid warming, and abrupt changes to water cycle. Magnitude of termination depends on the degree of warming offset.	Sudden and sustained termination would result in rapid warming, and abrupt changes to water cycle. Magnitude of termination depends on the degree of warming offset.	Sudden and sustained termination would result in rapid warming. Magnitude of termination depends on the degree of warming offset.	GBAM can be maintained over several years without major termination effects because of its regional scale of application. Magnitude of termination depends on the degree of warming offset.	Sudden and sustained termination would result in rapid warming. Magnitude of termination depends on the degree of warming offset.

SRM risks to human and natural systems and potential for risk reduction

Since AR5, hundreds of climate modelling studies have simulated effects of SRM on climate hazards (Kravitz et al., 2015; Tilmes et al., 2018). Modelling studies have shown SRM has the potential to offset some effects of increasing GHGs on global and regional climate, including the increase in frequency and intensity of extremes of temperature and precipitation, melting of Arctic sea ice and mountain glaciers, weakening of Atlantic meridional overturning circulation, changes in frequency and intensity of tropical cyclones, and decrease in soil moisture (WG1, Chapter 4). However, while SRM may be effective in alleviating anthropogenic climate warming either locally or globally, it would not maintain the climate in a present-day state nor return the climate to a pre-industrial state (climate averaged over 1850-1900, See WG1 Chapter 1, Box 1.2) in all regions and in all seasons even when used to fully offset the global mean warming *(high confidence);* WG1 Chapter 4}. This is because the climate forcing and response to SRM options are different from the forcing and response to GHG increase. Because of these differences in climate forcing and response patterns, the regional and seasonal climates of a world with a global mean warming of 1.5 or 2°C achieved via SRM would be different from a world with similar global mean warming but achieved through mitigation MacMartin et al. JGR2019}. At the regional scale and seasonal timescale there could be considerable residual climate change and/or overcompensating change (e.g., more cooling, wetting or drying than just what's needed to offset warming, drying or wetting due to anthropogenic greenhouse gas emissions), and there is low confidence in understanding of the climate response to SRM at the regional scale (WG1, Chapter 4).

SAI implemented to partially offset warming (e.g., offsetting half of global warming) may have potential to ameliorate hazards in multiple regions and reduce negative residual change, such as drying compared to present-day climate, that are associated with fully offsetting global mean warming (Irvine and Keith, 2020), but may also increase flood and drought risk in Europe compared to unmitigated warming (Jones et al., 2021). Recent modelling studies suggest it is conceptually possible to meet multiple climate objectives through optimally designed SRM strategies (WG1, Chapter 4). Nevertheless, large uncertainties still exist for climate processes associated with SRM options (e.g. aerosol-cloud-radiation interaction) (WG1, Chapter 4) (Kravitz and MacMartin, 2020).

Compared with climate hazards, many fewer studies have examined SRM risks—the potential adverse consequences to people and ecosystems from the combination of climate hazards, exposure and vulnerability—or the potential for SRM to reduce risk (Curry et al., 2014; Irvine et al., 2017). Risk analyses have often used inputs from climate models forced with stylized representations of SRM, such as dimming the sun. Fewer have used inputs from climate models that explicitly simulated injection of gases or aerosols into the atmosphere, which include more complex cloud-radiative feedbacks. Most studies have used scenarios where SAI is deployed to hold average global temperature constant despite high emissions.

There is *low confidence* and large uncertainty in projected impacts of SRM on crop yields due in part to a limited number of studies. Because SRM would result in only a slight reduction in CO_2 concentrations relative to the emission scenario without SRM (Chapter 5, WG1), the CO_2 fertilization effect on plant productivity is nearly the same in emissions scenarios with and without SRM. Nevertheless, changes in climate due to SRM are likely to have some impacts on crop yields. A single study indicates MCB may reduce crop failure rates compared to climate change from a doubling of CO_2 pre-industrial concentrations (Parkes et al., 2015). Models suggest SAI cooling would reduce crop productivity at higher latitudes compared to a scenario without SRM by reducing the growing season length, but benefit crop productivity in lower latitudes by reducing heat stress (Pongratz et al., 2012; Xia et al., 2014; Zhan et al., 2019). Crop productivity is also projected to be reduced where SAI reduces rainfall relative to the scenario without SRM, including a case where reduced Asian summer monsoon rainfall causes a reduction in groundnut yields (Xia et al., 2014; Yang et al., 2016). SAI will increase the fraction of diffuse sunlight, which is projected to increase photosynthesis in forested canopy, but will reduce the direct and total available sunlight, which tends to reduce photosynthesis. As total sunlight is reduced, there is a net reduction in crop photosynthesis with the result that any benefits to crops from avoided heat stress may be offset by reduced photosynthesis, as indicated by a single statistical modeling study (Proctor et al., 2018). SAI would reduce average surface ozone concentration (Xia et al., 2017) mainly as a result of aerosol-induced reduction in stratospheric ozone in polar regions, resulting in reduced downward transport of ozone to the troposphere (Pitari et al., 2014; Tilmes et al., 2018). The reduction in stratospheric ozone also allows more UV radiation to reach the surface. The reduction in surface ozone, together with an increase in surface UV radiation, would have important implications for crop yields but there is *low confidence* in our understanding of the net impact.

Few studies have assessed potential SRM impacts on human health and wellbeing. SAI using sulfate aerosols is projected to deplete the ozone layer, increasing mortality from skin cancer, and SAI could increase particulate matter due to offsetting warming, reduced precipitation and deposition of SAI aerosols, which would increase mortality, but SAI also reduces surface-level ozone exposure, which would reduce mortality from air pollution, with net changes in mortality uncertain and depending on aerosol type and deployment scenario (Effiong and Neitzel, 2016; Eastham et al., 2018; Dai et al., 2020). However, these effects may be small compared to changes in risk from infectious disease (e.g., mosquito-borne illnesses) or food security due to SRM influences on climate (Carlson et al., 2020). Using volcanic eruptions as a natural analog, a sudden implementation of SAI that forced the ENSO system may increase risk of severe cholera outbreaks in Bengal (Trisos et al., 2018; Pinke et al., 2019). Considering only mean annual temperature and precipitation, SAI that stabilizes global temperature at its present-day level is projected to reduce income inequality between countries compared to the highest warming pathway (RCP8.5) (Harding et al., 2020). Some integrated assessment model scenarios have included SAI (Arino et al., 2016; Emmerling and Tavoni, 2018; Heutel et al., 2018; Helwegen et al., 2019; Rickels et al., 2020) showing the indirect costs and benefits to welfare dominate, since the direct economic cost of SAI itself is expected to be relatively low (Moriyama et al., 2017; Smith and Wagner, 2018). There is a general lack of research on the wide scope of potential risk or risk reduction to human health, wellbeing and sustainable development from SRM and on their distribution across countries and vulnerable groups (Carlson et al., 2020; Honegger et al., 2021).

SRM may also introduce novel risks for international collaboration and peace. Conflicting temperature preferences between countries may lead to counter-geoengineering measures such as deliberate release of warming agents or destruction of deployment equipment (Parker et al., 2018). Game-theoretic models and laboratory experiments indicate a powerful actor or group with a higher preference for SRM may use SAI to cool the planet beyond what is socially optimal, imposing welfare losses on others although this cooling does not necessarily imply excluded countries would be worse off relative to a world of unmitigated warming (Ricke et al., 2013; Weitzman, 2015; Abatayo et al., 2020). In this context counter-geoengineering may promote international cooperation or lead to large welfare losses (Heyen et al., 2019; Abatayo et al., 2020).

Cooling caused by SRM would increase the global land and ocean CO_2 sinks (*medium confidence*), but this would not stop CO_2 from increasing in the atmosphere or affect the resulting ocean acidification under continued anthropogenic emissions (*high confidence*) (WG1 Chapter 5).

Few studies have assessed potential SRM impacts on ecosystems. SAI and MCB may reduce risk of coral reef bleaching compared to global warming with no SAI (Latham et al., 2013; Kwiatkowski et al., 2015), but risks to marine life from ocean acidification would remain, because SRM proposals do not reduce elevated levels of anthropogenic atmospheric CO_2 concentrations. MCB could cause changes in marine net primary productivity by reducing light availability in deployment regions, with important fishing regions off the west coast of South America showing both large increases and decreases in productivity (Partanen et al., 2016; Keller, 2018).

There is large uncertainty in terrestrial ecosystem responses to SRM. By decoupling increases in atmospheric greenhouse gas concentrations and temperature, SAI could generate substantial impacts on large-scale biogeochemical cycles, with feedbacks to regional and global climate variability and change (Zarnetske et al., 2021). Compared to a high CO_2 world without SRM, global-scale SRM simulations indicate reducing heat stress in low latitudes would increase plant productivity, but cooling would also slow down the process of nitrogen mineralization which could decrease plant productivity (Glienke et al., 2015; Duan et al., 2020). In high latitude and polar regions SRM may limit vegetation growth compared to a high CO_2 world without SRM, but net primary productivity may still be higher than pre-industrial climate (Glienke et al., 2015). Tropical forests cycle more carbon and water than other terrestrial biomes but large areas of the tropics may tip between savanna and tropical forest depending on rainfall and fire (Beer et al., 2010; Staver et al., 2011). Thus, SAI-induced reductions in precipitation in Amazonia and central Africa are expected to change the biogeography of tropical ecosystems in ways different both from present-day climate and global warming without SAI (Simpson et al., 2019; Zarnetske et al., 2021). This would have potentially large consequences for ecosystem services (Chapter 2 and Chapter 9). When designing and evaluating SAI scenarios, biome-specific responses need to be considered if SAI approaches are to benefit rather than harm ecosystems. Regional precipitation change and sea salt deposition over land from MCB may increase or decrease primary productivity in tropical rainforests (Muri et al., 2015). SRM that fully offsets warming could reduce the dispersal velocity required for species to track shifting temperature niches whereas partially offsetting warming with SAI would not reduce this risk unless rates of warming were also reduced (Trisos et al., 2018; Dagon and Schrag, 2019). SAI may reduce high fire risk weather in Australia, Europe and parts of the Americas, compared to global warming without SAI (Burton et al., 2018). Yet SAI using sulfur injection could shift the spatial distribution of acid-induced aluminum soil toxicity into relatively undisturbed ecosystems in Europe and North America (Visioni et al., 2020). For the same amount of global mean cooling, SAI, MCB, and CCT would have different effects on gross and net primary productivity because of different spatial patterns of temperature, available sunlight, and hydrological cycle changes (Duan et al., 2020). Large-scale modification of land surfaces for GBAM may have strong trade-offs with biodiversity and other ecosystem services, including food security (Seneviratne et al., 2018a). Although existing studies indicate SRM will have widespread impacts on ecosystems, risks and potential for risk reduction for marine and terrestrial ecosystems and biodiversity remain largely unknown.

A sudden and sustained termination of SRM in a high CO_2 emissions scenario would cause rapid climate change (*high confidence*; WG1 Chapter 4). More scenario analysis is needed on the potential likelihood of sudden termination (Kosugi, 2013; Irvine and Keith, 2020). A gradual phase-out of SRM combined with emission reduction and CDR could avoid these termination effects (*medium confidence*) (MacMartin et al., 2014; Keith and MacMartin, 2015; Tilmes et al., 2016). Several studies find that large and extremely rapid warming and abrupt changes to the water cycle would occur within a decade if a sudden termination of SAI occurred (McCusker et al., 2014; Crook et al., 2015b). The size of this 'termination shock' is proportional to the amount of radiative forcing being masked by SAI. A sudden termination of SAI could place many thousands of species at risk of extinction, because the resulting rapid warming would be too fast for species to track the changing climate (Trisos et al., 2018).

Public perceptions of SRM

Studies on the public perception of SRM have used multiple methods: questionnaire surveys, workshops, and focus group interviews (Burns et al., 2016; Cummings et al., 2017). Most studies have been limited to Western societies with some exceptions. Studies have repeatedly found that respondents are largely unaware of SRM (Merk et al., 2015). In the context of this general lack of familiarity, the publics prefer carbon dioxide removal (CDR) to SRM (Pidgeon et al., 2012), are very cautious about SRM deployment because of potential environmental side effects and governance concerns, and mostly reject deployment for the foreseeable future. Studies also suggest conditional and reluctant support for research, including proposed field experiments, with conditions of proper governance (Sugiyama et al., 2020). Recent studies show that the perception varies with the intensity of deliberation (Merk et al., 2019), and that the public distinguishes different funding sources (Nelson et al., 2021). Limited studies for developing countries show a tendency for respondents to be more open to SRM (Visschers et al., 2017; Sugiyama et al., 2020), perhaps because they experience climate change more directly (Carr and Yung, 2018). In some Anglophone countries, a small portion of the public believes in chemtrail conspiracy theories, which are easily found in social media (Tingley and Wagner, 2017; Allgaier, 2019). Since researchers rarely distinguish different SRM options in engagement studies, there remains uncertainty in public perception.

Ethics

There is broad literature on ethical considerations around SRM, mainly stemming from philosophy or political theory, and mainly focused on SAI (Flegal et al., 2019). There is concern that publicly debating, researching and potentially deploying SAI could involve a 'moral hazard', with potential to obstruct ongoing and future mitigation efforts (Morrow, 2014; Baatz, 2016; McLaren, 2016), while empirical evidence is limited and mostly at the individual, not societal, level (Burns et al., 2016; Merk et al., 2016; Merk et al., 2019). There is low agreement whether research and outdoors experimentation will create a 'slippery slope' toward eventual deployment, leading to a lock-in to long-term SRM, or can be effectively regulated at a later stage to avoid undesirable outcomes (Hulme, 2014; Parker, 2014; Callies, 2019; McKinnon, 2019). Regarding potential deployment of SRM, procedural, distributive and recognitional conceptions of justice are being explored, (Svoboda and Irvine, 2014; Svoboda, 2017; Preston and Carr, 2018; Hourdequin, 2019). With the SRM research community's increasing focus on distributional impacts of SAI, researchers have started more explicitly considering inequality in participation and inclusion of vulnerable countries and marginalized social groups (Flegal and Gupta, 2018; Whyte, 2018; Táíwò and Talati, 2021), including considering stopping research (Stephens and Surprise, 2020; National Academies of Sciences and Medicine, 2021a). There is recognition that SRM research has been conducted predominantly by a relatively small number of experts in the Global North, and that more can be done to enable participation from diverse peoples and geographies in setting research agendas and research governance priorities, and undertaking research, with initial efforts to this effect (e.g., Rahman et al., 2018), noting unequal power relations in participation could influence SRM research governance and potential implications for policy (Whyte, 2018; Táíwò and Talati, 2021) (Winickoff et al., 2015; Frumhoff and Stephens, 2018; Biermann and Möller, 2019; McLaren and Corry, 2021; National Academies of Sciences and Medicine, 2021b)

Governance of research and of deployment

Currently, there is no dedicated, formal international SRM governance for research, development, demonstration, or deployment (see WG3 Chapter 14). Some multilateral agreements—such as the UN Convention on Biological Diversity or the Vienna Convention on the Protection of the Ozone Layer—indirectly and partially cover SRM, but none is comprehensive and the lack of robust and formal SRM governance poses risks (Ricke et al., 2013; Talberg et al., 2018a; Reynolds, 2019a). While governance objectives range broadly, from prohibition to enabling research and potentially deployment (Sugiyama et al., 2018b; Gupta et al., 2020), there is agreement that SRM governance should cover all interacting stages of research through to any potential, eventual deployment with rules, institutions, and norms (Reynolds, 2019b). Accordingly, governance arrangements are co-evolving with respective SRM technologies across the interacting stages of research, development, demonstration, and—potentially—deployment (Rayner et al., 2013; Parker, 2014; Parson, 2014). Stakeholders are developing governance already in outdoors research; for example, for MCB and OAC experiments on the Great Barrier Reef (McDonald et al., 2019). Co-evolution of governance and SRM research provides a chance for responsibly developing SRM technologies with broader public participation and political legitimacy, guarding against potential risks and harms relevant across a full range of scenarios, and ensuring that SRM is considered only as a part of a broader portfolio of responses to climate change (Stilgoe, 2015; Nicholson et al., 2018). For SAI, large-scale outdoor experiments even with low radiative forcing could be transboundary and those with deployment-scale radiative forcing may not be distinguished from deployment, such that (MacMartin and Kravitz, 2019) argue for continued reliance on modeling until a decision on whether and how to deploy is made, with modeling helping governance development. For further discussion of SRM governance see Chapter 14, WG3.

16.6 Reasons for Concern Across Scales

This section builds on Section 16.5 which identifies and assesses key risks (KRs) and representative key risks (RKRs), including conditions contributing to their severity (i.e., Figure 16.10), in two ways. First, we consider those risks in the context of the global goal for sustainable development which can be impacted, as expressed in the United Nations 2030 Agenda for Sustainable Development and the Sustainable Development Goals (SDGs). This discussion supports further assessment in Chapter 18 on sustainable system transitions and climate resilient development pathways. Second, the potential global consequences are then elaborated in an updated assessment of five globally aggregated categories of risk, designated as Reasons for Concern (RFCs), that evaluates risk accrual by global warming level.

16.6.1 Key Risks and Sustainable Development

The United Nations 2030 Agenda for Sustainable Development, and the Sustainable Development Goals (SDGs) (UN, 2015), since 2015, have become an important vision for the United Nations member countries (Chimhowu, 2019) as well as for corporations to contribute towards sustainable growth (UNDP et al., 2016; Ike et al., 2019; van der Waal and Thijssens, 2020). Climate change risks, as embodied in the RKR and RFCs, can affect attainment of the SDGs and have consequences for lives and livelihoods (related to SDGs 1, 4, 8 and 9), health and well-being (related to SDGs 2, 3 and 6), ecosystems and species (related to SDGs 6, 14 and 15), economic (related to SDGs 1, 8 and 12), social and cultural assets (related to SDGs 5, 10, 11, 16 and 17), services including ecosystem services (related to SDGs 6, 7, 11, 12, 14 and 15), and infrastructure (related to SDGs 6, 7, 9, 11 and 12). This section assesses the level of linkages between key risks with sustainable development, in terms of the SDG targets and indicators. This informs on the key risks which are most relevant to consider with respect to the attainment of the SDGs.

16.6.1.1 Links Between Key Risks and SDGs

Within the AR6 cycle, the three IPCC Special Reports have all considered the relationships between climate change impacts and actions and the SDGs. SR15 discussed priorities for sustainable development in relation to climate adaptation efforts (Section 5.3.1, SR15); synergies and trade-offs of climate adaptation measures (Section 5.3.2, SR15); and the effect of adaptation pathways towards a 1.5ºC warmer world (Section 5.3.3 SR15). The SRCCL considered impacts of desertification on SDGs 1 (no poverty), 2 (zero hunger), 13 (climate), 15 (life on land), and 5 (gender) (IPCC, 2019a, Figure 3.9). Trade-offs and synergies between SDGs 2 (zero hunger) and 13 (climate action) at the global level were recognised (IPCC, 2019a, Section 5.6.6, Figure 5.16). Various integrated response options, interventions and investments were also evaluated within the SDG framework (IPCC, 2019a, Section 6.4.3). The SROCC (Chapter 5) concluded that climate change impacts on the ocean, overall, will negatively affect achieving the SDGs with 14 (life below water) being most relevant (Singh et al., 2019).

Many linkages between SDG 13 (climate action) and other SDGs have been identified *(very high confidence),* (Blanc, 2015; Kelman, 2015; Northrop et al., 2016; Hammill and Price-Kelly, 2017; ICSU, 2017; Mugambiwa and Tirivangasi, 2017; Dzebo et al., 2018; Major et al., 2018; Nilsson et al., 2018; Sanchez Rodriguez et al., 2018). In addition, interactions between different climate change actions and SDGs, and interactions among SDGs themselves, have also been assessed (Nilsson et al., 2016; IPCC, 2018; McCollum et al., 2018; Fuso-Nerini et al., 2019; IPCC, 2019b; Cernev and Fenner, 2020). The Cross-Chapter Box GENDER in Chapter 18 assessment indicates the importance of gender considerations in achieving success and benefits in adaptation efforts. Aligning climate change adaptation to the SDGs could bring potential co-benefits, increased efficiency in funding, and reduce the gap between adaptation planning and implementation (*very high confidence)* (IPCC, 2018; Sanchez Rodriguez et al., 2018; IPCC, 2019b; IPCC, 2019a).

Progress towards meeting the SDGs has been recognized to be able to reduce global disparities and support more climate resilient development pathways (IPCC WGII AR5, Chapter 13, p. 818; discussed further in Chapter 18). Nevertheless, we are still lagging in achieving the 2030 Goals (OECD, 2019; Sachs et al., 2021), and this affects societal vulnerability, readiness and risk response capacities (IPCC, 2019a, Chapters 6, 7, Chapters 6 and 8, this report). We assess the risk literature for linkages between key risks (grouped by RKRs) and the indicators of the SDGs (UN, 2015) using text analysis (details in Supplementary Material SM16.5) to identify the potential level of effect of different risks on the SDGs. Some 940 documents were analysed. The SDG status is associated with projected climate hazards, also called climatic impact-drivers (CID) (Ranasinghe et al., 2021) (panel a), and RKRs (panel c), summarising hazard and exposure with vulnerability aspects, as expressed by challenges in achieving the SDGs (panel d), on a regional level (Figure 16.12).

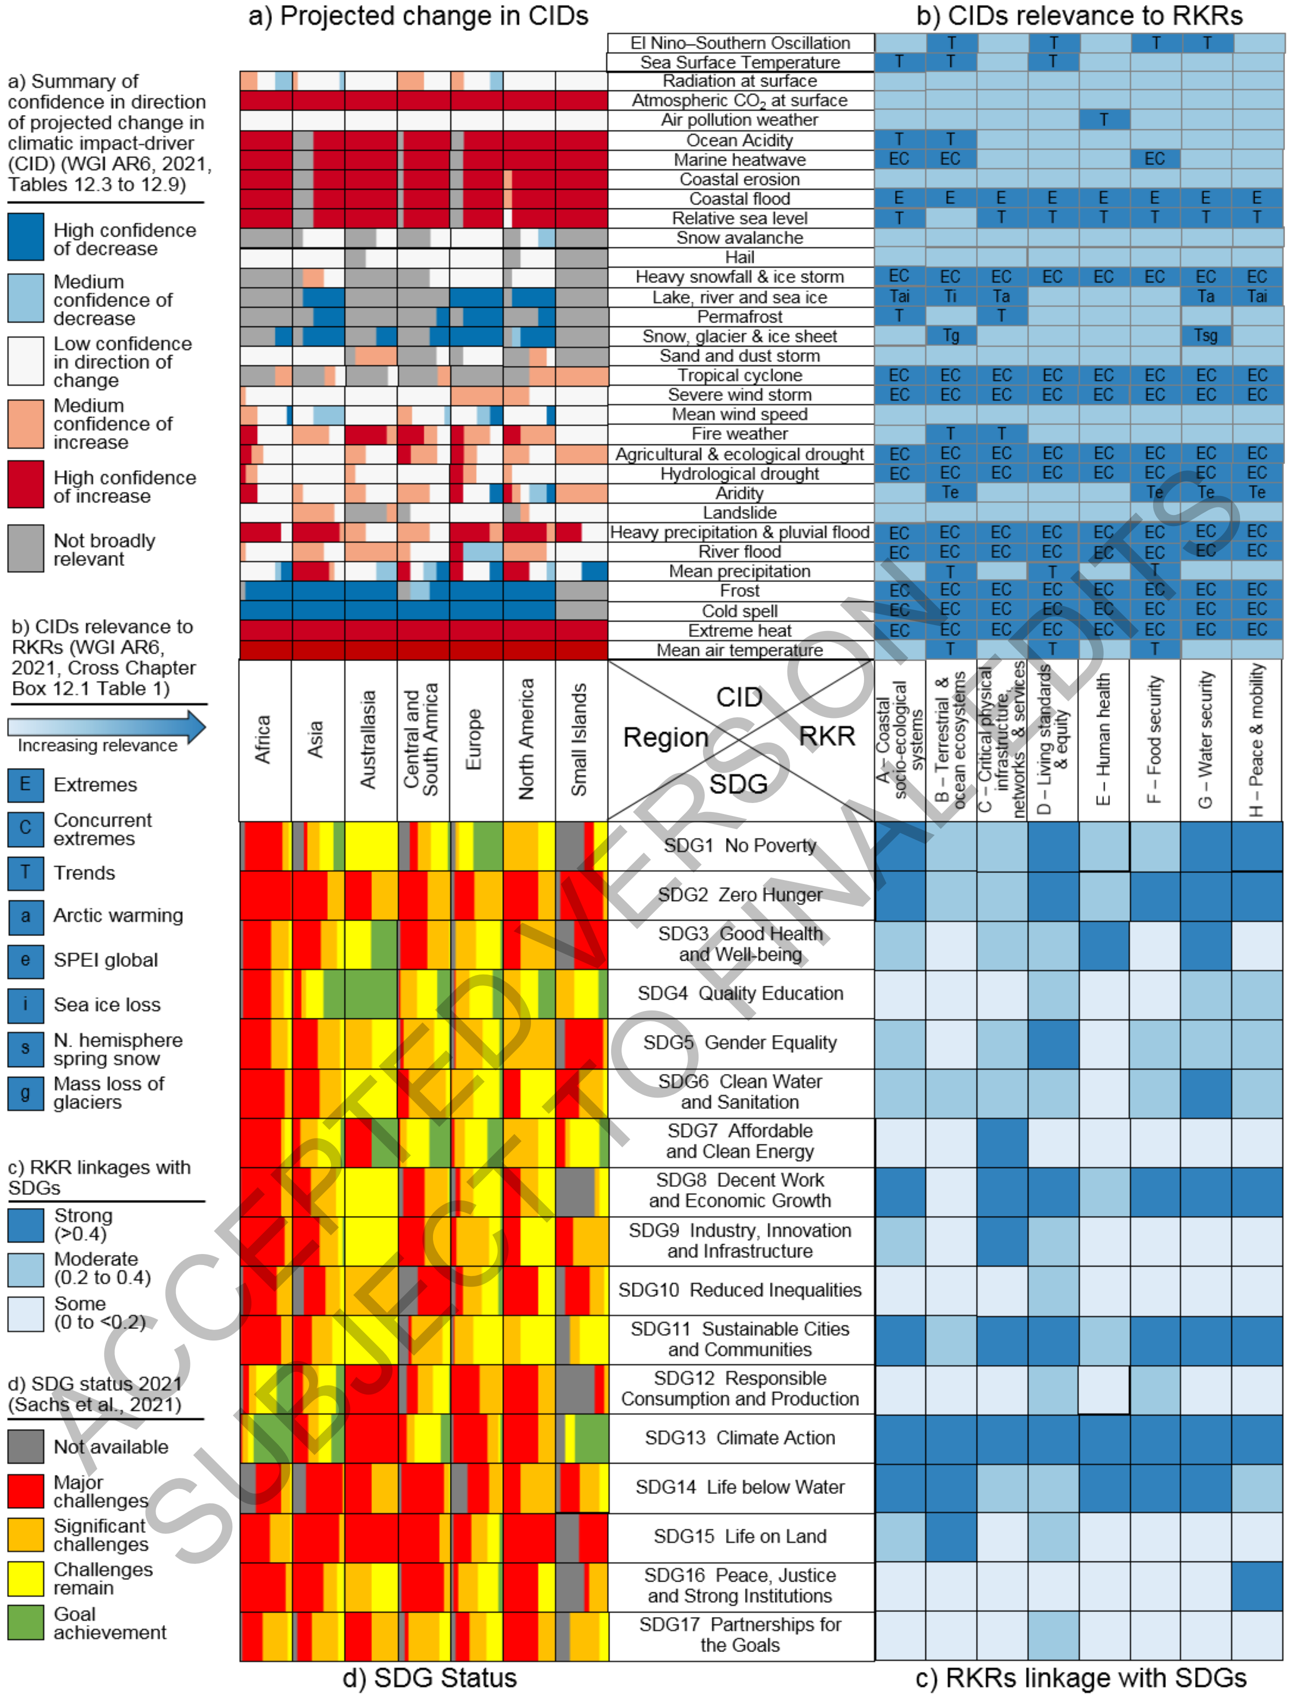

Figure 16.12: Linkages between the projected climatic impact-drivers (CIDs) by region, Sustainable Development Goals (SDGs) by region, and the Representative Key Risks (RKRs).

16.6.1.2 Results, Implications and Gaps

Linkages between the 17 SDGs and the eight RKRs (Figure 16.15 bottom left panel) are mapped to the regional SDG status (Figure 16.15 bottom right panel) and related to the climate hazards (CIDs) (Figure 16.15 top left panel). Interconnections between climate hazards (CIDs) and RKRs are complicated by the possibility of concurrent weather events, extremes and longer term trends. Risks are compounded by existing vulnerabilities (Iwama et al., 2016; Thomas et al., 2019b; Birkmann et al., 2021) and cascading consequences (Pescaroli and Alexander, 2015; Pescaroli and Alexander, 2018; Yokohata et al., 2019) (see for example Sections 3.4.3.5, 5.12, 6.2.6, 7.2.2.2) as well as interactions. The level of challenges faced in attaining the SDGs is one metric for assessing vulnerability and lack of capacity to manage risks (Cernev and Fenner, 2020). Other metrics are also available (Parker et al., 2019; Garschagen et al., 2021b; Birkmann et al., 2022). From Figure 16.12, aside from SDG13 (climate action), the strongest connections and risk challenges are with zero hunger (SDG2), sustainable cities and communities (SDG11), life below water (SDG14), decent work and economic growth (SDG8), no poverty (SDG1), clean water and sanitation (SDG6) and good health and well-being (SDG3) (*high confidence*). Other SDGs have strong linkages with specific RKRs, for example, terrestrial and marine ecosystems with Life on land (SDG15); infrastructure (RKR-C) with Industry, innovation and infrastructure (SDG9) and Affordable and clean energy (SDG7); living standards (RKR-D) with Gender equality (SDG5); and peace and mobility (RKR-H) with Peace, justice and strong institutions (SDG 16) (*high confidence*).

On a global scale, priority areas for regions can be evaluated from the intersection of climate hazards, risks and the level of challenges in SDG attainment (Moyer and Hedden, 2020; Sachs et al., 2021). The greatest linkages and effects on the SDGs will be due to risks to water (RKR-G), living standards (RKR-D), coastal socio-ecological systems (RKR-A) and Peace and human mobility (RKR-H) (*high confidence*) (details in Supplementary Material SM16.5).

In particular, coastal socio-ecological systems (RKR-A), living standards (RKR-D), food security (RKR-F), water security (RKR-G) and peace and mobility (RKR-H), have strong linkages with SDG 2 (zero hunger), for which there are significant to major challenges for all regions (*high confidence*). Almost all the RKRs are strongly linked to SDGs 8 (decent work and economic growth), and 11 (sustainable cities and communities) (*high confidence*), where regions such as Africa, Asia, and Central and South America face significant to major challenges in attaining targets. All regions also face major to significant challenges affecting SDGs 14 (life below water) and 15 (life on land), which relate to terrestrial and ocean ecosystems (RKR-B) (*high confidence*).

The analysis of RKR linkages to SDGs is also useful in identifying gaps and susceptibilities, especially for developing future climate resilient development targets. This aspect is discussed further in Chapter 18. Gaps may arise as SDG targets and indicators are not specifically focused on systems affected by climate change risks or impacts. For example, in the SRCCL Section 7.1.2 Hurlbert et al. (2019), noted the absence of an explicit goal for conserving fresh-water ecosystems and ecosystem services in the SDGs. Such gaps (Tasaki and Kameyama, 2015; Guppy et al., 2019) are inevitable as the current SDG targets and indicators focus on overall sustainable development. As another example, projected increases in frequency and intensity of hot temperature extremes are likely to result in increased heat-related illness and mortality, yet heat extremes are not called out as an SDG indicator under SDGs 3 (good health and well-being) nor 13 (climate action). The gaps on climate-related metrics for impacts on health are just beginning to be evaluated (Lloyd and Hales, 2019, see also Section 7.1.6). The current SDG 13 (climate action) targets also do not specifically track the possibility of differential impacts on society from disasters and extreme weather events (RFC2). For example, the first indicator (13.1.1.1), 'Number of deaths, missing persons and directly affected persons attributed to disasters per 100,000 population', does not include any requirement for disaggregated data, unlike several other socio-economic and population SDG indicators, making it difficult to track the different effects that climate-related disasters are expected to have on men, women, and children across different segments of society, relevant for distributional impacts (RFC3) (see also Section 8.3, Cross-Chapter Box GENDER in Chapter 18). The risk consequences identified and discussed in each RKR (Section 16.5.2) provide useful entry points for identifying indicators and metrics for monitoring and evaluating specific impacts of key climate change risks. In addition, the sector and region chapters have considered various adaptation responses relevant to the SDGs (see for example, Sections 3.6, 4.7.5, 5.13.3, 8.2.1.6, 10.6.1, 13.11.4, 14.6.3) with relevant metrics for evaluation.

In summary, key risks, and the consequences arising from them, are directly linked to and will affect specific indicators of the SDGs *(high confidence).* They also will be indirectly linked to, and thus affect, the SDGs overall, due to the interactions between the key risks (Section 16.5) and between the SDGs themselves (*very high confidence*). These results support previous findings that climate change impacts pose a risk to achieving sustainability (Ansuategi et al., 2015; Chirambo, 2016; ICSU, 2017; Pradhan et al., 2017; Gomez-Echeverri, 2018; IPCC, 2018; IPCC, 2019b; IPCC, 2019a; Cernev and Fenner, 2020). Not all observed or expected consequences arising from the key risks are fully captured by the SDG indicators, and nor were they designed to be. Therefore, for monitoring and assessing the climate risk impacts, it is useful to consider specific, climate change impact indicators and metrics (Enenkel et al., 2020) to capture any realised impacts.

In the near term, the strength of connection between the RKRs and the SDGs, with respect to existing SDG challenges, indicate probable systemic vulnerabilities and issues in responding to climatic hazards (UN-IATFFD, 2019; Leal Filho et al., 2020; Weaver et al., 2020; Tiedemann et al., 2021) (*high confidence*). In the medium to long term (associated with global warming levels of between 2°C and 2.7°C under SSP2-45 scenario), if such vulnerabilities and challenges cannot be substantially reduced, the hazards and risks resulting from the projected climate hazards (CIDs) (Figure 16.12b, c) will further stress systems relevant for sustainable development, based on current experience of the COVID-19 pandemic (UN-IATFFD, 2021, see also Cross-Chapter Box COVID in Chapter 7; Section 8.2, Section 8.3) (*medium confidence, based on medium evidence, high agreement*).

The potential impacts of the various climate hazards, the occurrence of extreme events, and the projected trends of climate hazards, give rise to complex risks for ecological and human systems, which are compounded by the exposure, vulnerability and sustainability challenges faced in different regions of the world. The potential global consequences are elaborated in the next section which describes the framework and approach for the assessment of the five Reasons for Concern.

16.6.2 Framework and Approach for Assessment of RFCs and Relation to RKRs

The 'Reasons for Concern' (RFC) framework communicates scientific understanding about accrual of risk in relation to varying levels of warming for five broad categories: risk associated with (1) unique and threatened systems, (2) extreme weather events, (3) distribution of impacts, (4) global aggregate impacts, and (5) large-scale singular events (Smith et al., 2001; Mastrandrea and Schneider, 2004; Schneider and Mastrandrea, 2005). The RFC framework was first developed during the Third Assessment Report (Smith et al., 2001) along with a visual representation of these risks as 'burning embers' figures, and this assessment framework has been further developed and updated in subsequent IPCC reports including AR5 (IPCC, 2014; Oppenheimer et al., 2014) and the recent IPCC Special Reports (SR15 2018; SRCCL 2019; SROCC 2019).

Relationship between RKRs and RFCs

RFCs reflect risks aggregated globally that together inform the interpretation of dangerous anthropogenic interference with the climate system. The five RFC categories are maintained as previously defined for consistency with earlier assessments. Compared to the synthesis of risk across RKRs in Section 16.5, we note that the RKRs and RFCs are complementary methods that aggregate individual risks into different but interconnected categories (Figure 16.13).

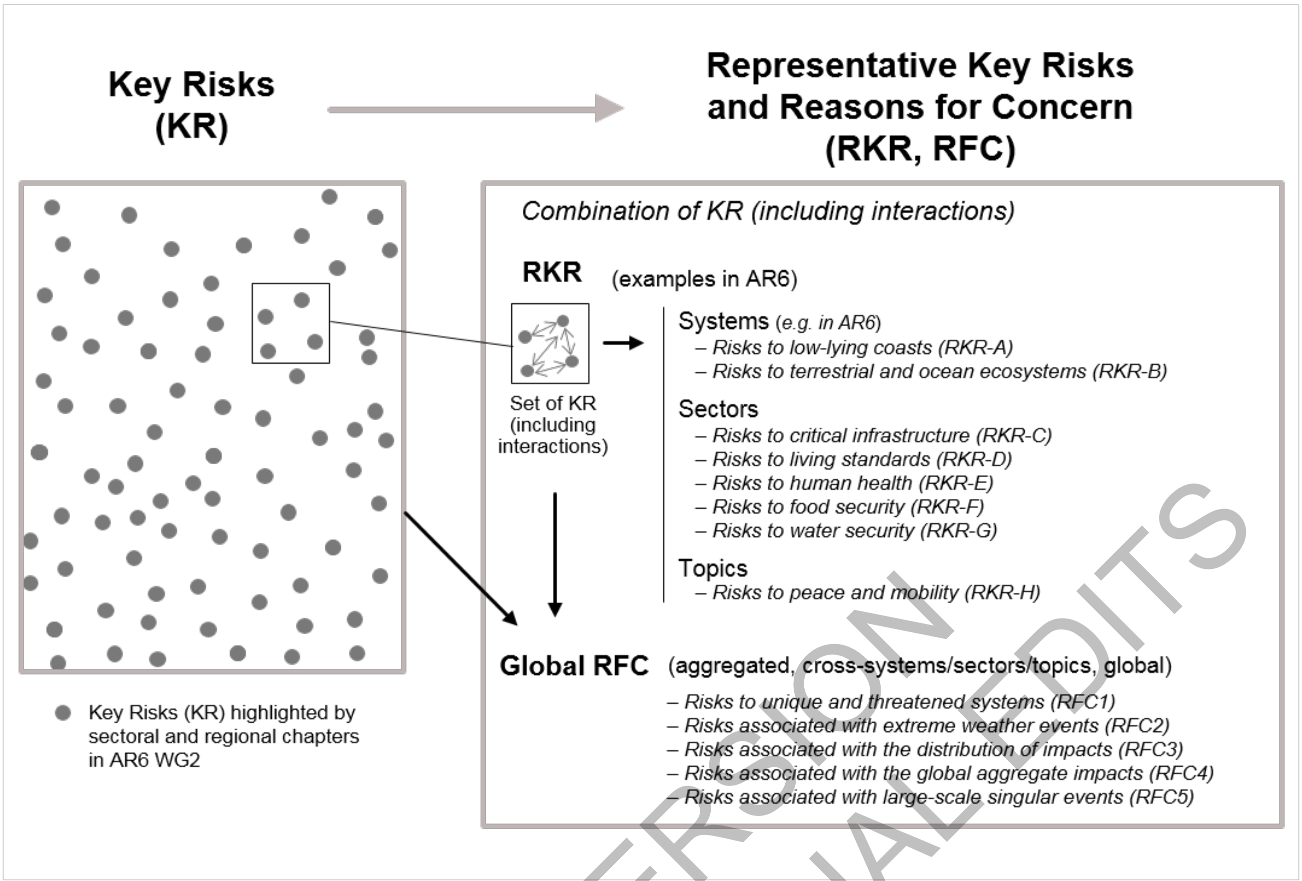

Figure 16.13 Interconnections between the Key Risks, Representative Key Risks and the Reasons for Concern

We draw important distinctions between RFC and RKR. First, RFCs assess risks that might be of global concern, while RKRs also include risks that may be of concern only locally or for specific population groups (Figure 16.13). RFCs focus on the full range of increasing risk, and locate transitions between four categories of risk: undetectable, moderate, high, and very high. RKRs focus on severe risks, and attempt to elaborate when/where severe impacts may occur. RKR assessments focus on the conditions under which some risks would become severe over the course of this century, while RFCs evaluate changes in risk levels against gradual increase in temperature levels. The RKR analysis used specific definitions of severity including quantified thresholds where possible, and this is distinct from the approach based on the combined elements of risk used in the RFC expert elicitation process. Severity as defined in the RKRs is associated with high or very high risk levels but does not align precisely with either of those categories, and a further difference arises from a more explicit emphasis on irreversibility and adaptation limits in the very high risk category in the RFCs. Thus RKR and RFC neither map directly to one another in terms of content, nor in terms of the response metric.

The treatment of vulnerability and adaptation is different in the RKR and RFC assessments. The RKR assessment considered specifically three alternative levels of vulnerability, whereas the RFC process did not explicitly differentiate risk by level of vulnerability. Therefore, the global warming levels at which the various RKR assessments identify risk of severe impacts are not directly comparable to risk transitions identified in the RFC assessments. In addition, RKRs consider implications of low vs. high adaptation in order to illustrate the potential role of ambitious adaptation efforts to limit risk severity; RFCs consider risks in a no/low adaptation scenario only, although there is some discussion of the potential role of adaptation in assessing the transition to very high risk. Last, both RKRs and RFCs focus on the 21st century scale, though recognizing risk will continue to increase after 2100, but treat this timing issue differently: RKRs assess severe risks over the course of this century and distinguish risks that are already severe, that will become severe by the mid-century, or that will become severe by the end of the century; while RFCs assess risk level irrespective of their timing, but according to different temperature levels.

Many of the elements of risk which contribute to RKRs also contribute to risk within one or more RFCs. In turn, elements of risk within some RFCs, such as extreme weather and changes in the earth system contribute to risk within one or more RKR. Hence RFCs may incorporate elements of many different RKRs, and vice versa. There are therefore common elements between some particular RKRs and RFCs: for example, risks to terrestrial and ocean ecosystems (RKR-B) contributes strongly to RFC1 (Unique and Threatened Systems) and RFC4 (Global Aggregate Impacts); while RFC2 (extreme weather events) has implications for all RKRs, including direct linkages with critical physical infrastructure, networks and services (RKR-C). Furthermore, risks emerging from the interaction of RKRs also contribute to the RFCs, but are only qualitatively described in Section 16.5.4. For example, the effects of risks to terrestrial and ocean ecosystems (RKR-A) affect living standards and equity (RKR-C), as does the associated decline in ecosystem services which then impacts livelihoods (RKR-D).

Elicitation Methodology

The method used to develop judgments on levels of risk builds on the approach described in WGII AR5 Chapter 19 (Oppenheimer et al., 2014) and outlined in more detail in (O'Neill et al., 2017), while integrating advances in the AR6 SRs including expert judgment (SRCCL, Zommers et al., 2020). We provide further details on the underlying judgements of risk level compared to previous assessments by indicating key risk criteria associated with each judgement: magnitude of adverse consequences, likelihood of adverse consequences, temporal profile of the risk, and ability to respond to the risk (Section 16.5.1). The definitions of risk levels used to make the expert judgements are presented in Table 16.7 (Section 16.5.1).

Table 16.7: Definition of Risk Levels for Reasons for Concern.

Level	Definition
Undetectable (White)	No associated impacts are detectable and attributable to climate change.
Moderate (Yellow)	Associated impacts are both detectable and attributable to climate change with at least medium confidence, also accounting for the other specific criteria for key risks.
High (Red)	Severe and widespread impacts that are judged to be high on one or more criteria for assessing key risks.
Very High (Purple)	Very high risk of severe impacts and the presence of significant irreversibility or the persistence of climate-related hazards, combined with limited ability to adapt due to the nature of the hazard or impacts/risks.

A brief summary of the framework that was used to carry out the risk assessment, synthesis and expert elicitation is presented here and details are provided in Supplementary Material SM16.5. Expert judgements about the qualitatively defined levels of risk (i.e., undetectable, moderate, high, and very high) reached at various levels of global average warming are informed by evidence of observed impacts illustrated in Section 16.2 and variations in individual key risks under different scenarios of climate change, socioeconomics and adaptation effort in Section 16.5. We follow the methodological advances from SRCCL Chapter 7 (Hurlbert et al., 2019), which used an expert elicitation protocol for developing the burning embers (Zommers et al., 2020). Specifically, we used expert participants from within the AR6 author team and a protocol based on the modified Delphi technique (Mukherjee et al., 2015) and the Sheffield Elicitation Framework (Oakley and O'Hagan, 2010; Gosling, 2018). This approach (Figure 16.14) includes a two-round elicitation process with a first round of independent anonymous judgements about the global warming level at which risk levels transition from one to the next, and a final round of group discussion and deliberation to develop consensus. The results are then reported and additional references made to findings from other relevant chapters in this report, and reviewed by authors who had not participated in the elicitation as part of independent appraisal.

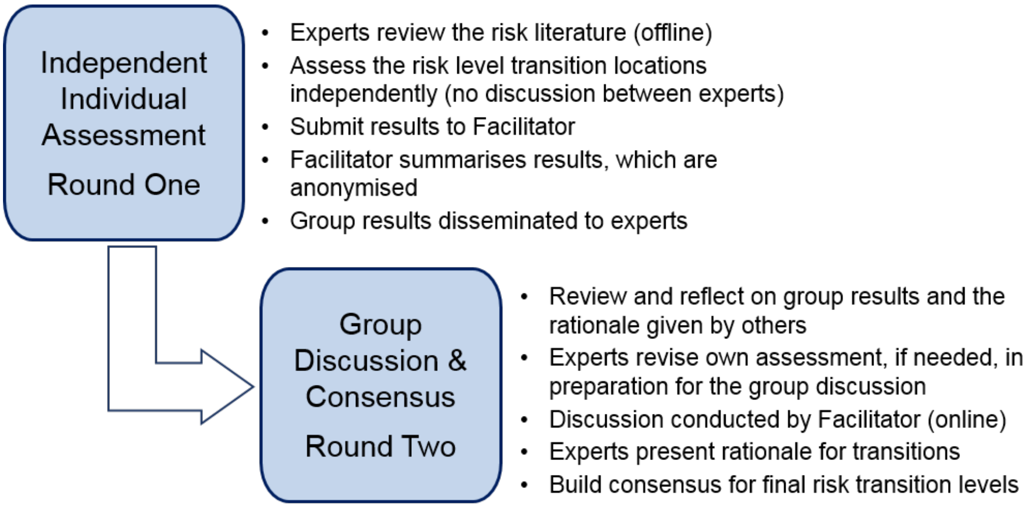

Figure 16.14 Expert elicitation approach for assessment of RFC risk level transitions. A more detailed description of the methodology used in this elicitation is provided in the Supplementary Material (SM16.5).

The resulting risk transition or 'ember' diagram illustrates the progression of socio-ecological risk from climate change as a function of global temperature change, taking into account the exposure and vulnerability of people and ecosystems, as assessed by literature-based expert judgment. Section 16.6.3 presents these diagrams for each Reason for Concern, providing information about the most important literature-based evidence that experts used to make their judgements. Similar assessments for selected individual KRs are discussed in Chapters 2, 7, 9, 12, 13, and 14.

Representation of Warming Levels
The RFC assessment reflects the latest understanding of warming reported in WGI AR6. Global surface temperature was 1.09 [0.95 to 1.20]ºC higher in 2011–2020 than 1850–1900, with stronger warming over land (1.59 [1.34 to 1.83]ºC) than over the ocean (0.88 [0.68 to 1.01]ºC) (WGI AR6 Cross Chapter Box 2.3 Table 1, Eyring et al. in Gulev et al., 2021). Warming levels are commonly reported and studied in the impacts literature using two scales of spatially averaged temperature rise, global surface air temperature (GSAT), commonly produced by General Circulation Models (GCMs) when projecting climate changes, and global mean surface temperature (GMST), commonly used in empirical studies. Both have the same reference point of pre-industrial of 1850–1900. The ember diagrams presented here use GSAT, which is consistent with most literature of projected risk (largely based on the output of climate models). To the extent that the embers also draw on the observed impacts literature using GMST, this potential variation is minimal as the average levels of GSAT and GMST have been shown to match closely (for further discussion on this see Cross-Chapter Box CLIMATE in Chapter 1). Hence the diagrams are presented with a single y-axis representing global temperature change, generally referring to global temperature rise irrespective of when it occurs: however, the majority of the literature assessed considers alternative levels of warming during the twenty-first century. For example, a warming level of 2ºC might occur in the 2050s, the 2080s, or in 2100 (see next section).

Furthermore, climate-related hazards associated with each of the RFCs are assessed in WGI AR6 Cross-Chapter Box 12.1 Table 1 (Tebaldi et al., 2021) which synthesizes information from various chapters of WGI on 35 such hazards according to global warming levels (GWLs) to inform understanding of their potential changes and associated risks with temperature levels in general.

Temporal dimension
When are the risks shown in the embers projected to occur? The issues associated with assessing transient risks are discussed in Chapter 3, SR15 (IPCC, 2018). Some of the literature, however, does explore the dynamics within human and natural systems (i.e., the way in which systems respond when a transient level of warming is first reached and then further, how they continue to develop if that transient level of warming is then maintained indefinitely). We note that this important factor is captured in the RFC assessment (and ember diagrams), since the timing of risk accrual is one of the criteria for the assessment of the level of risk (16.5.1). Risks that are known to evolve only over very long-time scales contribute less to the level of risk

than those which are known to occur rapidly. This is because sea level rise also depends on the dynamics of global warming, including the rate of change of radiative forcing, and time lags of several decades, including between atmospheric and ocean warming, and in reaching equilibrium sea level state (Oppenheimer et al., 2019; Fox-Kemper et al., 2021). However, longer-term risks that would arise if those transient temperatures were maintained are also included, and this is particularly important in RFC5 (large scale singular events). Note that risks that take place over a very long timescale are considered to be of lower concern than more imminent risks. However, changes of very large magnitude can still be very important even if far away in time, especially if these changes are irreversible (or reversible only on extremely long time scales) (see Section 16.5.1).

Although the embers do not indicate the decade in which certain risks are projected to occur, clearly this depends strongly on the level of mitigation action as well as the degree of adaptation. Hence, the ember diagram (Figure 16. 14) is shown alongside a graphic illustrating possible global temperature time series emerging from alternative future scenarios assessed by WGI AR6 which imply different levels of mitigation effort. For example, in a scenario with a high level of mitigation effort (SSP1-1.9) reaching net zero emissions in the 2050s, it is *extremely likely* that global warming remains below 2°C and more than 50% *likely* that it will remain below 1.6°C (AR6 WGI 4.3.1.1, Meinshausen et al., 2020). On the other hand, a level of 2°C warming is *extremely likely* to be exceeded during the 21st century under the three scenarios assessed by WGI AR6 in which greenhouse gas emissions do not fall below current levels before mid-century (i.e., SSP2-4.5, SSP3-7.0, SSP-8.5) (WGI AR6 4.3.1.1, Lee et al., 2021). WGI AR6 has assessed that 'global surface temperature averaged over 2081–2100 is *very likely* to be higher by 1.0°C–1.8°C under the lowest CO_2 emission scenario considered in this report (SSP1-1.9) and by 3.3°C–5.7°C under the highest CO_2 emission scenario (SSP5-8.5)'. However, almost all scenarios assessed by IPCC AR6 WGI reach 1.5°C global warming level in the early 2030s (WGI AR6 SPM, IPCC, 2021a).

Temperature overshoot

The concept of temperature overshoot, defined as 'exceedance of a specified global warming level followed by a decline to or below that level during a specified period of time' is a relevant consideration for this RFC risk assessment; however, the effect of overshoot has not explicitly been considered in the burning ember assessment due to the limited literature basis. However, despite the lack of directly assessed overshoot scenarios, the current literature provides several salient examples of irreversible changes that are projected to occur once global temperatures reach a particular level. For example, coral reefs are unable to survive repeated bleaching events that are too close together, leading to irreversible loss of the reefs even if bleaching were to cease (see Section 16.6.3.1 RFC1). Species extinction is irreversible, and Chapter 2 assesses that at ~1.6°C, >10% of species are projected to become endangered as compared with >20% at ~2.1°C (median) representing high and very high biodiversity risk, respectively *(medium confidence)* (Section 2.5.4). Similarly, WGI AR6 finds that 'Over the 21st century and beyond, abrupt and irreversible regional changes in the water cycle, including changes in seasonal precipitation, streamflow and aridity, cannot be excluded'. Thus, information about irreversibility provides information about the potential outcome of temperature overshoot scenarios. Other types of losses, such as loss of human or species life, are irreversible even if the loss process ceases in the future. The less resilient a system is, the more likely it is to suffer irreversible damage during a temperature overshoot; the more resilient it is, the more likely it is to be able to withstand the overshoot or recover afterwards. Very high levels of risk, as assessed here in the Reasons for Concern, are associated with a wide range of criteria for risk assessment including irreversibility. Whilst not all very high risks are irreversible, in general risks reaching a very high level include a component of irreversible risks that would persist during and after an overshooting of a given temperature level.

Risks associated with socioeconomic development, mitigation and mal-adaptation

The ember diagrams in Figure 16.14 capture only the risks arising from exposure of vulnerable socio-ecological systems to climatic hazards across a range of socioeconomic futures. They do not capture any risk component arising solely from changes in population or level of development. Importantly, they also do not capture additional risks that may arise from the human response to climate change, including climate change mitigation or unintended negative consequences of adaptation-related responses (i.e., maladaptation) (Section 17.5.1). Such risks are discussed in SRCCL Chapter 7, for example, adverse effects of the very large-scale use of land and water for primary bioenergy production on food production and biodiversity (Hurlbert et al., 2019). Contributions of mitigation or maladaptation to risk can be important, however, and are discussed further in the context of specific RFCs in Section 16.6.3. In general, such components of risk are difficult to quantify, and can be minimised by good design of climate change mitigation and adaptation. Thus, the effect is excluded from the ember diagrams to allow a more clear representation of the accrual of climate change risk with global warming.

Emergent Risk

AR5 Oppenheimer et al. (2014) defined 'emergent risk' as a risk that arises from the interaction of phenomena in a complex system. While emergent risk is a relevant consideration for this RFC risk assessment, this type of risk has not been explicitly accounted for in the burning ember assessment due to the limited literature basis. Unlike known or identified risks, emergent risks are characterized by the uncertainty of consequences and/or probabilities of occurrence. The International Risk Governance Council (IRGC) suggests three categories of emergent risks: 1) high uncertainty and a lack of knowledge about potential impacts and interactions with risk-absorbing systems; 2) increasing complexity, emergent interactions and systemic dependencies that can lead to non-linear impacts and surprises; and 3) changes in context (for example social and behavioural trends, organisational settings, regulations, natural environments) that may alter the nature, probability and magnitude of expected impacts. Feedback processes between climatic change, human interventions involving mitigation and adaptation actions, and processes in natural systems can be classified as emergent risks if they pose a threat to human security.

16.6.3 Global Reasons for Concern

In this section we present the results of the expert elicitation in the form of the burning embers diagram, alongside a description of the recent literature and scientific evidence for each of the RFCs in turn. The consensus transition values are illustrated in Figure 16.14, an updated version of the burning embers diagram that describes the additional risk due to climate change for each RFC when a temperature level is reached and then sustained or exceeded. (Table SM16.18 in Supplementary Material SM16.6 presents the consensus values of the transition range and median estimate in terms of global warming level by risk level for each of the five RFC embers). The shading of each ember provides a qualitative indication of the increase in risk with temperature, and we retain the color scheme employed in the most recent versions of this figure, where white, yellow, red, and purple indicate undetectable, moderate, high and very high additional risk, respectively. These transitions were assessed under conditions of low to no adaptation compared to today, in accordance with definitions provided in 16.3 (i.e., adaptation consists of fragmented, localized, incremental adjustments to existing practices), though the effect of adaptation on risk for individual RFCs and related literature is discussed further below.

The following subsections present the expert assessment and judgments made during the elicitation process to identify consensus transition values for each RFC. The description of these transitions is further extended with additional references to findings from underlying chapters in this report, and reviewed by Chapter 16 authors as part of independent appraisal. No changes were made to the transition values assessed through the expert elicitation.

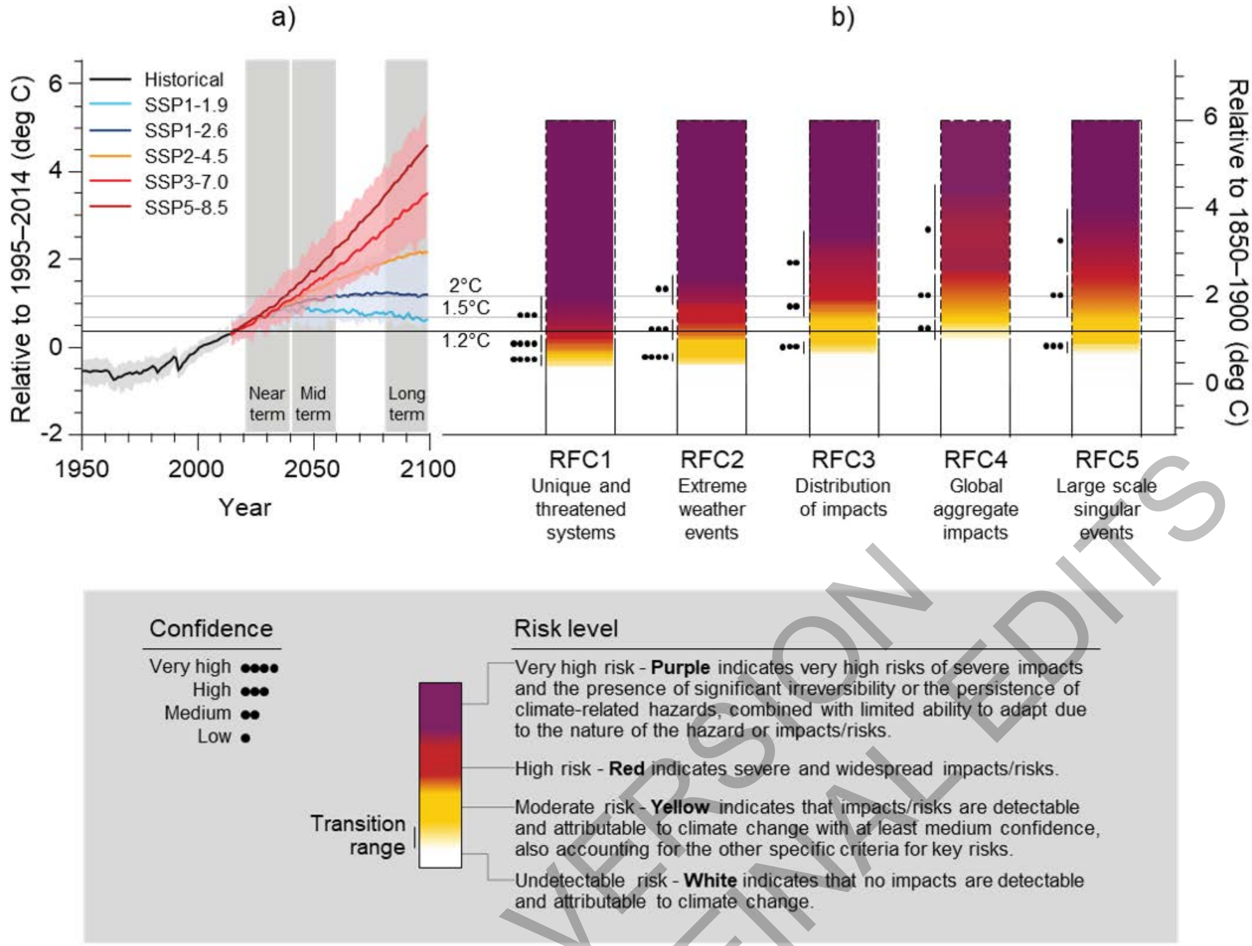

Figure 16.15: The dependence of risk associated with the Reasons for Concern (RFCs) on the level of climate change, updated by expert elicitation and reflecting new literature and scientific evidence since AR5 and SR15. (a) Global surface air temperature (GSAT), relative to 1995-2014 (left axis) and pre-industrial, 1850-1900 (right axis) (WGI AR6 Figure 4.2a, (Lee et al., 2021)). (b) Embers are shown for each RFC, assuming low to no adaptation (i.e., adaptation is fragmented, localized, incremental adjustments to existing practices). The horizontal line denotes the present global warming of 1.2°C (WMO, 2020) which is used to separate the observed, past impacts below the line from the future projected risks above it. **RFC1 Unique and threatened systems**: ecological and human systems that have restricted geographic ranges constrained by climate related conditions and have high endemism or other distinctive properties. Examples include coral reefs, the Arctic and its indigenous people, mountain glaciers and biodiversity hotspots. **RFC2 Extreme weather events**: risks/impacts to human health, livelihoods, assets and ecosystems from extreme weather events such as heatwaves, heavy rain, drought and associated wildfires, and coastal flooding. **RFC3 Distribution of impacts**: risks/impacts that disproportionately affect particular groups due to uneven distribution of physical climate change hazards, exposure or vulnerability. **RFC4 Global aggregate impacts**: impacts to socio-ecological systems that can be aggregated globally into a single metric, such as monetary damages, lives affected, species lost or ecosystem degradation at a global scale. **RFC5 Large-scale singular events**: relatively large, abrupt and sometimes irreversible changes in systems caused by global warming, such as ice sheet disintegration or thermohaline circulation slowing. Comparison of the increase of risk across RFCs indicates the relative sensitivity of RFCs to increases in GSAT. The levels of risk illustrated reflect the judgments of IPCC author experts from WGI and WGII.

16.6.3.1 Unique and Threatened Systems (RFC1)

This RFC addresses the potential for increased damage to or irreversible loss of a wide range of physical, biological, and human systems that are unique (i.e., restricted to relatively narrow geographical ranges and have high endemism or other distinctive properties) and are threatened by future changes in climate (Smith et al., 2001; Smith et al., 2009; Oppenheimer et al., 2014). The specific examples of such systems given in previous IPCC assessment reports has remained broadly consistent, with AR4 including 'coral reefs, tropical glaciers, endangered species, unique ecosystems, biodiversity hotspots, small island states, and indigenous communities' (Smith 2009), AR5 including 'a wide range of physical, biological, and human systems that are restricted to relatively narrow geographical ranges' and 'are threatened by future changes in climate'

(Smith et al., 2001), while SR15 Chapter 3 included 'ecological and human systems that have restricted geographic ranges constrained by climate related conditions and have high endemism or other distinctive properties. Examples include coral reefs, the Arctic and its indigenous people, mountain glaciers and biodiversity hotspots'. In this cycle, we retain the definition used in SR15 as most explicit and inclusive of the previous definitions.

AR5 (Oppenheimer et al., 2014) assessed the transition from undetectable to moderate risk for RFC1 to lie below recent global temperatures (1986-2005, which at the time was considered to correspond to a global warming level of 0.6°C above pre-industrial levels; AR6 WGI now considers this time period of 1986-2005 to correspond to a global warming or approximately 0.7°C). At that time, there was at least *medium confidence* in attribution of a major role for climate change for impacts on at least one each of ecosystems, physical systems, and human systems within this RFC. SR15 Section 3.5.2.1 (Hoegh-Guldberg et al., 2018b), concurred with *high confidence* that the transition to moderate risk had already occurred before the time of writing.

The transitions here are informed by these assessments, along with the assessment in Chapter 2 on species high extinction risk and on ecosystem transitions. It also draws substantially from information in Cross-Chapter Paper 1 and Table SM16.22 on risks to unique and threatened biological systems. Some unique and threatened systems, such as coral reefs and sea-ice dependent ecosystems, were already showing attributable impacts with *high confidence* (see table 16.1, Cross-Chapter Paper 1 and Chapter 2) based on data collected in the mid to latter 20th century, when global warming of 0.5°C above pre-industrial levels had taken place, as noted already in AR3. In this AR6 assessment, the temperature range for the transition from undetectable to moderate risk is still located at a median value of 0.5°C above pre-industrial levels, with *very high confidence.* Since impacts were first detected in coral reef systems in the 1980s when warming of ~0.4°C of global warming had occurred (SR15 Chapter 3), this provides the temperature at which the transition begins. The September Arctic sea ice volume has declined by 55-65% between 1979 and 2010 (AR6 WGI, Schweiger et al., 2019) as global warming increased from around 0.36°C in 1979 to around 0.9°C in 2010. These provide evidence of a start to the transition from undetectable to moderate risk at 0.4°C above pre-industrial levels. Recent evidence of observed impacts on mountaintop ecosystems, sea ice dependent species, and of range shifts in multiple ecosystems during 1990-2000, which AR6 WGI now assesses as corresponding to a global warming of 0.69°C (see WGI AR6 Cross-Chapter Box 2.3, Figure 1, Gulev et al., 2021) provides evidence for an upper limit to this transition of 0.7°C with *very high confidence*. Overall, the transition is located at a median of 0.5°C with lower and upper limits of 0.4 and 0.7°C respectively with *very high confidence.*

AR5 assessed the transition from moderate to high risk to lie around 1°C above 1986–2005 levels (which corresponded at that time to 1.6°C above pre-industrial levels but has been reassessed by AR6 WGI to correspond to 1.7°C) to reflect projected 'increasing risk to unique and threatened systems, including Arctic sea ice and coral reefs, as well as threatened species as temperature increases over this range.' SR15 relocated the transition slightly from 1.6°C to 1.5°C, owing to increased literature projecting the effects of climate change upon Arctic sea ice and new literature assessing projected impacts of climate change on biodiversity at 1.5°C warming.

In this AR6 assessment, the transition from moderate to high is based on the high level of observed impacts, and the areas projected to begin undergoing major transformations by 1.5ºC (see CCP1, Chapter 2 and SR15). A substantial number of unique and threatened systems are assessed to be in a high risk state owing to the influence of anthropogenic climate change by the 2000-2010 period, when global warming had reached approximately 0.85ºC (range 0.7-1ºC) (see WGI AR6 Cross-Chapter Box 2.3, Gulev et al., 2021) using the 1995-2014 figure as a proxy for 2000-2010).

The most prominent example of a system assessed to be already in a high risk state is that of coral reefs, which are already degrading rapidly. Observed impacts on coral reefs increased significantly during 2014-2017 (Table 16.2, corresponding to a global warming of about 0.9ºC). This includes mass bleaching in the Indian Ocean in 1998, 2010, 2015 and 2016 when bleaching intensity exceeded 20% in surveyed locations in the western Indian Ocean, eastern Indian Ocean and western Indonesia. In the tropical Pacific Ocean, climate-driven mass bleaching was reported in all countries in the region, with most bleaching reports coinciding with 2014-2017 marine heatwaves. 50% of coral within shallow-water reefs of the northern and central two-thirds of the Great Barrier Reef were killed in 2015/16. Subsequent coral recruitment in 2018 was reduced to only 11% of the long-term average, representing an unprecedented shift in the ecology of the northern and middle sections of the reef system to a highly degraded state. A second key example are sea ice dependent systems in the Arctic. During August-October of 2010-2019, corresponding to a global warming of about 0.9°C, average Arctic sea-ice area has declined in area by 25% relative to 1979-1988 (*high confidence*, AR6 WGI, Figure 9.13). September Arctic sea ice volume has declined by about 72 % between 1979 and 2016, with the latter deemed a conservative estimate (AR6 WGI, Schweiger et al., 2019).

Other important examples of observed impacts on unique ecosystems that indicate that risks are already at a high level (Table SM16.22) include mass tree mortalities, now well recorded in multiple unique forest and woodland ecosystems around the world. Sections 2.4.3.3 and 2.4.5 report that between 1945 and 2007, drought-induced tree mortality (sometimes associated with insect damage and wildfire) has caused the mortality of up to 20% of trees in western North America, the African Sahel, and North Africa, linked to a warming of 0.3-0.9ºC above pre-industrial levels, and is implicated in more than 100 other cases of drought-induced tree mortality in Africa, Asia, Australia, Europe, and North and South America (*high confidence*). Species in biodiversity hotspots already show changes in response to climate change (CCP1, *high confidence*). Román-Palacios and Wiens (2020) attribute local extinctions of several taxonomic groups between the latter 20th century and 2003-2012, (corresponding to warming of less than 0.85ºC) to climate-change related temperature extremes for up to 44% (0-75%) of species. Widespread declines of up to 35% in the species richness of the unique pollinator group, bumble bees, between 1901 - 1974 and 2000 - 2014 are also attributed to climate change, via increasing exceedance of their thermal tolerance limits across Europe and North America (Soroye et al., 2020). The first extinctions attributed to climate change have been now detected with the present 1.2ºC warming including that of the Bramble Cays Melomys (*Melomys rubicola*), a sub-species of the lemuroid ringtail possum (*Hemibelideus lemuroides*), and golden toad (*Incilius periglenes*) (Chapter 2). An increasing frequency or unprecedented occurrence of mass animal mortality due to climate-change enhanced heat waves have also been observed in recent years on more than one continent, including temperature vulnerable terrestrial birds and mammals in South Africa and Australia (Ratnayake et al., 2019; McKechnie et al., 2021). There have also been 90% declines in sea ice dependent species such as sea lions and penguins in the Antarctic (Table 16.2). A strong effect of climate change on the observed contraction of ranges of polar fish species and strong expansion of ranges of arcto-boreal or boreal fish was observed between 2004 and 2012 Frainer et al. (2017). Even if current human driven habitat loss is excluded, many hotspots are projected to cease to be refugia (i.e., to remain climatically suitable for >75% of the species they contain which have been modelled), at 1.0-1.5ºC (Cross-Chapter Paper 1).

Based on observed and modelled impacts to unique and threatened systems, including in particular coral reefs, sea ice dependent systems, and biodiversity hotspots, AR6 assesses that the transition to high risks for RFC1 have already occurred at a median level of 0.9ºC, with a lower bound at 0.7ºC and an upper bound at the present day level of global warming of 1.2ºC (WMO, 2020) *(very high confidence)*.

Identification of the transition to very high risk is associated by definition with the reaching of limits to natural and/or societal adaptation. Adaptation which occurs naturally is already included in the risk assessment, but experts also discussed the effect of additional human-planned adaptation in reducing risk levels in RFC1. This additional adaptation could help species to survive *in situ* despite a changing climate (for example by reducing current anthropogenic stresses such as over harvesting), or facilitate the ability of species to shift geographic range in response to changes in climate, and the potential benefits of nature-based solutions and restoration (see Cross-Chapter Box NATURAL and Section 2.6.5.1 in Chapter 2).

When considering planned adaptation, the main option often considered in terrestrial ecosystems is the expansion of the protected area network, which is broadly beneficial in increasing the resilience of ecosystems to climate change (e.g., Hannah et al., 2020). However, this action is not effective if the unique and threatened systems in question reach a hard limit to adaptation (as in the case of the loss of Arctic summer sea ice, the submergence of a small island, the contraction and elimination of a species' climatic niche from a mountaintop, or the degradation of a coral reef) (Section 16.4). Furthermore, adaptation benefits deriving from restoration rapidly diminish with increasing temperature (Cross-Chapter Paper 1). One study quantifies how land management (in terms of protecting existing ecosystems or restoring lost ones) might reduce extinctions in biodiversity hotspots or globally significant terrestrial biodiversity areas more generally (Warren et al., 2018b). Whilst the latter suggests that substantial benefits can result globally in terrestrial systems, allowing less unique systems to persist at higher levels of warming but only under a high adaptation scenario in which globally applied terrestrial ecosystem restoration and protected area expansion takes place, this is less likely for many of the unique and threatened terrestrial systems which are more vulnerable than the globally significant biodiversity areas treated in that study (which excludes coral reefs and Arctic sea ice dependent systems). Such high levels of adaptation globally are likely infeasible owing to competition for land use with food production (Pörtner et al., 2021). Novel targeted adaptation interventions for coral reefs such as artificial upwelling and local radiation management show some promise for reducing the adverse effects of thermal stress and resulting coral bleaching Condie et al. (2021), but are far from implementation (Sawall et al., 2020; Kleypas et al., 2021). Larger benefits in this RFC could theoretically accrue only if adaptation action became ubiquitous and extensive, which experts considered infeasible at the scales required. Small island communities are confronted by socio-ecological limits to adaptation well before 2100, especially those reliant on coral reef systems for their livelihoods, even for a low emissions pathway (Chapter 3) (*high confidence*). At warming levels beyond 1.5°C, the potential to reach biophysical limits to adaptation due to limited water resources are reported for Small Islands (*medium confidence*) and unique systems dependent on glaciers and snowmelt (Chapter 4) (*medium confidence*).

AR5 assessed with *high confidence* that the transition from high to very high risks for RFC1 to lie around 2°C above 1986–2005 levels (then considered to correspond to 2.6°C above pre-industrial levels) to reflect the very high risk to species and ecosystems projected to occur beyond that level as well as limited ability to adapt to impacts on coral reef systems and in Arctic sea ice-dependent systems. Using the additional literature which became available on projected risks to Arctic sea ice, biodiversity and ecosystems at 1.5°C vs 2°C warming above pre-industrial levels, SR15 assessed that the transition from high to very high risks in RFC1 lay between 1.5°C and 2°C above pre-industrial levels.

In AR6, risks are considered to start to transition from high to very high risks above 1.2°C warming (present day, WMO, 2020), with a median value of 1.5°C, owing in particular to the observation of a present day onset of ecosystem degradation in coral reefs, which are projected in the SR15 report 'to decline by a further 70–90% at 1.5ºC (*very high confidence*)' . The literature for projected increases in risk to other unique and threatened systems and their limited ability to adapt above 2ºC warming is substantial and robust and the confidence level in very high risk remains high. At 2ºC, 18% of 34,000 insects are projected to lose >50% climatically determined geographic range, as compared with 6% at 1.5ºC (Warren et al., 2018a). The risk of species extinction increases with warming in all climate change projections, for all native species studied in biodiversity hotspots (Cross-Chapter Paper 1, *high confidence*), being roughly threefold greater for endemic than more widespread species for global warming of 3°C above pre industrial levels than 1.5°C) (Manes et al., 2021, Cross-Chapter Paper 1) (*medium confidence*). The Arctic is projected to be practically ice free in September in some years for global warming of between 1.5 and 2ºC (WGI AR6 Section 9.3.1.1, Fox-Kemper et al., 2021), undermining the persistence of ice dependent species such as polar bears, ringed seals and walrus (Meredith et al., 2019), and adversely affecting indigenous communities. Warming of 1.5ºC is also assessed (Chapter 3) to reduce the habitability of small islands, due to the combined impacts of several key risks *(high confidence)*. Hence the transition from high to very high risk in these systems is assessed to occur with *high confidence* beginning at 1.2ºC, passing through a median value of 1.5°C, and completing (i.e. reaching its upper bound) at 2ºC warming.

16.6.3.2 Extreme Weather Events (RFC2)

This RFC addresses the risks to human health, livelihoods, assets and ecosystems from extreme weather events such as heatwaves, heavy rain, drought and associated wildfires, and coastal flooding (Hoegh-Guldberg et al., 2018b). Previous assessments of this RFC have focused mainly on changes to the hazard component of the risk, using the projected increase in hazard as an indicator of higher risk. However, in AR6 an expanding (although still smaller) body of evidence now allows also incorporation of the exposure and/or vulnerability components of risk and, to a limited extent, their trends.

AR5 identified a transition from undetectable to moderate risk below 'recent' temperatures (i.e., during 1986-2005, which then corresponded to a global warming of 0.6ºC above pre-industrial levels). SR15 Section 3.5.2.2 (Hoegh-Guldberg et al., 2018b), concluded that differences of 0.5ºC in global warming led to detectable changes in extreme weather and climate events on the global scale and for large regions. IPCC WGI AR6 Chapter 11 confirms this assessment and concludes that 'new evidence strengthens the conclusion from SR15 that even relatively small incremental increases in global warming (+0.5°C) cause statistically significant changes in extremes on the global scale and for large regions'. Substantial literature is available for comparisons at +1.5ºC vs +2ºC of global warming, but the conclusions are assessed to also apply at lower global warming levels and smaller increments of global warming given the identified linearity of regional responses of several extremes in relation to global warming(Seneviratne et al., 2016; Wartenburger et al., 2017; Tebaldi and Knutti, 2018) and the identification of emergence of global signals in climate extremes for global warming levels as small as 0.1°C (Seneviratne and Hauser, 2020, WGI AR6, Chapter 11, Figure 11.8; WGI Cross-Chapter Box 12.1). Further analyses are consistent with this assessment, based on model simulations (Fischer and Knutti, 2015; Schleussner et al., 2017; Kirchmeier-Young et al., 2019a; Seneviratne and Hauser, 2020) and observational evidence (Zwiers et al., 2011; Dunn et al., 2020). A global warming of +0.5ºC above pre-industrial conditions corresponds approximately to climate conditions in the 1980s (Chapter 2, Figure 2.11), a time frame at which detectable changes in some extremes were established at the global scale based on observations (Dunn et al., 2020). Heat-related mortality has also been assessed to have increased considerably because of climate change (Ebi et al., 2021; Vicedo-Cabrera et al., 2021). The onset, and also median location of the transitions of risk (Figure 16.15) from undetectable to moderate, is therefore considered to be 0.5ºC. Further strong new evidence shows that changes in extremes emerged during the 1990s and 2000s (Dunn et al., 2020) by which time +0.7ºC of global warming had taken place (IPCC SR15, Chapter 1; WGI AR6, Chapter 2). In AR5 Section 19.6.3.3 (Oppenheimer et al., 2014), a transition to moderate risk was assessed to have taken place at the then 'recent' global warming level of 0.6ºC, with high confidence. Owing to the increase in evidence, there is now *very high confidence* that the median value of the transition from undetectable to moderate risk is at 0.5ºC and led by heat extremes, with the lower estimate set at 0.5°C as well, and upper estimate at 0.7°C.

Further evidence of more recent observed changes in extreme weather and climate events, and their potential for associated adverse consequences across many aspects of society and ecosystems, has continued to accrue (WGI AR6 Chapter 11; WGI AR6 Chapter 12). Since a necessary condition for 'moderate' levels of risk is the detection and attribution of observed impacts, the following text provides an overview of some salient examples of this evidence. In particular, WGI AR6 Chapter 11 (Seneviratne et al., 2021) concludes that some recent hot extreme events that happened in the past decade (2010s) would have been *extremely unlikely* to occur without human influence on the climate system. Global warming in that decade reached approximately 1.09°C on average (IPCC WGI AR6 Chapter 2).

Assessment of a high level of risk requires a higher level of magnitude, severity and spatial extent of the risks. Events prior to that already had substantial impacts such as the 2003 European heatwave (IPCC SREX Chapter 9). Examples of impactful events in the early 2010s (at ca. 0.95°C of global warming, (WGI AR6 Chapter 2, Gulev et al., 2021) include the 2010 Russian heatwave (Barriopedro et al., 2011) and the 2010 Amazon drought (Lewis et al., 2011). Later impactful events include, among others, the 2013 heatwave in eastern China (Sun et al., 2014), the 2017 tropical cyclone Harvey (Risser and Wehner, 2017; Van Oldenborgh et al., 2017), and the 2018 concurrent north hemisphere heatwaves in Europe, North America and Asia (Vogel et al., 2019). Very recent events with severe and unprecedented impacts attributed to anthropogenic climate change indicate that thresholds to high risks may already have been crossed at recent levels of global warming (ca. 1.1°C-1.2°C) including the Siberian fires and the 2019 Australian bushfires that were linked to extreme heat and drought conditions (Van Oldenborgh et al., 2017) and extreme precipitation linked to increased storm activity in the US (Van Oldenborgh et al., 2017). Severe and unprecedented impacts occurred with current low levels of adaptation (16.2.3.4). The global-scale risk of wildfire considerably degrading ecosystems and increasing illnesses and death of people has been assessed to transition from undetectable to moderate over the range 0.6 to 0.9°C with *high confidence* (Chapter 2, Table 2.S.4, Figure 2.11).

In addition, long-term trends in various types of extremes are now detectable (WGI AR6 Chapter 11, Seneviratne et al., 2021). This includes increases in hot extremes over most land regions (*virtually certain*), increases in heavy precipitation at the global scale and over most regions with sufficient observations (*high confidence*), and increases in agricultural and ecological droughts in some regions (*medium confidence*) (WGI AR6 Chapter 11). There has also been overall a *likely* increase in the probability of compound events, such as an increase in concurrent heatwaves and droughts (*high confidence*) (WGI AR6 Chapter 11). There is *medium confidence* that weather conditions that promote wildfires (fire weather) have become more probable in southern Europe, northern Eurasia, the US, and Australia over the last century (WGI AR6 Chapter 11; SRCCL Chapter 2, Jolly et al., 2015; Abatzoglou and Williams, 2016). Furthermore, food security and livelihoods are being affected by short-term food shortages caused by climate extremes (5.12.1; Chapter 16, Food Security RKR) which have affected the productivity of all agricultural and fishery sectors (*high confidence*). The frequency of sudden food production losses has increased since at least mid-20th century on land and sea *(medium evidence, high agreement)*. Droughts, floods, and marine heatwaves contribute to reduced food availability and increased food prices, threatening food security, nutrition, and livelihoods of millions *(high confidence)*. Changes in sea surface temperatures drive simultaneous variation in climate extremes increasing the risk of multi-breadbasket failures (Cai et al., 2014; Perry et al., 2017). Droughts induced by the 2015-2016 El Niño, partially attributable to human influences (*medium confidence*), caused acute food insecurity in various regions, including eastern and southern Africa and the dry corridor of Central America (*high confidence*). Human-induced climate change warming also worsened the 2007 drought in southern Africa, causing food shortages, price spikes, and acute food insecurity in Lesotho (Verschuur et al., 2021). In the fisheries and aquaculture sector, marine heat waves are estimated to have doubled in frequency between 1982 and 2016, as well as increasing in intensity and length, with consequences for fish mortality (Ch 5) (Smale et al., 2019; Laufkötter et al., 2020). In the northeast Pacific, a recent 5-year warm period impacted the migration, distribution, and abundance of key fish resources (*high confidence*). At 1ºC warming the number of people affected by six categories of extreme events was found to have already increased by a factor of 2.3 relative to preindustrial (Lange et al., 2020).

The general picture is one of annual or more frequent occurrences of severe extremes with widespread impacts (as also reflected in section 16.2), and of multiple extremes, meeting the criteria for the 'severe and widespread' nature of risks that is required for classification at a 'high' level of risk. This is consistent with AR5 Chapter 19 (Oppenheimer et al., 2014), and gives *high confidence* that the lower threshold for entering high risks associated with extreme weather events is +1ºC, and that the best estimate is that this transition already occurred now that global warming has reached its present-day level of ca. 1.2ºC (WMO, 2020), slightly above the 1.09°C average conditions in the 2010s, i.e. 2011-2020 (IPCC WGI AR6 Chapter 2, Gulev et al., 2021).

A range of literature projects further substantial increases in several extreme event types with a global warming of +1.5ºC, notably hot extremes in most regions, heavy precipitation in several regions, and drought in some regions (IPCC SR15; WGI AR6 , Chapter 11). In particular, heavy precipitation and associated flooding are projected to intensify and be more frequent in most regions in Africa and Asia (*high confidence*), North America (*medium* to *high confidence* depending on the region), and Europe (*medium confidence*). Also, more frequent and/or severe agricultural and ecological droughts are projected in a few regions in all continents except Asia, compared to 1850–1900 (*medium confidence*); increases in meteorological droughts are also projected in a few regions (*medium confidence*). Increases at 1.5°C of global warming are projected in marine heatwaves (Laufkötter et al., 2020) and the occurrence of fire weather (IPCC, 2019a). Heat-related mortality is assessed to increase from moderate to high levels of risk under about 1.5ºC warming under SSP3, a socioeconomic scenario with large challenges to adaptation (Ebi et al., 2021) especially in urban centres (Chapter 6). An additional 350 million people living in urban areas are estimated would be exposed to water scarcity from severe droughts at 1.5°C warming (Section 6.1; Section 6.2.2; CCP2 Coastal Cities). In summary, there is *high confidence* that the best estimate for the transition from moderate to high risk is 1.2°C of global warming, with 1°C as lower estimate and 1.5°C as upper estimate. The latter would be set to 1.3°C for an assessment at *medium confidence*.

As in RFC1, one of the criteria for identification of very high risks is limits to adaptation. Though the literature explicitly considering societal adaptation to extreme weather events is limited, there is evidence that investments in hydro-meteorological information, early warning systems and anticipatory forecast-based finance are a cost-effective way to prevent some of the most adverse effects of extreme events (Coughlan de Perez et al., 2016; Fakhruddin and Schick, 2019; Merz et al., 2020). Despite a lack of systematic methods for assessing general adaptation effectiveness, there is some evidence of risk reduction for particular places and hazards, especially flood and heat vulnerability (16.3.2.4) including investment in flood protection, building design and monitoring and forecasting, air conditioning, reduced social vulnerability, and improved population health. One study finds declining global mortality and economic loss due to extreme weather events over the past four decades Formetta and Feyen (2019) especially in low income countries. Using SSP2 as a proxy for expanded adaptation, Ebi et al. (2021) assesses that the transition to high risk for heat-related mortality increases to 1.8ºC (compared to 1.5ºC with less adaptation under SSP3). There is evidence of adaptation avoiding heat-related mortality at low levels of global warming, using early warning and response systems and sustainable alterations of the thermal environment at the individual, building, urban, and landscape levels (Jay et al., 2021). Despite the evidence that adaptation can reduce risks of heat stress, the impact of projected climate change on temperature-related mortality is expected to be a net increase under a wide range of climate change scenarios, even with adaptation (Ch 7, *high confidence).* Much of the adaptation literature focuses on coping with long-term gradual climate change and largely does not take into account the increased difficulty of adapting to climate extremes and general higher variability in climate that is projected to occur in the future. However, expanding and more coordinated adaptation, including wider implementation and multi-level coordination, has the potential to reduce the risks to crops from heatwaves at intermediate (but not high) levels of warming.(IPCC AR5 Ch7, Ahmed et al., 2018; Ahmed et al., 2019, Section 16.3.2.2; EEA, 2019; Raza et al., 2019; Tripathi and Sindhi, 2020).

The transition from high to very high risk for the RFC2 was not assessed in the AR5 or in SR15. Some new evidence suggests, however, that very high risks associated with weather and climate extremes would be reached at higher levels of global warming. In particular, changes in several hazards would be more widespread and pronounced at 2°C compared to 1.5°C global warming, including increases in multiple and concurrent extremes (IPCC WGI AR6 SPM; IPCC WGI AR6 Chapter 11, IPCC WGI AR6 Chapter 12). On average over land, high temperature events that would have occurred once in 50 years in the absence of anthropogenic climate change are projected to become 13.9 times more likely with 2ºC warming, and 39.2 times more likely with 4ºC warming (IPCC AR6 WGI SPM Figure 6, IPCC, 2021b) indicating a non-linear increase with warming. Ch 2 has assessed that risk of wildfire transitions from moderate to high over the range 1.5ºC to 2.5ºC warming (*medium confidence,* Table 2.S.4, Figure 2.11). The intensity of heavy precipitation events increase overall by about 7% for each additional degree of global warming (IPCC AR6 WGI SPM), while their frequency increases non-linearly. Events that would have occurred once every 10 years in a climate without human influence are projected to become 1.7 times more likely with 2ºC warming, and 2.7 times more likely with 4ºC warming (IPCC AR6 WGI SPM Figure 6). Several AR6 regions are projected to be affected by increases in agricultural and ecological droughts at 2°C of global warming, including W. North-America, C. North-America, N. Central-America, S. Central-America, Caribbean, N. South-America, N.E. South-America, South-American-Monsoon, S.W. South-America, S. South-America, West & Central-Europe, Mediterranean, W. Southern-Africa, E. Southern-Africa, Madagascar, E. Australia, and S. Australia (IPCC WGI AR6, Chapter 11, Seneviratne et al., 2021). This is a substantially larger number compared to projections at 1.5°C (IPCC WGI AR6, Chapter 11, Seneviratne et al., 2021). In these drying regions, events that would have occurred once every 10 years in a climate without human influence are projected to happen 2.4 times more frequently at 2°C of global warming (IPCC WGI AR6 SPM Figure 6). Urban land exposed to floods and droughts is very likely to have more than doubled between 2000 and 2030, and the risk of flooding accelerates after 2050 (Ch 4). At 2ºC of global warming, there are also significant projected increases in fluvial flood frequency and resultant risks associated with higher populations exposed to these flood risks (Alfieri et al., 2017; Dottori et al., 2018) projected.

Heat-related mortality is assessed to increase from high to very high by 3°C under SSP3, a socioeconomic scenario with large challenges to adaptation (Ebi et al., 2021). SRCCL assessed that very high risks would be reached in association with wildfire above 3ºC of global warming (IPCC, 2019a). Chapter 2 has assessed that risk of fire weather itself transitions from high to very high over the range 3ºC to 4.5ºC warming (*medium confidence,* Table 2.S.4, Figure 2.11). Matthews et al. (2017) show that at 1.5ºC of global warming, about 40% of all megacities would be affected at least 1 day per year with a heat index above 40.6ºC (i.e., with 40.6ºC 'feels-like' temperatures, accounting for moisture effects). This number would reach about 65% of megacities at 2.7ºC and close to 80% at 4ºC. In addition, there is evidence for a higher risk of concurrent heat extremes at different locations with increasing global warming (Vogel et al., 2019), meaning that several cities could be affected by deadly heatwaves simultaneously. Laufkötter et al. (2020) found that marine heatwave events would become annual to decadal events under 3ºC of global warming, with consequences for aquaculture (Chapter 5). Gaupp et al. (2019) conclude that risks of simultaneous crop failure across worldwide breadbasket regions, due to changes in maximum temperatures in the crop-growth relevant season or cumulative precipitation in relevant time frames, increase disproportionately between 1.5ºC and 2ºC of global warming. Populations exposed to extreme weather and climate events may consume inadequate or insufficient food, leading to malnutrition and increasing the risk of disease (Ch 5, *high confidence*). Hence, there is the potential for very high risks associated with changes in climate extremes for food security in the low adaptation case, already above 2ºC of global warming. Finally, studies suggest that regional thresholds for climate extremes could be reached at 2ºC of global warming, for instance in the

Mediterranean (Guiot and Cramer, 2016). Samaniego et al. (2018) conclude that soil moisture droughts in that region would become 2–3 times longer than at the end of the 20th century at 2ºC, and 3–4 times longer (125 days long per year) at 3ºC of global warming. There is clear evidence of very high risk at 3ºC global warming for wildfires, marine heatwaves, and heatwaves in megacities (the latter being set at 2.7ºC).

Based on the available evidence, we assess that there is *medium confidence* that the transition to very high risk would happen at a median value 2ºC of global warming, considering the increased risk for breadbasket failure and irreversible impacts associated with changes in extremes at this warming level (e.g. damages to ecosystems, health impacts, severe coastal storms), but that due to the disproportionate increases in risk between 1.5 and 2ºC this transition begins already at 1.8ºC. The higher range for this transition is set with *medium confidence* at 2.5ºC in this low/no adaptation scenario, owing to the further projected non-linear increases in risks associated with high temperature events above 2ºC (WGI AR6 Figure SPM.6,, IPCC, 2021b; Cross-Chapter Box12.1, Ranasinghe et al., 2021), and also the limits to adaptation associated with dealing with a rapid escalation of extreme weather events globally during this century; extreme events are particularly difficult to adapt to and thus more often exceed hard limits to adaptation, particularly in natural ecosystem settings (Section 16.4).

16.6.3.3 Distribution of Impacts (RFC3)

RFC3 reflects how key risks are distributed unevenly across regions and different population groups, due to the non-uniform spatial distributions of physical climate change hazards, exposure, and vulnerability across regions. It addresses how risks disproportionately affect particularly vulnerable societies and socio-ecological systems, including disadvantaged people and communities in countries at all levels of development. AR5 concluded that low-latitude and less developed areas generally face greater risk than higher latitude and more developed countries, including for food- and health-related risks. This conclusion remains valid and is now supported by greater evidence across a range of sectors and geographic regions.

Note that the assessment here is largely based on the national and regional distribution of impacts, rather than sub-national distribution or explicit consideration of vulnerable elements of society. Climate risks are also strongly related to inequalities, often but not always intersecting with poverty (16.1), geographic location, political and socio-cultural aspects. Thus, countries with high inequality tend to be more vulnerable, and more exposed, to climate hazards (16.1). Whilst the literature assessed here tends to be insufficiently granular to resolve local inequalities, it does confirm the AR5 finding that low-latitude and less developed areas generally face greater risk.

AR6 continues to highlight the uneven regional distribution of projected climate change risks. Biodiversity loss is projected to affect a greater number of regions with increasing warming, and to be highest in northern South America, southern Africa, most of Australia, and northern high latitudes (Section 2.5.1.3, *medium confidence)*. Climate change is projected to increase the number of people at risk of hunger in mid-century, concentrated in Sub-Saharan Africa, South Asia and Central America (Chapter 5, *high confidence*), increasing undernutrition, stunting, and related childhood mortality particularly in Africa and Asia and disproportionately affecting children and pregnant women (Chapter 7, *high confidence*) strongly mediated by socio-economic factors (Section 7.2.4.4, 7.3.1, *very high confidence*). Strong geographical differences in heat-related mortality are projected to emerge later this century, mainly driven by growth in regions with tropical and subtropical climates (Section 7.3.1, *very high confidence*)

In AR5 and SR15, the transition from undetectable to moderate risk was located below what were at the time 'recent' temperatures of between 0.5 to 0.8°C above pre-industrial levels, with medium to high confidence, based on evidence of distributional impacts on crop production and water resources. New literature has continued to confirm this transition has already taken place including more recent observed impacts for regions and groups within the food and water sectors, strongly linked to Representative Key Risks for Health, Water and Food Security (Section 16.2; 16.5; 5.4.1, 5.5.1, 5.8.1 and 5.12; Chapter 7).
In AR6, moderate risks have already been assessed to have occurred in Africa for economic growth and reduced inequality, biodiversity and ecosystems, mortality and morbidity due to heat extremes and infectious disease, and food production in fisheries and crop production (Figure 9.6). In Europe moderate risks to heat stress, mortality and morbidity have already been reached, as well as for water scarcity in some regions (Figure 13.30, Figure 13.33). In Australasia, moderate risks are assessed as present already for heat related

mortality risk as well as cascading effects on cities and settlements; and also very high risks already present in coral reef systems, and high risks to kelp forests and alpine biodiversity (Figure 11.7). In North America, moderate risks have already been reached for freshwater scarcity, water quality (Figure 14.4), agriculture, forestry, tourism, transport, energy & mining and construction (Figure 14.10).

For this assessment, the transition to moderate risk was assessed to have occurred between 0.7°C and 1.0°C of warming with *high confidence*, demonstrating that a moderate level of risk exists at present. The 0.2°C increase in this temperature range as compared with AR5 reflects the fact that AR6 WGI has assessed that the level of global warming reached by 1986-2005 was 0.52-0.82°C (as opposed to 0.55-0.67°C in previous assessments), and also reflects the opportunity for observations to be have made of the observed consequences of the additional rise in temperature that has taken place since the literature underpinning the AR5 assessment was published.

In AR5, the transition from moderate to high risk was assessed to occur between 1.6°C and 2.6°C above the pre-industrial levels with medium confidence. In SR15, new literature on projected risks allowed this range to be narrowed to 1.5–2°C. There is now substantial literature providing robust evidence of larger regional risks at 2°C warming than 1.5°C and in a range of systems, including crop production (with risks of simultaneous crop failure) (Thiault et al.; Gaupp et al., 2019), aquaculture and fisheries (Cheung et al., 2018b; Froehlich et al., 2018; Stewart-Sinclair et al., 2020), nutrition-related health (Springmann et al., 2016; Lloyd et al., 2018; Sulser et al., 2021), and exposure to stressors such as drought, floods (Alfieri et al., 2017; Hirabayashi et al., 2021) and extreme heat (Dosio et al., 2018; Harrington et al., 2018; Sun et al., 2019). One study (Gaupp et al., 2019) found that the risk of simultaneous crop failure in maize is estimated to increase from 6% to 40% at 1.5 °C relative to the historical baseline climate. In particular, further research on projected regional yield declines of wheat and maize between 1.5ºC and 2ºC, especially in Africa, has accrued Asseng et al. (2015), including in Ethiopia (Abera et al., 2018) with associated economic effects (Wang et al., 2019). Optimum maize production areas in E Asia are projected to reduce in area by 38% for global warming of 1.5–2.0°C (He et al., 2019). A study of Jamaica also estimated that warming of less than 1.5°C will have an overall negative impact on crop suitability and a general reduction in the range of crops, but above 1.5°C, irreversible changes to Jamaica's agriculture sector were projected (Rhiney et al., 2018).

Projections of increasing flood risk associated with global warming of 1.5 and 2°C continue to highlight regional disparities, with larger than average increases projected in Asia and Africa (Hirabayashi et al., 2021), including in China, India and Bangladesh (Alfieri et al., 2017). Similarly, nearly 80% of the 8-80 million additional people projected to be at risk of hunger owing to climate change are located in Africa and Asia (Springmann et al., 2016; Lloyd and Oreskes, 2018; Nelson et al., 2018). Schleussner et al. (2016b) analysed hotspots of multi-sectoral risks with 1.5°C and especially 2°C warming, highlighted projected crop yield reductions in West Africa, South-East Asia, as well as Central and northern South America; a reduction in water availability in the Mediterranean; and widespread bleaching of tropical coral reefs.

High risks to crop production are assessed to occur in Africa ~1.5-2ºC warming (Figure 9.6), to agriculture in North America for ~1.5ºC warming (Figure 14.10), and ~ 2.8ºC Europe (Figure 13.30). High risks of mortality and morbidity due to heat extremes and infectious disease are assessed to be reached in Africa with ~1.5ºC warming (Figure 9.6); heat stress, mortality and morbidity in Europe is assessed to reach a high level of risk at ~2ºC (Figure 13.30). Heat related mortality risk transitions to a high level by ~1.5-2ºC warming in Australasia while cascading effects on cities reach high risk with ~1.2ºC warming (Figure 11.7). Risks to water scarcity, forestry, tourism and transportation in N America are projected to reach high levels with ~2ºC warming (Figure 14.4, Figure 14.10).

Two complementary multi-sectoral analyses indicates that South Asia and Africa become hotspots of multi-sectoral climate change risk, largely due to changes in water related indicators which also affect crop production (Arnell et al., 2018; Byers et al., 2018). For instance, Byers et al. (2018) found that the doubling in global exposure to multi-sector risks that accrues as warming increases from 1.5 to 2°C is concentrated in Asian and African regions (especially East Africa), which together account for 85-95% of the global exposure.
Considering this evidence, for this assessment, the temperature range for the transition from moderate to high risk is located between 1.5°C to 2°C above pre-industrial levels, with *high confidence* in the lower

bound of 1.5°C, but *medium confidence* in the upper bound of 2°C, because simulation studies do not account for climate variability and therefore risks could be higher.

Very high risk implies limited ability to adapt. Adaptation potential not only differs across sectors and regions, but also occurs on different timescales depending on the nature and implementation level of the adaptation option under consideration and the system in which it is to be deployed. The costs of adaptation actions that would be needed to offset projected climate change impacts for major crop production are projected to rise once global warming reaches 1.5 °C (Iizumi et al., 2020). It has been estimated that the number of additional people at risk of hunger with 2.0 °C global warming could be reduced from 40 million to 30 million by raising the level of adaptation action (Baldos and Hertel, 2014) but beyond this level of warming residual impacts are projected to escalate (Iizumi et al., 2020). Chapter 5 assessed the potential of existing farm management practices to reduce yield losses, finding an average 8% loss reduction in mid-century and 11% by end-century (Section 5.4.4.1), which is insufficient to offset the negative impacts from climate change, particularly in currently warmer regions (5.4.3.2). The literature indicates that globally, crop production may be sustained below 2.0 °C warming with adaptation, but negative impacts will prevail at 2.0 °C warming and above in currently warm regions (Section 5.4.4.1). Importantly, residual damage (that which cannot be avoided despite adaptation) is projected to rise around 2.0 °C global warming (Iizumi et al., 2020). Evidence of constraints and limits for food, fiber and other ecosystem products for the different regions is evident for the various regions (16.4.3.1) indicating limited ability to adapt. Adaptation costs are also higher relative to GDP in low-income countries, for example for the building of sea-dikes (Brown et al., 2021).

In previous reports, the transition from high to very high risk for the distribution of impacts was not assessed due to limited available literature, but there is now sufficient evidence to do so. A range of literature quantifies the increasing regional probability of drought as compared to the present day, with projected increases in the area exposed to drought (Carrão et al., 2018; Pokhrel et al., 2021), as well as the duration (Naumann et al., 2018) and frequency of droughts with higher warming levels. Naumann et al. (2018) showed that, for drying areas, drought durations are projected to rise from 2 months/°C below 1.5 °C to 4.2 months/°C near 3°C warming. Most of Africa, Australia, southern Europe, southern and central United States, Central America, the Caribbean, north-west China, and parts of Southern America are projected to experience more frequent droughts. Adverse effects of climate change on food production are projected to become much more severe (Section 5.4.3.2) when global temperatures rise more than 2ºC globally but there are predicted to be much more negative impacts experienced sooner on food security in low- to mid-latitudes (Richardson et al., 2018a) (Sections 5.4.1). For instance, climate change by 2050 is projected to increase the number of people at risk of hunger by between 8 and 80 million with 2–3°C warming compared to no climate change conditions (Baldos and Hertel, 2014; Hasegawa et al., 2018; Nelson et al., 2018; Janssens et al., 2020). In addition to effects upon crop yield, agricultural labour productivity, and food access, and food-related health are projected to be negatively impacted by 2–3°C warming (Springmann et al., 2016; de Lima et al., 2021). Regionally, substantial regional disparity in risks to food production is projected to persist at these higher levels of warming. Risks for heat-related morbidity and mortality, ozone-related mortality, malaria, dengue, Lyme disease, and West Nile fever are projected to increase regionally and globally (Chapter 7) with potential infestation areas for disease-carrying vectors in multiple geographic regions that could be five times higher at 4ºC than at 2ºC (Liu-Helmersson et al., 2019).

Very high risks to crop production are assessed to occur in Africa above ~2.5ºC warming (Figure 9.6) and below 4ºC in Europe (Figure 13.30). Very high risks of mortality and morbidity due to heat extremes and infectious disease are assessed to occur in Africa with 2.5ºC warming (Figure 9.6); heat stress, mortality and morbidity in Europe is assessed to reach a very high level of risk at ~3.2ºC (Figure 13.30). Heat related mortality risk and cascading effects on cities both transitions to a very high level by ~2.5C warming in Australasia (Figure 11.7). Risks to water scarcity in N America are projected to reach very high levels with 3.5C warming (Figure 14.4). Hence this assessment concludes with *medium confidence* that a transition from high to very high risks, in terms of distribution of impacts, begins at 2ºC global warming, with a full transition to very high risks completed by 3.5ºC. However, it should be noted that many studies upon which this assessment has been based have not taken into account the impacts of extreme weather events and oscillations in sea surface temperatures hence risks at a given level of global warming might be underestimated in the literature.

16.6.3.4 Global Aggregate Impacts (RFC4)

This RFC considers impacts to socio-ecological systems that can be aggregated globally into a single metric, such as monetary damages, lives affected, species lost or ecosystem degradation at a global scale (Oppenheimer et al., 2014; O'Neill et al., 2017). RFC4 shares underlying key risk components with other RFCs (e.g., RFC1 and RFC2, see O'Neill et al., 2017) and thus draws on a similar literature as those assessments; however, this RFC focuses on impacts that reach levels of concern at the global level and also weighs the composite effect of risk elements ranging from economic to biodiversity.

In AR5 Section 19.6.3.5 (Oppenheimer et al., 2014), the transition from undetectable to moderate risk was assessed between 1.6 and 2.6ºC above pre-industrial levels (i.e., 1ºC and 2ºC above the 1986-2005 level) based on impacts to both Earth's biodiversity and the overall global economy with *medium confidence*. The risk transition between moderate and high risk was set around 3.6ºC above pre-industrial levels (i.e., 3ºC above the 1986-2005 level), based on literature finding extensive species vulnerability and biodiversity damage with associated loss of ecosystem goods and services at 3.5ºC (Foden et al., 2013; Warren et al., 2013). In SR15 Section 3.5.2.4 (Hoegh-Guldberg et al., 2018b), economic literature on potential socio-economic threshold events as well as empirical studies of global economic damages, combined with new evidence on biome shifts, extinction risk, species range loss (especially noting the integral role of insects in ecosystem function), and ecosystem degradation, were assessed and the upper bound of the transition to moderate risk was lowered to 1.5ºC warming above pre-industrial levels, and the transition from moderate and high risk was lowered to between 1.5ºC and 2.5ºC (*medium confidence*). The boundary between high risk and very high risk was not assessed in either of these reports because the temperature threshold was beyond the scope of the assessment in the case of SR15 and due to the limited literature available for this highest transition in AR5.

Since AR5, many new global estimates of the aggregate, economy-wide risks of climate change have been produced, though, as was the case in AR5, these continue to exhibit a low level of agreement, including for today's level of global warming, due primarily to differences in methods. Cross-Working Group Box ECONOMIC in this chapter includes a more thorough discussion of advancements and limitations of global economic impact estimates and methodologies, finding significant variation in estimates that increases with warming, indicating higher risk in terms of economic costs at higher temperatures (*high confidence*). Climate change has been found to exacerbate poverty through declines in agricultural productivity, changes in agricultural prices and extreme weather events (Hertel and Lobell, 2014; Hallegatte and Rozenberg, 2017). In terms of biodiversity risks, the literature indicates that losses in terrestrial and marine ecosystems increase substantially between 1.5ºC and 2ºC of warming (Hoegh-Guldberg et al., 2018b). Since SR15, further evidence of degradation of biodiversity and ecosystem services and ocean acidification at the global aggregate level has continued to accrue due to climate change (see Chapter 2).

For this RFC, the transition from undetectable to moderate risk to global aggregate impacts is assessed with *medium confidence* to occur between 1.0ºC (start of transition) and 1.5ºC (completion of transition) with a median judgment of transition at 1.3ºC, based on evidence of a combination of economic consequences, widespread impacts to climate-sensitive livelihoods, changes in biomes and loss of terrestrial and marine biodiversity. The start of the transition from undetectable to moderate risk is located at recent temperatures based on observed impacts to biodiversity (16.2.3.1). Experts noted aggregate impacts on biodiversity are detectable, with damages that have had global significance (e.g., drought, pine bark beetles, coral reef ecosystems). Consistent with the start of this transition at 1ºC, a similar elicitation conducted in Chapter 2 assessed that risks to biodiversity globally have already transitioned to a moderate level with 1ºC warming; whilst risks of widespread tree mortality are already moderate with 0.9ºC warming and finds that moderate risks of ecosystem structure change began with warming of 0.5ºC (Table 2.S.4, Figure 2.11). Human-induced warming has slowed growth of agricultural productivity over the past 50 years in mid- and low-latitudes (Chapter 5; Hurlbert et al., 2019). Although there is not yet strong evidence of attributable loss of life and livelihoods at the global level (16.5.2.3.4, 16.5.2.3.5), experts found that regional evidence of such observed impacts were still relevant to defining the beginning of the transition (e.g., Table SM16.22, Chapter 9). Informing the median value and upper bound of the transition to moderate risk, empirical studies and scenario analyses have found that regions with high dependence on climate-sensitive livelihoods like agriculture, fisheries and forestry would be severely impacted even at low levels of warming under conditions of low adaptation (RKR-D, Lobell et al., 2011; Hoegh-Guldberg et al., 2018b).

The transition to high risk is assessed with *medium confidence* to occur between 1.5ºC (start of transition) and 2.5ºC (completion of transition) with a median judgment of transition at 2.0ºC. Though economic estimates exhibit wide variation and low agreement at warming levels above 1.5ºC, many estimates are nonlinear with marginal economic impacts increasing with temperature (see Cross-Working Group Box ECONOMIC in this Chapter). At 1.5ºC warming, most aggregate global impacts to Gross Domestic Product are negative across different estimation methods, including bottom-up estimation (e.g., Takakura et al., 2019), meta-analysis (e.g., Howard and Sterner, 2017) and empirical estimations (e.g., Pretis et al., 2018; Kalkuhl and Wenz, 2020). At 2°C Watts et al. (2021) estimate a relative decrease in effective labour by 10%, which would have profound economic consequences. Byers et al. (2018) found that global exposure to multi-sector risks approximately doubles between 1.5°C and 2°C, whilst the percentage of the global population exposed to flooding is projected to rise by 24% with 1.5°C warming and by 30% with 2.0°C warning (Hirabayashi et al., 2021).

Section 16.5.2.3.4 (RKR-D, underlying key risk on poverty) reports that under medium warming pathways, climate change risks to poverty would become severe if vulnerability is high and adaptation is low (limited evidence, high agreement). At and beyond 1.5ºC, approximately 200 million people with livelihoods derived from small-scale fisheries would face severe risk, given sensitivity to ocean warming, acidification, and coral reef loss (Cheung et al., 2018a; Froehlich et al., 2018; Free et al., 2019). Warming between 1.5 and 2ºC could expose 330–396 million people to lower agricultural yields and associated livelihood impacts (Byers et al., 2018; Hoegh-Guldberg et al., 2018a), due to a high dependency of climate-sensitive livelihoods to agriculture globally (World Bank, 2020). Models project that climate change will increase the number of people at risk of hunger in 2050 by 8-80 million people globally, with the range depending on the level of warming (1.5–2.9ºC) and SSPs (Nelson et al., 2018; Mbow et al., 2019; Janssens et al., 2020). Higher atmospheric concentrations of carbon dioxide reduce the nutritional quality of wheat, rice, and other major crops, potentially affecting millions of people at a doubling of carbon dioxide relative to pre-industrial (*very high confidence*) (Section 7.3.1). Global ocean animal biomass is projected to decrease on average by 5% per 1°C increase, hence a 2.5C level of warming is associated with ~13% decline in ocean animal biomass, which would considerably reduce marine food provisioning, fisheries distribution and revenue value, with further consequences for ecosystem functioning (Chapter 5, *medium confidence*).

Losses in terrestrial and marine biodiversity increase substantially beyond 1.5ºC of warming (Hoegh-Guldberg et al., 2018b). Section 16.5.2.3.2 (RKR-B, risks to terrestrial and marine ecosystems) finds that substantial biodiversity loss globally, abrupt local ecosystem mortality impacts, and ecological species disruption are all projected at global warming levels below 3ºC, with insular systems and biodiversity hotspots at risk below 2ºC (*medium confidence*). Insects play a critical role in providing vital ecosystem services that underpin human systems, with major losses of their climatically determined geographic range at 2°C warming implying adverse effects on ecosystem functioning. Consistent with the transitions presented here, a similar burning ember developed in Chapter 2 assessed a transition from moderate to high risks globally for marine and terrestrial biodiversity (e.g., widespread death of trees, damages to ecosystems, and reduced provision of ecosystem services, and structural change, including biome shifts) beginning between 1.0 and 2.0ºC warming (Table 2.S.4, Figure 2.11).

Though explicit treatment of adaptation is limited in the RFC4 impacts literature (i.e., studies that compare risks for specific adaptation scenarios in terms of globally aggregated impacts with quantified findings), there is evidence of the potential for investments in improved hydro-meteorological information and early warning systems to avoid some of the most adverse social and economic impacts from extreme weather events in both developed and developing countries, with benefits at a globally significant level (Hallegatte, 2012). Studies of adaptation in the agriculture sector (e.g., changing crop variety, timing of crop planting, new types of irrigation, etc.) and infrastructure (e.g., coastal protection, hardening of critical infrastructure, flood and climate resistant building materials and water storage) show large potential benefits in terms of reduced impacts to lives and livelihoods (van Hooff et al., 2015; Mees, 2017). At higher warming levels, however, potential adaptations to address biodiversity loss are expected to be limited due to the projected rate and magnitude of change as well as the resources required (Hannah et al., 2020).

The transition to very high risks is assessed to occur between a range of 2.5–4.5ºC with *medium confidence* over the range, and *low confidence* assessed over a narrowed 'best estimate' range of 2.7–3.7ºC. The lower end of the range reflects the loss of an increasingly large fraction of biodiversity globally. Chapter 2 has assessed a transition from high to very high risks globally for biodiversity (marine and terrestrial) completing at ~2.5ºC warming, noting widespread death of trees, damages to ecosystems, and reduced provision of ecosystem services over the temperature range 2.5ºC–4.5ºC (Table 2.S.4, Figure 2.11); and similarly a transition from high to very high risks of ecosystem structure change (including biome shifts) between 3ºC and 5ºC warming (Table 2.S.4, Figure 2.11). A global study of 115,000 common species projects climatically determined geographic range losses of over 50% in 49% of insects, 44% of plants and 26% of vertebrates with global warming of 3.2ºC, implying an associated effect on provisional and regulating ecosystem services that support human wellbeing, including pollination and detrivory (Warren et al., 2018a). The risk of abrupt impacts on ecosystems as multiple species approach tolerance limits simultaneously is projected to threaten up to 15% of ecological communities with 4ºC of warming (Trisos et al., 2020). Under a 4ºC warming scenario, models project global annual damages associated with sea level rise of $31,000 billion per year in 2100 (Brown et al., 2021)

In terms of global economic impact, while an emerging economic literature is addressing many gaps and critiques of previous damage estimates for high warming (e.g., Jensen and Traeger, 2014; Burke et al., 2015; Lontzek et al., 2015; Moore and Diaz, 2015; Lemoine and Traeger, 2016; Moore et al., 2017a; Cai and Lontzek; Takakura et al., 2019, discussed further in Cross-Working Group Box ECONOMIC; Carleton et al., 2020; Méjean et al., 2020; Rode et al., 2021), there remains wide variation across disparate methodologies, though the spread of estimates increases with warming in all methodologies, indicating higher risk in terms of economic costs at higher temperatures (*high confidence*). Section 16.5.2.3.4 (RKR-D) finds that risks to aggregate economic output would become severe at the global scale at high warming (~4.4ºC) and minimal adaptation (*medium confidence*), defining severity as 'the potential for persistent annual economic losses due to climate change to match or exceed losses during the world's worst historical economic recessions'. Furthermore, climate change impacts on income inequality could compound risks to living standards (*high confidence*, 16.5.2.3.4). Chapter 4 finds that at 4°C, 4 billion people are projected to be exposed to physical water scarcity *(medium confidence)*.

Cross-Working Group Box ECONOMIC: Estimating Global Economic Impacts from Climate Change

Authors: Steven Rose (USA), Delavane Diaz (USA), Tamma Carleton (USA), Laurent Drouet (Italy), Celine Guivarch (France), Aurélie Méjean (France), Franziska Piontek (Germany)

This Cross-Working Group Box assesses literature estimating the potential global aggregate economic costs of climate change and the social cost of carbon (SCC), where the former are sometimes referred to as estimates of global 'climate damages' and the latter are estimates of the potential monetized impacts to society of an additional metric ton of carbon dioxide emitted to the atmosphere. These measures include the economic costs of climate change that could be felt in market sectors such as agriculture, energy services, labour productivity, and coastal resources, as well as non-market impacts such as other types of human health risks (including mortality effects) and ecosystems. Global economic impacts estimates can inform decisions about global climate management strategy, while SCC estimates can inform globally incremental emissions decisions. In practice, economic damage estimates have been used to explore economically efficient ('economically optimal') global emissions pathways (e.g.', Nordhaus and Moffat, 2017), while SCCs have been used to inform federal and state-level policy assessment in some countries (Greenstone et al., 2013; Rose and Bistline, 2016), but the type of SCC and application matter (Rose, 2017). This literature has been assessed in previous WGII reports (e.g.., Arent et al., 2014) and this box serves this need for this report. The assessment in this box was performed jointly across WGII and WGIII, building on the foundation of WGII AR6 Chapter 16's 'Risk to living standards' assessment (Section 16.5.2.3.4), which includes consideration of severe risks to global aggregate economic output, and WGIII AR6 Chapter 3's assessment of the benefits of mitigation. It also informs Chapter 16's global aggregate impacts Reason for Concern and supports Chapter 18's assessment of global emissions transitions, risk management, and climate-resilient development. In keeping with the broad risk framing presented in Chapter 1 of this report, other lines of evidence regarding climate risks, beyond monetary estimates, should be considered in decision-making, including key risks and Reasons for Concern.

Methods for estimating global economic costs of climate impacts

There are several broad approaches to estimating climate damages, including biophysical process models, structural economic models, statistical methods (also called empirical or econometric) and hybrid approaches, with each methodology having strengths and weaknesses. Process models simulate physical, natural science, and/or engineering processes and their response to climate variables, that are then monetized (e.g., Anthoff and Tol, 2014; Sieg et al., 2019; Narita et al., 2020). Process approaches have the advantage of being explicit and interpretable, though they can be computationally intensive; may omit relevant impact channels, interactions, and market dynamics affecting valuation; and, often lack a rigorous empirical basis for calibration (Fisher-Vanden et al.). Structural economic modelling represents climate impacts on inputs, production, household consumption, aggregate investment, and markets for economic sectors and regional economies (e.g., Reilly et al., 2007; Roson and Van der Mensbrugghe, 2012; Anthoff and Tol, 2014; Dellink et al., 2019; Takakura et al., 2019), often using computable general equilibrium (CGE) frameworks. Structural models can evaluate how market and non-market impacts might enter and transmit through economies, and adaptation responses within input and output markets, consumer and investment choices, and inter-regional trade (e.g., Darwin and Tol, 2001; Dellink et al., 2019; Takakura et al., 2019). Statistical methods estimate economic impacts in a given sector (e.g., Auffhammer, 2018) or in aggregate (e.g., Dell et al., 2014; Burke et al., 2015; Hsiang et al., 2017; Pretis et al., 2018; Kahn et al., 2019), inferred from observed changes in economic factors, weather, and climate, with responses and net results constrained by available data. Since AR5, hybrid approaches have taken different forms to integrate process, statistical and/or structural methods, and represent a potentially promising means of leveraging the strengths of different approaches (e.g., Moore and Diaz, 2015; and Hsiang et al., 2017; Moore et al., 2017a; Ricke et al., 2018; Yumashev et al., 2019; Chen et al., 2020b). There is also a small literature that uses expert elicitation to gather subjective assessments of climate risks and potential economic impacts (Nordhaus, 1994; IPCC, 2019a; Pindyck, 2019).

In addition to differences in methods, there are also differences in scope – geographic, sectoral, and temporal. Global estimates are frequently based on an aggregation of independent sector and/or regional modelling and estimates; however, there are examples of estimates from global modelling that simulate multiple types of climate impacts and their potential interactions within a single, coherent framework (e.g., Roson and Van der Mensbrugghe, 2012; Dellink et al., 2019; Takakura et al., 2019). Differences in scope also represent strengths and weaknesses between the methodologies, with narrower scope allowing for more detailed assessment, but missing potential interactions with the scope not covered (e.g., other geographic areas, sectors, markets, or periods of time).

Comprehensive economic estimates are challenging to produce for many reasons, including complex interactions among physical, natural, and social systems; pervasive climate, socio-economic, and system response uncertainties; and the heterogeneous nature of climate impacts that vary across space and time. Critiques and commentaries of global estimation methods (Pindyck, 2013; Stern, 2013; van den Bergh and Botzen, 2015; Cropper et al., 2017; Diaz and Moore, 2017; Pindyck, 2017; Rose et al., 2017; Stoerk et al., 2018; DeFries et al., 2019; Pezzey, 2019; Calel et al., 2020; Warner et al., 2020; EPRI, 2021; Grubb et al., 2021; Newell et al., 2021) include, among other things, concerns about statistical methods estimating weather but not climate relationships, making out-of-sample extrapolations, and model specification uncertainty, concerns about the observational grounding of structural modelling, overall concerns about the lack of adaptation consideration, as well as representation and evaluation of potential large-scale singular events such as ice sheet destabilisation or biodiversity destruction, some questioning the ability to generate robust estimates (i.e., estimates insensitive to reasonable alternative inputs and specifications), and general concerns about methodological details, transparency, and justification.

Additional methodological challenges to address (see, for instance, EPRI, 2021; Piontek et al., 2021) include how to capture and represent uncertainty and variability in potential damage responses for a given climate and societal condition, combine estimates from different methods and sources (including aggregating independent sectoral and regional results), assess sensitivity and evaluate robustness of estimates (including sensitivity to model specification), capture interactions and spillovers between regions and sectors, estimate societal welfare implications (versus GDP changes) of market and non-market impacts, consider distributional effects, represent micro and macro adaptation processes (and adaptation costs), specify nongradual damages and non-linearities, and improve understanding of potential long-run economic growth effects. Note that, the treatment of time preference, risk aversion, and equity considerations have important welfare implications for the aggregation of both potential economic impacts and climate change mitigation costs.

In addition to updated and new methods and estimates, newer literature has explored nongradual damages, such as climatic and socioeconomic tipping points (Lontzek et al., 2015; Méjean et al., 2020), potential damage to economic growth (e.g., Burke et al., 2015; Moore and Diaz, 2015), valuing uncertainty in potential damages (Jensen and Traeger, 2014; Lemoine and Traeger, 2016; Cai and Lontzek), and representing adaptation (Takakura et al., 2019; Carleton et al., 2020; Rode et al., 2021). Going forward, to help advance science and decisions, a key research priority is to understand and evaluate methodological strengths and weaknesses in damage estimation, and reconcile the differences affecting comparability in such a way that it informs use of the different lines of evidence. This will require greater transparency and assessment of details and assumptions in individual methods, communication and evaluation of alternatives for specifying or calibrating climate damage functional representations with respect to climate and non-climate drivers and potential non-linearities, including evaluating data sufficiency for levels within and beyond observations and for characterizing physical system dynamics, and evaluating the sensitivity of results to model specification and input parameter choices (Cropper et al., 2017). Improving the robustness of economic impact estimates is an active area of research. Below we describe the latest estimates.

Global estimates of the economic costs of climate impacts

Since AR5, many new estimates of the global economic costs of climate change have been produced. Figure Cross-Working Group Box ECONOMIC.1 shows a wide spread of estimates, with growing variance at higher levels of warming, both within and across methodology types (i.e., statistical, structural, or meta-analysis). Meta-analysis is used here to refer to studies that treat other studies' estimates as data points in an attempt to derive a synthesized functional form.

Global aggregate economic impact estimates (Figure Cross-Working Group Box ECONOMIC.1) are generally found to increase with global average temperature change, as well as vary by other drivers, such as income and population and the composition of the economy. Most estimates are nonlinear with higher marginal economic impacts at higher temperature, although some recover declining marginal economic impacts and functional forms cannot be determined for all studies. The drivers of non-linearity found in economic impact estimates, and the differences in non-linearity across estimates (e.g., convex versus concave, degree of curvature), are not well understood, with methodology construction, assumptions, and data all potential factors. Relative to AR5, there have been more estimates and greater variation in estimates, including some recent estimates significantly higher than the range reported in AR5. For most of the studies shown in Figure Cross-Working Group Box ECONOMIC.1, the visible variation within a study represents alternative socioeconomic projections and climate modelling, not economic impacts response uncertainty for a given socioeconomic and climate condition. Response uncertainty could be significant as indicated by some of the results shown in the figure (e.g., Burke et al., 2015; Rose et al., 2017), but methodological differences in how uncertainty is characterized (model specification, errors, and confidence intervals versus distributions of results) limits comparability and assessment. Note that modeling factors between global temperature change and the economic impact calculation, such as regional temperature pattern assumptions or assumed sea level rise dynamics, can also impact calculated estimates (e.g., Warren et al, 2021 PAGE09 estimates versus those in Rose et al, 2017, Chen et al, 2020 PAGE-ICE estimates versus Burke et al, 2015).

From Figure Cross-Working Group Box ECONOMIC.1, we find a large span of damage estimates, even without considering uncertainty/confidence in damage responses, including for today's level of warming (about 1˚C). There is also evidence that some regions benefit from low levels of warming, leading to net benefits globally at these temperatures. The size of the span of estimates grows with global warming level, with variation across statistical estimates larger than variation in structural estimates. The structural and meta analyses estimates appear to be in closer agreement, but that outcome is contingent on the meta analyses data considerations and approach. Meta analyses to date have not assessed the alternative methods and dealt with the lack of comparability between methods.

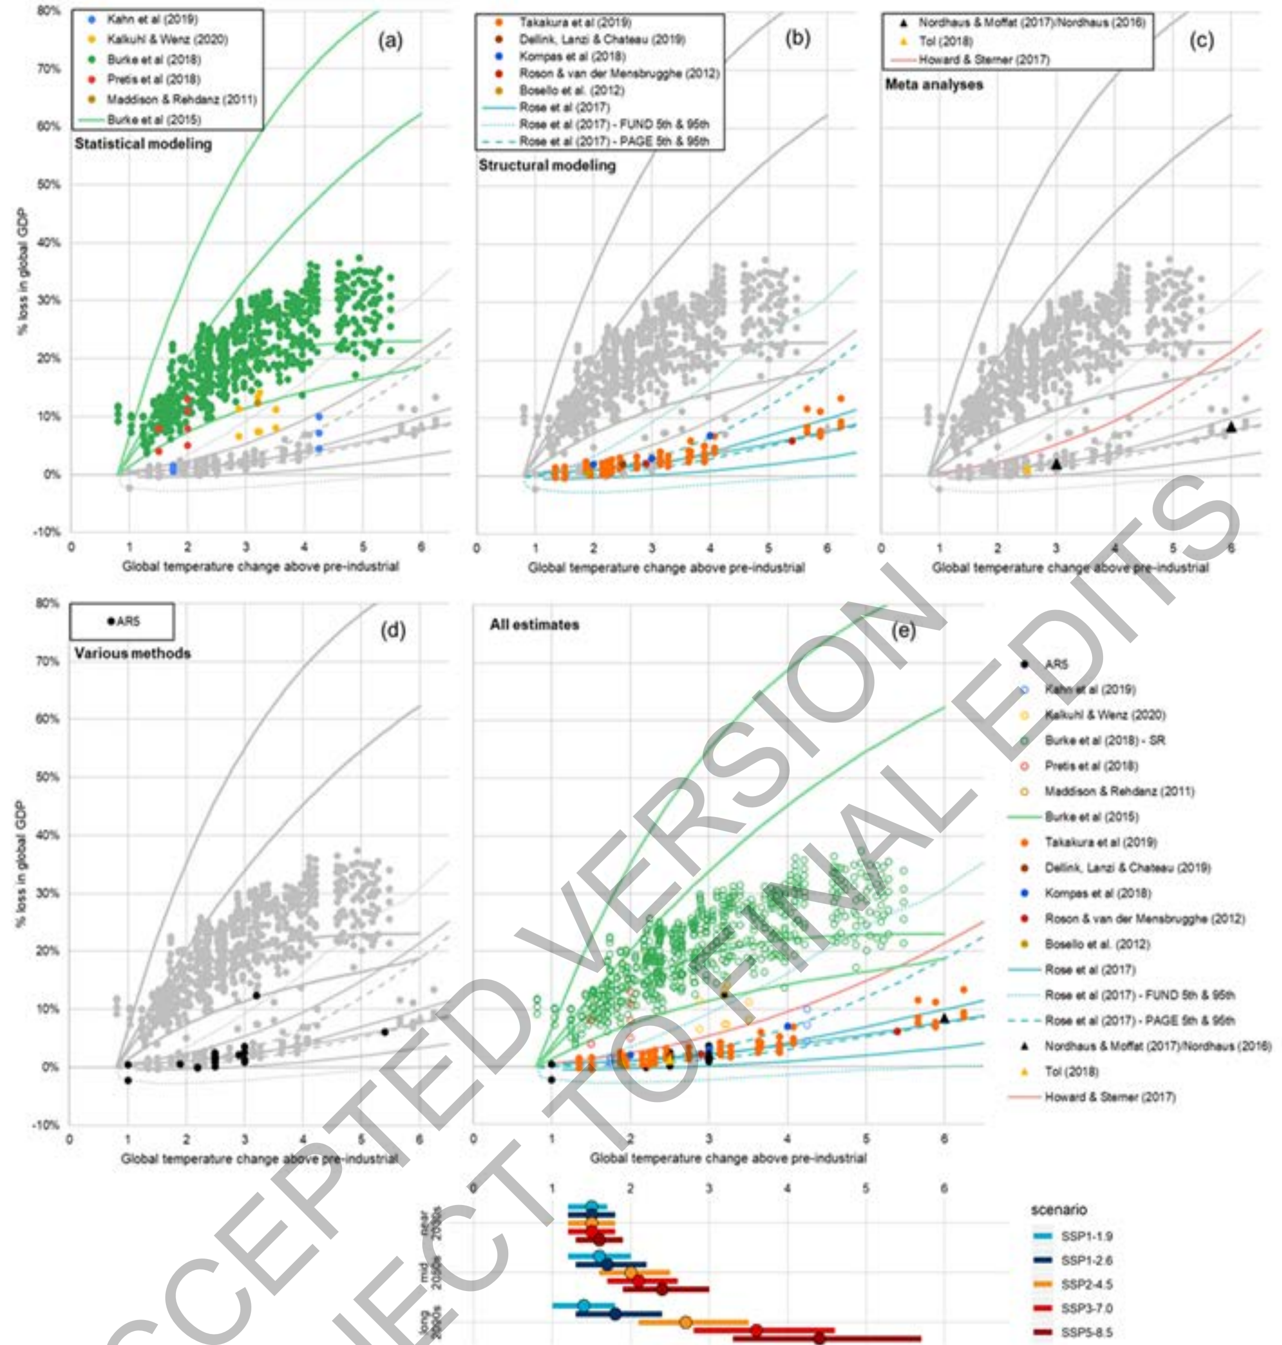

Figure Cross-Working Group Box ECONOMIC.1: Global aggregate economic impact estimates by global warming level (annual % global GDP loss relative to GDP without additional climate change). Top row panels present estimates by methodology type: (a) statistical modeling, (b) structural modeling, and (c) meta analyses, with all estimates from a paper in the same colour and estimates from methodologies other than that highlighted by the panel in grey for reference. Second row left panel (d) presents AR5 estimates. Second row right panel (e) presents all estimates in one figure, with the same colors as panels (a-d) using outlined dots for the statistical modelling estimates, solid dots for structural modelling estimates, and triangles for meta analysis estimates. In all panels, lines represent functions, with dashed and dotted lines 5th and 95th percentile functions from structural modelling. To avoid duplication, estimates from papers using the economic impacts estimates or model formulations already represented in the figure are not included (e.g., Diaz and Moore, 2017; Chen et al., 2020b; Glanemann et al., 2020; Warren et al., 2021). The exception is Burke et al. (2018), with the different estimates shown representing variation across climate scenarios for a given aggregate economic impacts specification from Burke et al. (2015) – the 'pooled, short run' statistical specification. Results shown for the latter are estimates with the author's different statistical model specifications (and a fixed climate scenario, SSP5). From top to bottom, the Burke et al. (2015) estimates are for the 'pooled, long run,' 'differentiated, long run,' 'pooled, short run' (authors' base case), and 'differentiated, short run' statistical specifications. For Howard and Sterner (2017), the authors' preferred function is shown. Overall, estimates shown in the figure can correspond to different future years, reflecting different socioeconomic conditions and climate pathways to a global warming level. Global average temperature change bars relative to the period 1850-1900 are shown below the economic cost estimates to provide context to potential future warming. Shown are the WGI AR6 assessed best estimates and 90% intervals for the illustrative emissions scenarios considered for the near term 2021-2040, mid-term 2041-2060, and long term 2081–2100.

Differences in methodology type and scope complicate comparison, assessment, and synthesis (Cropper et al., 2017; Diaz and Moore, 2017; EPRI, 2021; Piontek et al., 2021). In particular, structural economic modelling and empirical aggregate output modelling are fundamentally different, which has been identified as an issue affecting the comparability of results (Cropper et al., 2017). The different methodologies affect outcomes, with global aggregate estimates based on statistical methodologies typically higher than those from structural modelling (Figure Cross-Working Group Box ECONOMIC.1). This is, in part, due to the relationships in observational data captured by statistical modelling, assumed persistence of impacts in statistical modelling, broader adaptation responses in structural modelling, and differences in the representation of future societies and how they might evolve, respond, and interact. Within statistical modelling, results are also found to be very sensitive to the statistical model specification (e.g., Burke et al., 2015; Newell et al., 2021). Within structural modelling, differences in representations of biophysical changes and economic structural dynamics contribute to differences across structural estimates (e.g., Rose et al., 2017).

The wide range of estimates, and the lack of comparability between methodologies, does not allow for identification of a robust range of estimates with confidence (high confidence). Evaluating and reconciling differences in methodologies is a research priority for facilitating use of the different lines of evidence (high confidence). However, the existence of higher estimates than AR5 indicate that global aggregate economic impacts could be higher than previously estimated (low confidence due to the lack of comparability across methodologies and robustness of estimates).

While Figure Cross-Working Group Box ECONOMIC.1 summarizes global aggregate estimates, the literature exhibits significant heterogeneity in regional economic impacts that are also sensitive to methodology, model specification, and societal assumptions (with, for instance, larger estimates due to the assumed size of society, but offsetting adaptive capacity improvements and adaptation responses). Regional results illustrate the potential for overall net benefits in more temperate regions at lower levels of warming with potential lower energy demand and comparative advantages in agricultural markets; however, at higher levels of warming net losses are estimated. In addition, economic impacts for poorer households and poorer countries represent a smaller share in aggregate quantifications expressed in GDP terms than their influence on well-being or welfare (Byers et al., 2018; Hallegatte et al., 2020).

Social cost of carbon methods and estimates

The global economic impact estimates discussed in the previous section serve as a key input into the calculation of the value of potential net damages caused by a marginal ton of carbon dioxide emissions, or the SCC. To compute an SCC, damage estimates are commonly combined in a multi-century modelling framework with socioeconomic and emissions projections, a physical model of the climate, including a sea-level rise component, and assumptions about the discount rate, with current frameworks having highly stylized representations of these components. Though we do not present quantitative estimates here, due to the challenge of comparability, for economic impacts methodologies (as discussed above) as well as other SCC estimation elements, large variations in SCC estimates are found in the literature assessed due to, among other things, differences in modelling component representations, input and parameter assumptions, considerations of uncertainty, and discounting, inflation, and emissions year (e.g., Tol, 2009; Tol, 2018; Pezzey, 2019; Iese et al., 2021). There are also different 'variants' of SCC estimates that differ conceptually, and in magnitude, depending on the reference condition for evaluating the impact of a marginal metric ton--is it being evaluated relative to a no-climate-policy baseline, an economically efficient pathway that weighs the benefits and costs of emissions mitigation, or a pathway based on a particular climate policy or goal such as 2°C or a concentration target (Rose et al., 2017)? The variant of SCC has implications for its applicability to different policy contexts (Rose and Bistline, 2016).

In addition to the economic impacts methodological challenges discussed above with respect to aggregate economic impact estimates, the additional components needed for SCC calculations give rise to a new set of technical issues and critiques, including incorporation of uncertainties in the components beyond climate damages, links between components, and discounting (van den Bergh and Botzen, 2015; Cropper et al., 2017; Diaz and Moore, 2017; Pindyck, 2017; Rose et al., 2017; EPRI, 2021). For component-specific discussions and assessment, see Cropper et al. (2017), Rose et al. (2017), and EPRI (2021).

Substantial progress has been made in recent years to better reflect complexities in the global economy, the climate system, and their interaction. For example, recent studies have explored damages to natural capital (Bastien-Olvera and Moore, 2021), the influence of imperfect substitutability between environmental services and market goods (Sterner and Persson, 2008; Weitzman, 2012; Drupp and Hänsel, 2021), the implications of heterogeneous climate change impacts across income groups (Dennig et al., 2015; EPRI, 2021; Errickson et al., 2021), the potential for persistent climate impacts to economic growth instead of effects on levels of economic output (Dietz and Stern, 2015; Moore and Diaz, 2015; Ricke et al., 2018; Kikstra et al., 2021; Newell et al., 2021), valuing the risks of climate tipping points (Cai and Lontzek, 2019; Rising et al., 2020), valuing uncertainty under risk aversion (Jensen and Traeger, 2014; Lemoine and Traeger, 2016), and modelling a distinction between intertemporal inequality aversion and risk aversion in the social welfare utility function (Crost and Traeger, 2013; Jensen and Traeger, 2014; Daniel et al., 2015). These new studies have, in general, raised estimates of the SCC (Crost and Traeger, 2013; Jensen and Traeger, 2014; Gerlagh and Michielsen, 2015; Moore and Diaz, 2015; Faulwasser et al., 2018; Guivarch and Pottier, 2018; Budolfson et al., 2019; Cai and Lontzek, 2019; Dietz and Venmans, 2019; Kalkuhl and Wenz, 2020), in some cases by an order of magnitude (Ricke et al., 2018). However, challenges persist in terms of moving from conceptual to practical application, such as pinning down parameter specifications, modelling specific mechanisms for impacts, and more fully representing adaptation.

Despite these scientific advances, SCC estimates vary widely in the literature. Technical issues with past and current modelling (e.g.', Pezzey, 2019; Pindyck, 2019; EPRI, 2021) and the challenge of comparability across methodologies imply that many estimates are not robust (*high confidence*). Also, as a result, the issue of directional bias of past estimates remains unsettled. Better representation of uncertainty in methods can improve robustness, while detailed methodology assessment and comparison will help define the relative biases of methods (*high confidence*).

Application to decision-making

The literature has also assessed the application of aggregate economic impact cost and SCC estimates (Rose and Bistline, 2016; Rose et al., 2017; Kaufman et al., 2020) and identified conceptual and technical issues that need to be considered when using results to inform policy decisions. These issues include: accounting for endogenous marginal benefits and socioeconomic conditions in evaluating policies with non-incremental global emissions implications; consistency in assumptions and treatment of uncertainty across benefit and cost calculations; fully accounting for the streams of both mitigation costs and benefits over time; avoiding inefficiently valuing or pricing emissions more than once across policies and jurisdictions; and accounting for emissions leakage to capture net climate implications. Furthermore, concerns about the robustness of estimates have led some to recommend considering alternatives, such as using marginal mitigation cost estimates based on modelling of policy goals instead of the SCC (e.g., Rose, 2012; Pezzey, 2019; Kaufman et al., 2020), although this comes with its own set of assumptions and technical challenges.

[END CROSS-WORKING GROUP BOX ECONOMIC HERE]

16.6.3.5 Large-scale Singular Events (RFC5)

This RFC, large-scale singular events (sometimes called tipping points or critical thresholds), considers abrupt, drastic, and sometimes irreversible changes in physical, ecological, or social systems in response to smooth variations in driving forces (accompanied by natural variability) (Oppenheimer et al., 2014; O'Neill et al., 2017). SR15 Section 3.5.2.5 presented four examples, including the cryosphere (West Antarctic ice sheet, Greenland ice sheet), thermohaline circulation (slowdown of the Atlantic Meridional Overturning

Circulation), the El Niño–Southern Oscillation (ENSO) as a global mode of climate variability, and the role of the Southern Ocean in the global carbon cycle (Hoegh-Guldberg et al., 2018b). Whilst most of the literature assessed here focuses on the resultant changes to climate-related hazards such as sea level rise, in this assessment evidence about the implications of accelerated sea level rise for human and natural systems is also considered. If sea level rise is accelerated by ice sheet melt, the associated impacts are projected to occur decades earlier than otherwise, directly affecting coastal systems including cities and settlements by the sea (CCP2) and wetlands (Chapter 2). The associated disruption to ports is projected to severely compromise global supply chains and maritime trade with local-global geo-political and economic consequences. In order to compensate for this acceleration, adaptation would need to occur much faster and at a much greater scale than otherwise, or indeed than has previously been observed (CCP2). The costs of accommodating port growth and adapting to sea level rise amount to USD22-768 billion before 2050 globally (medium evidence, high agreement) (see Section 2.1; Section 2.2; Cross-Chapter Box SLR in Chapter 3).

In AR5 Section 19.6.3.6 (Oppenheimer et al., 2014), the boundary between undetectable and moderate risk is set at levels between 0.6 and 1.6ºC above pre-industrial levels (i.e., 0ºC and 1ºC above the 1986-2005 level) with high confidence, based on emerging early warning signals of regime shifts in Arctic and warm water coral reef systems. The risk transition boundary between moderate and high risk was set between 1.6 and 3.6ºC above pre-industrial levels (i.e., 1ºC and 3ºC above the 1986-2005 level), with medium confidence based on projections of ice sheet loss, with faster increase between 1ºC and 2ºC than between 2ºC and 3ºC. The literature available at the time did not allow AR5 to assess the boundary between high and very high risk.

In SR15 Section 3.5.2.5 (Hoegh-Guldberg et al., 2018b), new assessments of the potential collapse of the West Antarctic ice sheet (WAIS) initiated by marine ice sheet instability (MISI) resulted in lowering the upper end of the transition from undetectable and moderate risk from 1.6ºC to 1ºC warming above pre-industrial levels, and lowering the upper end of the transition from moderate to high risk to 2.5ºC. Although SR15 did not produce embers beyond 2.5ºC, authors reported that the transition to very high risk was assessed at lying above 5ºC in light of growing literature on ice sheet contributions to sea level rise.

AR6 provides new evidence that relates to the location of the transition from undetectable to moderate risk. At the time of SR15, observations were suggesting that MISI might already be taking place in some parts of the WAIS while AR5 supported assessment of an additional MISI contribution to sea-level rise of several additional tenths of a metre over the next two centuries. Since SR15, new observations (WGI AR6 Section 9.4.2.1, Fox-Kemper et al., 2021) support the assessment of enhanced grounding line retreat and subsequent mass loss through basal melt in various parts of Antarctica, and year 2100 sea-level projections for the RCP8.5 scenario have increased by 10-12 cm owing to ice dynamics. However, the onset of MISI is driven by ocean warming in specific locations (ice cavities beneath floating ice shelves) and the relation between these ocean temperatures and global mean temperature is indirect and ambiguous. In addition, MISI implies a self-sustaining instability in the absence of further forcing. Because forcing is still increasing, it cannot be unambiguously assessed whether MISI is driving the observed retreat of grounding lines in the WAIS, or whether this retreat is a purely forced response (and would stop if the warming stops), or is just a manifestation of natural variability in upwelling of warmer waters on the Antarctic continental shelves and, as a result is just a temporary effect. Consistent with SROCC, AR6 states with *medium confidence* that sustained mass losses of several major glaciers in the Amundsen Sea Embayment (ASE) are compatible with the onset of MISI, but that whether unstable WAIS retreat already has begun or is imminent remains a critical uncertainty.

Whether associated with MISI or not, WGI AR6 (Fox-Kemper et al., 2021) now assesses with *very high confidence* that mass loss from both the Antarctic (whether associated with MISI or not) and Greenland Ice Sheets, is more than seven times higher over the period 2010-2016 than over the period 1992-1999 for Greenland and four times higher for the same time-intervals for Antarctica. Given their multi-century commitments to global sea level rise this reinforces the assessment of estimating the boundary between undetectable and moderate risks for ice sheets to lie between 0.7ºC (the level of global warming in the 1990s when melting began to accelerate) and 1ºC (as in SR15), with a median at 0.9ºC.

In the Amazon forest, increases in tree mortality and a decline in the carbon sink are already reported (Brienen et al., 2015; Hubau et al., 2020) and old-growth Amazon rainforest may have become a net carbon source for the period 2010-2019 (Qin et al., 2021). Estimates which include land-use emissions indicate the region may have become a net carbon source (Gatti et al., 2021). Fire activity is an important driver and both bigger fires (Lizundia-Loiola et al., 2020) and longer fire season (Jolly et al., 2015) have been reported in South America, although this is strongly linked to land-use and land-use change as well as climate (Kelley et al., 2021), and indeed land use change may be a stronger driver of potential loss of the Amazon forest than climate change. The risk of climate-change related loss of the Amazon forest is assessed already above 'undetectable' – but has only emerged over the last few years, when global warming had reached 1ºC, and is linked to land-use as well as GSAT levels. Chapter 2 has assessed ecosystem carbon loss from tipping points in tropical forest and loss of Arctic permafrost, and finds a transition to moderate risk over the range 0.6 to 0.9C (*medium confidence*). Specifically, WGII AR6 Table 2.S.4 finds that 'Primary tropical forest comprised a net source of carbon to the atmosphere, 2001-2019 (emissions 0.6 Gt y^{-1}, net 0.1 Gt y^{-1}) (Harris et al., 2021). Anthropogenic climate change has thawed Arctic permafrost (Guo et al., 2020), carbon emissions 1.7 ± 0.8 Gt y^{-1}, 2003-2017 (Natali et al., 2019)'. This also supports the upper limit for this transition lying at 1ºC.

The potential global loss of an entire ecosystem type, coral reefs, is also considered a large-scale singular event. In the 1990's when global warming was around 0.7ºC large scale coral reef bleaching also became apparent (16.2.3.1), also supporting the lower boundary for this transition in respect of coral reefs.

Overall, given the above evidence on ice sheets, Amazon forest, and coral reefs, the transition from undetectable to moderate risk is therefore assessed to occur between 0.7ºC and 1ºC warming with a median of 0.9ºC with *high confidence*.

The transition from moderate to high risk is informed by an assessment of risks at higher levels of warming than present. Nearly all climate models do show warmer temperatures around Antarctica in conjunction with rising global mean temperature and all ice sheet models do show sustained mass loss from the WAIS after temperature increase halts (thus implying MISI takes place) at various levels between 1.5ºC and 5ºC, and an increasing fraction of ice sheet models shows additional sustained mass loss from the East Antarctic Ice Sheet (EAIS) for peak warming between 2ºC and 4ºC, and all ice sheet models show mass loss for peak warming higher than 4ºC. Therefore, we assess an increasing link between MISI, WAIS collapse and Antarctic mass loss, for increasing temperature levels *(high confidence)*.

There is *high confidence* in the existence of threshold behaviour of the Greenland Ice Sheet in a warmer climate (WGI AR6 Ch 9, Fox-Kemper et al., 2021), however there is low agreement on the nature of the thresholds and the associated tipping points. Similarly the likelihood for accelerated and irreversible mass loss from Antarctica increases with increasing temperatures but thresholds cannot yet be unambiguously identified. By the year 2100, sea-level projections (AR6 WG1 SPM Fig SPM 8) now range from 0.57 m (0.37-0.85) for the SSP1-1.9 scenario to 1.35 m (1.02-1.89) for the SS5-8.5 scenario and become 1.99 m for the latter scenario (1.02-4.83) in case of low-likelihood, high-impact outcomes resulting from ice sheet instability, for which there is *limited evidence*. It should be noted that inclusion of such low-likelihood, high-impact outcomes dominated by not-well understood processes affecting ice dynamics on the large icecaps of Greenland, and in particular Antarctica, would also enhance the sea-level projections for other scenarios, but to a lesser extent for increasingly weaker forcing. No quantitative assessment of their effect in other scenarios than SSP5-8.5 yet exists as such simulations with ice-sheet models have not been carried out, or only in a very limited amount.

It should be noted that ice sheets may take many centuries to respond, implying that risk levels increase over time for the same warming level. Therefore we base judgments about risk transitions related to ice sheets primarily on their implications for 2000-year commitments to sea level rise from sustained mass loss from both ice sheets as projected by various ice sheet models, reaching 2.3-3.1 m at 1.5°C peak warming and 2-6 m at 2.0°C peak warming (WGI AR6 TS, Box TS.4 Figure 1, (Arias et al., 2021)). This is an important feature of the approach to this RFC (i.e., it is not primarily focused on implications for the next 100-200 years). In addition, since the AR5, there is new evidence about the Last Interglacial (LIG), when global mean temperature was about 0.5-1.5°C above the pre-industrial era. AR6 assesses that it is *virtually certain* that sea-level was higher than today at that time, *likely* by 5–10 m (*medium confidence*) (B.5.4 WGI AR6

SPM,(IPCC, 2021a)). Mid-Pliocene temperatures of 2.5°C (about 3 million years ago when global temperatures were 2.5°C–4°C higher) also provide evidence as an upper limit for the transition to high risk associated with long-term equilibrium sea-level rise of 5-25 m (WGI AR6 SPM B.5.4). In 2300 projected sea-level rise in an RCP8.5 or SSP5-8.5 scenario (consistent with a peak warming range of 4ºC-6ºC, varies between 1.7-6.8 and 2.2-5.9m respectively (WGI AR6 TS Box TS.4, Arias et al., 2021)), and when accounting for Marine Ice Cliff Instability taking place on Antarctica these numbers may increase to a range of 9.5-16.2 m (WGI AR6 TS Box TS.4, Arias et al., 2021)).

CMIP6 climate models project drying in the Amazon – especially in June-July-August, irrespective of future forcing scenario, but which increases with GSAT/higher scenarios (Lee et al., 2021). For higher GSAT levels Burton et al. (2021) explore different forcing scenarios and found, regardless of scenario, burned area increases markedly with GSAT. New understanding of the role of vegetation stomata will act to exacerbate this drying (Richardson et al., 2018b). A transition to high risk of savannization for the Amazon alone was assessed to lie between 1.5 and 3ºC with a median value at 2.0ºC. A mean temperature increase of 2ºC could reduce Arctic permafrost area ~15% by 2100 (Comyn-Platt et al., 2018). Chapter 2 has assessed ecosystem carbon loss from tipping points in tropical forest and loss of Arctic permafrost, and finds a transition from moderate to high risk over the range 1.5 to 3ºC with a median of 2ºC (*medium confidence,* Table 2.S.4, Figure 2.11). Its assessment of the transition from high to very high risk is located over the range 3ºC - 5ºC (*low confidence,* Table 2.S.4, Figure 2.11) based on the potential for Amazon forest dieback between 4-5ºC temperature increase above the pre-industrial period (Salazar and Nobre, 2010).

One of the criteria for locating a transition to very high risk is a limited ability to adapt. In natural systems limiting warming to 1.5°C rather than 2°C would enhance the ability of coastal wetlands to adapt naturally to sea level rise, since natural sedimentation rates more likely keep up with sea level rise (SR15, Hoegh-Guldberg 2018). In human systems, there is *medium confidence* that technical limits will be reached for hard protection to SLR beyond 2100 under high emissions scenarios, with limits associated with socio-economic and governance issues reached before 2100 (CCP2).

We therefore estimate the boundary between moderate and high risk to lie between 1.5ºC and 2.5ºC, with a median at 2.0ºC, with *medium confidence* based on projections for melting ice sheets and drying in the Amazon. We also estimate the boundary between high and very high risk to lie between 2.5ºC and 4ºC, but with *low confidence* due to uncertainties in the projections of sea level rise at higher levels of warming and differences between levels of warming at which very high risks were assessed in different systems.

16.6.4 Summary

The updated Reasons for Concern (RFC) show that transitions between levels of risk are now assessed to occur at lower levels of global warming than in previous assessments *(high confidence*), levels of confidence in assigning transitions have generally increased, evidence on the potential for adaptation to adequately address risks at different warming levels remains limited, and transitions from high to very high levels of risk have been assessed for all five RFCs, compared to just two RFCs in AR5, together showing how literature published since AR5 is informing us on our future climate risks.

- In particular, risks to unique and threatened systems (RFC1) are now assessed to be already at a high level today, as compared with a moderate level in previous assessments, and transition to a very high level is assessed to occur beginning at 1.2ºC, passing through a median value of 1.5°C, and completing the transition at 2.0ºC warming (*high confidence)*.

- Risks associated with extreme weather events (RFC2) are assessed to have begun to transition to a high level already when global warming reached 1ºC, with that transition projected to complete for a warming of 1.5ºC *(high confidence)*. Newly in AR6, a transition between high and very high levels of risk was assessed to lie at 2.0ºC warming for RFC2 (range 1.8- 2.5ºC).

- For risks associated with the distribution of impacts (RFC3), there is now *high confidence* that a transition to moderate risk has already occurred, and the transition to high risk is now projected to occur between 1.5–2.0ºC warming with *medium confidence*. Furthermore, a transition from high to very high risk is provided for the first time in this AR6 assessment, between 2.0–3.5ºC warming (*medium confidence*).

- Global aggregate impacts (RFC4) are assessed to have begun to transition to a moderate level already when global warming reached 1ºC, and are projected to transition to a high level with warming of 1.5 - 2.5ºC (median 2ºC) with *medium confidence.* An assessment of a transition to very high risk is provided for the first time in AR6, over the range 2.5 to 4.5ºC with *low confidence*.

- Risks associated with large-scale singular events are assessed to have already completed transitioning to moderate with 1ºC warming (*high confidence*), with a transition to high risk between 1.5–2.5ºC [median 2ºC] (*medium confidence*). An assessment of a transition to very high risk is provided for the first time in AR6, over the range 2.5–4.5ºC with *low confidence*.

In summary, risks to unique and threatened systems (RFC1) are higher at recent and projected levels of warming than assessed previously (*very high confidence)*; risks associated with extreme weather events (RFC2) are assessed comparably to AR5 and SR15 at recent and low levels of warming, but notably much higher at projected warming above 1.8°C (*medium confidence)*; risks associated with distribution of impacts (RFC3) and global aggregate impacts (RFC4) are similar to SR15 and higher than AR5 above 2°C (*medium confidence)*; and those associated with large-scale singular events (RFC5) are similar to SR15 and higher at both recent and projected warming than AR5 (*medium confidence)*.

Limiting global warming to 1.5ºC would ensure risk levels remain moderate for RFC3, RFC4 and RFC5 (*medium confidence*) but risk for RFC2 would have transitioned to a high risk at 1.5ºC and RFC1 would be well into the transition to very high risk (*high confidence*). Remaining below 2ºC warming (but above 1.5ºC) would imply that risk for RFC3 through 5 would be transitioning to high, and risk for RFC1 and RFC2 would be transitioning to very high (*high confidence*). By 2.5ºC warming, RFC1 will be in very high risk (*high confidence*) and all other RFCs will have begun their transitions to very high risk (*medium confidence* for RFC2 and RFC3, *low confidence* for RFC4 and RFC5*)*. These highest levels of risk are associated with an irreversible component, such that some impacts would persist even were global temperatures to subsequently decline in an 'overshooting' scenario.

Lack of evidence on the potential for adaptation to adequately reduce risk is a critical gap in our ability to assess global risk transitions at the RFC level, but not only. In some cases, such as RFC1, the widespread nature and rapid speed of the escalating risks, in combination with limited ability to adapt means that transitions to high risk may occur despite medium or even high levels of adaptation. Risks that are largely natural and not widely mediated by human vulnerability, are thus less likely to have risk transitions that shift under higher societal adaptation. Risk transitions that are mediated through human systems, such as distribution impacts, for example, are more likely to shift in response to adaptation as impacts are strongly mediated through vulnerability within human systems, but such a shift is difficult to quantify given knowledge gaps in the literature (Section 16.3). However, in some circumstances, expanded global adaptation could slow some of these transitions *(low confidence)*; in the case of RFC2, RFC3 and RFC4, the literature suggests that coordinated global adaptation could increase the global temperature at which risks transition from moderate to high, for example the prevention of mortality associated with heat stress within RFC2.

A higher level of adaptation, applied globally and effectively, could have larger benefits for several RFC, either postponing the onset of a high level of risk until a higher level of warming is reached (and allowing time for mitigation efforts) or allowing a system to survive a temporary overshoot of a lower temperature threshold. Adaptations are likely to have significant potential to reduce risks (Magnan et al., 2021) in particular for risks mediated through human systems. However, there is limited evidence available to assess the extent to which current or potential adaptations are or would be adequate in reducing climate risks at different levels of warming, and adaptation implications for risk transitions will be highly localized. Pathways and opportunities for risk management and adaptation actions with transformational potential are discussed in Chapter 17, together with enabling factors, governance frameworks, financing, success factors, and monitoring and evaluation discussed in Chapter 18, supporting sustainable system transitions and leading to options for climate resilient development pathways.

[START FAQ16.1 HERE]

FAQ16.1: What are key risks in relation to climate change?

A few clusters of key risks can be identified which have the potential to become particularly severe and pose significant challenges for adaptation worldwide. These risks, therefore, deserve special attention. They include risks to important resources such as food and water, risks to critical infrastructures, economies, health and peace, as well as risks to threatened ecosystems and coastal areas.

The IPCC defines key risks related to climate change as potentially severe risks that are relevant to the primary goal of the United Nations Framework Convention on Climate Change treaty to avoid 'dangerous human interference with the climate system', and whatever the scale considered (global to local). What constitutes 'dangerous' or 'severe' risks is partly a value judgment and can therefore vary widely across people, communities, or countries. However, the severity of risks also depends on criteria like the magnitude, irreversibility, timing, likelihood of the impacts they describe, as well as the adaptive capacity of the affected systems (species or societies). The Working Group II authors use these criteria in various ways to identify those risks that could become especially large in the future due to the interaction of physical changes to the climate system with vulnerable populations and ecosystems exposed to them. For example, some natural systems may be at risk of collapsing, as is the case for warm water coral reefs by mid-century, even if global warming is limited to +1.5°C. For human systems, severe risks can include increasing restriction of water resources that are already being observed; mortality or economic damages that are large compared to historical crises; or impacts on coastal systems from sea level rise and storms that could make some locations uninhabitable.

More than 130 key risks across sectors and regions have been identified by the chapters of this report, which have then been clustered into a set of 8 overarching risks, called representative key risks, which can occur from global to local scales but are of potential significance for a wide diversity of regions and systems globally. As shown in figure FAQ16.1, the representative key risks include risks to (1) low-lying coastal areas, (2) terrestrial and marine ecosystems, (3) critical infrastructures and networks, (4) living standards, (5) human health, (6) food security, (7) water security and (8) peace and mobility.

These representative key risks are expected to increase in the coming decades and will depend strongly not only on how much climate change occurs, but also on how the exposure and vulnerability of society changes, as well as on the extent to which adaptation efforts will be effective enough to substantially reduce the magnitude of severe risks. The report finds that risks are highest when high warming combines with development pathways with continued high levels of poverty and inequality, poor health systems, lack of capacity to invest in infrastructure, and other characteristics making societies highly vulnerable. Some regions already have high levels of exposure and vulnerability, such as in many developing countries as well as communities in small islands, Arctic areas and high mountains; in these regions, even low levels of warming will contribute to severe risks in the coming decades. Some risks in industrialized countries could also become severe over the course of this century, for example if climate change affects critical infrastructure such as transport hubs, power plants, or financial centres. In some cases such as coral reef environments and areas already severely affected by intense extreme events (e.g. recent typhoons or wildfires), for example, climate risks are already considered severe.

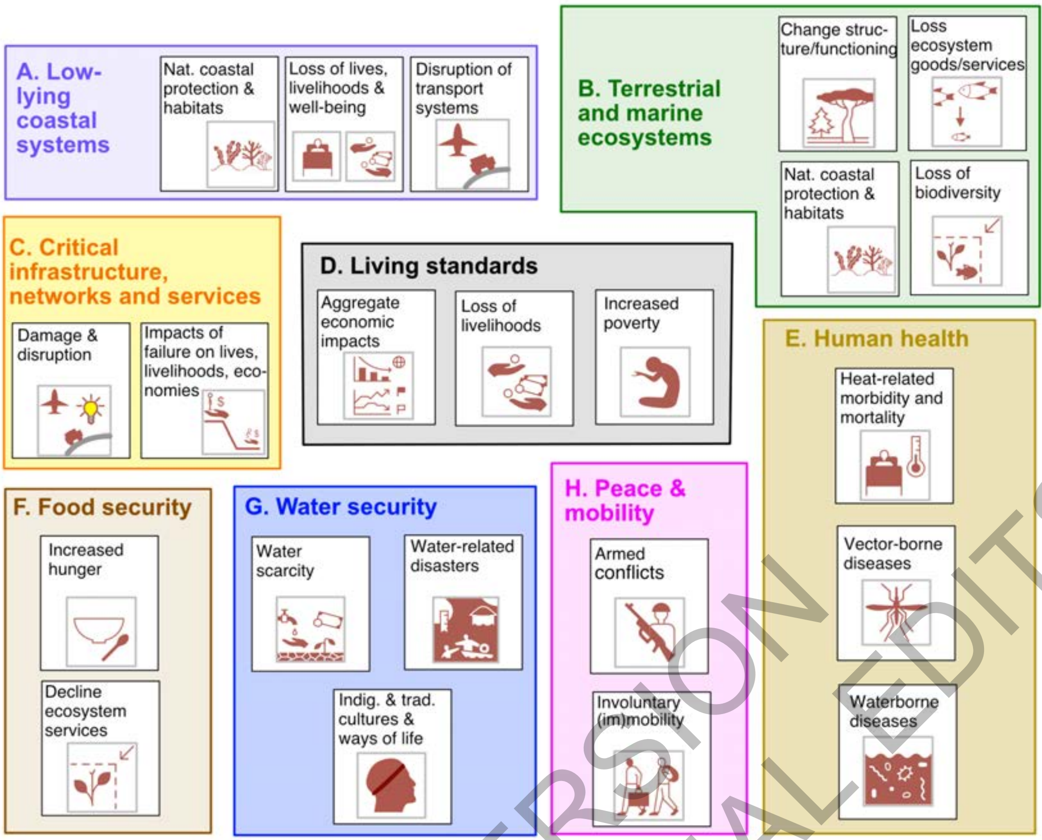

Figure FAQ16.1.1: Presentation of the 8 representative key risks assessed in this report (and their underlying main key risks).

[END FAQ16.1 HERE]

[START FAQ16.2 HERE]

FAQ16.2: How does adaptation help to manage key risks and what are its limits?

Adaptation helps to manage key risks by reducing vulnerability or exposure to climate hazards. However, constraining factors make it harder to plan or implement adaptation and result in adaptation limits beyond which risks cannot be prevented. Limits to adaptation are already being experienced, for instance by coastal communities, small-scale farmers and some natural systems.

Adaptation-related responses are actions that are taken with the intention of managing risks by reducing vulnerability or exposure to climate hazards. While mitigation responses aim to reduce greenhouse gas emissions and slow warming, adaptations respond to the impacts and risks that are unavoidable, either due to past emissions or failure to reduce emissions. However, while these responses intend to reduce risks, it is difficult to determine precise levels of risk reduction that can be attributed to adaptation. Changing levels of risk as well as other actions --such as economic development -- make it challenging to definitively connect specific levels of risk reduction with adaptation. Although it is not feasible to assess the adequacy of adaptation for risk reduction at global or regional levels, evidence from specific localized adaptation projects do show that adaptation-related responses reduce risk. Moreover, many adaptation measures offer near-term co-benefits related to mitigation and to sustainable development, including enhancing food security and reducing poverty.

Adaptation responses can occur in natural systems without the intervention of humans, such as species shifting their range, time of breeding, or migration behaviour. Humans can also assist adaptation in natural systems through, for example, conservation activities such as species regeneration projects or protecting ecosystem services. Other adaptation-related responses by humans aim to reduce risk by decreasing vulnerability and/or exposure of people to climate hazards. This includes infrastructural projects (e.g.

upgrading water systems to improve flood control), technological innovation (e.g. early warning systems for extreme events), behavioural change (e.g. shift to new crop types or livelihood strategies), cultural shifts (e.g. changing perspectives on urban greenspace, or increased recognition of Indigendous Knowledge and Local Knowledge), and institutional governance (e.g. adaptation planning, funding, and legislation).

While adaptation is important to reduce risk, adaptation cannot prevent all climate impacts from occurring. Adaptation has soft and hard limits, points at which adaptive actions are unable to prevent risks. Soft limits can change over time as additional adaptation options become available, while hard limits will not change as there are no additional adaptive actions that are possible. Soft limits occur largely due to constraints-- factors that make it harder to plan and implement adaptation, such as lack of financial resources or insufficient human capacity. Across regions and sectors, the most challenging constraints to adaptation are financial and those related to governance, institutions and policy measures. Limited funding and ineffective governance structures make it difficult to plan and implement adaptation-related responses which can lead to insufficient adaptation to prevent risks. Small-scale farmers and coastal communities are already facing soft limits to adaptation as measures that they have put in place are not enough to prevent loss. If constraints that are limiting adaptation are addressed, then additional adaptation can take place and these soft limits can be overcome. Evidence on limits to adaptation is largely focused on terrestrial and aquatic species and ecosystems, coastal communities, water security, agricultural production, and human health and heat.

Adaptation is critical for responding to unavoidable climate risks. Greater warming will mean more and more severe impacts requiring a high level of adaptation which may face greater constraints and reach soft and hard limits. At high levels of warming, it may not be possible to adapt to some severe impacts.

[END FAQ16.2 HERE]

[START FAQ16.3 HERE]

FAQ16.3: How do climate scientists differentiate between impacts of climate change and changes in natural or human systems that occur for other reasons?

We can already observe many impacts of climate change today. The large body of climatic impact data and research confirms this. To decide whether an observed change in a natural or human system is at least partly an impact of climate change we systematically compare the observed situation to a theoretical situation without observed levels of climate change. This is detection and attribution research.

Global mean temperature has already risen by more than 1°C and that also means that the impacts of climate change become more visible. Many natural and human systems are sensitive to weather conditions. Crop yields, river floods and associated damages, ecosystems such as coral reefs, or the extent of wildfires are affected by temperatures and precipitation changes. Other factors also come into play. So for example, crop yields around the world have increased over the last decades because of increasing fertilizer input, improved management and varieties. How do we detect the effect of climate change itself on these systems, when the other factors are excluded? This question is central for impact attribution. 'Impact of climate change' is defined as the difference between the observed state of the system (e.g., level of crop yields, damage induced by a river flood, coral bleaching) and the state of the system assuming the same observed levels of non-climate related drivers (e.g. fertilizer input, land use patterns, or settlement structures) but no climate change. So:
'Impact of climate change' is defined as the difference between the observed state of the system and the state of the system assuming the same observed levels of non-climate related drivers but no climate change. For example, we can compare the level of crop yields, damage induced by a river flood, and coral bleaching with differences in fertilizer input, land use patterns, or settlement structures, without climate change and with climate change occurring.

While this definition is quite clear, there certainly is the problem that in real life, we do not have a 'no climate change world' to compare with. We use model simulations where the influence of climate change can be eliminated to estimate what might have happened without climate change. In a situation where the influence of other non-climate related drivers is known to be minor (e.g., in very remote locations) the non-climate change situation can also be approximated by observation from an early period where climate change was still minor. Often a combination of different approaches increases our confidence in the quantification of the impact of climate change.

Impacts of climate change have been identified in a wide range of natural, human, and managed systems. For example, climate change is the major driver of observed widespread shifts in the timing of events in the annual cycle of marine and terrestrial species, the extent of areas burned by wildfires is increased by climate change in certain regions, it has increased heat-related mortality and had an impact on the expansion of vector-borne diseases.
In some other cases research has made considerable progress in identifying the sensitivity of certain processes to weather conditions without yet attributing observed changes to long-term climate change. Two examples of weather sensitivity without attribution are observed crop price fluctuations and waterborne diseases.

Finally it is important to note that 'attribution to climate change' does not necessarily mean 'attribution to anthropogenic climate change'. Instead, according to the IPCC definition, climate change means any long term change in the climate system no matter where it comes from.

FAQ16.4: What adaptation-related responses to climate change have already been observed, and do they help reduce climate risk?

Adaptation-related responses are the actions taken with the intention of managing risks by reducing vulnerability or exposure to climate hazards. Responses are increasing and expanding across global regions and sectors, although there is still a lot of opportunity for improvement. Examining the adequacy and effectiveness of the responses is important to guide, planning, implementation and expansion.

The most frequently reported adaptation-related responses are behavioural changes made by individuals and households in response to drought, flooding, and rainfall variability in Africa and Asia. Governments are increasingly undertaking planning, and implementing policy and legislation, including for example new zoning regulations and building codes, coordination mechanisms, disaster and emergency planning, or extension services to support farmer uptake of drought tolerant crops. Local governments are particularly active in adaptation-related responses, particularly in protecting infrastructure and services, such as water and sanitation. Across all regions, adaptation-related responses are strongly linked to food security, with poverty alleviation a key strategy in the Global South.

Overall, however, the extent of adaptation-related responses globally is low. On average, responses tend to be local, incremental, fragmented, and consistent with business-as-usual practices. There are no global regions or sectors where the overall adaptation-related response has been rapid, widespread, substantial, and has overcome or challenged key barriers. The extent of adaptation thus remains low globally, with significant potential for increased scope, depth, speed, and the challenging of adaptation limits. Examples of low extent adaptations include shifts by subsistence farmers in crop variety or timing, household flood barriers to protect houses and gardens, and harvesting of water for home and farm use. In contrast, high extent adaptation means that responses are widespread, coordinated, involve major shifts from normal practices, are rapid, and challenge existing constraints to adaptation. Examples of high extent adaptations include planned relocation of populations away from increasingly flood-prone areas, and widely implemented social support to communities to prevent migration or displacement due to climate hazards.

Increasing the extent of adaptation-related responses will require more widespread implementation and coordination, more novel and radical shifts from business-as-usual practices, more rapid transitions, and challenging or surmounting limits -- key barriers -- to adaptation. This might include, for example, best-practice programmes implemented in a few communities being expanded to a larger region or country, accelerated implementation of behaviours or regulatory frameworks, coordination mechanisms to support deep structural reform within and across governments, and strategic planning that challenges fundamental norms and underlying constraints to change.

We have very little information on whether existing adaptation-related responses that have already been implemented are reducing climate risks. There is evidence that risks due to extreme heat and flooding have declined, though it is not clear if these are due to specific adaptation-related responses or general and incremental socio-economic development. It is difficult to assess the effectiveness of adaptation-related responses, and even more difficult to know whether responses are adequate to adapt to rising climate risk. These remain unknown but important questions in guiding implementation and expansion of adaptation-related responses.

[START FAQ16.5 HERE]

FAQ16.5: How does climate risk vary with temperature?

Climate risk is a complex issue and communicating and it is fraught with difficulties. Risk generally increases with global warming, though it depends on a combination of many factors such as exposure, vulnerability and response. To present scientific findings succinctly, a risk variation diagram can help visualize the relationship between warming level and risk. The diagram can be useful in communicating the change in risk with warming for different types of risk across sectors and regions, as well as for five categories of global aggregate risk called 'Reasons for Concern'.

A picture speaks a thousand words. The use of images to share ideas and information to convey scientific understanding is an inclusive approach for communicating complex ideas. A risk variation diagram is a simple way to present the risk levels that have been evaluated for any particular system. These diagrams take the form of bar charts where each bar represents a different category of risk. The traffic light colour system is used as a basis for doing the risks, making it universally understandable. These diagrams are known colloquially as 'burning ember' diagrams, and have been a cornerstone of IPCC assessments since the Third Assessment Report, and further developed and updated in subsequent reports. The fact that the diagrams are designed to be simple, intuitive, and easily understood with the caption alone, has contributed to their longstanding effectiveness. Here, in Figure FAQ16.5.1 below, we provide a simplified figure of this chapter's burning embers for five categories of global aggregate risk, called Reasons for Concern (RFC), which collectively synthesize how global risk changes with temperature. The diagram shows the levels of concern that scientists have about the consequences of climate change (for a specified risk category and scope), and how this relates to the level of temperature rise.

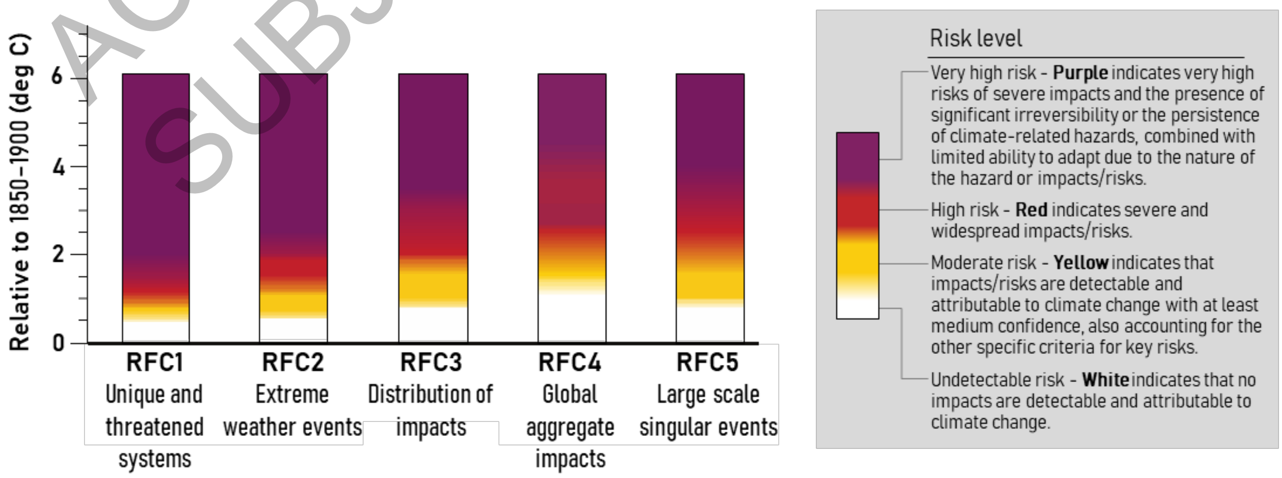

Figure FAQ16.5.1: Simplified presentation of the five Reasons for Concern burning ember diagrams as assessed in this report (adapted from Figure 16.15). The colours indicate the level of risk accrual with global warming for a low adaptation scenario. RFC1 Unique and threatened systems: ecological and human systems that have restricted geographic ranges constrained by climate related conditions and have high endemism or other distinctive properties. Examples include coral reefs, the Arctic and its indigenous people, mountain glaciers and biodiversity hotspots. RFC2 Extreme weather events: risks/impacts to human health, livelihoods, assets and ecosystems from extreme weather events such as heatwaves, heavy rain, drought and associated wildfires, and coastal flooding. RFC3 Distribution of impacts: risks/impacts that disproportionately affect particular groups due to uneven distribution of physical climate change hazards, exposure or vulnerability. RFC4 Global aggregate impacts: impacts to socio-ecological systems that can be aggregated globally into a single metric, such as monetary damages, lives affected, species lost or ecosystem degradation at a global scale. RFC5 Large-scale singular events: relatively large, abrupt and sometimes irreversible changes in systems caused by global warming, such as ice sheet disintegration or thermohaline circulation slowing.

In this diagram, the risk variation bars or embers are shown with temperature on the y-axis, and the base of the ember corresponds to a baseline temperature. Typically this baseline temperature is that before global warming started (i.e., average temperatures for the pre-industrial period of 1850 to 1900). This area of the ember appears white, which indicates no to negligible impacts due to climate change. Moving up the ember bar, changing colours show the increase in risk as the earth warms globally in terms of degrees Celsius – yellow for moderate risk, red for high risk, and purple for very high risk. Definitions of the risk levels are presented in Figure FAQ16.5.1 The risk transitions are informed by the latest literature and scientific evidence, and developed through consultation and development of consensus among experts. The bars depict an averaged assessment across the world which has the disadvantage of hiding regional variation. For example, some locations or regions could face high risk even when the global risk level is moderate.

When the embers for different risk categories are placed next to each other, it is possible to compare risk levels at different levels of global warming. For example, at 1ºC warming all embers appear yellow or white, so it is possible to say that keeping global warming below that particular temperature would help ensure risks remain moderate for all five categories of concern assessed. In contrast, at 2ºC warming, risk levels have transitioned to high for all categories assessed, and even reach a very high level of risk in the case of unique and threatened systems.

[START FAQ16.6 HERE]

FAQ16.6: What is the role of extreme weather events in the risks we face from climate change?

Climate change has often been perceived as a slow and gradual process but by now it is abundantly clear that many of its impacts arise through shocks, such as extreme weather events. Many places are facing more frequent and intense extremes, and also more surprises. The impact of such shocks is shaped by exposure and vulnerability, where we live, and how we are prepared for and able to cope with shocks and surprises.

The rising risk of extreme events is one of the major reasons for concern about climate change. It is clear that this risk has already increased today. Many recent disasters already have a fingerprint of climate change.

There are large differences in such risks from country to country, place to place, and person to person. This is of course partly due to differences in hazards such as heatwaves, floods, droughts, storms, storm surges, etc., and the way those hazards are influenced by climate change. However, an even more important aspect is people's exposure and vulnerability: do these hazards occur in places where people live and work, and how badly do they affect people's lives and livelihoods? Some groups are especially vulnerable, for instance elderly in the case of heatwaves, or people with disabilities in the case of floods. In general, poor and marginalised people tend to be much more affected than rich people, partly because they have less reserves and support systems that help them to prepare for, cope with and recover from a shock. On the other hand, absolute economic losses are generally higher in richer places, simply because more assets are at risk there.

Many problems caused by extreme weather do not just appear because of one weather extreme, but due to a combination of several events. For instance, dryness may increase the risk of a subsequent heatwave. But the increased risk may also cascade through human systems, for instance when several consecutive disasters erode people's savings, or when a heatwave reduces the ability of power plants to produce electricity, which subsequently affects availability of electricity to turn on air conditioning to cope with the heat. Many shocks also have impacts beyond the place where they occur, for instance when a failed harvest affects food prices elsewhere. Climate risks can also be aggravated by other shocks, such as in the case of COVID-19, which not only had a direct health impact, but also affected livelihoods around the world and left many people much more vulnerable to weather extremes.

Understanding the risks we face can help in planning for the future. This may be a combination of short-term preparation, such as early warning systems, and longer-term strategies to reduce vulnerability, for instance through urban planning, as well as reducing greenhouse gases to avoid longer-term increases in risk. Many interventions to increase people's resilience are effective in the face of a range of shocks. For instance, social safety nets can help mitigate the impact of a drought on farmers' livelihoods, but also of the economic impacts of COVID-19.

Climate-related shocks are threats to society, but they can also offer opportunities for learning and change. Recent disasters can motivate action during a short window of opportunity when awareness of the risks is higher and policy attention is focused on solutions to adapt and reduce risk. However, those windows tend to be short, and attention is often directed at the event that was recently experienced, rather than resilience in the face of a wider range of risks.

Executive Summary

Introduction and Framing

Chapter 17 assesses the options, processes and enabling conditions for climate risk management, a key component of climate resilient development. While Chapter 16 assesses the risks that society and ecosystems face, and residual risks after adaptation, this chapter focuses on the "how" of climate risk management and adaptation. It covers: the adaptation and risk management options that are available; the governance and applicability of options in different contexts; residual risk and Loss & Damage; the methods and tools that can be drawn on to support climate risk management planning and implementation; enabling conditions and drivers for adaptation; the role of monitoring and evaluation for integrated risk management and tracking progress, success and the risk of maladaptation; and finally, integration of risk management across sectors, jurisdictions and time horizons, under dynamic conditions of environmental and societal change.

Adaptation options for managing a wide range of climate risks have been proposed, planned, or implemented across all sectors and regions, with prospects for wide-ranging benefits to nearly all people and ecosystems (*high confidence*[1]) {17.2.1}. Many options are widely applicable and could be scaled up to reduce vulnerability or exposure for the majority of the world's population and the ecosystems they depend on (*high confidence*). These include nature restoration (*high confidence*), changing diets and reducing food waste (*high confidence*), infrastructure retrofitting (*high confidence*), building codes (*medium confidence*), disaster early warning (*high confidence*), and cooperative governance (*medium confidence*). The portfolio of adaptation options that could be successfully implemented varies across locations, with resource-limited and conflict-affected contexts bearing large amounts of residual risk (*high confidence*) {17.2, 17.5.1}.

The majority of climate risk management and adaptation currently being planned and implemented is incremental (*high confidence*). Transformational adaptation will become increasingly necessary at higher global warming levels *(medium confidence*) but can be associated with significant and inequitable trade-offs (*medium confidence*). Adaptations with some of the highest transformative potential include migration (*high confidence*), spatial planning (*medium confidence*), governance cooperation (*medium confidence*), universal access to healthcare (*medium confidence*) and changing food systems (*medium confidence*). Options that tend to modify existing systems incrementally include early warning systems (*high confidence)*, insurance (*medium confidence*), and improved water use efficiency (*high confidence*) {17.2, 17.5.1}.

Governance, especially when inclusive and context-sensitive, is an important enabling condition for climate risk management and adaptation (*very high confidence*). The use of formal and informal governance approaches, often in polycentric arrangements of public, private and community actors, is being increasingly recognised as important across many decision-making settings (*high confidence*) {17.3.2; 17.4.2}. Public governance leadership has the largest role for social safety nets, spatial planning, and building codes (*high confidence*) {17.2.1}. Private sector governance is important for insurance and for minimizing the stressors that can negatively impact ecosystems and their functions especially in the absence of public regulations or enforcement (*medium confidence*) {17.2.1}. Communities and individuals play the largest role in governance of adaptations to farming and fishery practices and ecosystem-based adaptations (*medium confidence*) {17.2.1}. Informal or individual-led decision-making is more common in food security and livelihood related adaptations, such as changes to diets, livelihood diversification and seasonal migration (*high confidence*) {17.2.1}. People who have experienced climate shocks are more likely to take on informal adaptation measures, and in places where people are more exposed to extreme events, autonomous adaptation is more common (*high confidence*) {17.2.1}.

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

National and international legal and policy frameworks and instruments support the planning and implementation of adaptation and climate risk management across scales, especially when combined with guidelines for action (*medium confidence*) {17.4.2}. Nationally Determined Contributions (NDCs) have been drivers of national adaptation planning, with cascading effects on sectors and sub-national action, especially in developing countries (*high confidence*) {17.4.2}. Nearly all developing countries (particularly SIDS) that included an adaptation component in their NDCs consider adaptation the most urgent aspect of their national climate change response (*high confidence*) {17.4.2}. A steady increase in national and sub-national laws, policies, along with regulations that mandate reporting and risk disclosure have promoted adaptation response across public agencies, private firms and community organizations *(high confidence*) {17.4.2}. Greater adaptation is present where national climate laws and policies require adaptation action from lower levels of government and include guidelines on how to do so (*medium confidence*) {17.4.2}.

Recognition of the critical role of financing for adaptation and resilience as an important enabler for climate risk management has strengthened (*high confidence*). Yet, since AR5, the gap between the estimated costs of adaptation and the documented (tracked) finance allocated to adaptation has widened (*high confidence*). Estimated global and regional costs of adaptation vary widely due to differences in assumptions, methods, and data; the majority of more recent estimates are higher than the figures presented in AR5 (*high confidence*). Although the estimated cost of adaptation is higher for developed countries (*medium confidence*), for developing countries they are much higher as a proportion of national income, making the self-financing of adaptation more difficult (*high confidence*). A high proportion of developing country NDC adaptation contributions are conditional on external financial support, underscoring the crucial role of international finance to achieve adaptation efforts commensurate with climate risks (*high confidence*) {17.4.2; Cross-Chapter Box FINANCE in this Chapter}. Developed country climate finance leveraged for developing countries for mitigation and adaptation has fallen short of the 100 USD billion per year Copenhagen commitment for 2020 (*very high confidence*) {Cross-Chapter Box FINANCE in this Chapter}. Substantial opportunities exist for improving access to climate finance, as well as its impact and effectiveness {17.4.2; Cross-Chapter Box FINANCE in this Chapter}.

Private sector financing for adaptation has been increasingly promoted as a response to realized adaptation finance needs (*high confidence*). However, private sector financing of adaptation has been limited, especially in developing countries (*high confidence*). Tracked private sector finance for climate change action has grown substantially since 2015, but the proportion directed towards adaptation has remained small (*high confidence*) {Cross-Chapter Box FINANCE in this Chapter}; in 2018 these contributions were 0.05% of total climate finance and 1% of adaptation finance. A key challenge for private sector financing of adaptation is demonstrating financial return on investment, as many benefits of adaptation arise as avoided damages or public goods, rather than direct revenue streams (*medium confidence*). Leveraging private finance in developing countries is often more difficult because of risk (perceived and real) to investors, reducing the pool of potential investors and/or raising the cost (interest) of investment (*medium confidence*) {17.4.3.; Cross-Chapter Box Finance in this Chapter}.

Information and knowledge on climate risk and adaptation options, derived from different knowledge systems, can support risk management and adaptation decisions (*high confidence*) {17.4.4}. Processes, such as co-production, that link scientific, Indigenous, local, practitioner and other forms of knowledge can make climate risk management processes and outcomes more effective and sustainable (*high confidence*) {17.3.2; 17.4.4}.

Climate services that provide reliable, relevant, and usable climate information for the short or long term are increasingly being produced and used in climate risk management (*high confidence*) {17.4.4}. In many regions and sectors, the utility of climate services is strengthened by sustained engagement between stakeholders and experts and by co-production (*medium confidence*) {17.4.4; Cross-Chapter Box Climate Services WGI Chapter 12}. Significant gaps remain in the evaluation of climate services, and some studies indicate that climate services often do not reach the most vulnerable and more isolated people, maintaining or exacerbating inequality.

Catalyzing conditions and windows of opportunity can drive shifts in motivation and adaptation effort, stimulating more rapid uptake of existing and new adaptation options (*medium confidence*) {17.4.5}. Decision-makers can take advantage of windows of opportunity to promote rapid and

effective responses in reactive and proactive cases {17.4.5}. Disaster events or shocks such as wildfires, tropical cyclones, heatwaves or coral bleaching have catalyzing characteristics (*high confidence*) {17.4.5.2}. Additional types of catalyzing conditions include climate litigation and the presence of individuals and organizations that act as policy and decision innovators, including government and business innovators in cities (*medium confidence*) {17.4.5.3}, stimulating action within and beyond their immediate contexts (*medium confidence*). Litigation on failure of government and business to adapt is becoming more frequent and is expected to increase as climate impact attribution science matures further (*high confidence*) {Cross-Chapter Box LOSS in this Chapter; 17.4.5.3}.

Urgency can stimulate prompt climate risk management *(high confidence*). A moderate level of urgency contributes to enhanced climate action, while both high and low levels of urgency can impede response (*high confidence*) {17.4.5.1}. Well-designed communication strategies can move decision makers from low to moderate levels of urgency, stimulating action. As conditions approach a crisis state, however, urgency can weaken decision-making rather than support it (*medium confidence*) {17.4.5.1}.

Decision support tools and decision-analytic methods are available and are being applied for managing climate risks in varied contexts, including where deep uncertainty is present (*high confidence*). These tools and methods have been shown to support deliberative processes where stakeholders jointly consider factors such as the rate and magnitude of change and their uncertainties, associated impacts and timescales of adaptation needed along multiple pathways and scenarios of future risks (*high confidence*) {17.3.2; Cross-Chapter Box DEEP in this Chapter}. However, comparative evidence on the relative utility of different analytical methods in their use by decision makers for managing climate risks is an important gap (*medium confidence*). Nevertheless, robust decision-making, using pathway analyses to determine 'no regrets' options amongst trade-offs, has been shown to be a useful starting point under deep uncertainty (*medium confidence*). Methods for analysing options differ across geo-political scales, with modeling studies being a particularly prominent method across scales from community and urban to regional and national (*high confidence*) {17.3.1; 17.6, Cross-Chapter Box DEEP in this Chapter}.

Successful adaptation and maladaptation form the opposite poles of a continuum (*medium confidence*). The evaluation of an adaptation option and its location on this continuum are context-specific and vary across time, place and evaluation perspectives (*high confidence*) {17.5.2}. Despite knowledge gaps, adaptation options can be assessed according to several criteria, such as benefits to humans, benefits to ecosystem services, benefits to equity (marginalized ethnic groups, gender, low-income populations), transformational potential, and contribution to greenhouse gas emission reduction (*medium confidence*) {17.5.1}. These factors can aid evaluation of co-benefits and trade-offs within and between adaptation responses (*high confidence*) facilitating successful adaptation and reducing the likelihood of maladaptation (*medium confidence*) {17.5.1}.

Adaptation options across a range of climate risk settings (Representative Key Risks) have potential for some degree of maladaptation alongside varied potential for success (*very high confidence*) {17.5.2}. Maladaptation can result from unaccounted trade-offs with low-income groups and the transformational potential of adaptation (*medium confidence*) {17.5.2}. Success is greatest when adaptation enhances gender equity (*medium confidence*) {17.5.2} and supports ecosystem function and services (*medium confidence*) {17.5.2}. Among adaptation options, coastal infrastructure is an example that has particularly high risk for maladaptation through trade-offs for natural system functioning and human vulnerability over time. Examples of options with high potential for successful adaptation are nature restoration (*medium confidence*) {17.5.2}, social safety nets (*medium confidence*) {17.5.2} and adaptations relating to changes of diets and reducing food waste (*medium confidence*) {17.5.2}.

Monitoring and evaluation (M&E) are key for iterative climate risk management, in particular tracking adaptation progress and learning about adaptation success and maladaptation (*high confidence*). M&E application has increased since AR5 at the local, project and national level, but is still at an early stage in most countries (*high confidence*) and underutilized as a way to assess adaptation outcomes at longer timeframes (*high confidence*) {17.5.2}. About one-third of countries have undertaken steps to develop national adaptation M&E systems, but fewer than half of these are reporting on implementation (*medium confidence*) {17.5.2}. M&E, as well as tracking global progress on adaptation, are confronted with a number of challenges (*high confidence*), such as a comparability in what counts as adaptation and limited availability of data across scales {17.5.2; Cross-Chapter Box PROGRESS in this Chapter}. The relative strength and weaknesses of different approaches and their applicability have not been systematically assessed, but the diversity of approaches being used could provide a more comprehensive assessment of global adaptation progress (Cross-Chapter Box PROGRESS in this Chapter).

Understanding of residual impacts and risks in vulnerable regions and implications for Loss & Damage (L&D) has become increasingly relevant as the limits to adaptation are projected to be reached in natural and human systems (*high confidence*) {17.2.2.5; Cross-Chapter Box LOSS in this Chapter}. The international L&D policy debate has seen heightened attention, with some coalescence around key issues, including risk management, limits to adaptation, existential risk, finance and support, including liability, compensation and litigation. Advisory groups have been set up with participation of policy and experts from research, civil society and practice to inform debate. Yet, the policy space and concrete remit for L&D has remained vague, which renders policy formulation complex (*high confidence*) {17.2; Cross-Chapter Box LOSS in this Chapter}.

Effective management of climate risks is dependent on systematically integrating adaptations across interacting climate risks, ensuring that measures of success include factors important to climate resilient development, and accounting for the dynamic nature of climate risks over time *(very high confidence)* {17.6}. Across the Working Group II report are examples of how managing adaptations to reduce climate risks can negatively or positively affect sustainable development, thereby impacting the potential for climate resilient development. Climate risks can emerge at different rates and time horizons, and the interactions between risks vary from region to region (*very high confidence*) {17.6}. The need to manage these risks in an integrated manner is demonstrated by the diverse and interacting impacts of climate risks on ecosystems, cities, health, and poverty and livelihoods, such as in the Water-Energy-Food nexus (*high confidence*) {17.6}. Expertise and resources for integrated risk management varies between the developed and developing countries (*high confidence*) {17.6}. Integrated pathways for managing climate risks will be most suitable when 'low regrets' anticipatory options are established jointly across sectors in a timely manner, path dependencies are avoided in order to not limit future options for climate resilient development, and maladaptations across sectors are avoided (*high confidence*) {17.6}. National Adaptation Plans have potential to integrate participatory, iterative processes to monitor, review, and update adaptations as knowledge, experience and resources become available {Cross-Chapter Box DEEP in this Chapter; 17.6}.

17.1 Objectives and Framing of the Chapter

17.1.1 Introduction

Addressing the impacts and risks associated with observed and projected climate change (see Chapter 16) is fundamentally and intricately tied to the decision-making options available to manage those risks. Climate risk decision-making focuses on the processes needed to identify and characterise those risks, generate plans, policies to reduce the likelihood and/or magnitude of adverse potential consequences, based on assessed or perceived risks (derived from the definition of risk and risk management in Chapter 1). This chapter presents an assessment of the evidence on climate risk decision-making as a set of processes that involve a range of actors in different contexts resulting in diverse outcomes. The climate risk decision-makers and their actions are the central focus of the assessment. The chapter is an assessment of the evidence of the decision-making options that are available in practice, and functions as a central pivot point between the identification of key climate risks (Chapter 16) and the means to integrate and leverage action on climate risk decision-making into the broader requirements of climate resilient development pathways (Chapter 18). This section introduces the main entry points on decision-making that have framed this assessment (Sections 17.1.1.1 to 17.1.1.5), as well as the key terms used to frame this assessment and its organisation in this chapter (Section 17.1.2).

A central framing point is the connection between climate risk decision-making and adaptation. Adaptation for human systems in this report is introduced in Chapter 1 and defined in the Glossary as 'the process of adjustment to actual or expected climate and its effects, in order to moderate harm or exploit beneficial opportunities'. In natural systems, adaptation is the process of adjustment to actual climate and its effects; human intervention may facilitate adjustment to expected climate and its effects (see AR6 Glossary). In this chapter, we consider adaptations that may be implemented by people, whether they be to support human, managed, or natural systems, and the processes and factors that underpin adaptation in these diverse settings. Different types of adaptation have been distinguished in Chapter 1, including anticipatory versus reactive, autonomous versus planned, and incremental versus transformational (IPCC WGII glossaries; Chapters 16-18). These dichotomies and interactions are assessed here. Implementation of adaptation through iterative risk management decision-making emphasizes that anticipating and responding to climate change does not consist of a single set of judgments at a single point in time, but rather an on-going cycle of assessment, action, reassessment, learn, and response' (Chapter 1).

17.1.1.1 Decision-Making for Managing Climate Risks in AR6

The UN 2030 Agenda for Sustainable Development and its 17 Sustainable Development Goals (SDGs), as well the UNFCCC Paris Climate Agreement, the UN Sendai Framework Disaster Risk Reduction, and the UN Habitat New Urban Agenda helped push climate risk management and adaptation forward from the global to the national level, from the planning stage into implementation and provides benchmarks for adaptation progress. To assess adaptation progress (17.5), the interplay between top-down (institutional) and bottom-up (individual/social/community) processes, multi-scale interaction (local, regional, national, and international), iterative risk management, differing forms of knowledge, and equity are especially crucial (particularly Sections 17.2, 17.4). Parallel to these advances is an understanding and assessment of appropriate decision support tools, methods, and evaluation metrics (Section 17.3).

Since AR5, significant advances have been made in regard to the understanding of the drivers of decision-making and contexts in which climate risk decision-making takes place. Climate risk decision-making generally, and adaptation specifically, has been a focus within the IPCC special reports in the sixth assessment cycle. An overall goal of climate risk management is to eliminate or reduce the risk to levels that are to a level that is socio-politically and economically acceptable. Risk management to an acceptable level may not be feasible because of limits or barriers to adaptation. Future potential risks are a more complex matter given the need to define time scales and spatial extent, and uncertainties. In the Special Report on the impacts of global warming of 1.5C [SR1.5] (IPCC, 2018a), the risks associated with climate-related impacts were found to be higher under emission scenarios above 1.5°C, raising awareness for the need to limit the impacts of warming through the acceleration of climate mitigation and both incremental and transformational adaptation (IPCC, 2018a).

The AR6 SRCCL (IPCC, 2019b) added the dimensions of pace, intensity, and scale of climate impacts and adaptation or mitigation responses and adverse consequences. Relevant land-based adverse consequences include those on lives, livelihoods, health and wellbeing, economic, social, and cultural assets and investments, infrastructure, services (including ecosystem services), ecosystems and species.

While a generic understanding of the decision-making process has emerged from the literature, the chapter assesses how these components and their dimensions interact across a range of temporal (short, long-term as defined in SROCC), scalar (household to global), institutional/governance (formal, informal, bottom up, top down), and magnitude (micro adaptation - small scale and macro adaptation - large scale) (Section 17.2). The IPCC SRCCL placed emphasis on acknowledging co-benefits and trade-offs to avoid barriers to implementation, with particular attention to land use decisions. It states that this coordination can be supported by building networks of decision-makers across scales and sectors, including local stakeholders from vulnerable groups, and by adopting and implementing policies in a flexible and iterative manner (IPCC, 2019b).

17.1.1.2 Approaches to Assess and Synthesise Options for Managing Risk

This chapter utilizes several points of departure to assess climate risk management that emerge from AR5 and AR6, specifically. SR Climate Change and Land, especially Chapter 7 and throughout SROCC. These works provide foundational assessment of evidence on decision-making systems that connect different spatial and temporal scales and diverse cultural contexts in which climate risk management takes place, the varying interactions of decision-makers and their stakeholder groups, and the barriers and enablers to decision making, including governance, finance, and knowledge (Section 17.4).

Another significant advance is that instead of cataloguing decision-making strategies, the literature has now evolved to the point where adaptation progress, effectiveness and efficiency can be more meaningfully assessed through increased monitoring and evaluation capacity. Although the ability to measure success and effectiveness is not fully developed and hampered by lack of data, agreed methods and terms, and time to fully evaluate adaptation actions (see Sections 17.3.3 and 17.5, Cross-Chapter Box PROGRESS in this Chapter).). The ambition to describe effectiveness and success illustrates further maturation of the literature on climate risk decision-making as a system process. Overall, the process of climate risk decision-making remains dynamic, and the chapter attempts to assess a variety of proactive management approaches being developed and tested to address adverse, diverse and complex risks in a wide range of developing and developed country contexts (see Figure 17.1). The chapter provides a synthesis of how these new approaches are reflected in the sectoral and regional chapters and cross-chapter papers of this report (Chapters 2-15; CCPs 1-7). Specifically, the goal is to provide a line of sight between the sectoral and regional chapters and cross-chapter papers' decision-making assessment to sections in this chapter. This synthesis also helps to present the varying and context-driven character of adaptation strategies now in practice and being considered.

17.1.1.3 Key Risks Considered in the Assessment of Climate Risk Decision-making

In AR6 (Chapter 16 and Cross-Chapter Papers), over 100 key risks have been identified across regions and sectors, which have the potential to manifest into severe impacts that are relevant to the interpretation of United Nations Framework Convention on Climate Change (UNFCCC) Article 2, specifically on the objective to avoid dangerous anthropogenic interference with the climate system. These risks are *likely*[2] to become more severe under higher warming scenarios and social-ecological conditions that yield high exposure and vulnerability to the associated climate-related hazards. In this report, these key risks have been grouped into categories represented by eight overarching risks (called Representative Key Risks, RKRs) relating to: 1) coastal socio-ecological systems; 2) terrestrial and ocean ecosystems; 3) critical physical infrastructure, networks, and services; 4) living standards; 5) human health; 6) food security; 7) water

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

security; and 8) peace and human mobility (see Chapter 16). Decision-making options for managing these risks, such as selecting the relevant adaptation options to implement, require an assessment of the local context in which these impacts are likely to be experienced, as well as the local to global collective implications of those actions (see Sections 17.2 and 17.5).

17.1.2 Objectives and Key Terms

17.1.2.1 Drivers

AR5 provides a broad overview of drivers as the determinants of climate decision-making by individuals and organizations, including social, institutional, and regulatory contexts, cultural values and norms, economic resources and constraints, and the availability of information and of tools to process it. This chapter expands the discussion of the contexts for decision-making in a number of ways (see Section 17.4), including an examination of informal as well as formal decisions, an attention to emerging actors, particularly social movements, and consideration of several dimensions of governance. It expands the treatment of decision processes, with particular attention to framing and to the integration of multiple time frames (Sections 17.3 and 17.6).

Since AR5, there has been an increasing ambition for adaptation, signalled by growing attention to the adaptation gaps and deficits, which call for extensive and intensive levels of action (Chen et al., 2016; UNEP, 2017; Tompkins et al., 2018; Valente and Veloso-Gomes, 2020; UNEP, 2021a), as well as increased attention to co-benefits between climate risk reduction and other benefits, such as equity and biodiversity conservation (Colloff et al., 2017, Section 17.5.1; Smith et al., 2020). Climate risk decision-making as an object of study has emerged in a more central location within the literature as adaptation moves from planning into the realm of practice. The broad sense of urgency (summarized in Wilson and Orlove, 2019; Wilson and Orlove, 2021), show growth of the term "urgency" in both scholarly publications and the popular press since 2014, building on earlier increases starting around 2005, and a dramatic spike of the terms "climate crisis" and "climate emergency." Paralleling this call for more extensive and rapid action is the emergence of the term "transformational" adaptation and decision-making. Transformational adaptation (defined and deeply examined in Chapter 1, Chapter 16, and Section 17.2) highlights efforts that involve large-scale, systemic change (Wilson et al., 2020) and involves "adapting to climate change resulting in significant changes in structure or function that go beyond adjusting existing practices including approaches that enable new ways of decision-making on adaptation" (IPCC, 2018a). The complex relationship between incremental adaptation and transformational adaptation is presented and reviewed in 17.2. Furthermore, the literature since the AR5 report has moved beyond the question of limits and barriers to adaptation as relevant aspects for decision-making to additionally assessing drivers of change, with increasing focus devoted to more nuanced and differentiated contexts for action.

17.1.2.2 Enabling Conditions

AR5 extensively assessed the conditions of adaptation with a focus on the role of governance, finance, knowledge, and capacity. AR6 extends this examination of adaptation and the decision-making process around it by focusing on enablers. Adaptation enablers are defined as those conditions or properties that specifically promote or advance the adaptation process (see Chapter 1). Enablers are positively associated with likelihood that adaptation planning occurs, and strategies will be put into practice. Three broad enabling conditions are presented in the chapter (Section 17.4): governance (legislation, regulation, institutions, litigation), finance (needs, sources, intermediaries, instruments flows, and equity) and knowledge (capacities, climate services, big data, indigenous/local knowledge, co-production, boundary organizations). As an extension of enabling conditions, the chapter also examines catalysing conditions for adaptation (Section 17.4.5). Catalysing conditions motivate and accelerate the process of decision-making leading to more frequent and potentially substantial adaptations. The chapter recognises that the relative influence of enabling conditions and catalysing conditions are set within the human dimensions of climate change including vulnerability, inequality, poverty, and the achievement/non-achievement of SDGs (see Figure 8.1).

17.1.2.3 Mechanisms for Decision-making

The mechanisms and conditions for decision-making provide the basis for the chapter. AR5 provided a detailed chapter on the support of climate decision-making. Chapter 2 of AR5 concluded, with high confidence, that risk management provides a useful framework for most climate change decision making, and that iterative risk management is most suitable in situations characterised by large uncertainties, long time frames, the potential for learning over time, and the influence of both climate as well as other socioeconomic and biophysical changes. Furthermore, decision support is situated at the intersection of data provision, expert knowledge, and human decision-making at a range of scales from the individual to the organization and institution.

The climate risk management decision-making process follows a set of general considerations. The detail of each decision is often highly context specific. Climate risk decision-making is bound to the question of how and under what circumstance it is appropriate to alter, reduce or transfer and retain risk. Different types of risk (e.g., gradual compared with catastrophic) and conditions of risk (e.g., known versus uncertain) are associated with different types of responses (e.g., incremental versus transformational). As the risk decision process precedes, individuals and organizations will formally or informally utilize any number of mechanisms to guide, aid, or facilitate the decision-making process. Decision-making can then take place in a linear set of steps or through a complex iterative process involving reflexive and recursive steps.

17.1.2.4 Costs and Non-Monetised Loss, Benefits, Synergies, and Trade-Off

AR5 provided an extensive discussion of the costs to human and natural systems associated with climate risks. It recognized the challenges which long time frames, uncertainty and the differing values held by stakeholders create for the monetisation of losses. The AR6 SROCC built on the discussion of cultural values—typically also difficult to monetise—through a consideration of cultural ecosystem services and cultural forms of valuation, with cases from high mountain areas and polar regions (Hock et al., 2019; Meredith et al., 2019; IPCC, 2019c). AR6 expands this discussion of multiple forms of valuation in several ways. It considers regulation and litigation as mechanisms for promoting the consideration of both monetisable and non-monetisable losses in decision-making (Cross-Chapter Box LOSS in this Chapter). AR5 treated the issues of equity and justice primarily with regard to mitigation, especially in WGIII AR5 Chapter 3; these issues in the adaptation sphere are considered extensively in this chapter in areas such as finance, governance, success of adaptation, maladaptation, and monitoring and evaluation. The discussions of maladaptation and success of adaptation (Section 17.5) consider questions of synergies and trade-offs across values and goals, while the consideration of decision processes and tools shows opportunities to use co-benefits to promote effective decision-making, including approaches to decision-making under conditions of deep uncertainty (Section 17.3; Cross-Chapter Box DEEP in this Chapter). Successful adaptation across the report (as specified in Ch1) is associated with conditions when co-benefits are high and (negative) trade-offs are low.

17.1.2.5 Monitoring and Evaluation

This chapter assesses the evidence of monitoring and evaluation (M&E) (see AR6 Glossary) and their approaches as part of the adaptation process at the national, local, and project level as well as in global assessments (17.5.2; Cross-Chapter Box PROGRESS in this Chapter). M&E can serve multiple functions, e.g., to: 1) facilitate an understanding on whether and how interventions work in achieving intended objectives; 2) inform ongoing and future implementation, and 3) provide information that helps to substantiate upward and downward accountability (Preston et al., 2009; UNFCCC, 2010b; Pringle, 2011; Spearman and McGray, 2011) (see BOX 17.1 for more discussion). This chapter also addresses the relevance of iterative learning as part of the design of M&E processes, as a means by which actors and institutions engaged in M&E acquire new insights on how these processes work (or not) to achieve set objectives.

[START BOX 17.1 HERE]

Box 17.1: How is Success in Adaptation Characterised in Chapter 17?

Whether an adaptation is considered successful is context specific. It depends on who evaluates adaptation and at what time as well as on the ability to compare the outcome of adaptation with a hypothetical situation without adaptation and without other parallel changes, such as development interventions (Singh et al., 2021; Dilling et al., 2019a). The ability to compare the risk situation post and prior adaptation is complicated through the long time-horizons at which adaptation outcomes often become apparent (see Cross-Chapter Box ADAPT in Chapter 1; Section 17.5.1; Dilling et al., 2019a).

However, a wealth of information has recently become available on how success and effectiveness of adaptation could be assessed, defined, or investigated in certain settings (Patt and Schröter, 2008; Morecroft Michael et al., 2019; Tubi and Williams, 2021) or across a larger set of adaptations (Hegger et al., 2012; Eriksen et al., 2015; Gajjar et al., 2019a; Owen, 2020; Singh et al., 2021). Accordingly, successful adaptation is understood as effective adaptation, in that it reduces climate impacts, vulnerabilities and risk, and additionally balances synergies and trade-offs across diverse objectives, perspectives, expectations, and values (Eriksen et al., 2015; Juhola et al., 2016; Gajjar et al., 2019a; Owen, 2020; Singh et al., 2021). Across this report, four factors are identified as enabling conditions of successful adaptation, which include a focus on recognitional, procedural, and distributional justice as well as flexible and strong institutions that seek policy integration and account for long-term goals.

To operationalizable 'success' in this chapter, it is characterised by the degree to which an adaptation response benefits (1) human systems (number of people); (2) ecosystems or ecosystem services; (3) marginalized ethnic groups, (4) women and girls, (5) and low-income populations, and can be characterised as (6) transformational adaptation, and (7) contributing to greenhouse gases emission reductions (Section 17.5.1). Overarching to these factors are uncertainty and potential path-dependency of decisions that may result in lock-in and maladaptation in the long-term, and recognition that what is successful in the near-term is not necessarily successful in the long-term.

Success in adaptation is antithetical to maladaptation. Maladaptation refers to current or potential future negative consequences, including failed or partially successful adaptation (or risk reduction), but also trade-offs or side-effects of adaptation (see Glossary). Thus, success of adaptation and maladaptation form the ends of a continuum that represents the balancing of synergies and trade-offs across regions, populations, or sectors (Singh et al., 2016; Magnan et al., 2020; Schipper, 2020). Every adaptation action may be placed along such a continuum reflecting the empirical evidence of adaptation practices and their assessment (Section 17.5).

[END BOX 17.1 HERE]

17.1.3 Outline of the Chapter

The chapter is organised around the broad narrative of climate risk decision-making and management (Figure 17.1), building from the assessment of risks within RKRs (Chapter 16) and options available to address these risks and within a broader context of climate resilient development pathways (Chapter 18). Decision-making is considered to be a reflexive and recursive process where different evidentiary threads and information inputs become relevant to the understanding and assessment of factors underlying specific decisions. Additionally, this is also a discursive process, whereby actors and institutions' interpretations of climate risks are also key to these deliberations.

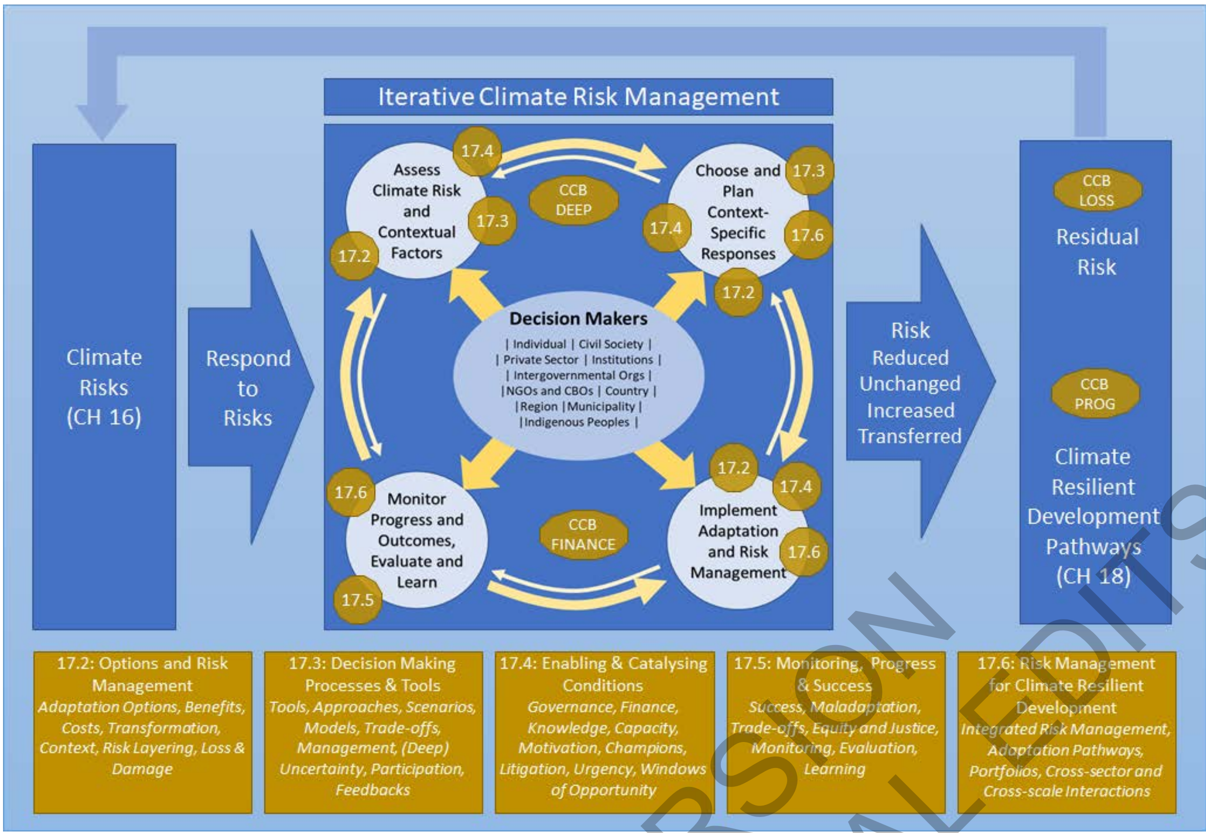

Figure 17.1: Schematic representation of the climate risk management decision-making process as introduced in Chapter 1 (Figure 1.6) and the key elements of this Chapter that address additional aspects of this process. In Chapter 17, climate risk management (middle box) is framed as the iterative response (i.e., what society could do and how it could be done) to the climate risks described in Chapter 16, with outcomes (ideally reduced risk) that can support (or perhaps hinder) climate resilient development, Chapter 18. Decision makers from diverse contexts sit at the centre of the climate risk decision making process, and interact with and drive these processes as they play out. The main sections of Chapter 17 (bottom panel of boxes) address a wide range of issues (keywords in bottom panel) that manifest at one or more stages of climate risk management processes, illustrated by icons for section numbers and Cross-Chapter Boxes in the interactive risk management process.

Decision-making processes of risk management and adaptation are varied and numerous. Section 17.2 assesses the risk management and adaptation options already in practice. Section 17.3 assesses decision-support methods and tools available for application and the effectiveness of these in supporting climate decision-making across degrees of uncertainties and levels of governance and expected reach (scale) across populations from households to international cooperation. Closely interlinked across the decision-making process, are the enabling and catalysing conditions for decisions on adaptation and risk management (section 17.4). Section 17.5 synthesizes evidence on maladaptation and adaptation successes, and assesses the current knowledge on M&E of adaptation, including financial accounting, to support learning on those, respectively. Here, M&E is considered distinct from the tracking of financial flows related to adaptation, given that financial accounting does not necessarily provide information on the implementation of adaptation measures and their results (see also Section 17.2.1.2). Finally, in Section 17.6, decision-making, climate risk responses, and their relevance for climate resilient development are presented, where evidence on their respective contributions to facilitate actions in the adaptation solution space within a broader context for development is shown (Chapter 18). Throughout the decision-making process, crucial feedback loops are present that define the results of specific actions and recursive nature of climate risk management and adaptation.

17.2 Risk Management and Adaptation Options

There has been substantial progress in risk management and adaptation responses around the world, as demonstrated in the sectoral and regional chapters of this report and illustrated in Chapter 16. This section presents an overview of different options available to manage risk, explaining how they are currently governed and the extent to which they can be applied around the world. This section contains an assessment of the ways in which different options are being combined to create adaptation portfolios, and describes how incremental and transformational change is starting to be considered. Based on the human dimension of climate change, as described in Chapter 8, vulnerability, inequality, and poverty influence these portfolios of adaptation and transformational change. Particularly for change where residual risks remain that may lead to exceeding the limits of adaptation, increasingly transformational adaptation and policy innovation will be important.17.2.1 assesses options for climate risk management from around the world that reduce, manage, or retain climate-related risks and assesses their contribution to reducing vulnerability and exposure, how they are governed, and the benefits to humans and ecosystems. 17.2.2 presents portfolios of risk management including the design principles and observed variations across the globe, before it discusses the need and potential for transformational adaptation to complement incremental adaptation, for which we present evidence across the report for selected adaptation options and some key risks. The Cross-Chapter Box LOSS in this Chapter synthesises recent literature and assesses key strands of the international dialogue policy on Loss & Damage, concerned with options that help to deal with residual impacts and risks in vulnerable countries.

17.2.1 Adaptation Options for Climate Risk Management

This section assesses options for climate risk management (CRM) across common risk settings that have been grouped into Representative Key Risks (RKRs). These risk management and adaptation actions target the components of risk: hazards, vulnerabilities, and exposure associated with sudden or slow-onset events (see Chapter 1 for more details on the definition of risk).

For each of the RKRs, three commonly discussed adaptation options are identified across the regional, sectoral, and cross-chapters papers of this report. These 24 options have been selected to cover a representative variety of strategies to adapt to climate change, while a particular adaptation option can be relevant to many of the RKRs. For example, the adaptations listed under the RKR of "Food security" are also related to the RKR on "Human health" (Ebi and Prats, 2015). See SM17.1 for more details. The list is not comprehensive of all possible adaptations listed in the regional and sectoral chapters. For example, this does not include adaptations by institutions who might become unable to cope with increasing pace and magnitude of extreme events (see Chapter 11).

17.2.1.1 Adaptation Options and Their Contribution to Reduce Vulnerability and Exposure

Table 17.1 provides examples of each of these 24 adaptation options from across AR6 WGII. Detailed information about sectors and regions where these adaptations are being discussed can be found in the indicated chapters. Note that this list is curated to ensure a diversity of options, therefore most of the options will apply to more than one RKR.

Table 17.1: Selected adaptation options per RKR, with examples of how each option can reduce vulnerability or exposure, or support risk financing. Many of the adaptation options are relevant to multiple RKRs, and have been selected to be representative of the wide variety of adaptation options implemented or suggested around the world.

RKR	Adaptation option	Examples from regional and sectoral chapters and cross-chapter papers
Risk to coastal socio-ecological systems	Coastal accommodation	Raising of dwellings, raising of coastal roads (15.5.2), amphibious building designs (CCP2), improved drainage (11.3.5.3)
	Coastal infrastructure	Seawalls, beach and shore nourishment (3.6, 15.5.1), breakwater structures (15.5.1), dikes, revetments, groynes, or tidal barriers. (6.3.4.8)., land reclamation (15.5.2)
	Strategic coastal retreat	Retreating from coastal areas (3.6, Cross-Chapter Box SLR in Chapter 3, 6.3.5.1, CCP2), relocation/resettlement (CCP2)
Risk to terrestrial and ocean ecosystems	Restore/create natural areas	Marine protected areas (FAQ 3.5), active restoration of coral reefs (3.6.2.3.2), ridge-to-reef management (CCP1), restoring dunes (CCP4), planting salinity-tolerant trees (4.5.2.1) Increasing forest cover (CCP7), detect and manage forest pests (11.3.4.3)
	Reduce ecosystem stress	Reduce pollution and eutrophication (3.3.3), reduce anthropogenic pressures on the Great Barrier Reef (Box 11.2), sustainable fisheries harvest (3.6.2), increasing connectivity between natural areas (2.6.2)
	Ecosystem-based adaptation	Marine habitats to protect against storm surge (3.6), agroecology (5.14.1.1), coastal and marine vegetation and reefs (6.3.3.4), vegetation corridors, greenspace, wetlands (FAQ 6.3), mangrove habitat restoration (8.5.2.2, 9.8.5.1), restoring coasts, rivers, wetlands to reduce flood risk (2.6.3, CCP1), wrban green space to reduce temperatures (2.6.3)
Risks associated with critical physical infrastructure, networks, and services	Infrastructure retrofitting	Air conditioning (6.3.4), using thermosiphons for permafrost degradation (10.4.6.4.1), increasing rooftop albedo (for reflectivity) (11.3.5.3), shading (13.A.4)
	Building codes	Drainage systems (4.5.2.1), architectural and urban design regulations (6.3.4.2), infrastructure standards initiatives (CCP6), Chile's Sustainable Housing Construction Code (12.5.5.3)
	Spatially redirect development	Zoning/land use planning (6.3.2.1), spatial development planning to regulate coastal development (CCP2)
Risk to living standards and equity	Insurance	Agricultural insurance and micro-credit (4.5.2.1, 10.4.5.5), index-based insurance, market and price insurance (5.14.1.3), flood insurance (10.5.3.2), collective insurance schemes (12.5.7.5)
	Diversification of livelihoods	Combining income-generating activities within fisheries sector (3.6.2.2) Community level adaptation by Pangnirtung Inuit through diversification to stabilize income and food resources (CCP6)
	Social safety nets	Food for work programmes (4.5.2.1), school feeding programmes (7.4.2.1.3), social protection programmes, such as unemployment compensation (10.5.6)
Risk to human health	Availability of health infrastructure	Safe drinking water infrastructure (4.5.2.1), temperature-controlled low-income housing (11.3.6.3), Health care clinics (6.4 case study), place-specific mental health infrastructure and “nature therapy” (14.4.6.8)
	Access to health care	Access to healthcare services (11.3.6.3), Access to Health, Nutrition Services and Healthy Environments (water and sanitation) (7.6), enhanced access to culturally-appropriate mental health resources; “Telemedicine” (information technologies and telecommunications for health and public health service delivery) (12.6.1.5)
	Disaster early warning	Early warning of marine heatwaves (3.6.2.3.3) early warning for pests (5.12.5), Heat Action Plans (HAP) (7.4.2.1.2), raising public awareness through campaigns (FAQ13.3)

Risk to food security	Farm/fishery improvements	Changing fishing gear or vessel power (3.6.2.2.3), change crop variety or timing (4.5.2.1, CCP5, 8.5), close productivity gaps (5.12.5), biotechnology (5.12.5), irrigation schemes (9.12.5.3), integrated crop/livestock systems (5.10.1), relocating livestock linked to improved pasture management (13.5.2)
	Food storage/distribution improvements	Improve transportation infrastructure and trade networks, shortened supply chains (5.12.5, 9.12.5.3), improved food storage (5.12.5, 7.4.2), local food production/chains (Cross-Chapter Box COVID in Chapter 7)
	Behaviour change in diets and food waste	Reduce food loss and waste (5.12.5), shifts to more plant-based diets (7.4.5.2), creating demand for organically sourced food (10.5.3.2)
Risk to water security	Water capture/storage	Farm ponds and revival of water bodies (4.5.2.1), rain gardens, bioswales or retention ponds (6.3.3.6), water storage tanks (10.5.3.2), multi-purpose water reservoirs and dams (CCP5)
	Efficient water use/demand	Precision/drip irrigation (4.5.2.1), Managed Aquifer Recharge (MAR) (9.4), cooperative policies across multiple sectors (CCP4), changing water consumption patterns (CCP4)
	Efficient water supply/distribution	Constructing irrigation infrastructure (4.5.2.1), inter-basin transfers (6.3.3.6), water reuse (13.A.3), slum/water upgrading (6.4.3)
Risk to peace and migration	Seasonal/temporary mobility	Fishing fleet mobility to follow species distribution (3.6.2.2.2), mobility for seasonal employment and remittances (4.5.2.1, Cross-Chapter Box MIGRATE in Chapter 7), legal/illegal labour migration (CCP3), pastoralist seasonal migrations (Cross-Chapter Box MIGRATE in Chapter 7)
	Cooperative governance	Transboundary fishing agreements (3.6.4.1), ocean governance (3.6.2.2), collective water management (4.5.2.1), indigenous water-sharing systems (4.5.2.1), enforcing the land rights of indigenous populations (CCP7), adaptive co-management in Arctic fisheries (CCP6), international compact on migration (Cross-Chapter Box MIGRATE in Chapter 7), policies for adaptive governance (8.5)
	Permanent migration	Resettlement of flood-prone communities (4.5.2.1), rural-urban migration (6.1 case study), internal migration (Box 10.2), international migration and remittances (8.6.3, 14.4.7.3)

Of this list of adaptation options, many focus on reducing vulnerability to climate change (*high confidence*), as vulnerability is one of the components of risk (see Chapter 1 and Chapter 8). Vulnerability is the propensity or predisposition to be adversely affected, including sensitivity or susceptibility to harm and lack of capacity to cope and adapt (see Chapter 1 for more details). In the world's threatened ecosystems, reducing vulnerability often means reducing other non-climate negative pressures on ecosystems, such as pesticide use or fishery overexploitation (see Chapter 3.3).

Vulnerability reduction is also a major focus in human systems, and this includes development of investments that help people adapt to climate change. Examples include irrigation or diversifying crops. Building infrastructure resilient to climate-related risks is another example; many of the structural and physical adaptation options can reduce sensitivity to disasters, such as elevating houses or doing beach nourishment in coastal areas (see Section 15.5 in Chapter 15). Extreme events often catalyse investment in adaptation to reduce vulnerability for the future (Kreibich et al., 2017; Slavíková et al., 2021).

Next to vulnerability reduction, a large number of adaptation options focus on reducing exposure to climate change (*high confidence*). Selecting low-risk locations is the most basic example of reducing exposure; for example, private companies are relocating factories to reduce flood-related disruptions to their supply chain (Neise and Revilla Diez, 2019) and species are autonomously adjusting their ranges to a changing climate (see Section 2.4). Land use planning or investing in resilient infrastructure can avoid exposure in rapidly urbanizing areas, however, the design and enforcement of these regulations can negatively impact marginalized people (Anguelovski et al., 2016).

Managed retreat is an example of exposure reduction that, while often controversial, is increasingly being considered and implemented (CCP 2.2.2, Section 15.3.4; Cross-Chapter Box LOSS in this Chapter; Siders et al., 2019). Examples include the US Hazard Mitigation Grant Programme, which, among other activities, has helped people resettle outside of flood zones, and a "no-build zone" established in the Philippines after Typhoon Haiyan (Hino et al., 2017). However, relocation is not always an option; immobility is sometimes involuntary, e.g., in the case of "trapped" populations in Zambia (Nawrotzki and DeWaard, 2018; Section 8.2.1.3).

However, adaptation efforts can have negative impacts on ecosystems and vulnerable groups (*high confidence*); see Table 17.2 and Section 17.5 for further information on maladaptation. While "hard" structural investments have been popular to reduce exposure to climate extremes, barrier-type measures provide protection only up to a certain limit, and are designed to fail in more extreme events. Given the risk of catastrophe from a climate extreme overcoming a physical barrier, policy advancements in recent years encourage any investment in structural measures to be complemented by "softer" vulnerability reduction measures, such as accommodating building construction (Wesselink, 2016).

When it comes to "softer" vulnerability reduction initiatives, these were traditionally seen as "no regrets" options for adaptation. However, subsequent studies have cautioned that notion as vulnerability is a dynamic quality, and can be co-created while development or adaptation efforts are being implemented (Schipper and Pelling, 2006; Tempels and Hartmann, 2014; Dilling et al., 2015). Some scholars have suggested the application of a "do no harm" principle to climate change adaptation efforts (Mayer, 2016).

17.2.1.2 Governance of Adaptation Options

For each adaptation option identified for the RKRs (Table 17.1), this section presents an assessment of how decisions are made and how the adaptations are being governed. The following section then covers benefits to humans and ecosystems, and potential for maladaptation is covered in section 17.5. See SM17.1 for more information on the assessment methods and underlying citations.

The following analysis of adaptation options provides a synthesized overview of adaptation globally, but does not prescribe how important each adaptation should be in specific locations. Chapter 16 finds that the "scope" and "speed" of adaptation is limited in many areas.

When it comes to decision-making, most of these 24 adaptations rely strongly on formal decision-making (*high confidence*), which follows the procedures of a group of people rather than ad-hoc individual action.

Formal decisions play a particularly strong role in the adaptations identified for infrastructure, early warning systems, and water systems (Kolen and Helsloot, 2014; Calvello et al., 2015; Zhao et al., 2017; Belčáková et al., 2019; Teo et al., 2019).

In contrast, informal or individual-led decision-making is more common in several food security-related and livelihood related adaptations, such as changes to diets, livelihood diversification and seasonal migration (*high confidence*) (Li et al., 2017; Radel et al., 2018; Robinson et al., 2020). People who have experienced climate shocks are more likely to take individual decisions to implement adaptation measures, and in countries where people are more exposed to extreme events, autonomous adaptation is more common (Koerth et al., 2017; Aerts et al., 2018b; van Valkengoed and Steg, 2019).

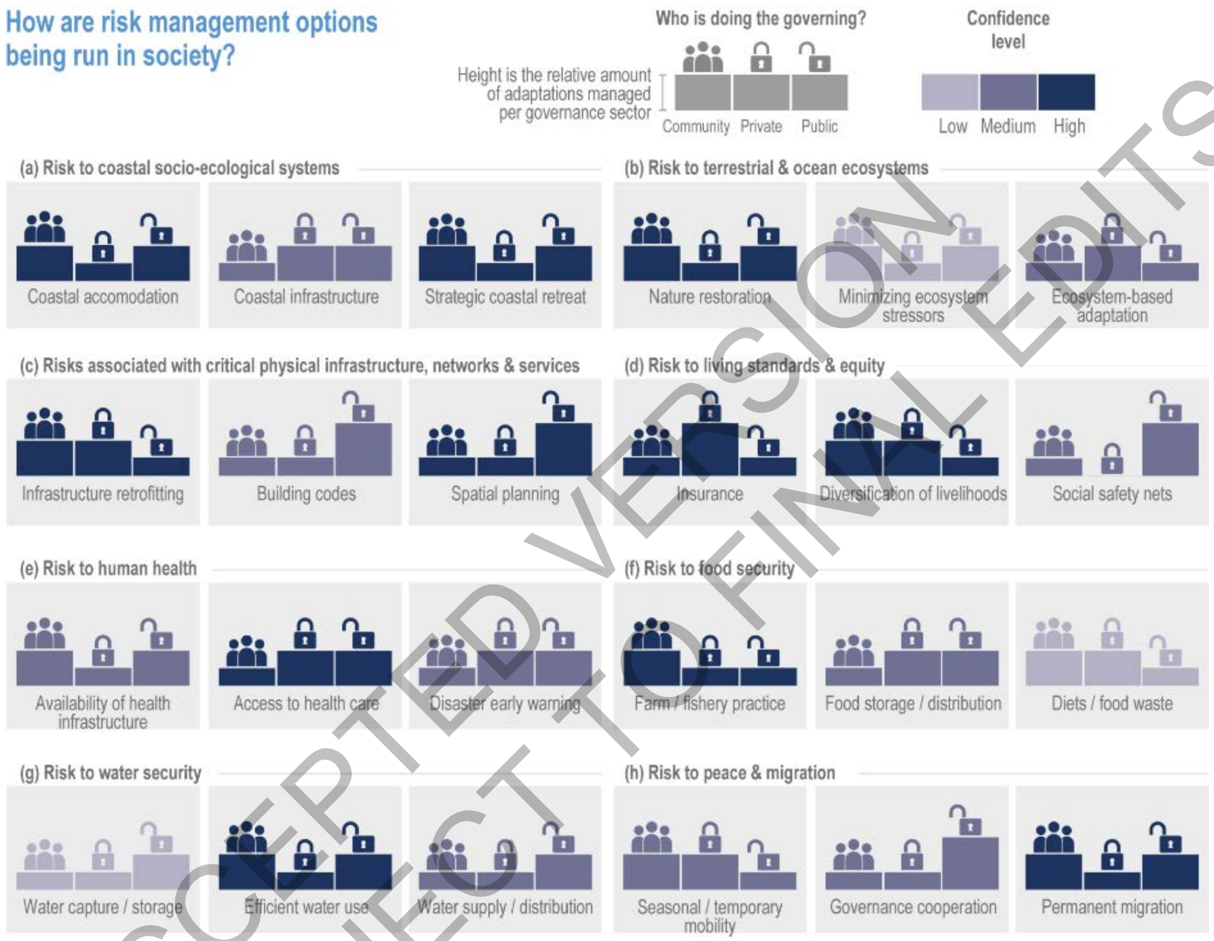

Figure 17.2: Governance of 24 major risk management options, grouped by relevance to the representative key risks. Each option depicts the relative governance roles, between communities/individuals, private sector, and public sector. The intensity of the colour refers to the level of confidence in the assessment.

All adaptation options can occur under a range of governance arrangements (*high confidence*), with cases of either private, public, or community governance typically playing the dominant role, as depicted in Figure 17.2. Public governance is the most frequent governance type for most adaptations considered. This is particularly true for social safety nets and spatial planning, where governments are often required to lead adaptation efforts *(high confidence)* (Mesquita and Bursztyn, 2016; Hssaisoune et al., 2020; Wang et al., 2021). While government actors do the day-to-day management of these systems, civil society and international organizations also play a role in shaping agendas and priorities of government actors (Nagle Alverio et al., 2021).

The private sector plays a large role in governance of insurance, minimizing ecosystem stressors, and livelihood diversification *(medium confidence)* (Allen et al., 2018; Mimet et al., 2020; Alam et al., 2020a). While having a key role in shaping and implementing many other adaptations, the private sector is not often the governing entity.

There are a number of adaptation options that tend to be governed by communities and individuals, including adaptations to farming and fishery practices and ecosystem-based adaptations *(high confidence)* (Reid, 2016; Basupi et al., 2019; Giffin et al., 2020; Karlsson and Mclean, 2020). In rapidly urbanizing areas of Asia and Africa, individual or community-led adaptation is the norm in informal settlements that have poor governance structures. Residents of Mathare slum in Nairobi have established methods to pool risks, such as pooling labour to police looting during flood events and developing community health centres in churches (Thorn et al., 2015). This is in addition to risk reduction measures such as building structures to withstand rising water levels (Thorn et al., 2015). Residents in Bangkok have built walls around settlements, dug informal drainage channels to vacant lots, and filled areas of land (Limthongsakul et al., 2017). In these cases, individual-lead adaptation can have negative side-effects, such as the building of flood defences in affluent communities increasing the flood impacts in less affluent regions of a city (Limthongsakul et al., 2017).

17.2.1.3 Benefit to Humans and Ecosystems

While some of the 24 adaptation options are specific to certain risk contexts (e.g. coastal areas, agricultural production), others are more widely applicable (e.g. early warning systems, health care systems, creation/restoration of natural areas). Figure 17.3 depicts which of these are most context-specific, e.g. benefitting less than 1 billion people. This is contrasted with the extent to which each adaptation option is beneficial to ecosystem services. Many of the more generalizable adaptations have also been shown to have benefits to ecosystem services, such as nature restoration and changes to diets/food waste (*medium confidence*). While health care systems and the establishment of health-related infrastructure can be widely used as adaptation options, their design and application to-date have not generally benefited ecosystems or ecosystem services (*medium evidence, low agreement*).

Table 17.2: Breadth of applicability of each adaptation option benefiting humans, i.e number of people (x axis), estimated by the degree to which each adaptation can be applied across multiple contexts. The benefit of each adaptation option for ecosystems and ecosystem services (y axis). See Annex A for literature underpinning each assessment. This figure uses the 24 representative adaptation options from Table 17.1 and Figure 17.2. Reduce water demand**

Benefit to humans & ecosystems
from representative adaptation options

Confidence level: • Low, •• Medium, ••• High

Breadth of applicability of each adaptation option in its benefit to humans

Benefits of each adaptation option for ecosystems & ecosystem services	Can reduce the exposure or vulnerability **of specific groups of people** i.e. <1 billion people	Can reduce the exposure or vulnerability **of many people** i.e. between 1–5 billion people	Can reduce the exposure or vulnerability **for most people in the world** i.e. >5 billion people
Highly beneficial	- Ecosystem-based adaptation (•••)	- Minimizing ecosystem stressors (••)	- Nature restoration (•••) - Diets/food waste (•••)
Moderately beneficial	- Strategic coastal retreat (•••) - Efficient water use/demand (••) - Seasonal/temporary mobility (••) - Permanent migration (••)	- Diversification of livelihoods (••) - Farm/fishery practice (•••)	- Infrastructure retrofitting (•••) - Building codes (••) - Disaster early warning (•••) - Governance cooperation (••)
No clear & different benefits / harms	- Coastal accommodation (••) - Food storage/distribution (••) - Water supply/distribution (•)	- Social safety nets (•) - Water capture/storage (•)	- Spatial planning (•) - Availability of health infrastructure (••) - Access to health care (••)
Worsens the situation	- Coastal infrastructure (•••)	- Insurance (••)	

As a general method related to adaptive management, "early warnings" are the most frequently discussed adaptation option to deal with a changing climate across all key risks, sectors, and regions. Early warning systems are an adaptation that can benefit more than 5 billion people (*high confidence*). Examples range from short-term disaster early warning systems to revision of sea level rise plans based on monitoring. For example, the humanitarian community is investing in forecast-based financing systems to prepare for extreme events (Coughlan de Perez et al., 2015; MacLeod et al., 2021). Forecasts are also used to manage hydropower dams (Ahmad and Hossain, 2020), to trigger interventions before public health emergencies (Chapter 7.4.2) and to alert fishermen of algal blooms in the world's oceans (Chapter 3.6.2.3.3). Table 17.3 provides examples of adaptations using early warning systems that have been used to address each of the key risks.

In addition to immediate investments that reduce vulnerability and exposure, monitoring and early warning systems allow people to take additional actions when there is an imminent event on the horizon (e.g. temporary evacuation during extreme events rather than permanent migration). This allows for ongoing adaptive decision making (Alessa et al., 2016; Ebi et al., 2016; Barnard et al., 2017; Haasnoot et al., 2018). However, these systems are only cost-effective for forecastable and actionable hazards, and require effective institutional governance (Wilkinson et al., 2018; IPCC, 2019c).

Table 17.3: Examples of adaptation investments and early warning system options for adaptive management for each of the key risks in Chapter 16.

Key risk	Adaptive Early Warning Systems-based measures
Risk to coastal socio-ecological systems	Storm surge early warnings (15.5.7) Early warnings of water-borne disease (Ch 3.6.2.3.3)
Risk to terrestrial and ocean ecosystems	Fishery marine heatwave warnings and mobile fishing equipment (Ch 3.6.2.3, 13) Forecast of shifts and regime changes in ecosystems (Pace et al., 2015; Bauch et al., 2016; Burthe et al., 2016).
Risks associated with critical physical infrastructure, networks, and services	Early warning for infrastructure and services (Ch 13.2.2.1, 10.4.6.4.1)
Risk to living standards and equity	Adaptive social protection systems (Schwan and Yu, 2018; Ulrichs et al., 2019; Daron et al., 2021).
Risk to human health	Heat health early warning systems (Ch 7.4.2.1.2) Health and disease monitoring and outbreak prediction (Ch 7.4.2.1.1, Ch 12.5.6)
Risk to food security	Forecasting rainfall and droughts for seed selection (Ch 10.5.2.2.3), Food price early warnings (Ch 7.4.2.1.3)
Risk to water security	Early warnings for flood and drought (Ch 4.4.1, 10.5.2.2.3, 15.5.7)
Risk to peace and migration	Transboundary flood early warnings (Tuncok, 2015).

17.2.2 Combining Adaptation Options: Portfolios of Risk Management and Risk Governance

While the above assessments underlying Figures 17.2 and 17.3 isolate specific risk management options for specific risks, several adaptation measures are present in any given location, affecting the overall risk of a particular place. Policymakers are charged to evaluate risk comprehensively, deciding on a variety of measures that are effective, feasible, and aligned with other policy goals for a specific place, or implementing a new activity because of how it complements the existing package of risk management activities (Girard et al., 2015).

17.2.2.1 From Risk Prevention to Risk Financing and Risk Retention

Portfolios of adaptation options generally include actions to reduce vulnerability and exposure, complemented by risk financing mechanisms that help people avoid the impacts of loss events, particularly very rare ones. There is also explicit or implicit risk retention, where further risk management is not desirable, cost-effective or feasible (Mechler and Deubelli, 2021). Risk financing can include a variety of instruments, with insurance as the most widely known. Formal insurance uptake is less in developing and emerging economies than in wealthier countries (Ali et al., 2020). To overcome some of the barriers to insurance uptake, index insurance has been offered for agriculture and livestock in many developing economies, with varying levels of success (Chantarat et al., 2013; Isakson, 2015; Dewi et al., 2018). In recent years, regional disaster insurance pools for sovereign states have been established, such as the Caribbean Catastrophe Risk Insurance Facility (CCRIF) (Iyahen and Syroka, 2018). Insurance can encourage the quantitative evaluation of climate-related risks and adaptation limits, and it can incentivize risk reduction by charging lower premiums for less risky situations (Schäfer et al., 2019).

While insurance is increasingly accepted as an adaptation option (Linnerooth-Bayer and Hochrainer-Stigler, 2015), positive outcomes are not guaranteed *(high confidence)*. First, there are concerns as to whether this will shift responsibility to the most vulnerable people to pay premiums (Surminski et al., 2016). There is also high risk for insurance to cause maladaptation (Müller et al., 2017); for example, Annan and Schlenker (2015) showed that insured crops were less well adapted to heat stress. To avoid this, people simultaneously invest in insurance and adaptations that reduce vulnerability/exposure *(medium confidence)* (Surminski et al., 2016; Highfield and Brody, 2017; Schäfer et al., 2019; Reguero et al., 2020).

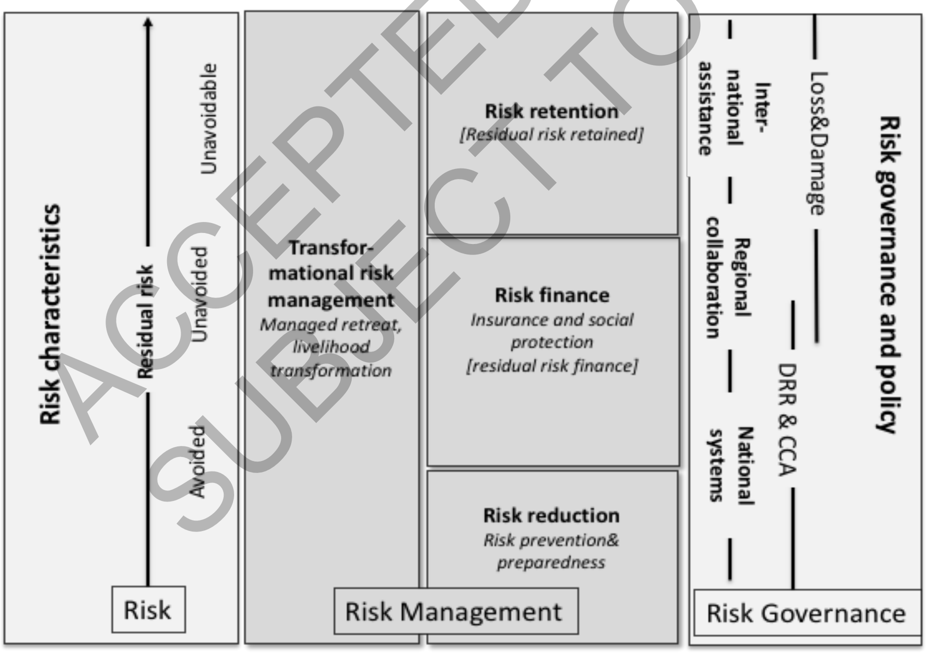

Figure 17.3: A graphical representation of layered risk management. Risks can be reduced or managed by risk finance (insurance and other means), but some residual risk remains, particularly for high impact unavoided and unavoidable risk, which is retained implicitly or explicitly. Where incremental and in situ adaptation is not effective in managing risks, transformational adaptation supports systemic change. Risk management occurs in national systems and regional insurance systems have stimulated regional collaboration. Particularly for high impact risks and impacts in specific events, international assistance is required. Policy domains on Disaster Risk Reduction (DRR) and CCA (Climate adaptation) as well as Loss&Damage overlap in their governance of risk management. Figure building on Mechler et al. (2014); Cummins and Mahul (2009); Lal et al. (2012); Mechler and Deubelli (2021).

The combination of interventions that reduce risk and risk finance for residual risk (often through insurance for sudden-onset events, or social protection for risks including linked to slow-onset processes) will reduce collective risk to a certain level. For very extreme and potentially catastrophic events, it is often impossible (or financially infeasible) to fully reduce vulnerability and exposure, and people, communities and countries therefore retain requiring the ex-post management of unavoided and unavoidable residual impacts in case of events.

Ex-post risk management relies on national assistance, social safety nets (Ch. 7.4.2.1.3; Béné et al., 2012; Elmi and Minja, 2019), and support from social networks as well as lending from international institutions (*high confidence*) (Hochrainer-Stigler et al., 2014). Even in places where normalized losses have stabilized in recent years with investments in adaptation, effective planning to manage losses remains necessary (Jongman, 2018). Resilient recovery can support adaptation goals in periods of loss and damage (Slavíková et al., 2021).

To coordinate between a suite of applicable risk management interventions, the concept of risk layering has been discussed and used in (financial) risk governance for disaster risk management (Mechler et al., 2006; Cummins and Mahul, 2009; Clarke and Mahul, 2011) and climate risk management (Lal et al., 2012; Mechler et al., 2014; Herron et al., 2015; Schäfer et al., 2016; Mechler and Deubelli, 2021). Incremental risk prevention and preparedness as well as risk financing occur within national systems. Over the years, regional cooperation, such as through the regional sovereign insurance pools in the Caribbean, Pacific, Africa, but also transboundary risk management elsewhere have become more important (*medium confidence*) (see Martinez-Diaz et al., 2019). Also, with risks increasingly experienced as severe and existential (Boyd et al., 2017), global governance and solidarity have been invoked (see, Linnerooth-Bayer et al., 2019; Pill, 2021), largely as part of the policy discourse on Loss & Damage (Mechler et al., 2019) with further momentum provided by discussions on the global goal of adaptation and recognition of climate risk as transboundary (Benzie and Persson, 2019; Cross-Chapter Box INTERREG in Chapter 16). Transformational risk management has emerged where incremental and in situ adaptation is not effective in managing risks, such as for managed or strategic retreat for communities facing severe coastal and riverine flooding (Siders et al., 2019). Transformation has not been well documented including as to its governance (see 17.2.2.5).

17.2.2.2 Global Variation in Portfolios of Risk Management

While many studies assess adaptation trends by geographical region or by sector, the amount of residual risk varies across countries with different income and governance structures. Vulnerability, poverty, and inequality, which constitute the human dimensions of climate change, affect how these portfolios of adaptation options are structured around the world (see Chapter 8). Figure 17.4 depicts several illustrative "typologies" of how risk is addressed. While no country or location fits any one typology, this illustrates a range of risk portfolios found in different contexts.

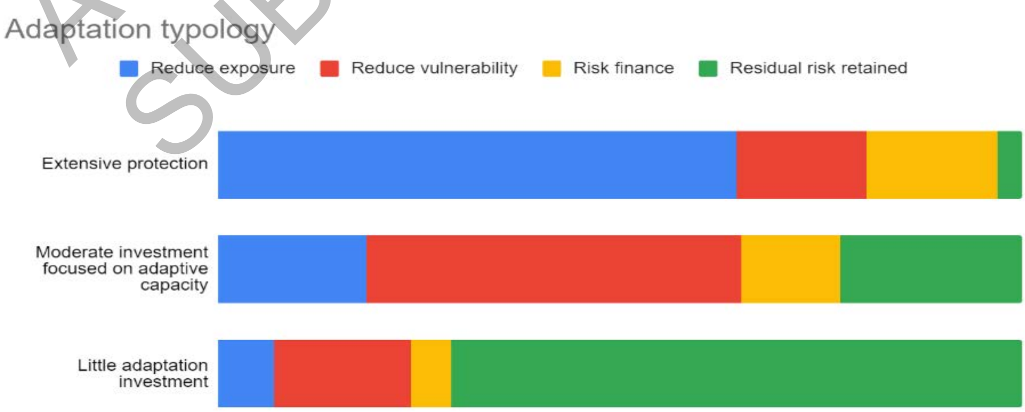

Figure 17.4: Several illustrative typologies for how risk has been managed. The first is "extensive protection", in which the bulk of investments are made in reducing exposure, through protection up to limits (e.g. flood levees) and including

retreat. The second category is "Moderate investment focused on adaptive capacity", in which the bulk of investment is made in reducing vulnerability (e.g. improved housing). The third category is "Little adaptation investment", in which there is little investment in either reducing vulnerability or exposure, and the bulk of risk is residual, borne by the population.

Extensive protection category

The first category in this typology, that of "extensive protection", requires substantial financial investment (Figure 17.4). In higher-income contexts, this is often more feasible than in contexts with limited resources, and adaptation investments are more likely to include structural measures to reduce exposure, complemented by vulnerability-reducing measures and insurance protections (*medium confidence*). While this typology is not universally representative of high-income areas (within or between countries), expensive exposure-reduction measures tend to be easier to implement in high-income countries. For example, flood protection is largest in countries with larger amounts of public spending and least amounts of corruption (Scussolini et al., 2016). It is seen as more economically efficient to invest in expensive protection measures in wealthy regions, under different scenarios of sea level rise and river flooding, although these calculations have equity and justice implications (Peduzzi, 2017; Lincke and Hinkel, 2018). After flood events happen in regions with high levels of protection, damages are comparatively limited, and people tend to continue living in close proximity to the protected river (Mard et al., 2018). In contrast, flood displacement is higher in low-income countries (Kakinuma et al., 2020).

Risk financing, especially insurance, is also common in higher-income countries with well-developed insurance markets and higher levels of insurance penetration than in lower income countries, illustrated by the green bar in Figure 17.4 (*high confidence*) (Linnerooth-Bayer et al., 2019). Of climate-related disasters, floods and storms cause the largest amount of reported economic losses, however, at least 40% of these losses are uninsured, even in the regions with high insurance penetration (Baur et al., 2018). Government involvement in insurance schemes is associated with higher penetration rates of the general population (Paleari, 2019). While some, predominantly high income countries can make use of disaster contingency funds or dedicated budget items, these do not exist or are not well endowed to adequately support relief, recovery and reconstruction (Linnerooth-Bayer and Hochrainer-Stigler, 2015). To help stabilize public finance in regions with little market-based insurance coverage and fiscal response mechanisms, regional public insurance pools have been set up with donor assistance, e.g., in the Caribbean, Africa and the Pacific for flood and droughts (Schäfer et al., 2016; Surminski et al., 2016; Linnerooth-Bayer et al., 2019).

Moderate investment focused on adaptive capacity

In contrast to the "extensive protection" scenario, many regions of the world bear greater resemblance to the second typology in Figure 17.4 "moderate investment focused on adaptive capacity" (*medium confidence*). These contexts see greater adaptation funding invested in capacity building activities to reduce vulnerability, rather than structural or ecosystem-based protection measures to reduce exposure (Biagini et al., 2014). Because of limited international and domestic finance for large structural investments to reduce exposure, the most prevalent adaptation choices in low-income contexts are household-level vulnerability-reducing measures (Koerth et al., 2017).

Lack of access to finance can be one of the reasons countries engage more readily in adaptive capacity-building activities. Countries that rank highly on the Corruption Perceptions Index engage less in technological solutions for risk management (Berrang-Ford et al., 2014). In addition, countries with higher levels of corruption receive less adaptation aid (Betzold and Mohamed, 2017; Weiler et al., 2018). Countries are more likely to receive adaptation aid if they import goods from a donor country, or are a former colony of that donor (Betzold and Mohamed, 2017; Weiler et al., 2018). In countries with poor governance and limited aid flows, remittances make up a substantial portion of finance available to the local population for risk management (Samuwai and Hills, 2018).

Risk financing does play a large role in the "moderate investment" category; there are a variety of instruments in use globally. Many countries in the Global South have created national policies and a number of regional catastrophe risk insurance pools, subsidized by international assistance, which make pay-outs to the national government of affected nations when an extreme event happens and have helped to build risk awareness (Clarke et al., 2015; Thirawat et al., 2017). Beyond this, residual risk is often borne directly by affected people (Andrianarimanana, 2015).

Little adaptation investment typology

In the third typology, there are limited resources for adaptation, and populations bear large amounts of residual risk (depicted by the orange bar in the third typology in Figure 17.4, "little adaptation investment"). Small Island Developing States can often find themselves in this situation, because small populations, small economies, lack of economies of scale, subsistence livelihoods, and other challenges mean risk reduction and risk financing are both costly (see Chapter 15).

Another example of this third typology are people living in conflict-affected areas. These populations are highly vulnerable to the impacts of climate change (Basher, 2006; OCHA, 2011; IPCC, 2012; Zommers and Singh, 2014; Marktanner et al., 2015; Walch, 2018; Eckstein et al., 2019; Peters et al., 2019). In conflict-affected areas similar to the third category of "little adaptation investment", a combination of high vulnerability and relatively few supports for adaptation means that there is a large amount of "residual risk", in which residents cope with the impacts of extreme events on a regular basis (*high confidence*). For example, deaths from "natural" disasters are 40% higher in areas that are undergoing armed conflict (Marktanner et al., 2015) (see Box 17.2).

[START BOX 17.2 HERE]

Box 17.2: Climate Risk Management in Conflict-affected Areas

Consequences of conflict that exacerbate vulnerability to climate change include: displacement, loss of access to employment leading to illegal livelihoods, gender-based violence, lack of land tenure, low literacy, poor access to social and health services, destruction, looting and theft of key assets, such as houses, food stocks and livestock, among others (Jaspars and Maxwell, 2009; Chandra et al., 2017; Anguita Olmedo and González Gómez del Miño, 2019). Such impacts perpetuate cycles of poverty (World Bank, 2013), making conflict-affected populations more susceptible to suffer from climate related events (Basher, 2006; Coughlan de Perez et al., 2019). For example, in Mindanao, Philippines, poverty is closely linked to long-standing armed conflicts; both climate change and conflict have significantly increased smallholder vulnerability, resulting in loss of livelihoods, financial assets, agricultural yield and the worsening of debt problems (Chandra et al., 2017). In Colombia, displacement induced by conflict has pushed the population to live in high-risk areas such as steep slopes susceptible to landslides and river banks exposed to flooding (Albuja and Adarve, 2011). This conflict-induced vulnerability, with little adaptation activity, has in turn resulted in climate-related disasters (Kuipers, 2019; Siddiqi et al., 2019).

Conflict can also limit the effectiveness of adaptation measures that do exist; a study across Africa, the Caribbean, and Asia concluded that poor governance can limit the effectiveness of early warning systems in these regions (Lumbroso et al., 2016). Poor state services have health consequences and can limit social support networks (Peters, 2018). States are unable (even if they are willing) to assist or protect citizens in disasters. Non-governmental stakeholders play a large role in these contexts, but questions of long-term implications and accountability remain unaddressed (Peters, 2018).

Climate risk management and adaptation in conflict-affected contexts is challenging, first, given the complex and dynamic nature of vulnerability (Hilhorst, 2003; Frerks et al., 2004) and second given factors such as weak or nonexistence disaster risk governance, restricted access, human rights violations, power dynamics between parties in conflict, and environmental degradation, among others (Kloos et al., 2013; Marktanner et al., 2015; ICRC, 2016; Quinn et al., 2017; Field and Kelman, 2018; Siddiqi, 2018). Climate can also be a contributing factor to conflict (Mach et al., 2019). There is little peer-reviewed documentation available on adaptation in climate-affected contexts, and what exists is narrowly focused on agriculture at the expense of other sectors, such as cities, infrastructure, and humanitarian operations (Sitati et al., Accepted).

To address risks to livelihoods, conflict-sensitive livelihood programming has used vouchers to meet immediate needs, legal support to resolve land disputes, and disaster preparedness planning to identify safe places for displacement (Jaspars and Maxwell, 2009). For example, cooperation in the Philippines between

Moro Islamic Liberation Front and United Nations agencies included training of farmers in disaster risk reduction, drought management, and production of improved crop varieties to support a transition away from subsistence farming (Walch, 2018). In Mali, negotiations on fertilizer access and safe transport to agricultural lands were brokered by the International Committee of the Red Cross, and in Afghanistan, conflict-sensitive approaches have promoted ecosystem-based adaptation to support reforestation (Walch, 2018; Mena and Hilhorst, 2020). Despite several examples of conflict-sensitive adaptation practices, little is known about the effectiveness of such efforts in reducing climate risks in these complex contexts (see Section 17.5 for further discussion of "effectiveness").

[END BOX 17.2 HERE]

17.2.2.3 Adaptation Beyond Risk: Exploiting Opportunities

Several studies and many government planning documents reference how people can benefit from a changed climate, beyond reducing risks. For example, several regions are expecting an increase in visitors to eco-tourism sites or national parks with a changing climate (Fisichelli NA, 2015; Lwasa, 2015). In Europe, several national adaptation plans include planning for potential benefits of a changing climate, including reduced winter mortality and improved conditions for hydropower (Biesbroek et al., 2010). Recognizing the need for economic diversification, people working in certain industries, such as coastal management, perceive climate change as a factor increasing the need for their services (Fatorić et al., 2017). Northern countries are taking advantage of ice-free waters for shipping routes in the Arctic (Eguiluz et al., 2016; Melia et al., 2016; IPCC, 2019e-a). In Africa, opportunistic adaptation has been observed by smallholder farmers, who plant crops that are better suited for a changing climate (Lalou et al., 2019). Similar agricultural adaptation in Pakistan has been associated with improved food security and reduced poverty (Ali and Erenstein, 2017; Rahman et al., 2020). In each of these cases documenting benefits, there are also potential negative impacts on other populations or ecosystems, such as ecosystem impacts from increased Arctic shipping (Ng et al., 2018).

While adaptation is rarely focused on taking advantage of opportunities presented by a changed climate, there are numerous co-benefits of adaptation opportunities, from health to reduced emissions to ecosystem services (*high confidence*) (Watts et al., 2015; Geneletti and Zardo, 2016; Spencer et al., 2016). There is also literature proposing that the actual process of adaptation planning can enable people to take advantage of opportunities, including, e.g., opportunities for larger policy and governance reform (Coleman and Sandhu, 1965; Ernst and Preston, 2017; Brown et al., 2017a).

17.2.2.4 The Spectrum from Incremental to Transformational Adaptation [Or Maybe Measures] in Risk Management Portfolios

Chapter 1.4.5 noted that transformational adaptation is increasingly being considered necessary to allow a system to extend beyond its (soft) limits as incremental adaptation cannot guarantee to avoid intolerable risks. Chapter 16.4 presents evidence on RKRs where a need for transformational adaptation and climate risk management has been identified in order to further reduce climate risks and avoid breaching adaptation limits. The following section identifies how the 24 adaptation options representative of the RKRs may support incremental and transformational risk management/adaptation that can lead to small, medium, and large systemic change, often as part of portfolios of options. This subsection further discusses the role of transformational adaptation vis a vis incremental adaptation by reviewing evidence across chapters (see also Box 17.3). The Cross Chapter Box on Loss and Damage further expands on the international debate regarding the role of decision-making on incremental and transformational adaptation for dealing with residual risks to address soft as well as hard adaptation limits (see Cross-Chapter Box LOSS in this Chapter).

As the literature distinguishes active transformation to shape future risks from passive and unintended transformation (Lonsdale et al., 2015; Chapter 1), the section queries how to inspire actors to consider how to develop or implement transformational adaptation to complement incremental adaptation/risk management when and where appropriate.

In contrast to a broadening literature on conceptualization and policy proposal, there has been little evidence reported in the literature of transformational adaptation and risk management at scale of implementation (*high confidence*) (Klein et al., 2017; Ajibade and Egge, 2019; Tàbara et al., 2019; Mechler and Deubelli, 2021). Deubelli and Venkateswaran (2021) review evidence on largely NGO -implemented community-level adaptation for floods, heat and drought across the globe. They suggest that transformational adaptation success, while multi-facetted and challenging, depends on the availability of appropriate enabling environments including experiential and niche learning, alignment of transformational change objectives with strategic (government or other actor's) priorities, strong bottom-up governance grounded in local contexts, phased long-term program support and appropriate financing.

In order to distinguish incremental from transformational adaptation, Lonsdale et al. (2015), building on Mustelin and Handmer (2013), identify criteria related to framing, learning and decision-making, space and time, power, and type of change management. Tàbara et al. (2019), additionally, discuss transformation in light of informing climate pathways, strategies and solutions. Broadly considering these criteria, they identify twelve dimensions with additional discussion of change with regard to systems and dynamics, options and solutions, agency, and the consideration of equity (see also Chapters 1, 6, 18 for more discussion). In particular, the following key aspects for understanding the spectrum from incremental to transformational adaptation are of relevance: change - within or across the system; agency-single or heterogenous, a role for visioning and normative futures, the type of learning required (from first order, business-as-usual, to second order), as well as how equity and distributional issues are explicit.

Applying these key aspects to the list of 24 adaptation options from Table 17.1, certain options are assessed to be more transformational, often requiring large system changes that go beyond addressing individual risks. Adaptations that are more transformative offer potential to lead to systemic change. Less transformative adaptations allow people to address specific climate-related risks while maintaining existing systems (See SM17.1 for more details; see also Box 17.3).

For example, several adaptations related to the RKR on risks to peace and migration, namely permanent migration, and cooperative governance, require moderate to high levels of transformation (*high confidence*). Some behavioural adaptations, such as changing diets and reducing food waste, can also require large transformations in land use and food culture (*medium confidence*). Spatial planning, including urban zoning, also tends to be more transformative (*medium confidence*).

On the other end of the spectrum, disaster early warning systems tend to be incremental rather than transformational (*high confidence*), because they enable people to maintain/protect existing systems. Several other adaptations allow people to maintain livelihoods and systems in the face of changing risks. For example, improvements in agricultural and fishing practices can be done with moderate transformation to systems (*medium confidence*). Similarly, insurance tends to require less transformation, as it can allow people to maintain existing systems while being more resilient to climate-related shocks (*medium confidence*).

None of the 24 adaptation options are consistently beneficial for vulnerable and marginalized groups (*high confidence*). For each adaptation, there are examples of how it has been implemented in a way that benefits poor, low-income, ethnic groups and/ or females, and other examples of implementation in different contexts that have worsened the risks for those groups specifically. For example, while the goal of cooperative governance can be to support the marginalized, these same marginalised groups are usually excluded from participating in the design of the solutions, and many articles criticise governance results as protecting only the interests of the wealthier and more powerful parties in the negotiations, especially in governance of migration (Groutsis et al., 2015; Pijnenburg et al., 2018). This reinforces the need for context-specific planning to ensure marginalized groups will benefit from an adaptation plan. See Table 17.4 for examples of how each adaptation option can have or not have equity benefits.

Table 17.4: The 24 adaptation options from Table 17.1 grouped and coloured by their potential for transformation. (See Appendix A for assessment methodology.) Adaptations in red tend to require small amounts of transformation, adaptations in orange tend to require middling levels of transformation, and adaptations in yellow tend to require large levels of transformation, or systemic change. Each option is paired with examples of how that adaptation can be done in a way that does not benefit, or worsens the situation for marginalized groups, as well as an example in which that

adaptation has benefitted those groups. Examples of equity focus on benefits to poor, low-income, ethnic groups, or females.
** low confidence, ** medium confidence, *** high confidence*

Adaptation	Example of the adaptation excluding or worsening the situation for marginalized groups	Example of the adaptation benefitting marginalized groups
Less transformation (small systemic change)		
Insurance**	Index-based insurance policies in Mongolia were accessible primarily to wealthy herders (Taylor, 2016b).	The availability of capital after disaster events can avoid a poverty trap from disasters (Alam et al., 2020a).
Coastal accommodation***	Accommodation strategies in Jakarta have led to a false sense of security in an impoverished and vulnerable neighbourhood (Esteban et al., 2017).	The mosaic restoration project provided training for women to support local accommodation of climate changes on Yap (Krishnapillai, 2018).
Early warning systems***	People of higher socio-economic status tend to receive warnings, while marginalized groups can be left out (Baudoin et al., 2016).	Famine and drought early warning systems have helped avoid starvation among the world's most vulnerable people (Funk et al., 2019).
Water use/demand***	Small farmers were unable to access supports to implement drip irrigation in Morocco, and uptake was greater among wealthy farmers (Jobbins et al., 2015).	Retrofits for water use efficiency were made available free of charge to low-income communities in the US (Lee and Tansel, 2013).
Coastal hard protection**	Construction of hard barriers increased flood risk for several low-income communities in Bangladesh (Adnan et al., 2020).	Successful coastal embankments can help people avoid poverty traps in Bangladesh by reducing exposure to flood events (Borgomeo et al., 2017).
Moderate transformation (medium systemic change)		
Infrastructure retrofitting**	Low-income people often do not own their homes, and there are few incentives for landlords to upgrade (Tardy and Lee, 2019).	Energy policy could promote solar infrastructure in Nigeria, which can offer electrification in underserved regions (Ohunakin et al., 2014).
Building codes***	Building codes in Nepal and Bangladesh often fail to increase resilience because many buildings are built informally (Ahmed et al., 2019).	Slum upgrading projects in Latin America reduced the vulnerability of informal settlements by improving built infrastructure (Núñez Collado and Wang, 2020).
Farm/fishery practice**	Many agriculture improvement strategies create higher workloads for women and do not directly enfranchise them, as seen in Uganda, Ghana, and Bangladesh (Jost et al., 2015).	Improved crop varieties have supported the income of low-income farmers in Zambia (Khonje et al., 2015).
Diversification of livelihoods*	Diversifying livelihoods can increase women's workloads, in a review of semi-arid	A study on diversity of income sources in Ghana indicated that diversification can

	regions across Africa and Asia (Rao et al., 2020).	make people less vulnerable to extreme events (Baffoe and Matsuda, 2017).
Social safety nets**	Social protection systems in Bangladesh focus on specific groups in rural areas, and they often fail to reach urban poor and other very disadvantaged people (Coirolo et al., 2013).	Adaptive social protection can help poor people avoid the impact of extreme events by scaling up support at critical moments (Bowen et al., 2020).
Infrastructure for health***	The development of sanitary water infrastructure in Germany had less benefit in areas with higher income inequality (Gallardo-Albarrán, 2020).	Improvements to water and sanitation infrastructure that avoid people fetching water is associated with improvements to women's health (Geere and Hunter, 2020).
Food storage/distribution**	Increasing/improving livestock markets can favour high-income livestock producers (Gautier et al., 2016).	Investments in large produce storage houses has supported indigenous livelihoods in the face of climate change (Mugambiwa, 2018).
Restoration/creation of natural areas**	Urban greening programmes in the US avoided minority neighbourhoods or caused displacement of people of colour (Anguelovski et al., 2016; Watkins et al., 2016).	Afforestation reduced landslide risk for informal settlements in Brazil (Sandholz et al., 2018).
Minimizing ecosystem stressors*	Fish quota reduction had negative economic impacts when done quickly (Barbeaux et al., 2020).	South Africa's Working for Water programme employed poor people to control invasive species (van Wilgen and Wannenburgh, 2016).
Ecosystem-based adaptation**	Payments to indigenous groups in return for protecting conservation land can be less than their original livelihoods and disadvantage those not receiving the payments, such as women (Bedelian and Ogutu, 2017).	Integrated water resource management is proposed in the Caribbean as a way to maintain ecosystem services while improving economic welfare (Mycoo, 2017).
Water supply/distribution**	Water tariffs during the Cape Town drought negatively impacted poor households (Millington and Scheba, 2021).	City Water Forums in Nepal have focused on equitable water allocation as an adaptation (Pandey and Bajracharya, 2017).
Seasonal/temporary mobility**	Women tend to have greater restrictions on mobility than men (Lama, 2018).	Indigenous communities in Guatemala use temporary migration to manage rainfall variability (Ruano and Milan, 2014).
Most transformation (largest systemic changes needed)		
Spatial planning**	Spatial planning in American cities has often resulted in less green space in ethnic minority neighbourhoods (Connolly and Anguelovski, 2021)	While difficult, strategic approaches to urban planning can promote inclusive development (Chu et al., 2017).
Diets/food waste*	Low-income groups have less opportunity to diversify diets if certain foods become more expensive or difficult to obtain (Reynolds et al., 2019).	Changing dietary intake during heatwaves (e.g. eating cooler foods) is seen as a low-cost adaptation accessible to low-income people in the UK (Porter et al., 2014).
Health care systems**	Facilities in poor communities are often poorly sited and can lack capacity to support	Universal health coverage can be highly beneficial to poor people (Atun et al., 2015),

	people during climate-related extreme events (Codjoe et al., 2020).	when needed for climate-related health outcomes.
Water capture/storage**	Many indignous populations have been negatively affected by loss of their land when displaced for dam construction (Siciliano and Urban, 2017).	Improving water harvesting supports marginalized populations in dryland areas (Bobadoye et al., 2016).
Cooperative governance**	International cooperation among national governments regarding migration can encourage human rights abuses and increase migration (Crawley and Skleparis, 2018).	International cooperation has the potential to remove barriers to adaptation in informal settlements in developing countries by sharing knowledge and expectations (Oberlack and Eisenack, 2014).
Permanent migration***	Permanent migration from small island nations can entail a loss of identity for indigenous groups (Bordner et al., 2020).	Migration supported by social protection systems can be sustainable for poor populations (Schwan and Yu, 2018).
Strategic coastal retreat***	Muslim people faced tensions with host communities when relocated in India, and faced difficulties in terms of fishing access and land size (Mortreux et al., 2018).	In several cases of post-disaster relocation, community members initiated the retreat and there were broader benefits to society (Hino et al., 2017).

17.2.2.5 Incremental and Transformational Adaptation for Managing Risk in the Context of Adaptation Limits

With evidence on soft and hard limits being experienced in natural and human systems including in terrestrial, aquatic and marine ecosystems, coastal and island systems, agriculture, health systems, urban spaces and tourism (Table 16.5, 16.4.2, *medium confidence*) transformation is also being considered to expand the adaptation space beyond soft limits and before hard limits are being reached. As a key area of advancement since AR5, this section assesses the relationship of residual risks, limits and incremental as well transformational adaptation integrating the assessment of limits in 16.4 with ch.17 adaptation and risk management assessment along a spectrum of adaptation change. 17.2.2.5 thus contributes to understanding in which systems and regions transformational adaptation is increasingly required and considered once incremental adjustments are exhausted in the context of soft and hard limits.

Assessing risk and limits requires in-depth analysis of the adaptability of human and natural systems under different warming and risk levels, also considering socio-economic exposure and vulnerability drivers, informed by perspectives on what breaching limits means, especially if significant change and losses and damages may occur (see 16.4, 8.4). Assessments differ between natural systems (where adaptation potential is often very limited; Klein et al., 2014) and human systems where incremental and transformational adaptation can help to extend soft limits so that hard limits are not met or to buy time until hard limits are reached with higher levels of warming.

The assessment synthesises global and regional evidence across regional and thematic report chapters along a continuum from observed to projected impacts and risks, the spectrum of incremental and transformational adaptation, and finally any evidence on soft and hard limits. We present regional evidence for two types of salient natural and human systems and Representative Key Risks: RKR-B (risk to terrestrial and ocean ecosystems), where we assess risks from marine heatwaves to coral reefs; and RKR- E (risk of heat on human health as a human system). Both RKRs and systems are facing substantial (residual) risk, characterised by adaptation limits and share heatwaves as the hazard, for which climate change has been considered the major driver of increasing intensity and frequency (*high confidence*)(IPCC, 2021). The assessment synthesises evidence on transformation as reported in the chapters as well as categorizes identified adaptation options along an adaptation spectrum according to the criteria discussed in 17.2.2.4, specifically whether adaptation leads to systems' change or only change within a system, is driven by multi-scale agency and considers equity impacts specifically.

Figure 17.5 organises global and regional findings for observed and projected health risks from heat (RKR-E) from chapters across the report and organizes options according to findings on the potential for transformational change as presented in17.2 and table 17.4. The discussion shows that heat has become a significant health risk globally, incurring severe mortality and morbidity in all world regions with annual heat related deaths estimated around ~300 000 with millions affected (*high confidence*) (9.3.1). Evidence shows that adaptation and risk management, can be effective in reducing (relative) risks in developed countries, with inconclusive evidence in low-middle incomes states (9.2.4.1, 13.7.3, 13.6). In absolute terms, risk in terms of heat-related mortality and morbidity is projected to increase under medium and high heating scenarios in many regions, even with implemented adaptation. By 2050 (compared to 1961-1991 and for a mid-range emissions scenario), an excess of 94,000 deaths per year is projected globally as attributable to climate change (9.3.1).

Planned and implemented adaptation interventions in all regions have remained largely incremental, while uptake is being intensified in some regions; options have included air conditioning (as autonomously deployed), public cooling spaces, heat action plans that incorporate early warning and response and heat-adapted building design (9.9.5, 11.3.6, 12.5.6.1.1,13.11.3, 13.11.3, 15.6.2).

Given increasing risks projected and already reported soft and hard limits, transformation is being considered as a complement potentially leading to systemic and transformational change. Adaptation, if upgraded to also consider transformational interventions, will thus help to reduce heat risks (medium-high confidence, limited evidence) albeit with reduced effectiveness at higher levels of warming, particularly in regions (Africa, Asia) where lethal heat waves are projected to occur almost annually towards later in the 21st (*medium confidence*) (9.1, 10.4.7).

This may involve urban redesign using nature-based solutions (such as green roofs and infrastructure) as well as rescheduling of outdoor labour or cross-sectorial coordination. Integrated approaches across interdependent systems (e.g. ecosystem- based approaches and climate-sensitive urban design) are being proposed. Also, it may mean bolstering social safety nets and health systems that better attend to heat impacts by providing universal coverage. Societal and political transformations to reduce climate change risks for vulnerable groups are considered particularly relevant in some regions (9.4.2.1.2, 9.9.5, 10.4.6.4.3, 12.5.3.2, 13.6.2.1, 14.6). Yet, across all regions there is limited evidence on proposed transformational adaptation and very little evidence regarding implementation (*high confidence*).

As a consequence, studies project soft limits to be further reached as increased mortality and morbidity will add stress to health systems, and labour productivity will be severely hampered impacting economic systems (*medium to high confidence*) at medium to higher levels of global warming (7.2.4.1, 9.10, 10.4.4.4, 11.9.1, 13.6.2.3, 13.7.2, 13.7.4, 13.10.2.1, 13.8, 15.3.4.9).

Hard limits may be breached in some regions where critical heat tolerance thresholds are projected to be surpassed at medium to higher levels of global warming, such as physiological survivability thresholds, which, e.g., may render urban outdoor labour in Asia, Africa and North America infeasible (10.4.6.3.2, 14.8, Box 9.1).

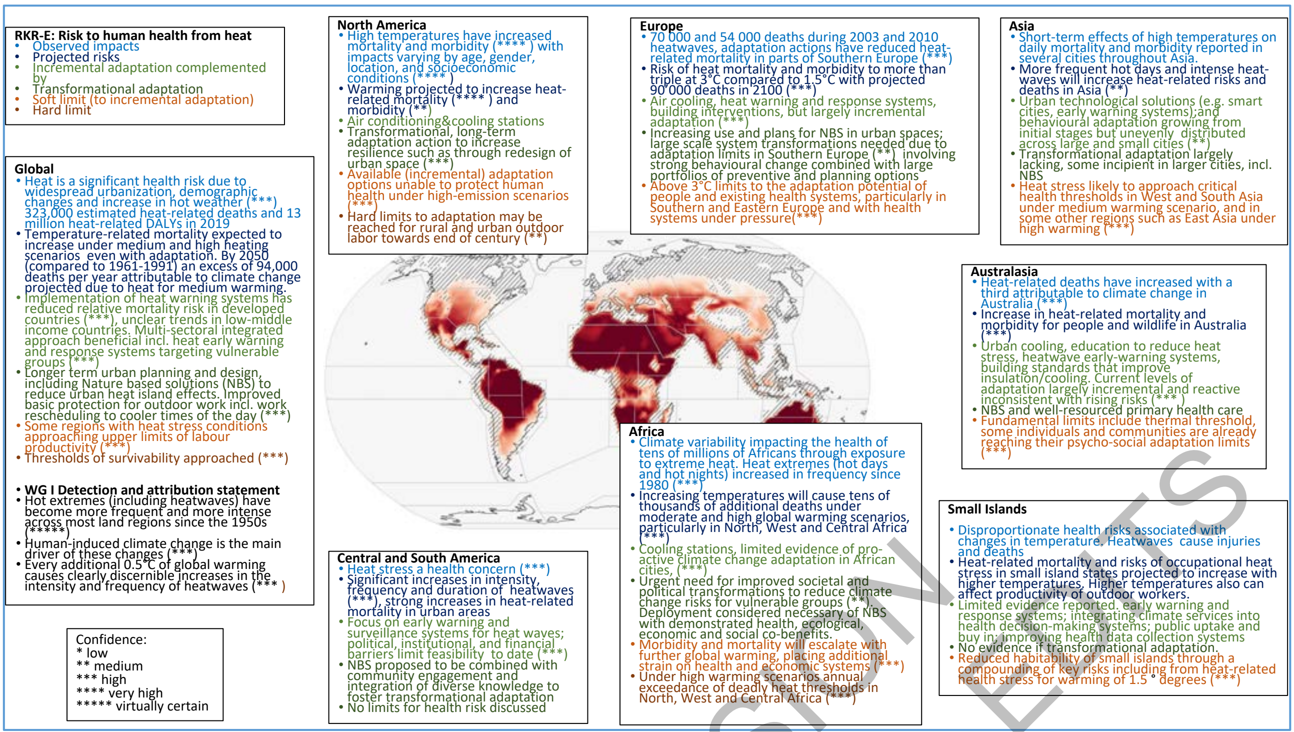

Figure 17.5: Understanding the spectrum of incremental to transformational planned adaptation for managing climate related heat risk to health including associated soft and hard adaptation limits (RKR-E). Evidence from regional and thematic chapters. The figure from the WG I Atlas shows the change in extreme hot days (above 35ºC) across regions for a medium-term scenario and medium global warming relative to 1850-1900. See table SI 17.2.2.5 RKR E.

Marine heatwaves have affected tropical coral reefs, which are analysed as part of RKR-B (see SM17.4). Coral reefs across the tropic have recently seen massive bleaching events (such as for the Great Barrier reefs) (*very high confidence*) Risks are projected to be further exacerbated by increases in intensity, frequency and duration of marine heatwaves (*high confidence*) as well as impacts from extreme events such as tropical cyclones (*low to medium confidence*) (3.4.2).

Although there is some evidence of autonomous natural thermal adaptation, as indicated by the presence of stress tolerant symbionts adapted to higher thermal thresholds observed in the Persian/Arabian Gulf. Yet, there is low confidence (with limited evidence, low agreement) that enhanced thermal tolerance can be maintained over time (Ch.3 Box 5) as the adaptability in natural system is considered very limited and risk are driven by water temperature. Evidence suggests that already at further warming of 1.5C coral reefs are put at large risk (*very high confidence*) (3.4.2.1).

Planned adaptation can help to buy some limited time including through recovery and restoration efforts that target resistant coral populations and interventions to culture heat-tolerant algal symbionts as well as by setting up marine protected areas. Under higher warming levels, transformation has been proposed as possibly complementing available management approaches with high-risk interventions, including enhanced corals and reef shading, which may help to sustain some coral reef systems beyond 1.5°C of global warming. Modelling has shown, however, that the effectiveness of such high-risk interventions declines beyond 2°C of global warming (Figure 3.23, 3.4.2.1) (*medium confidence*).

Already for limited warming beyond 1.5°C for mid-century with increasing intensity and frequency of marine heatwaves hard limits are projected to become manifest in terms of widespread decline and loss of structural integrity (*very high confidence*) (3.4.2.1), including for the two largest such systems, the Great Barrier Reef and the Mesoamerican coral reef (11.3.2, Box 11.2, Table 11.14, 12.4).

In terms of planned adaptation options that would provide benefits to populations, evidence suggest these are very limited, uncertain and bring along substantial risks to people, culture and ecosystems (3.5.2. Cross-Chapter Box SLR). Concurrent with the loss of coral reefs important ecosystem services, including to fishery, tourism and coastal protection would be lost. Transformational adaptation, while requiring to make difficult choices, is being discussed to help overcome soft limits through livelihood diversification for alternative income sources, assisted migration and planned relocation of communities dependent on the services provided by the reef ecosystem (*medium confidence*) (3.5.2).

[START CROSS-CHAPTER BOX LOSS HERE]

Cross-Chapter Box LOSS: Loss and Damage

Authors: Reinhard Mechler (17), Adelle Thomas (16), Christian Huggel [MR1] (12), Emily Boyd (8), Veruska Muccione (13), Ivo Wallimann-Helmer (CA), Laurens Bouwer (CA), Sirkku Juhola (CA), Chandni Singh (10), Carolina Adler (17), Kris Ebi (7), Patricia Pinho (8), Rawshan Ara Begum (1), Adugna Woyessa (9), Johanna Nalau (15), Katja Frieler (16), Richard Jones (WG I), Riyanti Djalante (8), Rosa Perez (18), Tabea Lissner (4), Anita Wreford (11), Mark Pelling (6), Francois Gemenne (8), Nick Simpson (9), Doreen Stabinsky (WG III)

An intensifying dialogue

This Cross-Chapter Box offers an assessment of the growing literature on Loss & Damage. Capitalised letter ‘Loss and Damage’ (L&D) has been used to refer to political negotiation under the UNFCCC. Research has used lowercase ‘losses and damages’ for residual effects from (observed) impacts and (projected) risks (see Glossary).

Dialogue around L&D issues started with a proposal for insurance and compensation by the Alliance of Small Island States (AOSIS) (INC, 1991) and has intensified over recent years with suggestions made to consider complements to adaptation in order to manage residual impacts and risks ‘beyond adaptation’ in vulnerable developing countries (1.4.5). L&D was formally recognized in 2013 at COP19 through the *Warsaw International Mechanism on Loss and Damage* (UNFCCC, 2013), governed by an Executive Committee (ExCom), to advance knowledge, foster dialogue as well as enhance action and support. Article 8 of the Paris Agreement provided a permanent legal basis for the WIM (UN, 2015).

IPCC’s first assessment of L&D in 2018 found residual risks to rise with further global warming leading to soft and hard adaptation limits in some natural and human systems (e.g., coral reefs, human health, coastal livelihoods (Roy et al., 2018). Sections 8.4.5.6, 16.4 and 17.2 corroborate these findings concluding that, depending on mitigation and adaptation pathways residual risks in key systems in many regions will create potential for negative impacts beyond adaptation limits (*medium confidence*). The assessment in 2018 also noted that there is “not one definition of L&D.” This ambiguity has persisted and a policy space for L&D has not clearly been delimited (*high confidence*). There is, however, coalescence in dialogue among academia, civil society and policy around a distinct set of themes as identified by stakeholder surveys as well as literature, methods and evidence reviews (Vanhala and Hestbaek, 2016; Boyd et al., 2017; Mechler et al., 2018; Calliari, 2019; McNamara and Jackson, 2019): risk management, limits to adaptation, existential risk, finance and support including liability, compensation and litigation (8.3, 16.4; *medium confidence;* Figure Cross-Chapter Box LOSS.1). Various advisory groups have been set up with participation of policy and experts from research, civil society and practice to help inform the implementation of WIM workplans (UN, 2015; UN, 2019).

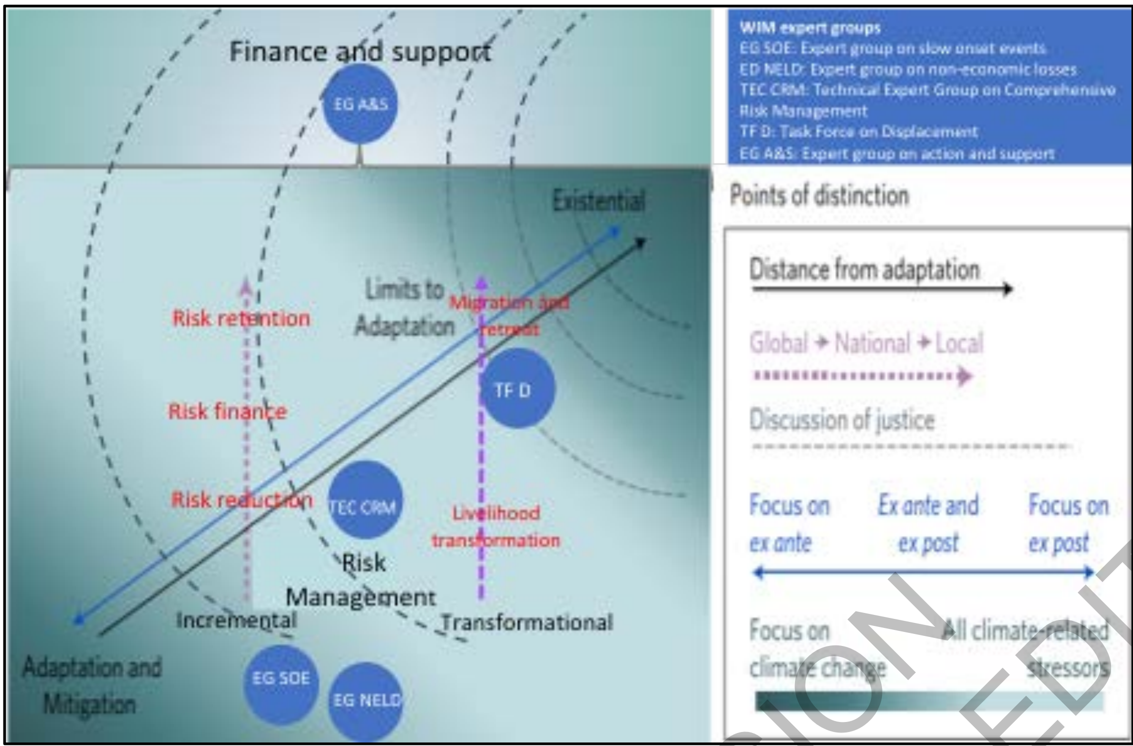

Figure Box Cross-Chapter Box LOSS.1: Charting out the L&D discursive and policy space. The figure shows key discursive strands relevant for L&D including their interrelationships with and distinction from adaptation. The figure also identifies expert groups set up under the WIM and showcases the scale of responses discussed, a focus on ex ante risk management and ex post attention to losses and damages as well as contributions by climate change and other stresses for the themes. Adapted from Boyd et al. (2017) and building on Vanhala and Hestbaek (2016), Mechler et al. (2018), McNamara and Jackson (2019), and Calliari (2019).

Risk management

An increasing body of research has focussed on the role of climate risk management (8.3; 16.4 and 17.2; *high confidence*) (Birkmann and Welle, 2015; Gall, 2015; van der Geest and Warner, 2015; Mechler and Schinko, 2016; Boyd et al., 2017; IPCC, 2018b; IPCC, 2019b; Boda et al., 2020; Broberg and Romera, 2020). A technical advisory group on comprehensive risk management (TEG CRM) advises the WIM ExCom while other expert groups focus on slow-onset events and non-economic L&D (UNFCCC, 2019a).

There is evidence that, without strong risk management and adaptation, losses and damages will continue to affect the poorest vulnerable populations potentially creating poverty traps (*high confidence*) (8.3; 8.4.5.6 and Table 8.7; 17.2; Serdeczny, 2019; Tschakert et al., 2019; Thomas et al., 2020). Research has started to develop global inventories on losses and damages including on intangible effects (Tschakert et al., 2019; Otto et al., 2020) and engaged with the practice community for data collection. Practice has provided guidance to report on losses and damages in countries' (I)NDCs (WWF & Practical Action, 2020). Yet, systematic risk assessments of climate-related losses and damages including adaptation limits (see, e.g. Leal Filho and Nalau, 2018; Robinson, 2018) have remained scarce (16.4; *high confidence*). Thus many vulnerable countries lack comprehensive data at scale of risk management including on economic (e.g. loss of livelihood assets and infrastructure), and non-economic losses and damages (e.g. culture, health, biodiversity) thus hampering effective risk management (Thomas and Benjamin, 2018; Martyr-Koller et al., 2021; Singh et al. 2021). van den Homberg and McQuistan (2019) propose a losses and damages inventory also to be used to monitor how technologies may shape risks as well as adaptation limits. While early warning and other risk reduction options as well as risk retention considerations are being discussed, L&D dialogue has strongly focussed on risk finance for residual risks, particularly through the donor-supported provision of public insurance systems (Linnerooth-Bayer et al., 2019; Schäfer et al., 2019; Broberg and Romera, 2020; Nordlander et al., 2020).

Transformation

The role of transformation in risk management for overcoming any soft limits to adaptation is seeing emerging attention (*medium confidence*, *limited evidence*), and the TEG CRM has also been tasked to consider transformation. Relocation and retreat of assets and communities, where *in situ* adaptation is considered impossible, is increasingly being debated in research and practice, including in terms of finance and L&D implications (8.4.4; Boston et al., 2021; Desai et al., 2021; Mach and Siders, 2021; van der Geest and van den Berg, 2021; Zickgraf, 2021). Livelihood transformation occurs where current livelihoods become unfeasible in the face of multiple climatic and non-climatic stressors (8.3.4.1) requiring change within sectors (such as switching from cropping to livestock rearing (Escarcha et al., 2020) or across sectors, when farming households relocate to offer labour elsewhere (9.1; Rasel et al., 2013). Biermann and Boas (2017) suggest revamping global governance systems to effectively address the protection and voluntary resettlement of those displaced by climate variability and change. A WIM taskforce on displacement is tasked to further advise on human mobility, including migration, displacement and planned relocation (UNFCCC, 2019a).

The *existential dimension*

There has been less and often implicit discussion on the existential dimension of climate-related risk as pertaining to L&D (*medium confidence*).McNamara and Jackson (2019) infer an existential dimension from notions of inevitability and irreversibility associated with migration and relocation of communities (Eckersley, 2015; Mayer, 2017; McNamara et al., 2018), socio-cultural impacts linked to glacial retreat (Jurt et al., 2015), as well as adverse psychological and intersubjective effects (Herington, 2017; Adams et al., 2021). Many SIDS in their NDCs refer to sea level rise in particular posing existential threats, and call for enhanced international support for L&D (Thomas and Benjamin, 2017).

Finance and support

International support and finance, including compensation for losses and damages, have been in the spotlight from the beginning of the dialogue (*high confidence*), starting with AOSIS' proposal (INC, 1991). Recent work has focussed on *finance sources*, such as solidarity-based donor and other support for experienced losses and damages and climate-induced displacement as well as questions of compensation and litigation (Roberts et al., 2017; Gewirtzman et al., 2018; Mechler and Deubelli, 2021; Robinson et al., 2021). A selection of finance *options* has also been explored such as donor-supported insurance systems with built-in risk reduction provisions (Gewirtzman et al., 2018) as well as roles for social protection (Aleksandrova and Costella, 2021). International policy and donors have provided technical assistance for insurance-related options such as (Insuresilience Global Partnership, 2018).

As national and donor-related funding for impacts and risk management remains limited (Schäfer and Künzel, 2019; 17.2; Serdeczny, 2019) even at current global warming, many highly exposed developing countries remain financially constrained in their capacity to attend to residual impacts and risk management needs (Linnerooth-Bayer and Hochrainer-Stigler, 2015; Roberts et al., 2017; UNEP, 2021a) (*high confidence*). Discussion on options for the risk retention layer 'beyond adaptation" are likely to see further attention as the dialogue proceeds.

Although there is no explicit mandate regarding L&D, about a quarter of the Green Climate Fund's approved projects explicitly refer to L&D while 16% of projects have thematic links to L&D across their main project activities (Kempa et al., 2021). Any estimate of L&D finance needs and spending, however, remains highly speculative, as long as its exact remit including in relation to adaptation has not been clarified politically (*medium evidence, high agreement*) (Markandya and González-Eguino, 2019).

Liability and compensation, implying legally defined reimbursement of losses and damages attributable to climate change, remain contentious in L&D dialogue (*high confidence*). In half of the academic and grey literature surveyed by McNamara and Jackson (2019), compensation is mentioned. Studies have laid out responsibility principles, such as historical responsibility based on the polluter pays principle, beneficiary pays, as well as ability to pay. Discussions on compensation are closely linked to justice and equity scholarship which has studied compensatory, distributive and procedural equity considerations for burden sharing (Roser et al., 2015; Wallimann-Helmer, 2015; Huggel et al., 2016; Boran, 2017; Page and Heyward, 2017; Roberts et al., 2017; Shockley and Hourdequin, 2017; Wallimann-Helmer et al., 2019; Garcia-Portela, 2020).

Litigation and liability are linked and a growing research body has examined the role of litigation and international law for the L&D context finding that litigation risks for governments and business may increase as the science, particularly on attribution matures further (Mayer, 2016; Banda and Fulton, 2017; WGI CWGB Attribution, 8.2.1.2); Marjanac and Patton, 2018; James et al., 2019; Simlinger and Mayer, 2019; Wewerinke-Singh and Salili, 2019; Toussaint and Martinez Blanco, 2020) (*high agreement, medium evidence*).

Outlook

The WIM has been reviewed twice as to its delivery on its key functions. As an outcome of the second review in 2019, an expert group on Action and Support has been set up to further discuss issues pertaining to finance, technology and capacity-building and a Santiago Network for Technical Assistance will be established to consider providing technical support directly to developing countries (UNFCCC, 2019b). Overall, the L&D dialogue under the WIM supported by an increasing body of research has made important advances with regard to the two functions of knowledge generation and coordination; however, less so on action and support (*medium confidence*) (Calliari et al., 2020). Resolution on the last item will need additional attention as, despite the coalescence of themes, the L&D dialogue continues to proceed across interlinked yet contested discussion strands.

[END CROSS-CHAPTER BOX LOSS HERE]

17.3 Decision-making Processes of Risk Management and Adaptation

AR5 (Chambwera et al., 2014; Jones et al., 2014; Klein et al., 2014; Kunreuther et al., 2014; Mimura et al., 2014) represented a significant step forward in focusing attention on how decision-making may facilitate effective and robust responses to climate risks remaining after mitigation measures have been taken, following recognition of these needs in AR4, including the diverse contexts that face decision-makers (Klein et al., 2007).

AR5 (Jones et al., 2014; Kunreuther et al., 2014) recognised that the decision-making procedures are as important to consider in managing risks as are the options for responding to climate change, mostly because the procedures can themselves constrain the choices of actions, which could, in turn, lead to constrained pathways which are undesirable. It emphasised the importance of iterative risk management because risk and adaptation are dynamic. It also identified that (i) risk assessments, decision-support tools, early warning systems, accounting for uncertainty and delivering no-regret options by examining trade-offs are important, (ii) integration across different governance portfolios is needed due to potential conflict of different actions between portfolios, and (iii) planning, implementation and decision-making, including the use of methods, are dependent on local context.

Since AR5, the IPCC special reports have provided assessed the value of integrated assessment processes for assessing trade-offs and synergies (IPCC, 2018a), adaptive management and governance, the roles of formal and informal decision making (IPCC, 2019b), and the importance of developing policy and governance options for risk management, including managing disasters, enhancing resilience, addressing decision-relevant uncertainties, and being prepared for abrupt change and extreme events (IPCC, 2019c)

Chapter 16 has shown that climate risks vary greatly from small to large, local to regional, uncertain to deeply uncertain. The plethora of risks means there are many types of decisions, and many forms of analyses and processes that may be drawn on. Decisions can differ according to whether they are strategic, tactical or operational; whether there are one or many decision makers, from a domestic setting to national governments; the level of uncertainty present; the time available to take the decision; and many more factors (Chapter 1; Section 17.1).

The pathway to a decision may not be linear, depending on when and in what detail the decision-making or consultative group may need to be understanding the climate risk and its real world context (*sense-making, modelling*), has sufficient background to analyse and explore options for ameliorating the risk (*analysis, exploration*), or is ready for interpreting the analyses and deciding on the requirements and strategies for implementing a chosen strategy (*interpretation-implementation*) (*high confidence*) (Figure 17.6; French et al., 2020). The development of decision-support tools for climate risk management (Palutikof et al., 2019a; Palutikof et al., 2019b) and more generally (Papathanasiou et al., 2016) along with archives of experiences from practitioners (Watkiss and Hunt, 2013; Section 17.5; Bowyer et al., 2014; French, 2020a) means that some aspects of the decision-making process can be circumvented or at least streamlined as that experience is re-used (*high confidence*).

No single approach to decision making best suits an individual climate risk across any adaptation context (Richards et al., 2013), although there is now a greater awareness of the methods and approaches that are available and their requirements for best practice (Hurlbert et al., 2019) (*high confidence*). This section aims, firstly, to assess the factors that people responsible for organising and facilitating decision-making may wish to consider in choosing the methods and approach for them to make decisions in their context. It also assesses existing experience in analysing the utility of methods for climate risk decision-making. The second part then assesses progress in integrating decision-making across a portfolio of risks.

Processes and methods to facilitate decision-making, from problem recognition to implementing a solution, have evolved in many contexts, disciplines and applications over the last century (*high confidence*). As a result, decision-making terminology has a vast number of synonyms that are not compiled here. For clarity, the term 'decision-analytic methods' refers to procedures or tools that may be used by decision-makers to help develop, analyse and contrast alternative actions/adaptations; 'approaches' refers to processes that may be undertaken by decision-makers to facilitate the development of proposed actions/adaptations; 'decision-support tools' refers to software or procedures that facilitate the use of knowledge and data (Papathanasiou et al., 2016).

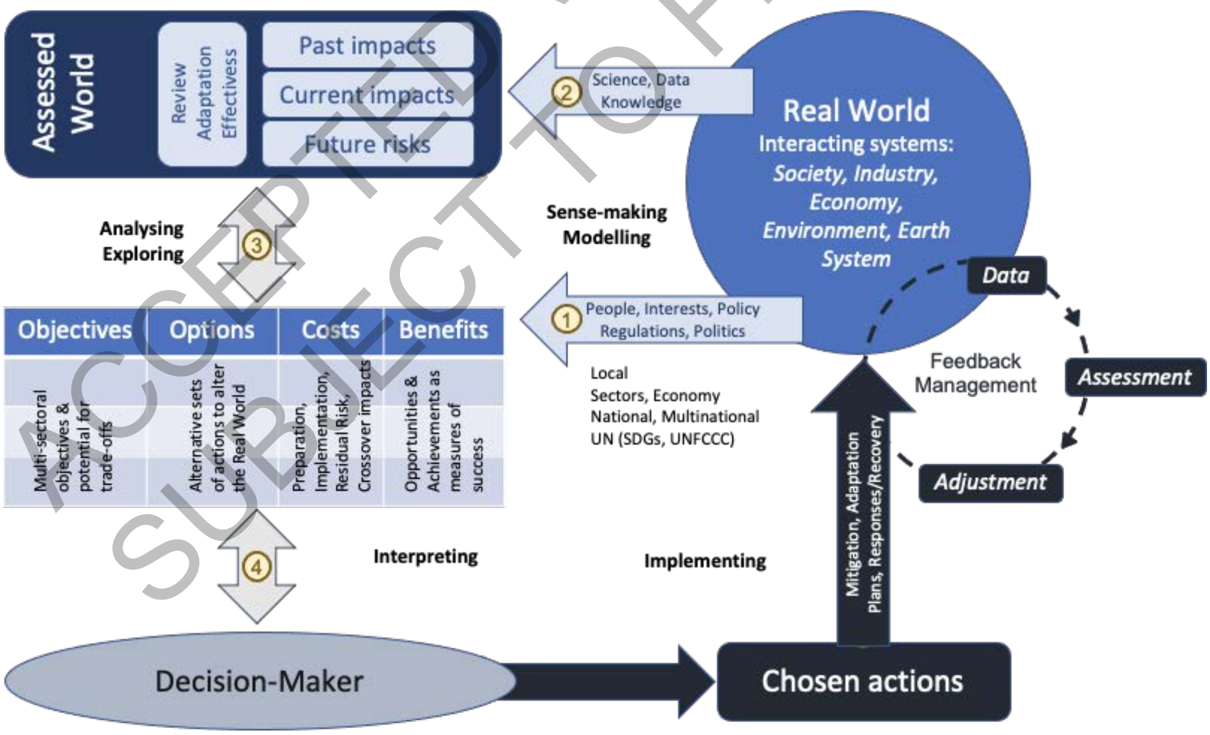

Figure 17.6: Relationships between different processes of decision-making to manage climate-related risks in the real world, noting that, when appropriate, some aspects may only require experience to be re-used. **1.** Formulation of risks of concern and accompanying policies and objectives for managing those risks, forming prescriptive models for the decision maker. **2.** Knowledge, understanding and observations of the real world are used to assess past and current impacts and future risks using descriptive models, based on the perspectives and prescriptive models arising from (1). If not well formulated from other experience, processes in (1) and (2) interact to make sense of the world and what

needs to be done. In iterative management, (1) and (2) also form the basis for monitoring, reviewing, and evaluating effectiveness of adaptations. **3.** Use of decision-support and decision-analytic tools to appraise costs and benefits of different options for ameliorating future risks. The double-headed arrow indicates where two-way interactions occur between different activities (likely to be iterative, feedback and non-linear processes) – modelling and assessments are repeated and revised in tandem with the planning and evaluation of options, based on interactions with the policy-makers and stakeholders. **4.** The decision-maker, which may be a group of people, interacts with the evaluation of options (two-way interaction) and interprets the efficacy of the options and the implications for the real world, ultimately choosing one or more actions to satisfy the policy objectives to manage the risks. **5.** Implementation of the actions in the real world, which may be once-only actions or instigation of a feedback management system that enables ongoing adjustments to meet objectives.

17.3.1 Decision-analytic Methods and Approaches

Different classes of decision-analytic methods have been variously presented in IPCC reports since AR4 but without a summary assessment of their capacity to deal with different contexts of the decision maker. 'Communities-of-practice' are developing tool-boxes to support analysing and making of decisions generally (French, 2020a). These communities of decision analysts can act like broad-based statisticians to advise on matching methods to the climate risk and its context, before individual decision specialists are consulted. Some scientific literature is presenting guides for choosing different methods, tools and approaches (Shi et al., 2019). This sub-subsection provides a summary guide for policy analysts and decision-makers to help identify the classes of decision-analytic methods that may be suitable for their context for managing climate risks. It focuses on decision-analytic methods, noting that decision-support tools will underpin many of these methods by organising information (Bourne et al., 2016; Papathanasiou et al., 2016; Ceccato et al., 2018; Haße and Kind, 2018) or support modelling (Papathanasiou et al., 2016; Kwakkel, 2017; Gardiner et al., 2018), sometimes with a particular decision-analytic process in mind (Hadka et al., 2015; Torresan et al., 2016; Tonmoy et al., 2018).

17.3.1.1 Factors to Consider in Selecting Methods to Facilitate Decision-Making

The choice of methods and approaches to decision-making for climate risks (next section) will depend on (i) the cognitive needs of the deliberations, otherwise considered to be the phase in developing a decision, (ii) the types of models and modelling available to facilitate the deliberations, (iii) the degree of uncertainty surrounding the choices, and the (iv) context of a choice (*high confidence*) (Richards et al., 2013; Jones et al., 2014; Shi et al., 2019; French, 2021).

17.3.1.1.1 Cognitive phases of decision making

The decision process often involves overlapping and iterative development of the components leading toward a decision, resulting in the blurring of stages but involving different phases of cognitive activity (Figure 17.6; Holtzman, 1989; French, 2015; French, 2020a). Framing the problem (Orlove et al., 2020), by modelling its relationships with the human and natural systems and eliciting objectives, values and scope of the problem from stakeholders, is a precursor to analyses of options but may be returned to whenever a phase of '*sense-making and modelling*' is required (*high confidence*) (Ackermann, 2012; Keeney, 2012; Slotte and Hämäläinen, 2014; Abbas and Howard, 2015; Marttunen et al., 2017; Korhonen and Wallenius, 2020; French, 2021).

The cognitive phase of *'analysing and exploring'* uses models and existing data and/or knowledge services as available to explore the relevance/efficacy of adaptations to ameliorate risk or to meet other adaptation objectives, as well as possible flow-on effects of those actions (Section 17.3.1.4). Sensitivity and robustness analyses can be useful if conditions are favourable to supplement the decision analysis, setting bounds on some of the residual uncertainty (*high confidence*) (Borgonovo and Plischke, 2016; Ferretti et al., 2016). Validation of models and verification of data (Tittensor et al., 2018) are becoming highlighted as important steps in this phase or in the sense-making phase, particularly in their capacity to understand and test decision-makers and stakeholders' perceptions (*medium confidence*). Randomisation methods, Bayesian methods, interval methods, MCDA, DMDU and economic and financial approaches (e.g., Real Options Analysis) are tools of choice in this phase (*high confidence*) (Table 17.5) (Abbas and Howard, 2015; Bendoly and Clark, 2016; Borgonovo and Plischke, 2016; Iooss and Saltelli, 2017; Korhonen and Wallenius, 2020; Saltelli et al., 2020). Decision-support tools in the provision of data and/or modelling methods are regularly used in this and the sense-making phase (*high confidence*) (17.3.1.2).

The phase of interpreting the analyses to make decisions on climate adaptation followed by implementation are the least described in the literature (Figure 17.7). Decision process management tools and methods for communicating choices, outcomes and implementation are expected to be used to provide support in this phase, particularly for understanding whether the advice is fit-for-purpose, and the efficacy of choices are clear (*low confidence*) (Spetzler et al., 2016).

17.3.1.1.2 Types and capacity of models to support decision making

'Descriptive models' of socio-biophysical systems and their responses to different drivers (Argyris and French, 2017; French and Argyris, 2018; Saltelli et al., 2020) and 'prescriptive models', which capture the beliefs, values and objectives of decision-makers and stakeholders (Parnell et al., 2013; Keisler et al., 2014; French and Argyris, 2018), provide the foundations of sense making (*high confidence*) and thereby influencing the options and choices available in the phase of analysis and exploration (*medium confidence*) (Gorddard et al., 2016).

Socio-biophysical models may be qualitative network models, statistical models or dynamic mathematical models (Melbourne-Thomas et al., 2017). Qualitative network modelling can help assess the nature and consequences of the interactions, as well as facilitating understanding of possible structures to be used in dynamic models for assessing long term adaptation options (Reckien et al., 2013; Reckien, 2014; Reckien and Luedeke, 2014; Symstad et al., 2017). These approaches help articulate the direct and indirect effects of fixed, long-term engineering or structural adaptations. Dynamic stochastic modelling (Fulton and Link, 2014; Ianelli et al., 2016) has been used to assess short to medium term interactions of more dynamic and variable sectors, such as those with annual adjustments and management of water, agriculture, land and marine uses (Holsman et al., 2019; Hollowed et al., 2020; Bahri et al., 2021). On a longer timeframe, scenarios are used to test long term interactions but often with less variability and chance (Giupponi et al., 2013; Adam et al., 2014; Rosenzweig et al., 2017).

Many sensitivity analyses based on scenarios, including procedures to randomise across model uncertainty, relate to descriptive dynamic mathematical models with the user of the models characterised as an objective observer (Borgonovo and Plischke, 2016; Ferretti et al., 2016; Symstad et al., 2017; French, 2020a). Bayesian approaches enable these descriptive analyses to take account of the subjective choices in model construction and implementation (Abbas and Howard, 2015; Sperotto et al., 2017; Jäger et al., 2018; Sperotto et al., 2019; French, 2020a). Organising descriptive analyses and deciding on a suitable option across a diversity of opinions amongst stakeholders use prescriptive processes, which can be supported with prescriptive modelling tools (Williamson and Goldstein, 2012; Gelman et al., 2013; Abbas and Howard, 2015; Dias et al., 2018; Phan et al., 2019; Hanea et al., 2021). These approaches are subjective, in that they are constrained or directed by the particular views and emphases of the decision-making group (Gorddard et al., 2016). Not all tools are appropriate for all these activities.

Decision-makers will be better able to choose decision-analytic methods when they have an understanding of the types, scale and breadth of uncertainties around the climate risk (*high confidence*) (Symstad et al., 2017). The *Cynefin* framework (Snowden, 2002; French, 2013) is a policy-driven framework that broadly categorises the decision context of uncertainty within which decision makers and policy analysts may find themselves (*medium confidence*) (Hurlbert et al., 2019; Helmrich and Chester, 2020). As *Cynefin* has helped frame previous IPCC presentations on contexts of uncertainty (Hurlbert et al., 2019) and has a community of practice to consult on its use (French, 2020a), it is used here, also because it considers the uncertainty in knowledge around cause and effect in general terms, rather than specifically focussing on uncertainty in formal models. Helmrich and Chester (2020) show how *Cynefin* can be used to frame climate adaptation decision making in the infrastructure sector.

The *Cynefin* contexts relate to how well the system is understood for knowing precisely the outcomes of actions that may be taken - range from known, knowable, complex to chaotic. If a context is known or knowable, then it will be possible to build sophisticated models and make sound predictions. If the context is complex and chaotic the outcomes of actions will be less predictable, no matter how complex the models may be, although more complex dynamic models may be useful to test 'what if' scenarios in these cases

(Marchau et al., 2019). Under complex and chaotic circumstances an ensemble of models and approaches may be needed to help categorise a satisfactory 'solution space' across the broad knowledge of relationships and dependencies, but will need to have iterative processes to update and refine adaptations as knowledge improves (Marchau et al., 2019).

17.3.1.1.3 Uncertainty and attitudes to risk

Uncertainty does not just relate to what might happen given climate drivers or adaptations, but also about how much one values potential consequences (Butler et al., 2016; Beven et al., 2018a; Cross-Chapter Boc DEEP; Beven et al., 2018b; French, 2020a) *(high confidence);* the balance between how particular decision analyses address uncertainties relating to the external world (descriptive models) and those relating to the values driving the decision making (prescriptive models) is important (Butler et al., 2016). Some analyses partially ignore uncertainties relating to the former in order to focus on conflicts in the values held by different stakeholders and help structure debate (Korhonen and Wallenius, 2020; French, 2020a), while others build very sophisticated models of the external world to predict potential consequences, but in doing so lose transparency and risk becoming untrustworthy black boxes to many stakeholders (*low confidence*) (Peterson and Thompson, 2020).

Much of the readily-available literature on how uncertainties affect decision-making relates to the uncertainty in the biophysical models, with a recognition that the choice of tools will be influenced by the types of uncertainty to be addressed (Le Cozannet et al., 2017; Symstad et al., 2017; Beven et al., 2018a; Beven et al., 2018b; Durbach and Stewart, 2020b; French, 2020a). While terminology varies amongst disciplines, three types of uncertainty are important in understanding assessments of the future from descriptive models – epistemic (uncertainty in model construction relating to the lack of knowledge about the system being represented), analytic (the degree to which a model fits observations, and its accuracy), and stochastic (the natural variability or randomness in the system). The probability of an event arising in the future is determined from all three uncertainties, noting that stochastic uncertainty is a property of the system rather than a limitation of research (Le Cozannet et al., 2017; Beven et al., 2018a; Beven et al., 2018b).

Uncertainty in what constitutes a risk of concern is increasingly identified as important to consider when managing risk (Chapter 16; Butler et al., 2016; Prober et al., 2017; French et al., 2020; Reis and Shortridge, 2020). The uncertainty here arises from what is an acceptable risk. Acceptability relates to the value or importance of the consequence, which may include moral and ethical uncertainties (Prober et al., 2017), as well as how ambiguous the understanding of the consequence may be between different groups (Beven et al., 2018a; Beven et al., 2018b). The development of strategies to ameliorate risk will benefit from considering these two uncertainties in specifying the risk to be managed (Prober et al., 2017; French et al., 2020) because they can help set boundaries on a required likelihood of success, rather than simply casting stakeholders or decision-makers as risk averse or risk tolerant, and can help identify and accept pathways of success (Gregory et al., 2012). This can be important when decisions need to be made well in advance of the actions needing to take effect, such as for many climate risks (Chapter 1; Chapter 16; Section 17.2.3; Cross-Chapter Box DEEP in this Chapter).

Elicitation methods help reduce these uncertainties (*high confidence*) (Butler et al., 2016; Prober et al., 2017; Symstad et al., 2017; Beven et al., 2018b). In addition, informal decision processes can assist in developing consensus in approaches and outcomes (Orlove et al., 2020).

17.3.1.2 Decision Analytic Methods Used in Decision-Making and Climate Risk Management

Entities making decisions (countries, regions, organisations and individuals) select methods that best suit them in their context (Fünfgeld et al., 2018; Shi et al., 2019; French, 2020a) *(high confidence)*.
Classes of tools (Watkiss and Hunt, 2013; French, 2020a) include Bayesian methods, Interval methods, decision making under deep uncertainty (DMDU; see Cross-Chapter Box DEEP in this Chapter), cost-benefit analyses, multicriteria decision analysis, elicitation and general decision support tools (Table 17.5). A summary guide for policy analysts and decision-makers is presented in Table 17.5 to help identify the classes of decision-analytic methods that may be suitable for their context for managing climate risks. The table summarises how well the methods address the *Cynefin* context, phase of decision making, the types of uncertainties that exist through the decision-making process and the resources required. As terminology may vary between disciplines and research groups, suitable references to better explain the methods within the

class are provided. Also, there may be overlap between the classes as individual methods are often paired with other methods to address specific requirements and approaches (Buurman and Babovic, 2016; Haasnoot et al., 2019). In that respect, these methods are referred to in the next section discussing advances in the different approaches to managing climate risks.

Case studies in Table 17.5 describe the utility of classes of decision-analytic tools to facilitate decisions about climate adaptations (SM 17.2). These case studies are presented in Figure 17.7 according to the type of decision-making body and mapped according to their contribution to a decision outcome relative to the geopolitical scale of the actions being assessed. The effectiveness of these methods and tools in Table 17.5 in the context of climate change adaptation (Box 17.1) has yet to be evaluated.

Table 17.5: Characteristics of the main approaches to decision analysis with respect to their *Cynefin* context, the manner in which they can be used to address different uncertainties, where they may be used in different cognitive phases of the decision-making process, the resources required, and some case studies for further exploring how they might be used. Numbers in square brackets after references in Case Studies refer to the references plotted in Figure 17.7.

<table>
<tr><td colspan="5">Bayesian Methods (Keeney and Raiffa, 1993; Smith, 2010; Gelman et al., 2013; Reilly and Clemen, 2013; Abbas and Howard, 2015; Sperotto et al., 2017; Marchau et al., 2019)
A structured approach to assembling information around the consequences of choices, either by modelling, analysis of multiple scenarios or by structuring deliberation; Underpinned by a theoretical base, coherent assumptions and powerful computational methods; Can use both observational data and expert knowledge, weighting them appropriately; Same approaches as in Artificial Intelligence algorithms. Biases (information, stakeholders, decision-makers) can be made explicit. Traditionally, Bayesian methods computationally identify an ‘optimal’ decision, based on maximising the expected utility across a number of specified requirements, represented as functions.</td></tr>

Uncertainties		***Cynefin context***			
Stochastic, Epistemic, Analytical (Descriptive Modelling)	*Ambiguity Value (Prescriptive Modelling)*	*Known*	*Knowable*	*Complex*	*Chaotic*
All can be modelled probabilistically, perhaps supplemented by sensitivity analysis (Rios Insua, 1999; Rios Insua and Ruggeri, 2000; Iooss and Saltelli, 2017). Deep uncertainties can be investigated via scenarios (French, 2020a).	Uncertainties resolved or reduced by discussion, then values modelled by multi-attribute values and utilities (Keeney, 1992; Keeney and Raiffa, 1993; Gregory et al., 2012). Residual uncertainties explored via sensitivity analysis.	Any stochastic uncertainties modelled probabilistically; otherwise, deterministic modelling with sensitivity analysis. Value functions tend to be used more than utility functions (Keeney and Raiffa, 1993; Goodwin and Wright, 2014).	Epistemic uncertainties updated via Bayesian statistics/machine learning, then remaining stochastic uncertainties modelled probabilistically. Full Bayesian decision modelling possible (French et al., 2009; Smith, 2010; Abbas and Howard, 2015).	More exploratory analysis (Gelman, 2003) to understand behaviours with less complex Bayesian modelling support by sensitivity and robustness studies (Rios Insua, 1999; French, 2003). Scenario focused decision analysis to cope with deep uncertainties (French, 2020a). Careful deliberations to construct values and utilities. (Keeney and Raiffa, 1993; Gregory et al., 2012).	Formal modelling impossible. Much exploratory work to identify potential causes and effects. Little if any complex analysis.

Decision-making under deep uncertainty (DMDU) (Hallegatte et al., 2012; Weaver et al., 2013; Marchau et al., 2019; Workman et al., 2021)

Deep uncertainty relates to circumstances in which data are too sparse, experts in too much disagreement or time is too short to model the uncertainty. As such, DMDU methods are focused on working in the *Cynefin* Complex Space context. Approaches emphasise robustness ("no regrets" options) and the use of scenarios, and often link well with scenario-focused robust Bayesian studies (Cross-Chapter Box DEEP in this Chapter). DMDU studies draw in many other approaches to decision analysis, using them to identify robust rather than optimal strategies, as in Robust Decision Making (RDM). DMDU analyses can help decision makers to think contingently and build a more wide-ranging recognition of the risks. They often integrate with other classes of tools.

Examples include RDM for hydro-power design using down-scaled climate data in sub-Saharan Africa (Taner et al., 2017), RDM for water management in California, USA (Lempert and Groves, 2010), the Colorado River, USA, and for international climate investment strategies (Groves et al., 2019), use of decision-scaling (Brown et al., 2019), comparison of RDM and Info-gap methods (Hall et al., 2012) and review of using climate modelling in RDM (Weaver et al., 2013).

Uncertainties		***Cynefin context***			
Stochastic, Epistemic, Analytical (Descriptive Modelling)	*Ambiguity Value (Prescriptive Modelling)*	*Known*	*Knowable*	*Complex*	*Chaotic*
Methods are designed for deep epistemic uncertainties. Some can deal with stochastic uncertainties. Analytical uncertainties seldom accounted for.	Some DMDU methods draw on MCDA methods and thus consider ambiguity and value uncertainties. In any case, DMDU methods support wide deliberation with stakeholders.	Deep uncertainty is absent but the principles and processes of decision making may be used.	Deep uncertainty is absent but the principles of decision making may be used.	The complex and chaotic spaces are home to deep uncertainties. DMDU tools and more particularly processes are relevant here. The emphasis on robustness is very relevant. The tools themselves are relatively simply structured but are effective at stimulating discussion.	Deep uncertainties are rife in the chaotic contexts. DMDU emphases on robustness and possible scenarios can stimulate creative discussions of ill understood issues.

Decision Process Management (Raz and Micheal, 2001; Dalkir, 2005; Burstein and W. Holsapple, 2008; Jashapara, 2011; Bonczek et al., 2014; Sauter, 2014; Holsapple et al., 2019)
A range of tools and techniques to help manage the decision-making process and support risk management and the implementation of the chosen strategy. Some tools organise data and analyses, often being built on a geographic information system, known as decision support tools. Others manage processes, organising workflows. Some have inevitably expanded in function to support decision-making itself, even though their primary focus might be on, say, implementation and monitoring risks. Such tools are closely related to knowledge management systems; knowledge management processes and decision process management differ more in terminology than in substance.

Examples include tools for agriculture (Biehl et al., 2017), evaluating and comparing CMIP climate models (Parding et al., 2020), development of action cycles (Park et al., 2012), and decision support systems across a range of sectors and decision-group applications (Papathanasiou et al., 2016).

Uncertainties		***Cynefin context***			
Stochastic, Epistemic, Analytical (Descriptive Modelling)	*Ambiguity Value (Prescriptive Modelling)*	*Known*	*Knowable*	*Complex*	*Chaotic*
Not designed to address uncertainties involved in the decision itself, but may handle project risks in the decision process, especially implementation.	Not usually addressed, since ambiguities and value uncertainties will be addressed in the decision making itself, but may use those values in risk management of implementation.	Simple project management tools may be sufficient here.	Project management and risk management tools apply easily here.	Project management and risk management tools may be used but attention needs to be paid to risks that are complex in nature with little knowledge of precise relationships between cause and effects.	Project management and risk management tools may be used but attention needs to be paid to risks that are complex in nature with little knowledge of precise relationships between cause and effects.

Economic and Financial Methods (Howell et al., 2001; Pearce et al., 2006; Boardman et al., 2017; Atkinson et al., 2018a; Hurlbert et al., 2019)
Stem from economic theory and accounting practices: e.g. cost-benefit analysis, which seeks to price out all aspects of the consequence of a strategy, portfolio analysis, or real options theory, which seeks to value financial investments allowing for their risks and the contingent buying and selling. Such methods are perceived as objective when dealing with tangibles, but are more controversial in their valuing of intangibles. Since these methods model uncertainties with probabilities and then work with expectations, they share much in common with Bayesian methods. However, many applications of cost-benefit analysis omit any detailed treatment of uncertainty.

Examples examine the economic costs and benefits of adaptation pathways for storm water infrastructure in Singapore (Manocha and Babovic, 2017), and a coastal mega city, Los Angeles in the USA (de Ruig et al., 2019)

Cognitive Phase			***Resources required***	***Case Studies***
Sense-making and Modelling	*Analysing and Exploring*	*Interpreting and Implementing*		

In themselves, these methods do not support sense-making and modelling, though discussions of how to value impacts, both tangible and intangible can be catalytic in understanding the issues.	These tools focus mainly on analysis and evaluating the costs and benefits of various options. They are not designed to be used interactively so are more often deployed and communicated via reports than interactive workshops.	Since CBA methods do not emphasise the analysis of uncertainties and risks, they are less suited for use in developing and communicating an implementation plan. Real options with their emphasis on contingency are much more suited (Fischhoff, 2015).	Cost benefit analysis for complex projects is a major undertaking with much data collection needed to value outcomes. Real options also require data on risks and uncertainties. Both may have high computational needs.	(de Ruig et al., 2019) [21], (Manocha and Babovic, 2017) [22]

Uncertainties		***Cynefin context***			
Stochastic, Epistemic, Analytical (Descriptive Modelling)	*Ambiguity Value (Prescriptive Modelling)*	*Known*	*Knowable*	*Complex*	*Chaotic*
Cost-benefit methods usually deal with uncertainty via expectations with little attention to probability distributions; real options methods tend to treat uncertainty in much more sophisticated ways. Both methods, when applied fully have many points of contact with Bayesian methods (Neely and de Neufville, 2001; Bedford et al., 2005)	These methods reduce all value and preference information to financial equivalents. The key issue is to find a market in which all outcomes may be valued financially. Modern CBA methods use much more subtle techniques for this than those applied in the last century (Bedford et al., 2005; Saarikoski et al., 2016).	Although CBA and many financial methods work in theory, the complexity makes it seldom worth the effort.	The methods may be applied to evaluate complex projects but CBA tends to 'average out' rather than analyse uncertainty.	The recognition of the need to treat deep uncertainties using real options has been investigated (Hallegatte et al., 2012; Buurman and Babovic, 2016).	Formal modelling impossible. Much exploratory work to identify potential causes and effects. Little if any complex analysis.

Interval Methods (Shafer, 1976; Pedrycz et al., 2011)
Because of concerns that the statistical accuracy of some data is unknown, and that decision-makers and experts cannot make numerical judgements accurately, analyses have been suggested which work with ranges of values in categories (intervals) as their inputs. While avoiding accuracy issues, weakening the arithmetic may result in other foundational assumptions not being met, including some basic principles of rationality. Different types of uncertainty can often be confused, and the analyses can contradict basic probability theory. Interval models of semantics and imprecision can be useful in exploring ambiguity and value uncertainty, though modelling rather than resolving such uncertainties does not necessary help in decision-making. Some interval methods can be thought of more as sensitivity techniques applied to other decision analytic approaches. Typical approaches here relate to the fuzzy or possibility theory, and evidential reasoning.

Examples include using fuzzy methods to. assessing climate adaptations in ports in China (Yang et al., 2018), water supply vulnerability in South Korea (Kim and Chung, 2013) and resilience of the Nile River delta (Batisha, 2015); and evidential reasoning in an environmental impact assessment for flood mitigation in Manila Philippines (Gilbuena et al., 2013).

Cognitive Phase			***Resources required***	***Case Studies***
Sense-making and Modelling	*Analysing and Exploring*	*Interpreting and Implementing*		
The emphasis on modelling ambiguity may help structure a model initially, but the lack of structures to model and explore complex interdependencies may inhibit the ability to build a valid representation of the issues.	If there is substantial data available, then even the simplest of these methods can produce useful results. But with small quantities of data, their data analysis may be too inefficient. Evidential reasoning MCDA can be insightful on the preference side.	The emphasis on linguistic uncertainty may in some cases it may mask some of the issues (French, 1995).	Many methods are rather simple in application and require only moderate resources, but they may face issues in scaling up to major complex problems.	(Batisha, 2015) [23], (Gilbuena et al., 2013) [24], (Kim and Chung, 2013) [25], (Yang et al., 2018) [26]

Uncertainties		***Cynefin context***			
Stochastic, Epistemic, Analytical (Descriptive Modelling)	*Ambiguity Value (Prescriptive Modelling)*	*Known*	*Knowable*	*Complex*	*Chaotic*
There are issues of operational definition of quantities in some methodologies. Some simpler interval methods have no concept of conditionality so cannot model learning effectively, but there are some very sophisticated theories of evidence that can. Interval methods can also provide sensitivity analyses for Bayesian and MCDA methods (Shafer, 1976; Rios Insua, 1990).	Some methods can be simplistic with quantities not being operationally defined. The evidential reasoning approach to MCDA allows exploration of the relative weights on different criteria or between levels in criteria (Xu, 2012; Zhang et al., 2017).	Methods can be applied here without major issue, possibly because the simple, repetitive nature of the problem allows access to much data and the possibility of tuning the methods to the application.	Since the methods often capture rather than explore and resolve ambiguity and value uncertainties, they can hide issues. Also, the lack, in some cases, of operational definitions may mean that some quantification is dubious. Evidential reasoning methods can help analyse conflicting objectives (French, 1995; Xu, 2012).	The recognition of the need to treat deep uncertainties using real options has been investigated (Hallegatte et al., 2012; Buurman and Babovic, 2016).	The ability to deal with ambiguity may be helpful in poorly understood situations, but the emphasis on capturing ambiguity may ultimately slow the building of understanding.

Multi-Criteria Decision Analysis (MCDA): Full ranking and optimal seeking (Bell et al., 2001; Belton and Stewart, 2002; Bouyssou et al., 2006; Zopounidis and Pardalos, 2010; Tzeng and Huang, 2011; Velasquez and Hester, 2013; Kumar et al., 2017)

Covers many approaches: indeed, Bayesian, DMDU and interval methods are sometimes considered MCDA. Some MCDA seek an optimal or best strategy; others form partial rankings, eliminating weak strategies but not discriminating fully between the better ones. Many MCDA methods eschew dealing with uncertainties and focus on modelling and exploring conflicting objectives and balancing these. MCDA techniques are especially useful in working with senior decision-makers in setting policy and broad objectives, and in processes of stakeholder engagement.

Examples include ranking adaptation and mitigation priorities at a national level in the Netherlands (de Bruin et al., 2009), Lithuania (Streimikiene and Balezentis, 2013) and Bangladesh (Haque, 2016), in the forestry sector in Nicaragua (Guillén Bolaños et al., 2018); and in emissions trading in the European Union (Konidari and Mavrakis, 2007).

Cognitive Phase			***Resources required***	***Case Studies***
Sense-making and Modelling	*Analysing and Exploring*	*Interpreting and Implementing*		
There is growing experience in combining soft elicitation with tools to formulate problems (Marttunen et al., 2017). Many MCDA tools naturally encourage discussion and deliberation on developing appropriate value structures. However, exploration and formulation of stochastic and epistemological uncertainties is less developed (Durbach and Stewart, 2020a).	Emphasis is usually on analysing and exploring, resolving conflicting objectives. MCDA Methods come into their own at this stage of the process. Sensitivity tools and intuitive graphical displays exist for many of the methods (Gunawan and Azarm, 2005; Boardman et al., 2017).	Use of graphical models and sensitivity plots can help explain reasoning for strategy to stakeholders and implementers (Bendoly and Clark, 2016).	The more exploratory methods can be quite light in terms of computational resource, but require interactions with decision makers and stakeholders in workshops. Methods with use complex stochastic mathematical programming can be computationally demanding and require substantial data.	(de Bruin et al., 2009) [27], (Guillén Bolaños et al., 2018) [28], (Haque, 2016) [29], (Konidari and Mavrakis, 2007) [30], (Streimikiene and Balezentis, 2013) [31]

Uncertainties		***Cynefin context***			
Stochastic, Epistemic, Analytical (Descriptive Modelling)	*Ambiguity Value (Prescriptive Modelling)*	*Known*	*Knowable*	*Complex*	*Chaotic*
These methods tend to focus on balancing and resolving conflicting objectives and include little or no analysis of stochastic and epistemic uncertainties. Interactive	Many methods here use multi-attribute value functions and focus on using weights to explore different emphases on conflicting objectives. One very popular method is AHP	Usually in the known context, the objective function is well understood; but in cases where it is not, interactive multi-objective programming can offer a way forward (Klamroth et al., 2018).	If the objective function is not well understood, then these methods can be useful and can be extended to stochastic programming, but epistemic uncertainties are not really addressed	Methods can explore conflicting objectives, but seldom are able to address deep epistemic uncertainties, unless combined with scenarios (Stewart et al., 2013; Marchau et	Formal modelling impossible. Much exploratory work to identify potential causes and effects. Little if any complex analysis.

methods that use complex objective functions do need to consider convergence criteria for analytic uncertainties.	(Saaty, 1980) though this has issues in scaling up to evaluate more than a handful of policies.		(Gutjahr and Pichler, 2016).	al., 2019; Durbach and Stewart, 2020a).	

Multi-Criteria Decision Analysis (MCDA): Partial ranking (Roy, 1996; Bell et al., 2001; Belton and Stewart, 2002; Bouyssou et al., 2006; Behzadian et al., 2010; Zopounidis and Pardalos, 2010; Tzeng and Huang, 2011; Bouyssou and others, 2012; De Smet and Lidouh, 2012; Velasquez and Hester, 2013; Figueira et al., 2016; Govindan and Jepsen, 2016)
Examples include developing criteria for assessing climate protection strategies and applying these to retrofitting a school to manage climate risks in Germany (Markl-Hummel and Geldermann, 2014); evaluating outranking approaches for managing heat stress in a large city in Australia (El-Zein and Tonmoy, 2015); using MCDA to manage the interactions of climate change with tourism in Greece (Michailidou et al., 2016); and identifying priorities to manage droughts and floods in agriculture in Bangladesh (Xenarios and Polatidis, 2015).

Cognitive Phase			***Resources required***	***Case Studies***
Sense-making and Modelling	*Analysing and Exploring*	*Interpreting and Implementing*		
Graphical representations of partial orders are useful in model formulation, and the emphasis on exploring what can be said objectively about dominance relations can build a kernel of consensus between decision-makers and stakeholders.	ELECTRE and PROMETHEE implementations of outranking approaches have many tools for exploring partial relations and analysing agreements and the reasoning behind these.	The analysis of dominance can provide a sound footing for building risk registers to aid implementation. Understanding the kernel of consensus can also aid communication.	If an outranking algorithm is essentially combinatorial in its approach, then for complex problems there may be computational problems. Some of the methods may require less interaction with decision-makers and stakeholders if they can deduce many partial relations from objective data.	(El-Zein and Tonmoy, 2015) [32], (Markl-Hummel and Geldermann, 2014) [33], (Michailidou et al., 2016) [34], (Xenarios and Polatidis, 2015) [35]

Uncertainties		***Cynefin context***			
Stochastic, Epistemic, Analytical (Descriptive Modelling)	*Ambiguity Value (Prescriptive Modelling)*	*Known*	*Knowable*	*Complex*	*Chaotic*
Modelling of all forms of uncertainty including epistemic uncertainty is not the primary objective of these methods. Stochastic uncertainty may be included as probability distributions but there is no formalism for	Partial ranking or outranking methods seek, first of all, to identify dominance between options and preference relations that can be agreed somewhat	Usually in the known context, the objective function is well understood; but when it is not, outranking methods can identify a partial ranking without need too many	Since epistemic uncertainties are not fully addressed, these methods can only help in relation to conflicting objectives, but robustness to uncertainties will need addressing	Outranking methods may be combined with scenarios to explore and analyse decisions under deep uncertainty (Hyde et al., 2003; Durbach, 2014).	Formal modelling impossible. Much exploratory work to identify potential causes and effects. Little if any

learning to address epistemic uncertainties (Hyde et al., 2003; Behzadian et al., 2010; Gervásio and Simões da Silva, 2012).	objectively. Thus, first they eliminate suboptimal alternatives before seeking a fuller ranking. Ambiguity and value uncertainty may also be quantified (Behzadian et al., 2010; Figueira et al., 2016; Govindan and Jepsen, 2016).	interactions with problem-owners.	(Hyde et al., 2003).		complex analysis.

Soft Elicitation (Rosenhead and Mingers, 2001; Shaw et al., 2006; Shaw et al., 2007; Ackermann, 2012; Bendoly and Clark, 2016)

Also known as problem structuring, it is the process of asking problem owners, experts and stakeholders for the knowledge, perceptions, beliefs, uncertainties and values that a model needs to embody before being populated with numbers. Methods here help in problem formulation, structuring understanding: e.g. cognitive maps, soft operational research diagrams, soft systems, prompts such as PESTLE and other qualitative tools (Prober et al., 2017; Symstad et al., 2017). The output of soft elicitation can lead to the building of sophisticated quantitative models (Symstad et al., 2017); and can also structure communications and deliberations with stakeholders. Exploratory data analysis and visual analytics are also relevant. Soft elicitation has enormous advantages in setting the frame for communication between all parties (Prober et al., 2017); there are many cases in which the clarity brought by framing the issues well has obviated the need for formal quantitative analysis.

Examples include Adaptation Pathway planning and elicitation on managing a national park in the USA (Symstad et al., 2017), poverty alleviation in a province in Indonesia (Butler et al., 2016), woodland landscapes in Australia (Prober et al., 2017), as well as general considerations for contested adaptations (Bosomworth et al., 2017).

Cognitive Phase			***Resources required***	***Case Studies***
Sense-making and Modelling	*Analysing and Exploring*	*Interpreting and Implementing*		
Soft elicitation tools provide much support to sense-making, formulating problems and identifying relevant issues to be addressed (Shaw et al., 2006; Shaw et al., 2007; Ackermann, 2012).	Soft elicitation is not relevant to quantitative analysis and evaluation per se, but can support the exploration of residuals to understand the quality of the models and detect further factors to be addressed.	The results of soft elicitation provide the dimensions for communication by identifying the issues that are important to stakeholders and building understanding in those implementing the policies.	Physical resources requirements are relatively slight: sometimes post-its and a white board can be sufficient, though modern visual analytics can require substantial computing resource. However, the demands on the time of problem-owners, stakeholders and experts can be significant	(Bosomworth et al., 2017) [36], (Butler et al., 2016) [37], (Prober et al., 2017) [38], (Symstad et al., 2017) [39]

Uncertainties		***Cynefin context***			
Stochastic, Epistemic, Analytical	*Ambiguity Value*	*Known*	*Knowable*	*Complex*	*Chaotic*

(Descriptive Modelling)	*(Prescriptive Modelling)*				
Soft elicitation tools are available to elicit problem-owners' and experts' perceptions of these uncertainties and, more particularly, dependences and independences between them. Exploratory data analysis is also relevant (Steed et al., 2013; Bendoly and Clark, 2016).	There are tools to catalyse deliberations and help problem-owners and stakeholders clarify their meanings and contextualise their values to the specific issues being considered (Keeney, 1992).	Usually problems falling into known contexts are well-understood and there is little need to elicit or structure models to perform analyses.	Problems falling into knowable space are usually well structured and problem owners' values are also well understood. However, there may be a need to explore error structures in preparation to estimate parameters in the models (Gelman, 2003; Steed et al., 2013; Fekete and Primet, 2016).	Many soft elicitation tools were developed for complex contexts: 'wicked' problems with deep uncertainties: e.g., soft systems, cognitive maps and similar tools to elicit perceptions of relationships between entities and problem-owners' and stakeholder's values (Keeney, 1992; Rosenhead and Mingers, 2001)	Soft elicitation tools and processes can be used to catalyse creative thinking about poorly understood contexts.

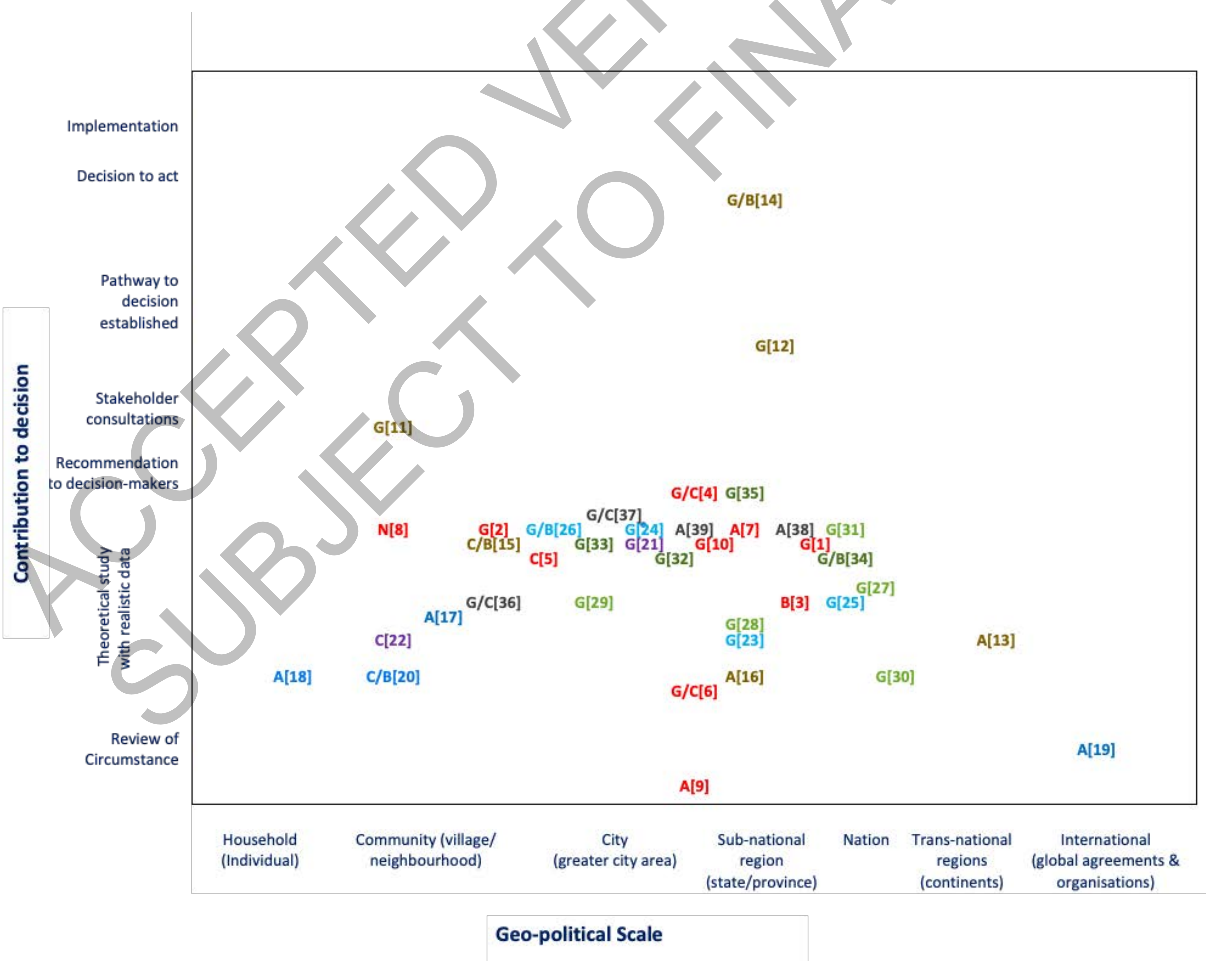

Figure 17.7: Decision-analytic tools used across different geo-political scales and how they contributed to decision outcomes. Points comprise the type of decision-making body (C = Community; G = Government; B = Business/Industry; F = Finance; N = NGO; A = All categories) coupled with the reference number in square brackets, which correspond to numbered references in the case studies of Table 17.5. Colours of the points correspond to the

class of decision-analytic tool as presented in Table 17.3: Bayesian (red), DMDU (Decision Making under Deep Uncertainty) (brown), Decision Process Management (dark blue), Economic and Financial Methods (purple), Interval Methods (light blue), MCDA – full ranking (light green) or partial ranking (dark green), Soft Elicitation (Black).

Many published studies on the utility of decision-analytic methods in managing climate risks are theoretical and therefore it is difficult to find studies on p the value of analytic methods for underpinning final decisions on climate risk adaptation. Bayesian, Deep Uncertainty and elicitation methods and tools to support decision making were the most easily located classes of methods to be used in different contexts (Figure 17.6) while the other classes were more oriented towards government processes. This result highlights a key gap at present in the need to have real world experiences published and mapped for their utility for different tasks, thereby creating a resource for policy-makers to identify suitable tools, such as in emerging communities-of-practice of decision practitioners (Watkiss and Hunt, 2013; Street et al., 2019; French, 2020a).

17.3.1.3 Approaches to Support Decision-making

The common approaches presented here are not undertaken in isolation and are often combined throughout, or applied at different stages of, a decision process, as illustrated in Figure 17.6.

17.3.1.3.1 Role of informal processes

Informal decision-making pervades decision-making in all contexts (*high confidence*) (Orlove et al., 2020); decisions relating to climate change are affected not only by rational processes but also by many informal, often behavioural responses to the situation, some of which may not require formal processes. Informal processes were officially studied in only a few of the publications contributing to Figure 17.7, but all of the studies have hints to informal decision-making that pervades all levels of governance. Although there are not many concrete studies, citing roles of study participants can lead to a perception of a disconnect between the process and the outcome that resulted (see Section 17.5.1 for enablers of success).

Generally, while governance requirements may define the processes of formal deliberations and decision-making, informal deliberations will carry on in parallel, supported by social media, and these informal deliberations may be used to affect the outcome of the formal processes. Stakeholders may feel excluded from the formal deliberations either by governance structures or because they do not agree with their representatives. Conflicting value systems may cause some stakeholders to feel side-lined, particularly if some of the key decision-makers are perceived holding different personal views and interests or to have engaged in political horse-trading, which connect independent decisions. There may be emotional responses, driven by poor comprehension of risk and probabilistic information, and potential for group biases or insularity of participants (Engler et al., 2019). Well-designed decision processes recognise the informal and seek to gain information from it without introducing bias (*medium confidence*) (French and Argyris, 2018).

17.3.1.3.2 Stakeholder engagement

Stakeholder engagement has become increasingly part of climate-relevant decision processes (Orlove et al., 2020). The degree of stakeholder engagement ranges from instructive, consultative to cooperative that are equivalent to information exchange, influence, and partners in decision-making (Sen, 2000; Cattino and Reckien, in press). Since the AR5, climate change adaptation and resilience literature has seen an increase in participatory approaches that deepen engagement and overcome challenges, as well as making some assessments of their effectiveness (Newton Mann et al., 2017; Wamsler, 2017; Esteve et al., 2018), including structured interactions among different types of stakeholders, the use of place-based boundary organizations to strengthen the interactions and heighten the awareness of the institutional context. A higher degree of public participation can lead to more transformational adaptation as well as to higher ambition for local mitigation (*medium confidence*) (17.4.4.2; Cattino and Reckien, in press). Challenges to stakeholder participation are access to state-of-the-art science, capacity to recognize and respond to non-reliable or false climate science information, and the removal of cognitive and other biases (*high confidence*) (Gorddard et al., 2016; Engler et al., 2019; Fulton, 2021).

Participatory and elicitation approaches, where the concerns and involvement of a broader range of interest groups and stakeholders are taken into account, can improve the effectiveness of decision-making (*medium confidence*) (Gregory et al., 2012; Cvitanovic et al., 2019). Participatory planning includes a variety of cogenerative strategies and approaches (e.g., qualitative scenario or adaptation pathway development) through which goals and objectives, knowledge, and strategy implementation and evaluation can be decided collaboratively between practitioners, policymaking, local interests and groups, and scientists (Butler et al., 2016; Prober et al., 2017; Symstad et al., 2017). Specifically, for climate change adaptation, these decision-making strategies can incorporate expert, indigenous and local knowledge (*high confidence*) (Cross-Chapter Box INDIG; Gustafson et al., 2016). The challenge will be to bring together these different actors, as stakeholders tend to act within rather than among systems and procedures, and it is important that platforms are developed to integrate data effectively (Rizzo et al., 2020). Furthermore, reflexive and iterative risk management may further ensure acceptance by participating groups.

Bayesian Methods are increasingly used in advancing approaches for decision-making and support in climate adaptation (Sperotto et al., 2017), by being able to include stakeholder and decision-maker perceptions and biases (Dias et al., 2018; Engler et al., 2019; Phan et al., 2019; Fulton, 2021) in a transparent modelling environment, thereby facilitating consensus and impartiality (*medium confidence*) (Catenacci and Giupponi, 2013; Gelman and Hennig, 2017). Increasing computational efficiency means that these methods can enable different approaches to be addressed and different descriptive and prescriptive models to be included within a single probabilistic environment, which also can be updated in iterative processes (*high confidence*) (Table 17.5; Sperotto et al., 2017; Phan et al., 2019).

17.3.1.3.3 Scenario analyses

Scenarios are described in SR1.5 (IPCC, 2018a) and SRCCL (IPCC, 2019b) as a description of how the future may develop based on a coherent and internally consistent set of assumptions about key driving forces (e.g. rate of technological change, prices) and relationships. Scenarios are neither predictions nor forecasts but are used to provide narratives and trajectories equipped with alternate outcomes. SR1.5 and the SRCCL describe a range of scenarios methods and how scenarios are used to guide risk management decision making. Scenario analysis includes a range of potential future conditions from low end, mid-range, to high-end projections. Scenarios can also include a temporal component from short term, medium term and long term, as defined in the SROCC (IPCC, 2019c).

Scenarios and pathways, combined with elicitation methods, are becoming widely used to assess adaptation and resilience strategies (*high confidence*) (Butler et al., 2016; Prober et al., 2017; Symstad et al., 2017; Lawrence et al., 2019; Phan et al., 2019; Sperotto et al., 2019; Haasnoot et al., 2020a). They can support the consideration of a wide range of alternative possible futures (Catenacci and Giupponi, 2013; Jäger et al., 2018), enabling identification of potential path dependencies caused by adaptation options (*high confidence*) (Pretorius, 2017; Haasnoot et al., 2020a). They can also increase the willingness of stakeholders to consider costly actions, by placing them within broader sequences of action (*limited evidence*) (Barnett et al., 2014). The development, consideration and understanding of scenarios can be enhanced by using visualisation tools to better display storylines, enabling the discussion of alternative futures by participants in decision-making processes (*limited evidence*) (Winters et al., 2016).

17.3.1.3.4 Evaluating trade-offs, robust decision making, and deep uncertainty

Trade-offs are pervasive in decision-making for climate change adaptation, including between adaptation and mitigation, economic/social and environmental cost including distributional/equity considerations, affordability and risk reduction, short and long-term consequences, and spatial variations (Borgomeo et al., 2016; Hudson et al., 2016; Gil et al., 2018; Landauer et al., 2019).

Trade-offs are often directly compared in cost-benefit analyses which require rigorous estimation of the monetized costs and benefits, where monetization is feasible and values uncontested (such as for infrastructure) (*high confidence*) (de Ruig et al., 2019; Table 17.5). Other tools can be employed, such as cost-effectiveness analysis and multi-criteria analysis in order to draw stakeholders into the process (Posner, 2004; Matheny, 2007; Mechler and Schinko, 2016). Stakeholder participation in measuring costs and benefits and in the modelling can aid the process (Doukas and Nikas, 2020).

Logic trees include a range of decision protocols and multi-criteria rules, either based on quantitative or qualitative categories (Roncoli et al., 2016), often termed multi-criteria analyses. The concept of the logic tree has been increasingly applied in climate risk decision-making contexts (Nikas et al., 2018).

Since the AR5, robust decision-making methods are increasingly used to account for deep uncertainty in many climate related risks (*high confidence*) (Marchau et al., 2019; Table 17.5), particularly when decisions need to be made well in advance of when the adaptations need to be implemented (Cross-Chapter Box.5 in SROCC Chapter 1; Cross-Chapter Box DEEP in this Chapter). Reducing risk and building resilience under the context of these types of wicked problems require asking "what if" questions about the future, remain flexible in the face of uncertainty, and seek out policies that provide good outcomes no matter what the future climate might bring (*high confidence*) (17.6; e.g. Larson et al., 2015; Bhave et al., 2016; Bhave et al., 2018). In these cases, trade-offs can be assessed and options can be prioritized through iterative decision-making processes, such as multi-criteria decision-making, robust decision-making, and dynamic adaptation pathway planning (*high confidence*) (Table 17.5; Kwakkel et al., 2014; Kwakkel et al., 2016; Shortridge et al., 2016; Lawrence and Haasnoot, 2017; Haasnoot et al., 2019; Lempert, 2019; Roelich and Giesekam, 2019; Haasnoot et al., 2020a). They can address limitations of data-intensive robust decision-making in developing countries (Daron, 2015), can use proxy data to enable the use of robust decisions in data scarce contexts (Shortridge and Guikema, 2016; Ahmad et al., 2019), incorporate multiple-objectives into robust decision making (Singh et al., 2015), and pathway development supplemented by real options analysis (Buurman and Babovic, 2016; Smet, 2017; Haasnoot et al., 2019; Lawrence et al., 2019). Often, there are close synergies between the application of these methods and using scenario analyses (Workman et al., 2021).

[START CROSS CHAPTER BOX DEEP HERE]

Cross Chapter Box DEEP: Effective adaptation and decision-making under deep uncertainties

Authors: Carolina Adler, Robert Lempert, Andrew Constable, Marjolijn Haasnoot, Judy Lawrence, Katharine J. Mach, Simon French, Robert Kopp, Camille Parmesan, Mauricio Domínguez Aguilar, Elisabeth A. Gilmore, Rachel Bezner Kerr, Adugna Gemeda, Cristina Tirado-von der Pahlen, Debora Ley, Rupa Mukerji.

Decision relevant uncertainties for managing climate risk

Adaptation decision-making can benefit from assessments that support planning for both 'what is most likely' as well as for stress-testing adaptation options over a range of scenarios (Sections 11.7 and 17.3; Cross-Chapter Box.5 in SROCC Chapter 1). This Cross-Chapter Box summarises how deep uncertainties (Section 1.2; IPCC, 2019a) can be assessed in decision-making and addressed practically for adaptation. The concept of deep uncertainty has evolved in IPCC assessments, expanding beyond a focus on reducing uncertainty, to also considering a range of tools and approaches that guide robust and timely decisions to address climate risks. Deep uncertainty is defined as circumstances where experts or stakeholders do not know or cannot agree on one or more of the following: (1) appropriate conceptual models that describe relationships among drivers in a system; (2) the probability distributions used to represent uncertainty about variables and parameters; and/or (3) how to weigh and value desirable alternative outcomes (Cross-Chapter Box.5 in Chapter 1; Lempert et al., 2003; IPCC, 2019a; IPCC, 2019c).

Decisions by individuals, households, the private sector, governments, and public-private partnerships are generally made with partial or uncertain information. This is also the case for adaptation and development decisions where there is often deep uncertainty about the impacts and the societal conditions, preferences and priorities, and responses over time. Under such conditions, decision-makers employ decision processes and scientific information differently from situations where most decision-relevant information is available, uncontested, and confidently characterized with single joint probability distribution. Assuming scientific information is certain, when it is not, is a barrier to effective communication of risks and to successful decisions under uncertainty, increasing the potential for failure and regret of investments, lost opportunities, and transfers of costs to future generations (Sarewitz and Byerly, 2000; Marchau et al., 2019; Sections 11.7 and 17.6).

Addressing deep uncertainty is contextual as it depends on the decision options available, outcomes at stake, and the available scientific information (Box 1.1. in Marchau et al., 2019). The IPCC uncertainty guidance note (Mastrandrea et al., 2010) addresses only the latter (see also Mastrandrea and Mach, 2011; Section

1.3.4). Deep uncertainty is generally more salient when policy-relevant statements have *low confidence* or lack relevant data or information, or in cases where significant uncertainty contributes to disagreements and disputes (Sriver et al., 2018). Recent work has also included moral uncertainty (MacAskill et al., 2020) by evaluating the outcomes of alternative strategies with analyses organized around different perspectives on the appropriate principles of justice (Ciullo et al., 2020; Section 17.3; Jafino et al., 2021; Lempert and Turner, 2021).

To better communicate deep uncertainty, WGI AR6 complements projections of likely global mean sea-level change, driven by processes in which there is at least *medium confidence*, with projections that incorporate ice-sheet processes in which there is *low confidence* (Section 9.6.3 in Fox-Kemper et al., 2021). The latter are accompanied by storylines to highlight the physical processes that would generate extreme outcomes (Box 9.4 in Fox-Kemper et al., 2021). These low-confidence projections and storylines are useful because the likelihood of high-end (> 1.5 m) global mean sea level (GMSL) rise in the 21st century is difficult to determine but important to consider in coastal settings (e.g., CCP2; Cross-Chapter Box SLR in Chapter 3). High-end GMSL rise by 2100 could be caused by earlier-than-projected disintegration of marine ice shelves, the abrupt, widespread onset of Marine Ice Sheet Instability and Marine Ice Cliff Instability around Antarctica, or faster-than-projected changes in the surface mass balance and dynamical ice loss from Greenland (Box TS.4 in Arias et al., 2021; Box 9.4 in Fox-Kemper et al., 2021). In a low-likelihood, high-impact storyline and a high CO_2 emissions scenario, such processes could in combination contribute more than one additional meter of sea level rise by 2100 (Box TS.4 in Arias et al., 2021; Section 9.6.3 and Box 9.4 in Fox-Kemper et al., 2021). Other hazards assessed in WGI AR6 that address similar aspects that are relevant for decision-making under deep uncertainty, include drought (Section 8.4.1.6 in Douville et al., 2021; Section 11.6.5 in Seneviratne et al., 2021), flood (Section 8.4.1.5 in Douville et al., 2021); (Section 11.5.5 in Seneviratne et al., 2021), wildfire weather (days) (Section 11.8.3 and Box 11.2 in Seneviratne et al., 2021), among others.

Approaches and information requirements for managing deep uncertainty

Many approaches are available for evaluating robust decisions under conditions of deep uncertainty (Sections 17.3 and 11.7; Box 11.5 in Chapter 11). The majority use multiple scenarios to stress-test adaptation options and explore how alternative adaptation pathways might evolve under a range of different conditions (Swanson). Approaches differ in terms of their focus, types of strategies best addressed, and data and other resources required (Marchau et al., 2019).

"Low regret" options are one simple and common approach to deep uncertainty (Sections 17.3 and 17.6) expected to perform well over a wide range of scenarios and represent one example of robust strategies. However, such options will generally be insufficient for adaptive responses to adapt over long timeframes and to avoid lock-in of investments (Section 11.7; Box 11.5 in Chapter 11).

"Adaptation pathways" provide another approach for addressing deep uncertainty and staging decisions over time (Haasnoot et al., 2013), by linking the choice of near-term adaptation actions with predetermined future thresholds. Observation of such thresholds trigger subsequent actions in the planning or implementation stages of adaptation strategies. Adaptation pathways can begin with low-regret, near-term actions that aim to create and preserve future options to adjust if and when necessary. Alternative pathways can be explored and evaluated to design an adaptive plan with short-term actions and long-term options.

Climate resilient development (CRD), and the pathways to it, can also involve decision making under deep uncertainty. Literature assessed in sectoral and regional chapters of this report present several examples of potential risks to achieving development goals under climate change, at global as well as national and local levels (*high confidence*) (Chapter 18). Achieving CRD depends on negotiation, contestation, and reconciliation of trade-offs among diverse actors, who in turn value preferred outcomes differently with respect to associated climate risks and uncertainties, hence the prospect for deep uncertainty to manifest (Section 18.5). Deep uncertainty also characterizes the development process itself, given that fundamental changes and disruptions are part of the transformational changes required to shift towards CRDPs.
The "keeping options open" approach, plans by using a series of sequential decisions and actions in the near-term to avoid closing off potentially promising future options (Rosenhead, 2001; Section 2.6), or by using real options, take near-term actions that create currently unavailable options in the future (Kwakkel, 2020).

Deep uncertainty approaches use a wide range of storylines as scenarios to test low regret options and to provide information relevant for potential thresholds for use in adaptation pathways (Haasnoot et al., 2013; Box 11.4; Box 11.6; Sections 11.7; 17.3).

Deep uncertainty approaches enhance the value of monitoring to detect signals of change in a timely manner (*medium confidence*). Actionable warning can come from climate signals, and socio-economic indicators/signposts, including drivers of change, vulnerability, and impacts, best suited for timely, reliable and convincing signals for decision making that anticipate future changes and the need for adaptation or the potential to seize opportunities (Hermans et al., 2017; Haasnoot et al., 2018; Stephens et al., 2018; Oppenheimer et al., 2019). For early warning signals to be decision-relevant, they need to have institutional connectivity to enable action (Haasnoot et al., 2018; Sections 1.4; 11.4; 11.7; Table 11.18) (*medium confidence*).

Examples and case studies from across the WGII report

There are diverse examples of the practical application of deep uncertainty methods across different climate change hazards in many regions of the world. For instance, low-regret options have been used to address the impacts and risks of landslides and debris flows in mountains (Section CCP5.2.6). Their frequency and magnitude are already widely experienced (Section CCP5.2.6) and projected to increase (Section CCP5.3.2.1). However, managing these associated risks also requires joint consideration of projected vulnerabilities and exposure of people and infrastructure, including the multiple and dynamic non-climate related factors that are relevant for how the impacts manifest in context, such as population growth and land use planning (CCP5.2.6). Here, context-specific deliberative processes are used that include scenarios to guide and specify preventive measures with higher effectiveness than protective (infrastructure) measures could achieve alone. Low-regret adaptation involves raising awareness and accounting for long planning horizons to address the uncertainties associated with such risks, for instance in mountain regions, including education (Sections CCP5.4.1; CCP5.2.6), with co-benefits such as addressing changes in water availability for supply and demand (CCP5.4.1).

Adaptation pathways have been used to address SLR and changes in extreme rainfall through flood risk and management (Cross-Chapter Box SLR in Chapter 3; CCP2; Sections 13.2, 11.3 and 11.7): for example, adaptive plans in the Netherlands (Van Alphen, 2016; Bloemen et al., 2019), climate resilient development in Bangladesh (Hossain et al., 2018; Zevenbergen et al., 2018), adaptive spatial pathways for infrastructure retreat and for flood risk management in New Zealand (Lawrence et al., 2019a; Kool et al., 2020) and adaptive strategies such as in the cities of London (Ranger et al., 2013; Hall et al., 2019), New York (Rosenzweig and Solecki, 2014), and Los Angeles (Aerts et al., 2018a). This approach is mainstreamed into guidance documents such as the Climate Risk Informed Decision Analysis (CRIDA) (Mendoza et al., 2018), national guidance and policy briefs to address coastal hazards and sea-level rise planning in New Zealand (Lawrence et al., 2018; Lawrence et al., 2019b), planning for sea-level rise in California (OCP, 2018), and synthesis documents by the government of Canada on marine coasts (Lemmen et al., 2016). Furthermore, examples from the United Kingdom, New Zealand and The Netherlands point to the development of monitoring plans to detect signals for climate adaptation (Stephens et al., 2017; Haasnoot et al., 2018; Bloemen et al., 2019).

Climate smart planning, with a focus on keeping options open, can play a role in reducing species extinction rates (Sections 2.5; 2.6). When and where and for whom particular irreversible impacts will occur is deeply uncertain, for example the extinction of a species. Even at the lowest emissions scenarios, some local species will become extinct, but estimates of extinction risk are highly uncertain, typically varying by factors of 2-3 even for one species (Section 2.5) (*medium confidence*). Risks of species' extinctions are lowered by reducing emissions but keeping options open for as long as possible and avoiding irreversible actions are key to developing a climate-resilient adaptive pathway so that real-time climate-driven changes can inform actions. Nature-based solutions (NBS) are emerging as key players for mitigation. With smart planning, NBS offer approaches that not only provide substantial mitigation, but also considerable adaptation benefit to biodiversity, and human health and well-being. Done poorly, such projects can result in large negative impacts on humans and nature. An NBS climate-sensitive decision framework leading to "win-win" solutions for mitigation and adaptation is shown in Figure 1 Cross-Chapter Box NATURAL in Chapter 2 (see also Sections 2.4.2.5, 2.5, 2.6, 5.4.4.4, and 5.14.1; Cross-Chapter Box ILLNES in Chapter 2; Cross-Chapter Box COVID in Chapter 7).

In view of these multiple and diverse examples, it is evident that the application of deep uncertainty methods is enabling decisions to be made in a timely manner that avoid foreseeable and undesirable outcomes and take opportunities as they arise (*high confidence*).

Prospects for adaptation decision-making

Deep uncertainty is increasingly salient for decision-making as recognition of climate-related risks and related uncertainties has increased (*high confidence*). These risks can compound and cascade to become new risks, increasing the breadth, frequency and severity of climate change impacts and the consequently increasing scale and scope of adaptation (*high confidence*) (Cross-Chapter Box Extremes in Chapter 2; Sections 1.3.1.2, 2.3, 2.5, 2.6, 11.5, 11.7, and CCP5.3.1). Waiting until uncertainties are resolved (if they ever can) may leave little or no time to adapt. The lead-time for planning and implementation of adaptation can take decades (Haasnoot et al., 2020b; Cross-Chapter Box SLR in Chapter 3) and socio-economic developments can lock-in undesirable pathways where underlying vulnerabilities and exposure, such as poverty, conflict, and their associated displacement of people, remain unaddressed (Sections 5.13.4; 16.5.2.3.8; Cross-Chapter Box Migrate in Chapter 7).

Overall, there is growing evidence that effective implementation of strategies developed for deeply uncertain problems require adequate mandates and funding frameworks, preparedness and disaster response plans, and monitoring and evaluation of the strategy outcomes, against how the future unfolds (*medium confidence*). Collaborative and adaptive governance arrangements, and education and awareness raising, promote learning environments for community engagement, and are essential for the effective implementation of robust adaptation plans (*medium confidence*) (Sections 5.14.1; 17.3 and 11.7).

[END CROSS CHAPTER BOX DEEP HERE]

17.3.1.3.5 Adaptive feedback management

Iterative decision making requires that the implementation of adaptations are reviewed to determine whether the adaptation effectively achieved the objectives, and whether adjustments or additional actions were required (17.5). Adaptive feedback management is an approach to managing dynamic climate risks by designing a field monitoring program to provide data to an assessment procedure which in turn advises on what adjustments need to be made to a 'control action', all of which are part of the adaptation to be implemented (Hurlbert et al., 2019; Figure 17.6). Adaptive feedback management is more able to account for the dynamic nature of risk and the future emergence of unforeseen risks because of the active design of how to adjust the management approach (Dickey-Collas, 2014).

Adaptive feedback management is important for managing climate risks that fall within the *Cynefin* context of chaos, relying on observations and indicators to learn about the system and to trigger actions (*medium confidence*) (Helmrich and Chester, 2020). It has been a valued approach for managing wildfish fisheries in many oceans (*high confidence*) (Fulton et al., 2019; Hollowed et al., 2020; Bahri et al., 2021), and is important for responding to the challenges of climate change (*high confidence*) (Holsman et al., 2019; Hollowed et al., 2020; Bahri et al., 2021).

While the benefits of investment in data and assessments can outweigh the costs of implementation (*low confidence*) (Fulton et al., 2019), the implementation may take time when resources are limited, particularly in developing nations, where low-cost approaches will be needed for deciding on pathways for adaptation (Bhave et al., 2016; Shortridge et al., 2016).

Iterative decision making and adaptive feedback management meet when the feedback management procedure is reviewed in total for its effectiveness in one of the review and adjustment iterations. At present, a common approach for assessing different adaptation options and their interaction is by using, e.g., scenarios in dynamic models (Adam et al., 2014; Girard et al., 2015). An emerging field in adapting fisheries to climate change is to embed the decision-making system in the scenario models in order to assess the capability of feedback management (decision-making, monitoring and capacity for adjustment of the options over time) to achieve satisfactory trade-offs amongst the objectives of the different stakeholders (*medium confidence*) (Melbourne-Thomas et al., 2017; Holsman et al., 2019; Hollowed et al., 2020). This method can enable prospective evaluation of future whole-of-management scenarios described in this chapter.

17.3.2 Integration Across Portfolios of Adaptation Responses

In recent years, methods for simultaneously considering multiple societal and sectoral objectives, climate risks and adaptation options have been emerging, often termed 'integrated' approaches (Hadka et al., 2015; Garner et al., 2016; Rosenzweig et al., 2017; Giupponi and Gain, 2017a; Stelzenmuller et al., 2018; Marchau et al., 2019). Different decision-making approaches can be complementary (Kwakkel et al., 2016) and multiple approaches will be needed to manage risks across sectors, in space and over short to long time scales (see Section 17.6).

Higher level integration was first presented in SREX (Burton et al., 2012; Lal et al., 2012; O'Brien et al., 2012) and includes concepts of planning, coordination and mainstreaming (Lal et al., 2012), consideration of cross-scale dynamics and nested vulnerabilities (Klein et al., 2014), as well as decision-making across governments and sectors (Denton et al., 2014; Mimura et al., 2014).

Since AR5, recognition of the importance of using integrated adaptation to improve climate risk management across the nexus between many sectors and across regions has increased *(high confidence)* (Harrison et al., 2016; Challinor et al., 2018). This was highlighted in the Special Report on Climate Change and Land (Hurlbert et al., 2019); advanced planning and integration of adaptation responses are needed over many levels *(medium confidence)* (Göpfert et al., 2019; Section 17.6; Woodruff and Regan, 2019). The complexity of managing this nexus may be compounded by the potential for antagonistic or synergistic effects among and between climate impacts, and changes arising from local sectoral activities and independent adaptation responses to those risks *(high confidence)* (Crain et al., 2008; Piggott et al., 2015; Adger et al., 2018; Brown et al., 2018; Stelzenmuller et al., 2018; Simpson et al., 2021), such as the cross-sectoral demands for freshwater (Xue et al., 2015; Azhoni et al., 2018). Integrated adaptation will also help facilitate management of new and emerging risks, help identify when response plans may need to be changed in light of the dynamics of risk over time, and help identify solutions that are less likely to constrain future options for adapting to future needs (Wise et al., 2016).

Implicit to managing cross-sectoral interactions, including the nexus concept, is that the interlinkages between multiple sectors are systemic, and therefore solutions to challenges arising from any one sector can only be satisfactorily addressed by considering the connections to other sectors at the same time (Wichelns, 2017). Challenges for integrated adaptation include: (1) to sufficiently capture the complexities between the nexus dimensions (Weitz et al., 2017); (2) to adequately consider the time, costs and challenges of coordination and cooperation (Wichelns, 2017); (3) to consider the political economy in which progress toward more integrated solutions could take place, not only account for technological requirements(Leck and Roberts, 2015); (4) to obtain sufficient temporal or spatial data to capture the interactions between natural and social processes (Shannak et al., 2018); (5) to connect these considerations to decision-making and policy processes in order to gain insights into the conditions for collaboration and coordination across sectors, including external dynamics and political and cognitive factors determining change (Weitz et al., 2017); and (6) to develop a coherent framework against which to assess results and observations (Crain et al., 2008; Wichelns, 2017).

17.4 Enabling and Catalysing Conditions for Adaptation and Risk Management

17.4.1 Introduction

The WGII AR5 identified - with high confidence - a range of factors that could enable or limit planning and implementation of adaptation options and potentially their effectiveness (Klein et al., 2014; Mimura et al., 2014; Noble et al., 2014). These included governance, finance, knowledge and capacity as enabling factors, as well as cultural, social, political and economic differences that influence individual and collective willingness and capability to act. The AR6 SRs (specifically, de Coninck et al., 2018; Roy et al., 2018;

Collins et al., 2019; Hurlbert et al., 2019) reinforced the AR5 findings, further noting that the transitions needed for climate resilient development would need to be supported by radical shifts in governance, knowledge development, technology application, finance and economics, and social norms.

This section builds on the AR5 and AR6 SRs by reviewing new evidence on three key enablers identified in the AR5: governance, finance and knowledge. The focus is on assessing new evidence on (i) understanding of these enabling conditions, (ii) how they have changed on the ground, and (iii) whether these conditions have enabled progress on adaptation and risk management. The section also addresses an emerging related topic, the role of catalysing conditions and actors in accelerating action on climate change adaptation, such as litigation on failure to adapt, understandings of urgency, and the aftermath of extreme weather events. While enabling conditions are necessary for action, they are not by their presence enough; catalyzing conditions emerge when game-changing circumstances become present, such as when a high-profile extreme weather event occurs or when a champion drives change in an organisation.

17.4.2 Enabling Condition 1: Governance

Governance is an inclusive concept of the range of means for deciding, managing, implementing, and monitoring climate change responses. It can involve the contributions of various levels of government (global, international, regional, sub-national and local) along with those from the private sector, of nongovernmental organisations, and of civil society. The importance of supportive governance arrangements is reiterated widely across regional and sectoral chapters in this report, in multiple different contexts (very high confidence).

17.4.2.1 Legal, Policy and Regulatory Instruments

17.4.2.1.1 Climate legislation

Legal systems play an important governance role in facilitating responses to climate change across all levels of society (*high confidence*) (Ruhl, 2010; McDonald and Styles, 2014; Mehling, 2015). Laws can facilitate climate action in multiple ways, including through: (i) mandating and guiding the behaviour of governance structures and actors, (ii) fostering coordination between different levels of government, (iii) enforcing climate responses, (iv) its symbolic value as well as (iv) aligning scientific evidence and societal norms (Mehling, 2015; Scotford et al., 2017). Laws also can embed climate change planning within the administrative structure of a state rendering policy less vulnerable to revocation (Scotford et al., 2017). Extensive revision to laws has occurred in the last decade: a survey of 164 countries showed that over 1200 climate-related national laws and policies have been published with approximately 44% being acts of parliament (Nachmany et al., 2017).

National climate change laws are important for transposing ratified international commitments into domestic regimes, such as the Paris Agreement and the Convention on Biodiversity, as well as voluntary agreements such as the Sendai Framework for Disaster Risk Reduction. In turn, the enactment of domestic laws can yield useful experiences and foster engagements that positively influence and support the development of international commitments (Townshend and Matthews, 2013; Mehling, 2015). Strong and consistent regulatory frameworks also support the flow of climate finance to developing countries that have such frameworks (Nachmany et al., 2017). The successful implementation of national and sub-national climate change and related policies and strategies are often contingent upon the underlying legislative framework empowering, mandating or guiding their review, implementation and enforcement (Averchenkova and Matikainen, 2017; Scotford et al., 2017) (*medium confidence*).

Existing legal systems also pose potential barriers to adaptation, as described in Chapter 9 (Africa) and Chapter 8 (Poverty, Livelihoods and Sustainable Development). Laws may reinforce governance arrangements and regulations state that do not support responses to climate change, and exacerbate existing vulnerabilities and inequalities (Craig, 2010; Arnold and Gunderson, 2013; Wenta et al., 2019). In such cases laws may require review and revision or replacement, and at the same be written in ways that foster adaptive management (Craig, 2010; Ruhl, 2010; Cosens et al., 2017).

Even though there is no agreed definition of or typology for climate change laws (Mehling, 2015), studies have tended to classify climate change laws as being ‘framework’ or ‘sectoral’ (see Table 17.6 for examples). Framework laws offer a comprehensive, unifying basis for climate change policy, addressing multiple aspects or areas of climate change mitigation or adaptation (or both) in a holistic and overarching manner (Townshend et al., 2011; Fankhauser et al., 2014; Nachmany et al., 2015; Clare et al., 2017b); they are powerful levers for setting national and sub-national agendas, creating climate change institutional structures, enabling policy implementation, and driving the passage of additional sectoral legislation and regulations (Clare et al., 2017b). Prior to 2010, national framework laws tended to have a mitigation focus while more recent laws or amendments thereto have an increased adaptation focus (Rumble, 2019b). No evidence indicates whether general or specific framework laws yield better outcomes; however, reviews of more recent examples of framework laws in Africa suggest a trend towards more specificity in the required content of adaptation strategies and duties (Rumble, 2019b).

A sectoral approach to climate change legislation grafts climate-related provisions into existing laws, such as environmental impact assessment, flood insurance and infrastructure planning, collectively creating an aggregated legal landscape (Townshend et al., 2011; Gerrard and Fischer, 2012; Nachmany et al., 2015; Scotford et al., 2017; Rumble, 2019a). This approach is particularly relevant to adaptation challenges which intersect with numerous bodies of law that are dedicated to other societal concerns (Gerrard and Fischer, 2012). However, integrating such considerations can be challenging in certain areas of law, particularly those relating to property rights, water rights and endangered species protection (Gerrard and Fischer, 2012). The incorporation of adaptive management principles (including monitoring, periodic evaluation, and response modification) within existing laws can enhance their enabling role and foster greater resilience (Godden, 2012; Arnold and Gunderson, 2013; McDonald and Styles, 2014).

The legal regime for adaptation is too embryonic for assessment of good practice design and content, although similarities can be seen in the framework laws and draft bills across several countries. Some studies highlight the importance of domestic ‘whole of legal system’ analysis prior to developing of modifying law. This can identify the range of existing legislative instruments that can directly intersect with climate change, along with related contextual factors such as national circumstances, governance frameworks, and political and economic realities as well as national administrative culture (Scotford et al., 2017). This helps any new climate change laws to be absorbed into, and harmonise with, the established legal system of each country (Scotford et al., 2017). Efforts are underway to assist countries in such assessments and the identification of areas for legislative reform, for example through the Commonwealth and UN Environment’s Law and Climate Change Toolkit. Similarly, databases such as the Grantham Research Institute on Climate Change and the Environment and the Sabin Center on Climate Change Law are expanding the knowledge base of national climate legislation developments.

Table 17.6: Selected examples of framework and sectoral law approaches adopted by different nations that represent a variety of regional contexts.

Example	Legal Approach	Description	References
United Kingdom Climate Change Act 2008	Framework	Provides for development of climate change impact reports and programmes for adaptation. Dedicated institutional structure with advisory body, adaptation planning provision, reporting/information obligations, climate change mainstreaming, climate change trusts, or financial arrangements.	(Averchenkova et al., 2021)
Kenya Climate Change Act 2016	Framework	Modelled on the United Kingdom Climate Change Act. Provides for development of climate change impact reports and programmes for adaptation. Dedicated institutional structure with advisory body, adaptation planning provision, reporting/information obligations, climate change mainstreaming, climate change trusts, or financial arrangements.	(Rumble, 2019b)

Mexican General Law on Climate Change 2012	Framework	Imposes positive duties upon government to implement "adaptation actions" - conservation, sustainable use and rehabilitation of beaches and coasts; water programmes for watersheds; the establishment of protected areas and biological corridors; the development of risk atlases; human settlement and urban development programmes; and prevention programs targeting diseases exacerbated by climate change. Includes development of economic instruments including fiscal incentives, credits, bonds, civil liability insurance, market-based instruments.	(Averchenkova and Guzman Luna, 2018)
New Zealand Exclusive Economic Zone and Continental Shelf (Environmental Effects) Act 2012	Sectoral	Incorporates adaptive management principles by regulating the issuance of marine consents with conditions allowing change based on ecological change and indicators.	(Godden, 2012)
Seychelles Conservation and Climate Adaptation Trust of Seychelles Act 18 of 2015	Sectoral	Provides for the establishment of a dedicated trust fund for conservation measures and climate change adaptation measures.	(Etongo et al., 2021)
Commonwealth of Dominica Climate Resilience Act 16 of 2018	Sectoral	Promotes disaster recovery and resilience building. Establishes the Dominica Climate Resilience Policy Board and sets out its functions and duties. Requires the development of a Climate Resilience and Recovery Plan.	(Government of the Commonwealth of Dominica, 2018)
Swedish National Strategy for Climate Change Adaptation (Government Proposition 2017/18:163)	Sectoral	Amends Sweden's Planning and Building Act (2010: 900) by requiring Municipalities to assess the risk of damage to the built environment from climate risks well as how such risks may change in the future; requires detailed plans for measures to address land permeability when issuing a land permit; adopts the Swedish National Climate Strategy into law.	(Government of Sweden, 2017)
Argentinian Glaciers Preservation Law N 32.016 (2010)	Sectoral	Provides for minimum budgets to protect the national glacial water sources that supply the Mendoza oasis. Establishes that all of Argentina's glaciers and its periglacial environment are to be protected, irrespective of size.	(Warner et al., 2019)
Netherlands Delta Act on Water Safety and Fresh Water Supply	Sectoral	Protects the Netherlands from risks such as sea level rise and extreme rainfall. Establishes a Delta Programme to secure fresh water supply and address climate risks/sea level rise; a Delta Fund to operate the Programme and a Commissioner.	(Van Alphen, 2016)

17.4.2.1.2 Climate change policies, strategies and plans

Climate change policies and plans are important in the translation of national commitments and legal requirements into specific on the ground strategies and guidelines, which enable actions across multiple spheres and scales of government and non-government institutions and actors.

Substantial developments in adaptation policy have occurred since AR5 (*high confidence*). Perhaps the most significant is the Nationally Determined Contributions (NDCs) required under the Paris Agreement, where 184 out of 197 parties to the UNFCCC have already submitted their first plans (UNDP and UNFCCC, 2019). The NDCs have allowed countries to articulate their priorities and ambition with respect to climate action and it has been suggested that these can in turn lead to cascading policies (and laws) that drive and enable adaptation and climate risk management. Analysis of the first NDCs submitted in the lead up to and after the

Paris Agreement showed that adaptation priorities were more often articulated by developing countries and least developed countries, while developed countries and emerging economies focused mostly on mitigation (Pauw et al., 2019). As of 2019, over 90 developing nations are at various stages of preparing National Adaptation Plans and 112 nations have indicated their intention to revise their NDCs for the 2020 update (UNDP and UNFCCC, 2019).

Several other international agreements including the Sendai Framework for Disaster Risk Reduction and the UN Agenda 2030 Sustainable Development Goals have had significant impacts on the adaptation and risk-management decision-making processes. For example, the Sendai Framework articulates the need for improved understanding of disaster risk in all its dimensions of exposure, vulnerability and hazard characteristics; accountability for disaster risk management; preparedness to "Build Back Better"; recognition of stakeholders and their roles; mobilization of risk-sensitive investment to avoid the creation of new risk resilience of health infrastructure, cultural heritage and workplaces; strengthening of international cooperation and partnership, and risk-informed donor policies and programs, including financial support and loans from international financial institutions.

Specific adaptation policies have been formulated at national, regional/state and local levels across 68 countries and 136 coastal cities (Olazabal et al., 2019a). At the national level, the quantity and complexity of adaptation policies have increased since AR5, with most policies coming into force since 2009 (Nachmany and Setzer, 2018). Adaptation is addressed in the executive climate policies of at least 170 countries (Nachmany et al., 2019a). Documented sub-national adaptation policies are more prevalent in developed countries and emerging economies, as compared with low- and middle-income ones (Olazabal et al., 2019b). For example, by 2017 26% of large and medium-sized European cities had an adaptation plan or a joint adaptation-mitigation plan in place (Reckien et al., 2018a).

Adaptation policies often comprise multiple goals and instruments, which develop over time, especially where jurisdiction over policy issues is shared among agencies or levels of government (Río and Howlett, 2013). The increase in the number and complexity of policy instruments across geared towards adaptation raises questions of coherence and alignment between the selected policy mixes and their effectiveness (England et al., 2018; Ranabhat et al., 2018; Lesnikowski et al., 2019).

Evaluation of national adaptation plans (NAPs) has only recently been undertaken. Woodruff and Regan (2019) compared national adaptation plans from 38 countries and concluded that most were strong in identifying vulnerabilities and identifying potential adaptation options but were weaker in articulating implementation pathways and monitoring of progress; plans written by multi-agency teams were nearly always of higher quality. Garschagen et al. (2021) showed that while most NAPs consider future changes in climate hazard, many do not consider how vulnerability and exposure might change, concluding that this limits the potential effectiveness of the plans. Morgan et al. (2019) showed that NAPs that are consistent with the Paris Agreement can enable development pathways that promote synergies between environmental, social, and economic goals.

17.4.2.1.3 Impact of legal and policy instruments

Commitment to act, and guidance on how to do so, from international and national governance levels can drive national and sub-national adaptation (Reckien et al., 2013; Heidrich et al., 2016; Reckien et al., 2018a). For example, more local plans have been developed in European countries where it is obligatory for local municipalities to develop climate change plans (Reckien et al., 2018a). Local government have also drawn on non-binding national climate frameworks, as well as international frameworks (such as European law) or international networks (such as Global Covenant of Mayors for Climate and Energy) to guide their actions (Reckien et al., 2013; De Gregorio Hurtado et al., 2015; Reckien et al., 2015; Heidrich et al., 2016; Reckien et al., 2018a).

However, a national framework is not always sufficient to trigger climate change action on the lower level, in particular when the national guiding document fails to clearly formulate how it should be used and “translated down” to lower governance levels (De Gregorio Hurtado et al., 2015). Guidance on how to apply a national framework at lower governance levels can assist in their uptake.

In the case of climate change legislation, research on the impact of adaptation laws is limited, save for a few studies (Averchenkova and Matikainen, 2017), because many framework laws, particularly those with more of an adaptation focus, have only been published recently (Rumble, 2019b). Reviews of the implementation of the risk assessment and adaptation components of the UK's Climate Change Act 2008 suggest that they had a weaker implementation record compared to mitigation provisions (Fankhauser et al., 2018), potentially because implementation of adaptation is more complex as compared to mitigation as shown for the local level (Reckien et al., 2019). However, the UK Act is considered to have made action on climate change more predictable, more structured and more evidence-based (Averchenkova et al., 2021).

There are numerous examples of regulatory and project-based innovations by local governments. Their impact, however, is uneven, with much depending on the implementation capacity of local governments and other socio-institutional barriers, including those relating to mandate and joint project implementation, cross-departmental working, planning cycles, concerns relating to legal liability and compensation, political appetite and cost (Godden, 2012; Taylor, 2016a). Notwithstanding implementation challenges, evidence is emerging that overarching framework laws play a foundational and distinctive role in supporting effective climate governance, including adaptation governance (Fankhauser et al., 2018) and are drivers of subsequent activity (Townshend et al., 2011; Fankhauser et al., 2014; Clare et al., 2017b), especially when formulated with clear guidance for all related actors, including lower level of governance (De Gregorio Hurtado et al., 2015). This may explain the rapid increase in both local and national climate change laws, now with an increased emphasis on regulatory provisions to increase resilience and reduce vulnerability.

17.4.2.1.4 Regulations and standards

The presence and articulation of regulations and standards that address climate risk, such as building codes and land use zoning are key enabling factors for effective decision-making (Kim et al., 2020). Regulations and standards provide a framework for common understanding of when and under what conditions action should be taken specifically in relation to the construction and maintenance of the built environment, infrastructure and environmental and social practice (Grynning et al., 2020). Regulations and standards for climate action emerge primarily from two settings. First, as an addition or augmentation to existing regulations and standards that emerged initially to address existing potential climate extremes and stresses (e.g. size of culverts in response to maximum rainfall and runoff conditions). And second, new regulations and standards that were developed in direct response to new or emergent climate risks (e.g. regulations in response to new presence of mean monthly high tide flooding) (Qiao et al., 2018). Commonly agreed upon social norms and conventions also can be described as regulatory and providing a set of standards.

The regional and sectoral chapters of this report provide significant evidence of how regulations and standards enhance or hinder opportunities for climate risk management and adaptation. Relevant regulations and standards are especially evident in the oceans and coastal domains (Chapter 3 and CCP2, in cities and infrastructure (Chapter 6), and the water (Chapter 4) and food sectors (Chapter 5). Europe and North and South America (Chapters 12, 13 and 14) have the most frequent documented occurrences of examples of regulations and standards. Regulations and standards focused on building codes to protect against extreme event and loss, water regulations and agreements to protect water supply and lessen drought impacts, and health codes to limit heat exposure are the most frequent examples of such practices. Deficiencies of regulations and standards have been noted with respect to their capacity to manage species migrating from climate change, and to provide opportunities for transformative adaptation. The evidence from the sectors and chapters illustrate that more comprehensive regulations and standards lead to positive adaptation outcomes.

17.4.2.1.5 Environmental and social governance

Environmental and social governance refers to voluntary or non-legally required actions taken by participating parties to achieve a commonly defined goal (Bodin, 2017; DeCaro et al., 2017; Partzsch, 2020). While not explicitly described in the sectoral and regional chapters of this report, the maintenance and exercise of environmental and social governance decision-making strategies do enable adaptation practice and have become especially important when formal legal and policy regimes are not yet present. As formal regulation promotes clear and common understanding of climate risks and mechanisms to develop context specific appropriate solutions, voluntary code-making and self-regulation can forestall the need for legal action or can function as precursors to the formulation and implementation of legislation, laws, and regulations.

Social and environmental governance long has been presented within climate risk decision-making, although more typically in the domain of climate mitigation (Wright and Nyberg, 2016; Vandenbergh and Gilligan, 2017). Corporate climate decision-making emphasizes the importance of profit motives in shaping decisions however reputational factors as appropriate environmental stewards also can be important when linked to sensitivity of other stakeholders such as investors, lenders, customers, and employees (Vandenbergh and Gilligan, 2017). Pulver (2011) notes that climate issues influence corporate decision-making more strongly in organizations that are networked with other organizations that also consider these issues and through direct experience with climate-related events and associated organizational learning.

Since AR5, more case studies of social and environmental governance within the domain of climate adaptation have become evident, especially within the context of adaptive management experimentation (Vella et al., 2016; Beunen and Patterson, 2019; Blühdorn and Deflorian, 2019). Environmental and social governance strategies for climate adaptation are diverse and reflect context specific conditions of the decision-making process including the role of the state, the individual and private interests, formality/informality, social responsibility, sources of financing, and transparency. Environmental and social governance enables the testing and definition of implementation solutions, enhancing the opportunities for defining successful adaptation (Surminski, 2013). Several models and approaches to adaptive governance to promote adaptation and resilience in response to extreme weather events have been observed. These include polycentric and multi-layered institutions, participation and collaboration, self-organization and networks, and learning and innovation (Djalante et al., 2011).

The effectiveness of social and environmental governance varies by sector. For example, in the private business sector, Aragòn-Correa et al. (2019) assess the effects of mandatory and voluntary regulatory pressure on firms' environmental strategies. In summary, they find that analyses of the effects of voluntary pressure demonstrate that by themselves they are unlikely to bring about significant improvement in environmental outcomes. Professional organisations, however, have made progress in addressing sectoral standards relative to the adaptation process. This includes the development of new industry guidelines, codes, standards, specifications, in addition to the implementation of infrastructure inventories that incorporate evaluation of vulnerabilities and identification of priority at-risk areas (Chapter 14). Voluntary pressures by themselves are not likely to result in positive outcomes and instead should be coupled with mandatory regulatory pressure to achieve the environmental response desired (Bianco, 2020).

Since AR5, another key development in environmental and social governance has been the establishment of the Task Force on Climate-related Financial Disclosures (TCFD), which aimed to develop guidelines for companies to voluntarily report the financial implications of two broad categories of climate risk: the transition risks of shifting to a lower-carbon economy and the physical risks of climate change itself (TCFD, 2017). As of 2019, ~1,340 companies with a market capitalization of USD12.6 trillion and financial institutions responsible for assets of USD 150 trillion have expressed support for the TCFD (TCFD, 2020). An analysis of reports to the TCFD in 2016 showed that 83% of companies report on physical risks of climate change, and of these 82% reported on strategies to adapt to some of the identified risks (Goldstein et al., 2019). The same analysis also noted that: (i) the total of estimates of assets at risk were two orders of magnitude lower than generally accepted estimates of total financial risk; (ii) a minority of companies consider risks outside of their own operations or in their value chains; (iii) most underestimate or do not estimate the costs of adaptation; and (iv) many assume linear impacts and responses, neglecting the potential for tipping points or acceleration in risk and potentially transformative adaptation requirements. At this stage, TCFD has influenced many companies' thinking and comprehension of physical climate risk, but it appears too early to assess whether this has driven substantive responses to manage these risks.

17.4.3 Enabling Condition 2: Finance

Finance has long been recognised as an important enabling and catalysing factor for adaptation, climate resilient development and climate risk management. In Chapter 17, financing for adaptation and climate risk management is covered in the extended cross chapter box, Financing for Adaptation and Resilience (FAR), below. The Cross-Chapter Box aims to highlight key emerging evidence on financing of adaptation, covering both public and private sources and instruments. Climate finance is also covered in a dedicated chapter in the WGIII Report (WGIII AR6 Chapter 15), and readers should refer to this Chapter for a more comprehensive assessment of this subject from both a mitigation and adaptation perspective.

Cross-Chapter Box FINANCE: Finance for Adaptation and Resilience

Authors: Mark New, Madeleine Rawlins, David Viner, Charlene Watson, Lily Burge, Lionel Mok, Lauren Arendse, Vita Karoblyte, Liane Schalatek and Neha Rai and Baysa Naran, So-Min Cheong, Nicoletta Giulivi.

Introduction

This Cross-Chapter Box reports on: (i) new evidence on the finance needed for adaptation and resilience, and uncertainties in these estimates; (ii) the emerging public and private climate finance architecture; (iii) the status of financing for AR, including sources, total flows, regional and sectoral distributions, (iv) equity considerations; (iv) opportunities and challenges for financing adaptation and resilience during and after the COVID-19 pandemic. This Cross-Chapter Box does not focus on finance for mitigation, which is covered in WGIII Chapter 15, nor the economic damages of climate change or financial aspects of Loss and Damage, which are covered in Cross-Working Group Box ECONOMIC (Chapter 16) and Cross-Chapter Box LOSS (this chapter), respectively.

Successive reports of the IPCC (Vellinga et al., 2001; Mimura et al., 2008; Yohe et al., 2008; Klein et al., 2014) and the AR6 Special Reports have noted the importance of finance as an enabler for adaptation, across both developed and developing nations. While various definitions for climate finance have been suggested, and the UNFCCC has yet to have an agreed definition, the IPCC (see Glossary) defines climate financing as "*the financial resources devoted to addressing climate change by all public and private actors from global to local scales, including international financial flows to developing countries to assist them in addressing climate change. [It] aims to reduce net greenhouse gas emissions and/or to enhance adaptation and increase resilience to the impacts of current and projected climate change. Finance can come from private and public sources, channelled by various intermediaries, and is delivered by a range of instruments, including grants, concessional and non-concessional debt, and internal budget reallocations".* Adaptation and resilience are often used interchangeably in climate finance discussions, although adaptation is a process while resilience (to climate risk) is the ability to progress towards desired outcomes in face of impacts from a changing climate (see Section 1.2.1).

[START BOX CROSS-CHAPTER BOX FINANCE.1 HERE]

Box Cross-Chapter Box FINANCE.1: The 100 Billion Climate Finance Commitment to Developing Countries

At COP16 in Copenhagen in 2009, developed country Parties to the UNFCCC committed to a goal of jointly mobilizing USD 100 billion per year by 2020 to address the climate change needs of developing countries (UNFCCC, 2009). This was in response to a threat by developing countries to walk out of the negotiations, as they perceived developed country support to be lagging and lacking in ambition (Roberts et al., 2021). The commitment was formalized in the Cancun Agreements (Decision 1/CP.16) in 2010 and was reaffirmed as a key element of the Paris Agreement in 2015 (Article 9, paragraph 4). At COP26 in 2021, formal deliberations will begin on a new climate finance goal to be adopted in 2025; the current USD 100 billion target will serve as the annual minimum until 2025 (Chhetri et al., 2020).

The "100 Billion" does not represent the total need to respond to climate change in developing countries, nor the global cost across all countries, as is sometimes interpreted in the literature and media. As shown below in this Cross-Chapter Box, the estimated cost of adaptation for developing countries ranges 15-411 billion USD per year for climate change impacts out to 2030, with the majority of estimates being well above 100 billion.

Proposed sources for the developed country commitment included "*a wide variety of sources, public and private, bilateral and multilateral, including alternative sources of finance"* and several instruments including grants and loans. Nonetheless, there remain differences of opinion on the types of finance that should count towards this goal, with several issues identified (*high confidence)* (Bodnar et al., 2015; Bhattacharya et al., 2020; Roberts et al., 2021), including: (i) counting non-grant finance, such as market and concessional loans (public and private), where developing countries ultimately have to repay the investment; (ii) what is counted as "climate" by different funders, especially when climate is not the prime objective; (iii) the extent to which some funds are "new and additional" rather than a repurposing of development finance.

Progress towards the 100 Billion target has shown an upward trend over the last several years *(high confidence)*, but will fall short in 2020, even when the most generous criteria are included *(high confidence)*. In 2017/18, the most recent year for which data have been comprehensively analysed, estimates using different (but overlapping) data sources and methods were in the range 48-75 billion USD per year, compared to 45-75 in 2015/16 and 41-52 in 2013/14 (Carty et al., 2020; SM17.3; CPI, 2020; OECD, 2020; UNFCCC, 2020). The distribution between adaptation and mitigation has remained strongly weighted towards mitigation, although the proportion allocated to adaptation has increased from 17-25% in 2013/14 to 19-30% in 2017/18 *(high confidence)*. One analysis that excludes debt repayments indicates that the debt-adjusted flows are about half the total flows reported above, of which circa 31-33 % was for adaptation between 2015/16 and 2017/18 (Carty et al., 2020).

[END BOX CROSS-CHAPTER BOX FINANCE.1 HERE]

Adaptation Finance Needs

Estimates of global, regional, or national finance needs for adaptation and resilience vary depending on both analysis approach, the level of climate change, and the geographic and sectoral scope of analysis *(high confidence)* (UNEP, 2016; Chapagain et al., 2020; UNEP, 2020). Recent estimates have adopted one of main approaches: (i) aggregation of individual case studies, along with scaling to generate global or regional costs; (ii) analysis of NDC adaptation cost estimates (Weischer et al., 2016; Hallegatte et al., 2018); (iii) integrated assessment model simulation of impacts and adaptation costs (Markandya and González-Eguino, 2019; Chapagain et al., 2020).

All approaches suffer from limitations that can cause both over and underestimates, including incomplete coverage of sectors and risks, inability to account for autonomous/unreported adaptation; incorrect cost estimations; soft and hard limits to adaptation; balance between adaptation, mitigation, and residual cost; benefits and co-benefits on cost; and learning and innovation as climate change progresses (UNEP, 2020). Global or developing region estimates based on scaling NDC data is particularly uncertain, as most NDCs did not specify how the costs were calculated. Also, scaling from a relatively small set of NDCs with costs to the global scale is not particularly robust, indicating a need for more transparency and better guidance for calculating adaptation costs (Watkiss et al., 2015b; Zhang and Pan, 2016; Hallegatte et al., 2018; AfDB, 2019).

Most estimated of adaptation cost in the literature are for developing countries. Chapagain et al. (2020) assessed various estimates of adaptation for developing countries, under different emissions scenarios for 2030 and 2050. The median estimates (and range) from these studies are 127 (15-411) and 295 (47-1088) billion USD per year for climate change impacts out to 2030 and 2050, respectively (see SM17.3). All but one study report adaptation costs higher than the 70-100 billion estimated in 2010 by the World Bank (World Bank, 2010).

The cost of adaptation for developed countries is rarely reported; most literature either reports a global cost or developing country costs, or costs for a specific country or sector. Baarsch et al. (2015), using an IAM, report adaptation annual costs (2012 prices) in 2030 (and 2050) as 272 (660) billion globally and 205 (521) in developing countries only under the RCP2.6 scenario, indicating that developed country costs are around 25 (21) % of total cost.

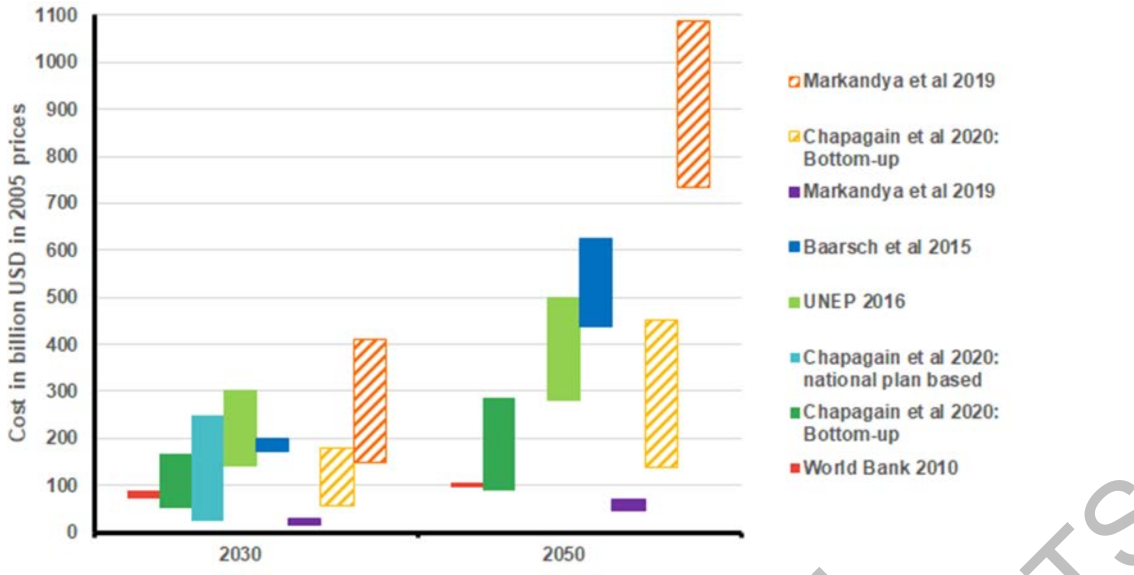

Figure Cross-Chapter Box FINANCE.1: Comparison of recent studies that estimated developing country adaptation costs in billion USD (in 2005 prices) per year, for 2030 and 2050. Figure based on Chapagain et al. (2020). Major studies are World Bank (2010), Chapagain et al. (2020), UNEP (2016), Baarsch et al. (2015) and Markandya and González-Eguino (2019). The solid-coloured bars are based on RCP2.6 and pattern-bars are based on RCP 8.5; the width of the bars indicates the range of estimates (maximum and minimum) produced in each study.

In addition to global estimated adaptation costs, there are many studies that have focused on specific regions, countries, or sectors, such as estimated adaptation cost for coastal environments, water related infrastructure, urban infrastructure, agriculture, energy (UNEP, 2014; Watkiss et al., 2015b; UNEP, 2016). Examples of such estimates are reported in various chapters in this report and summarised in SM17.3.

Estimating the benefit of adaptation, in terms of damage avoided, remains challenging. For example, Ricke et al. (2018) show that the social cost of carbon (monetary damage per tCO_2 emitted) varies by up to two orders of magnitude depending on country, socio-economic scenario, damage function, total GHG forcing, and local climate change. In addition, non-monetary benefits such as cultural identity, sacred places, human health and lives are often ignored (Tschakert et al., 2017; Serdeczny, 2019; see also Cross-Working Group Box ECONOMIC in Chapter 16; Cross-Chapter Box LOSS, this chapter). Recent case studies and global level analyses continue to support the conclusion in IPCC AR5 WGII Chapter 17 (Chambwera et al., 2014) that the benefits of adaptation generally remain larger than the costs *(medium confidence)*, but the cost-benefit ratio varies widely by context and assumptions (OECD, 2015; Global Commission on Adaptation, 2019; WRI, 2019)

The Climate Finance Landscape

The adaptation and resilience finance landscape spans multiple sources, intermediaries, instruments, and recipients, operating across global to sub-national scales (Buchner et al., 2019; Carter, 2020; Watson and Schalatek, 2021). Public finance is provided by national and subnational governments and distributed directly by government or intermediaries such as development finance institutions and climate funds, either nationally or internationally. Private finance comes from five main sources: commercial financial institutions (banks), institutional investors (including asset managers, insurance companies, and pension funds), other private equity (venture capital and infrastructure funds), non-financial corporations such as renewable energy or water companies, individual households and communities. Across these different sources, the main instruments used are grants, concessional debt, market debt, internal budget allocation, including personal savings in households, and insurance. Public and private sources of funding can be blended into a single instrument, for example for insurance where public funds provide capital for both sovereign catastrophe instruments and microinsurance (Jarzabkowski et al., 2019) or for concessional loans. Similarly, public finance is often ultimately be derived from commercial debt instruments such as bonds.

International public climate finance

International public climate finance flows are realised through bilateral and multilateral channels (Watson and Schalatek, 2021) where contributions to these channels are received from Annex II and non-Annex I countries (UNFCCC SCF, 2018; Buchner et al., 2019). Annex II countries contribute as part of their commitments in the Paris Agreement, while non-Annex I countries commit climate finance through these channels on a voluntary basis (Pickering et al., 2015; Roberts and Weikmans, 2017; Egli and Stünzi, 2019). Bilateral intermediaries include development cooperation agencies and national development banks. These institutions often have long standing development-cooperation experience, and offer climate change projects, facilities and financial instruments based on their differing mandates, structures and priorities (Atteridge et al., 2009; Buchner et al., 2019).

Multilateral channels include the UNFCCC financial mechanisms, such as the Green Climate Fund, and the multilateral development banks (MDBs), such as the World Bank. Both pool contributor resources before committing such resources for climate change projects and programmes. Funding through multilateral channels promotes recipient country engagement in the governance and prioritisation of funding decisions, with concurrent processes in the multilaterals often existing to support country ownership of funded climate action (Ciplet et al., 2013; Ha et al., 2016).

There are five multilateral climate change funds of the UNFCCC and Paris Agreement financial mechanisms. There are further multilateral climate change funds that are not governed by the UNFCCC or Paris Agreement, the largest of which is the World Bank governed Climate Investment Funds (Watson and Schalatek, 2021). Some of the major multilateral climate change funds have been established with a specific focus on adaptation, while some bilateral donors have thematic or sectoral priorities. Multilateral climate change funds operate through accredited implementing entities. These have historically been multilateral in nature, such as the development banks, but recent years have seen a rise in the accreditation of national and regional institutions (UNFCCC SCF, 2018). In addition to programming funds from external sources, such as through the multilateral climate change funds, the MDBs also raise and programme their own climate finance (UNFCCC SCF, 2018; MDBs, 2019).

Several major multilateral climate change funds work through grant-only programmes, whereas others include concessional loan, equity and guarantee instruments. The broader suite of instruments used by the MDBs includes grant, investment loan, equity, guarantee, line of credit, policy-based financing and results-based financing (MDBs, 2019).

Public funding of a concessional nature that flows from Annex II to non-Annex I countries supports research and capacity building and can also facilitate private finance flows into climate action, with the intention to avoid creating a high debt burden in developing countries, in response to climate impacts for which they have little historic responsibility (Watson, 2016; Carter, 2020; Schalatek, 2020). Less concessional public finance flows include other official flows that are not developmental in nature and can be trade related, including for example export credits.

Critiques of the public climate finance architecture are aimed at the overlapping mandates of the institutions programming climate finance, particularly the multilateral climate funds, and the challenges in accessing funding (Nakhooda et al., 2014; Amerasinghe et al., 2017; Pickering et al., 2017). However, Pickering et al. (2017) further note that institutional fragmentation of climate finance could result in more flexibility, resilience and innovation. There have also been important governance changes leveraged by some of these funds and instruments, such as integration of gender considerations into projects (Schalatek, 2020).

Private financing of adaptation and resilience

There is an increasing focus on the role of the private sector to support large-scale financing of adaptation and resilience (UNEP, 2016; UNEP, 2018). To date it has been difficult to track adaptation and resilience finance within the private sector (UNEP, 2016)as it is either not disclosed or not easily identifiable, since it is often built into capital and operating expenditure and is not a standalone investment. Several private mechanisms are emerging as important sources of climate finance (Gupta et al., 2014; Eccles and Krzus, 2018; Miller et al., 2019).

Green, social impact and resilience bonds are similar to traditional bonds - fixed-income financial instruments raised on commercial markets by companies, governments or financial institutions - but the proceeds are used to fund activities that have positive environmental, social or climate benefit (Tuhkanen, 2020). Green bonds align to voluntary principles, such as the Green Bond Principles set out by the International Capital Market Association, the Climate Bonds Initiative's Climate Resilience Principles (Sartzetakis, 2020)Given the voluntary nature and lack of standardization of green bond principles, there are concerns around their additionality and there is also a lack of data on how green bonds contribute to a scaling up of green projects (Dupre et al., 2018).

Green bond annual issuance reached 260 billion in 2019 (CBI, 2020) but, as of 2018, only 3-5% (USD 12 billion) of green bond total proceeds can be explicitly traced to climate resilience related efforts (CBI, 2019). Examples of AR focused bonds include those issued by Fiji in 2017, dedicating 91% of spending to adaptation and resilience (Shukla and Peyraud, 2017; Ministry of Economy, 2019), and by the European Bank for Reconstruction and Development's 2019 Climate Resilience Bond for USD 700 million to finance climate resilient infrastructure, commercial operations, agriculture or ecological systems (EBRD, 2019).

Dedicated investment vehicles are equity funds that are created to invest in products and services that enhance resilience and reduce risks. An example is the Climate Resilience and Adaptation Finance and Technology Transfer Facility that is proposed as a USD 500 million private equity fund to invest in companies providing climate resilience solutions for developing countries. Initial funding has been provided by donors (Miller et al., 2019).

Balance sheet finance occurs when an entity directly invests in resilience and adaptation rather than as a separate project. This source of funding may be from exiting reserves, reallocation from other budget lines, or via external commercial finance, but the investment is financed by the firm rather than as a separate project (Gupta et al., 2014; Buchner et al., 2019).

Insurance can play an important role in managing residual climate risks at any given level of adaptation, but insurers can also be important r risk assessment and risk reduction as part of any insurance package (Jarzabkowski et al., 2019; Chapter 11.3.8.3). While traditional indemnity insurance is important for repair and rebuilding of damaged property and infrastructure, parametric insurance has become increasingly popular for supporting rapid post-disaster responses such as drought, hurricane damage and flooding. Examples include sovereign insurance facilities such as African Risk Capacity and the Caribbean Catastrophe Risk Insurance Facility (Broberg, 2019) as well as weather-index insurance targeted at individuals, especially in agriculture (Greatrex et al., 2015; Isakson, 2015; Surminski et al., 2016; Jensen and Barrett, 2017; Fischer, 2019). The role of insurance as a climate risk management option, as well as limitations, is covered in more depth in Section 17.2 and Cross-Chapter Box LOSS (this Chapter).

Mainstreaming physical climate risks and resilience in the private sector

The data on tracked climate finance and green bond issuance for adaptation and resilience both show a substantial gap between the adaptation needs and the finance deployed. Scaling up these instruments is unlikely to close this gap given the challenges with financing adaptation projects, particularly from the private sector. There is therefore a need for more systematic action to manage climate risks and mainstream climate change considerations (Miller et al., 2019).

The financial case for mitigation investment can often be demonstrated through revenues from, for example, the sale of renewable electricity. On contrast, the benefits from investment in adaptation and resilience are typically considered in terms of avoided losses and cost benefit ratios. For example, the Global Commission on Adaptation (2019) estimates that the overall rate of return on investments in improved resilience is very high, with benefit-cost ratios ranging from 2:1 to 10:1, and in some cases even higher.

The private sector is becoming increasingly aware of the need to assess physical climate risks to avoid the long-term risks to assets and enhance climate resilience. The task force on climate-related financial disclosures (TCFD) is likely to create additional pressure from investors for companies to identify, manage and reduce risks from climate change (Eccles and Krzus, 2018; ERM and CBEY, 2018; Tuhkanen, 2020).

A key factor for the impact of the TCFD on mainstreaming of physical climate risks and demonstrating the case for investment in adaptation and resilience will be how investors systematically incorporate physical climate risks, adaptation, and resilience into their investment decisions. The Coalition for Climate Resilient Investment (DFID et al., 2019) was established to look at this from the private sector viewpoint and is working to systematically incorporate resilience into cash flow modelling and asset valuation practices, so that investors may quantify the investment in resilience for an asset and the benefits associated with reduced costs and more reliable revenue streams.

Recent trends in climate finance flows

Considerable progress has been made in tracking climate finance since AR5, but substantial gaps remain, especially regarding domestic public finance and private sector balance sheet investment in adaptation (Section 17.5.1.5; CPI, 2020; Richmond et al., 2020). The best documented information comes from international climate funds, which provide detail at the project level. Most bilateral and multilateral investment institutions report on whether debt, grants and other instruments are for climate projects, but with less detail. Private finance is harder to track, as reporting is voluntary; even for green bonds, where certification identifies the range of sectors a bond aims to cover, reporting of how the bond is spent is infrequent.

The Climate Policy Initiative (CPI) has been tracking climate finance since 2009, allowing for trends to be assessed; however, trends reported are a function of both real changes in finance and changes in methods and information sources (Richmond et al., 2020). Total climate finance tracked by CPI has increased from USD 364 billion per year in 2010/11 to 579 billion in 2017/18 (SM17.3). Tracked finance remained relatively constant from 2010/11 to 2013/14 but has increased steeply in more recent years. The proportion of finance allocated to adaptation has remained small throughout, between 4 and 8% *(high confidence)*; a further 1-2% of global finance has been classified as “multiple-objectives”. The large majority of tracked adaptation finance is from public sources *(high confidence)*, with only 2% coming from private sources in 2017/18 (CPI, 2020). This is at least partly because of the difficulty in demonstrating financial (as opposed to public good and avoided damages) return on investment for adaptation.

The majority of the most recently (2017/18) tracked adaptation and multiple-objective finance was supplied through public donors, largely through grants, concessional and non-concessional instruments (Figure FAR.1). Most finance (44,1%) was spent transregionally (allocated in specific projects to recipients in more than a single region). For regionally specific funding, Sub-Saharan Africa, South Asia, along with the Latin America & Caribbean region, received the largest gross amounts, although Oceania has received the greatest per-capita funding. The largest proportion of AR funding has been allocated to increasing the resilience of infrastructure, energy, and the built environment, followed by agriculture, forestry, and natural management, and then water and wastewater.

Across financial instruments, sub-Saharan Africa received the highest relative proportion through grants (38%), followed by the Latin America & Caribbean region (23%), with other non-OECD regions receiving between 16 and 10% (SM17.3). Concessional debt as a proportion of the regional total varies from 84% in South Asia to as low as 29% in Latin America & Caribbean, which has the highest proportion of non-concessional debt (48%).

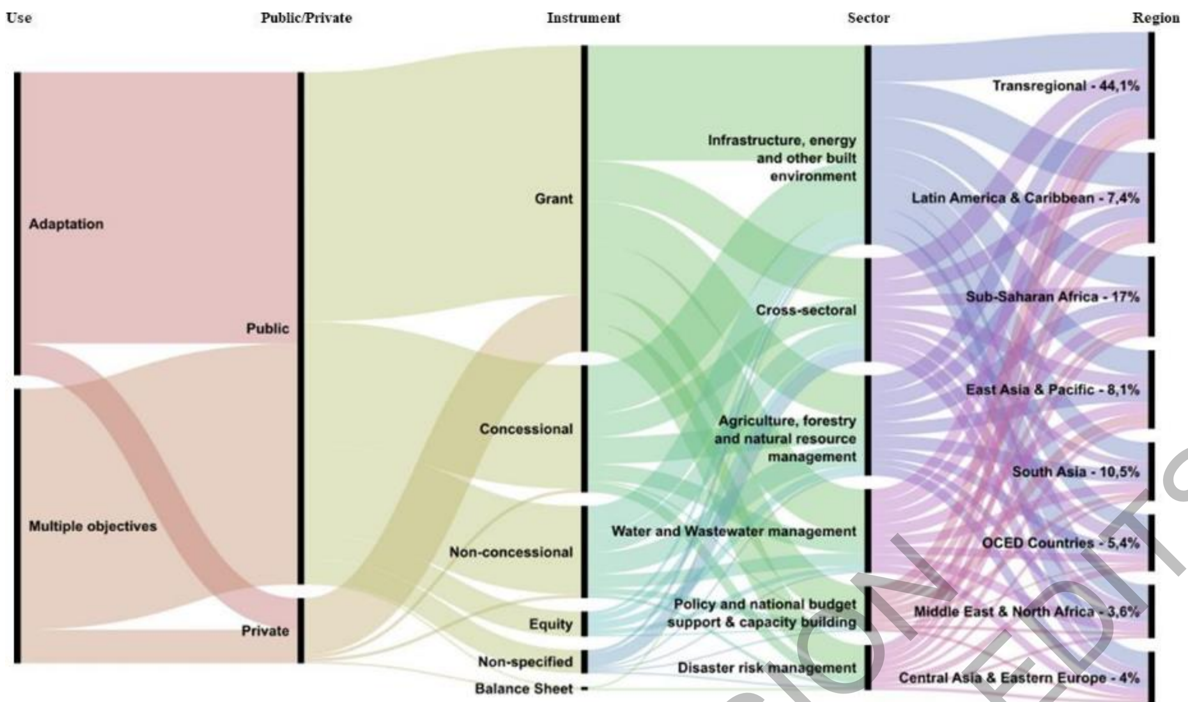

Figure Cross-Chapter Box FINANCE.2: The flow and distribution of globally tracked adaptation and resilience finance in 2018 from different sources, through different instruments into different sectors and regions. Each strand shows the relative proportion of finance flowing from one category to another (for example from private or public sources to different instruments). Categories from left to right are: (a) whether the finance is solely for adaptation or for adaptation and other objectives, including mitigation (multiple objectives); (b) whether the finance comes from public or private sources; (c) the financing instrument; (d) the broad sectoral allocation; (e) the geographical distribution of funding (proportion of total in % and per-capita allocation). Based on data collated by CPI (2020).

The importance of public and private finance for adaptation and resilience

Adaptation finance provided by international public mechanisms remains the core source of tracked flows in support of adaptation and resilience to developing countries (Micale et al., 2018; UNEP, 2018), although these public funds alone are insufficient to meet rapidly growing needs and constitute only a minority share of all public climate finance flows (UNEP, 2016; Global Commission on Adaptation, 2019).

Public mechanisms can play a role in leveraging private sector finance for adaptation by addressing real and perceived regulatory, cost and market barriers through blended finance approaches, public-private partnerships or innovative financial instruments and structuring in support of private sector requirements for risk management and guaranteed investment returns (Pillay et al., 2017; Miller et al., 2019).

There is growing agreement on the sectors (such as infrastructure, agriculture or water management) and approaches (contingency finance or insurance) where private sector adaptation investments alone, or leveraged by public mechanisms, might be best targeted, such as by reducing the risk of providing financial services for adaptation investments to domestic micro-, small-, and medium enterprises or agricultural smallholders, many of them women (Biagini and Miller, 2013; Chambwera et al., 2014; Pauw et al., 2016; Global Commission on Adaptation, 2019; Miller et al., 2019; Resurrección et al., 2019; Richmond et al., 2020). A remaining open question is how to allocate limited public adaptation funds in a way that is equitable, effective and efficient between mobilizing private investments and safeguarding adequate financial support for necessary adaptation efforts, such as the provision of public goods, which the private sector will not invest in (Fankhauser and Burton, 2011; Abadie et al., 2013; Baatz, 2018; Omari-Motsumi et al., 2019).

Many adaptation interventions in the most vulnerable countries, communities and people provide no adequate financial return on investments and can therefore can only be funded with highly concessional public finance. Grant support is most appropriate for measures such as capacity building, planning, public policy and regulatory reforms, disaster risk management and response, community engagement or support for social safety nets, and for addressing social vulnerabilities, including poverty or gender inequality, which constrain adaptation (Grasso, 2010a; Pillay et al., 2017; Agrawal et al., 2019; Buchner et al., 2019). Access to adequate adaptation grant finance is further constrained because several public mechanisms provide grants only for the additional costs of adaptation measures compared to a development baseline in the absence of climate impacts. Calculating the incremental costs of adaptation measures imposes additional time and resource burden on the most vulnerable recipients, who are often faced with data gaps or technical capacity constraints (Chambwera et al., 2014; GCF, 2018; UNEP, 2018; Omari-Motsumi et al., 2019). An exact delineation of respective costs for adaptation and development components is difficult and might be unsuitable as many adaptation measures are intrinsically linked to development. It may also prevent realizing necessary synergies between both (McGray et al., 2007; Smith et al., 2011; Denton et al., 2014; Resch et al., 2017; Micale et al., 2018).

Equality and fairness in climate finance

Climate finance literature recognises that poor and least developed households, communities, and countries are most affected and marginalized by climate change, and least responsible for its causes, but receive relatively little financial support for adaptation (Chapter 15; Chapter 8; Olsson et al., 2014; Rozenberg and Hallegatte, 2015; Hallegatte et al., 2016; Rai and Fisher, 2017; Shakya and Byrnes, 2017).

Several factors affecting fair and just financing in developing countries have been identified in recent literature (Klein et al., 2014; Colenbrander et al., 2018; Mfitumukiza et al., 2019; Khan et al., 2019a; Doshi and Garschagen, 2020). First, financing is skewed in favour of mitigation, and therefore towards fast-growing upper- and middle-income countries offering the biggest gains in emission reductions, especially in Southeast Asia, but also in Sub-Saharan Africa (Rai et al., 2016). Further, as much of current finance uses debt-based instruments, mitigation projects are further preferred as returns are more assured (Lee and Hong, 2018; Carty et al., 2020).

Second, the requirement of many funders for readiness and fiduciary capacity means that LDCs have been less able to access finance, despite many support mechanisms being offered. Additionally, geopolitical preferences of some countries mean that some developing countries are preferred to others for bilateral funding (Doshi and Garschagen, 2020). This is exacerbated for private sector investment, where lower credit ratings make finance more expensive, and increasing understanding of exposure to physical climate risks could lead to ‘capital flight’ from most vulnerable countries (Global Commission on Adaptation, 2019; Miller et al., 2019; Cooper, 2020).

Third, within climate-vulnerable countries, very little is channelled to local communities who need it most; the few analyses available suggest that less than 10% of total climate finance supports decentralized actions (Rai et al., 2016; Soanes et al., 2017). Reasons include: (i) lack of consideration of procedural equity in programme design (Grasso, 2010b; Wang and Gao, 2018; Venn, 2019; Khan et al., 2019a); (ii) finance being managed by multilateral implementers, rather than agencies that are closer to local communities; (iii) the higher transaction costs of decentralized projects in low-income communities reduce their attractiveness to funders as well as the ability of local organisations to meet the fiduciary standards (Fonta et al., 2018; Omari-Motsumi et al., 2019).

It has been proposed that, as middle-income countries can leverage mitigation finance from the private sector, targeting scarce public finance towards LDCs and SIDS may be necessary to ensure sufficient funds reach these countries (Steele, 2015). Matching domestic climate spending with international support is one way to ensure LDCs get the funds they need (Grasso, 2010b; Bird, 2014). Targeting specific marginalized communities and women within countries can also help make climate finance more effective and fairer, such as the Asian Development Bank’s efforts to make lending portfolios more inclusive and pro-poor (ADB, 2018).

Post-COVID recovery packages, debt relief and finance for adaptation and resilience

Recent literature has highlighted the opportunity that COVID recovery packages offer for environmentally sustainable, low carbon and climate resilient economic growth (Forster et al., 2020; Hepburn et al., 2020; Hanna et al., 2021). Assessment of whether this is indeed happening is limited, although the few available studies suggest that that this opportunity is not being realised in many nations (O'Callaghan and Murdock, 2021; VIVID Economics, 2021). One study of the G20 and 10 other nations suggested that stimulus packages would have net negative environmental impact in two thirds of these countries (VIVID Economics, 2021), while another showed that around half of G20 recovery investment targeted at energy has had gone towards fossil fuels, rather than to cleaner energy sources (Dibley et al., 2021).

Concerns have also been raised about the interactions between debt service, COVID economic recession and post COVID recovery in developing countries (Simmons et al., 2021; Volz et al., 2021). Debt service grows as a proportion of national budget during recession, reducing scope for investment in recovery, is a self-reinforcing cycle. It has been suggested that linking debt-relief to Paris-aligned objectives can act as an additional source of climate finance (Fenton et al., 2014). The G20 has begun addressing this debt crisis through its Debt Service Suspension Initiative and the Common Framework for Debt Treatments (IMF, 2020). It has been suggested that these initiatives could be expanded to prioritize climate-focused debt-relief instruments and to include more countries (Steele and Patel, 2020; Volz et al., 2021). If debt-relief is used to invest in national instrument for green and inclusive recovery, national ownership of the use of the finance can occur, avoiding some of the negative connotations of historical debt restructuring (Volz et al., 2021).

17.4.4 Enabling Condition 3: Knowledge and Capacity

17.4.4.1 Overview of Knowledge Systems

AR5 emphasized the importance of knowledge systems as an enabling condition for decision making, as did earlier ARs, all of which include a focus on the policy-relevance of knowledge (Section 1.1.4) First introduced in IPCC reports in AR4, the term "knowledge system" is used extensively in AR5 and the SRs. The discussion below follows a widely-cited definition of knowledge systems as sets of interacting "agents, practices and institutions that organize the production, transfer and use of knowledge" (Cornell et al., 2013: 61). This definition emphasizes the social nature of knowledge and the importance of the link between knowledge and action, rather than presenting knowledge simply as information about past, present and future states of the world which can be of use to decision-makers.

This definition of knowledge systems indicates the importance of capacity--the ability and the motivation to use knowledge for action--since capacity is an important feature which allows knowledge systems to function. Capacity is a necessary enabling condition for knowledge to be put to use in adaptation activities (*high confidence*), as shown across sectors such as water (Section 4.5.2), food security (Sections 5.12.3, 5.14.3), cities and settlements (Sections 6.4.2, 6.4.4) and health and well-being (Sections 7.1.3, 7.2.6), and across regions, including Africa (Sections 9.13.1, 9.14.5), Asia (Sections 10.3.6, 10.4.4) and North America (Section 14.4.5).

Some research on knowledge systems retains the earlier attention to information as a resource for decision-makers. A major focus, discussed elsewhere in this chapter, has been increasing the precision about the certainty, likelihood, and the confidence with which certain statements are made in relation to underlying evidence (See Cross-Chapter Box DEEP in this Chapter). This topic, which was first introduced in AR4, advanced significantly in AR5 (Mach et al., 2017).

In addition to these characteristics of information, the social and organizational aspects of knowledge systems have also been the subject of recent research. One strand of this discussion emphasizes the distinctiveness of different knowledge systems, often focusing on three types of knowledge: scientific, Indigenous, and local, and the latter two sometimes grouped as "traditional" knowledge (See Cross-Chapter Box INDIG in Chapter 18). This strand emphasizes the specific forms of knowledge production and circulation in each type. Another strand of discussion emphasizes the networks of interactions between different groups. This strand follows the influential "Knowledge systems for sustainable development" (Cash et al., 2003), which was cited in Chapter 2, 7 and 8 in WGII AR5; Cash et al. (2003) emphasizes the usability and acceptability of scientific knowledge, and underscores the relations between knowledge producers and users. The discussion in 17.4.4 on knowledge as an enabling factor integrates these two strands of discussion of knowledge systems.

It was well established in AR5 and SRs that a component of knowledge systems for good climate decision-making is the production of "information on climate, its impacts, potential risks, and vulnerability" which can "be integrated into an existing or proposed decision-making context" (Jones et al., 2014: 200). Also important are two other components of knowledge: of response options and knowledge of other enabling conditions, particularly governance and finance, which were mentioned less frequently and more indirectly in AR5 and SR1.5, SROCC and SRLAND. Decision-makers assess the feasibility of different alternatives (see Cross-Chapter Box FEASIB) and develop strategies for the implementation and modification of the alternative, requiring a level of knowledge of the governance, policy and finance landscapes at national (Tanner et al., 2019; Lopes et al., 2020; Roberts et al., 2020) and international scales (Woodruff, 2018).

Examples of the importance of these other two components--knowledge of response options and knowledge of enabling conditions--are provided by networks of cities, including internal institutional networks (Aylett, 2015), intermunicipal networks (e.g., those supported by ICLEI- Local Governments for Sustainability and the international United Cities and Local Governments (UCLG) network), transnational municipal networks (e.g. 100 Resilient Cities, Asian Cities Climate Change Resilience Network (ACCCRN), and city to city regional transdisciplinary learning networks (Ndebele-Murisa et al., 2020). These networks generate and exchange knowledge which can be critical to decision-makers for understanding and evaluating the feasibility of different response options, identifying synergies across sectors, and mainstreaming adaptation to climate change (Haupt et al., 2020). However, the question of how to finance such network activities remains under-studied (Bracking, 2021; See Box 17.3).

In addition to these general considerations of knowledge systems, research since AR5 has contributed to the understanding of specific types of knowledge. Scientific knowledge is thoroughly discussed in Chapter 1, especially in Section 1.3 Understanding and Evaluating Climate Risk, which shows recent advances in the well-established IPCC categories of observation of past conditions and model-based projections of future conditions. We add here a consideration of a new area within scientific knowledge, artificial intelligence, which offers new methods for producing information that can be incorporated into knowledge systems.

Applying Artificial Intelligence (AI) to climate change is predominantly in the area of climate modelling and forecasting, inclusive of weather extremes (Monteleoni et al., 2013; Jones, 2017; Huntingford et al., 2019). Recent efforts conceptualize the potential uses of AI for mitigation and adaptation (Rolnick et al., 2019; Cheong et al., 2020b) in addition to forecasting (Rolnick et al., 2019; Chattopadhyay et al., 2020; Cheong et al., 2020b; Prabhat et al., 2021). There are very few cases to assess AI applications in these domains given that AI is a new field for climate change impact and adaptation. To this date, sectoral applications of AI relevant to climate change adaptation and risk reduction mainly have advanced in the areas of crop yields, early warning system, and water management.

These sectoral advances using AI employ various learning techniques inclusive of supervised and unsupervised learning, multimodal learning and transfer learning techniques to generate more accurate predictions than afforded by traditional climate projection methods (Cheong et al., 2020b; Camps-Valls et al., 2021). AI applications use finer resolution data such as sub-daily weather-related data, remote and wearable sensor data, text data, and real-time survey data. They are fed into neural networks and semi/unsupervised learning to configure detailed and more precise predictions of climate change impact on crop yields (Crane-Droesch, 2018), early warning (Moon et al., 2019), impact of extreme heat on older adults (Cheong et al., 2020a), poverty in Africa (Oshri et al., 2018), and multi-scale water management combining blockchain technology with remote water sensors (Lin et al., 2018).

Indigenous knowledge and local knowledge are thoroughly covered in SROCC (Abram et al., 2019; IPCC, 2019c; IPCC, 2019e-b) and in Section 1.3.3. We here add relevant points to decision making, and an additional form of knowledge, practitioner knowledge.

Indigenous knowledge and local knowledge are gaining recognition at multiple scales (Kleiche-Dray and Waast, 2016; David-Chavez and Gavin, 2018; Nakashima et al., 2018). Of note is their association with ecosystem-based adaptations, showcasing the long-term place-based knowledge of Indigenous peoples

(Johnson et al., 2015; Walshe and Argumedo, 2016; Carter, 2019; Mazzocchi, 2020). These knowledges and practices can be an important enabling condition in decision making processes, complementing scientific information by identifying impacts (Fernández-Llamazares et al., 2017; Katz et al., 2020), emphasizing values to consider (Huambachano, 2018), offering solutions (Chanza and de Wit, 2016; Cuaton and Su, 2020; Orlove et al., 2020), guiding land use and resource management (Brondízio et al., 2021) and filling gaps in scientific knowledge (Hiwasaki et al., 2014; Audefroy and Sánchez, 2017; Makondo and Thomas, 2018; Son et al., 2019; Latulippe and Klenk, 2020; Wheeler et al., 2020a).

Practitioner knowledge—the pragmatic, practice-based knowledge that comes from the regular exercise of craft or professional work—was also acknowledged briefly in AR5 (Jones et al., 2014) and treated significantly in SROCC (Abram et al., 2019). Practitioner knowledge resembles local knowledge in that it is acquired through participation in activities, and yet it differs from local knowledge, which is often place-based and tied directly to specific landscapes and communities. Local knowledge typically covers a variety of environmental domains. Practitioner knowledge may be shared with people in different locations and is often more focused on a narrower set of work activities. Recent calls have recommended bringing practitioners more fully into the IPCC assessment process, to promote more effective decision-making (Howarth et al., 2018).

Practitioner knowledge makes significant contributions to decision-making by broadening the range of alternatives which are considered and by bringing in understandings of systems to the selection and implementation of alternatives. Such knowledge is applicable to a large number domains, including biodiversity management (Tengö et al., 2014; Rathwell et al., 2015), and natural hazard risk management in urban settings, as reported in Denmark (Madsen et al., 2019), the US (Matsler, 2019), Canada (Yumagulova and Vertinsky, 2019), Mexico (Aguilar-Barajas et al., 2019), and the Caribbean (Ramsey et al., 2019). Other contexts, all at regional scales, include watershed management in Peru (Ostovar, 2019), livestock management in Finland (Rasmus et al., 2020), agricultural adaptation in a context of water scarcity in Iran (Zarei et al., 2020), and the water-energy nexus in the US (Gim et al., 2019).

Literature indicates the importance of effective governance for promoting integration of local and practitioner knowledge with scientific knowledge (*high confidence*). This integration is most extensive, and promotes a wider consideration of alternatives, where governance arrangements promote ongoing exchanges of information and discussion of solutions, whether through formal mechanisms such as regional committees (Gim et al., 2019; Ostovar, 2019; Rasmus et al., 2020; Zarei et al., 2020) or informal mechanisms such as personal networks and local discussion groups (Madsen et al., 2019; Yumagulova and Vertinsky, 2019). Where such arrangements are absent, practitioner knowledge is side-lined from the formulation and implementation of decisions (Aguilar-Barajas et al., 2019; Matsler, 2019; Ramsey et al., 2019).

17.4.4.2 Co-production and Other Composite Knowledge Systems

There is strong evidence that composite knowledge systems – characterized by interactions between the producers and potential users of climate change information -- can help facilitate climate-related decision making (Prokopy and Power, 2015; Richards, 2018; Ramsey et al., 2019). Several institutional forms and structures have been created to link scientific knowledge, Indigenous knowledge, and local and practitioner knowledge, to climate change decision making.

17.4.4.2.1 Co-production

The co-production of knowledge by different actors provides important avenues for exchanging and integrating climate-related knowledge in decisions made across society (*high confidence*). Though many definitions of co-production have been offered in recent years (Bremer and Meisch, 2017; Vincent et al., 2018; Bremer et al., 2019; Harvey et al., 2019a), most describe a set of individuals or organizations who work together to generate a set of products that entail new knowledge products and that guide action (Miller and Wyborn, 2020). Some major forms of co-production include action research (Baztan et al., 2017; Laursen et al., 2018; Zanocco et al., 2018a), trans-disciplinarity (Howarth and Monasterolo, 2016; Wamsler, 2017; Lanier et al., 2018; Scott et al., 2018; Knapp et al., 2019; Young et al., 2019a); rapid assessment processes (Atkinson et al., 2018b); and participatory integrated assessments (Howarth et al., 2018; Krkoška Lorencová et al., 2018; Bitsura-Meszaros et al., 2019; Carter et al., 2019a; Cremades et al., 2019; Leitch et al., 2019; Martínez-Tagüeña et al., 2020; Section 17.3.1.3.1).

Co-production promotes iterative dialogue, experimentation, the tailoring of knowledge to context, needs and priorities, and learning, often promoting integration of Indigenous knowledge, local knowledge and practitioner knowledge with scientific knowledge (*high confidence*). It generally entails long-lasting ties and fully inclusive partnerships between different parties (Kench et al., 2018). Governance measures and adequate financing can act as enablers of such co-production. This integration is most extensive, and promotes a wider consideration of alternatives where governance arrangements promote ongoing exchanges of information and discussion of solutions, whether through formal mechanisms such as regional committees (Gim et al., 2019; Ostovar, 2019; Rasmus et al., 2020; Zarei et al., 2020) or informal mechanisms such as personal networks and local discussion groups (Madsen et al., 2019; Yumagulova and Vertinsky, 2019). Where such arrangements are absent, practitioner knowledge is side-lined from the formulation and implementation of decisions (Orleans Reed et al., 2013; Aguilar-Barajas et al., 2019; Matsler, 2019; Ramsey et al., 2019).

An important mechanism of co-production is the boundary organization, a knowledge-producing organization comprised of individuals who reflect different disciplines or knowledge systems and who represent different activities, sectors or forms of governance (Blades et al., 2016; Graham and Mitchell, 2016; Guido et al., 2016; Jeuring et al., 2019; Serrao-Neumann et al., 2020; Zarei et al., 2020). Boundary organizations themselves can be linked into boundary chains (Lemos et al., 2014; Meyer et al., 2015; Kirchhoff et al., 2015a; Pretorius et al., 2019; Daniels et al., 2020). When individuals and organizations from different disciplinary backgrounds and missions coordinate their activities informally, the resulting ties have been termed ‘knowledge networks’ (Ziaja and Fullerton, 2015; Brugger et al., 2016; Guido et al., 2016; Davies et al., 2018; Klenk, 2018; Muccione et al., 2019; Ziaja, 2019). When such networks interact with each other, the resulting associations have been called “communities of practice,” which can work to collectively shape information to shared contextual circumstances (Orsato et al., 2018; Wang et al., 2019b).

There is extensive evidence that co-production can generate useful climate knowledge (Djenontin and Meadow, 2018; Bisbal, 2019; Ryan and Bustos, 2019; Hewitt et al., 2020; Jack et al., 2020; Lavorel et al., 2020; Ruiz-Mallén, 2020) and that it can increase the likelihood that knowledge will be used in decision-making (Vogel et al., 2016; Prokopy et al., 2017; Skelton et al., 2017; Sylvester and Brooks, 2020). Co-production is not without its costs, since it requires more time, money, facilitation expertise and personal commitment from participants than more conventional modes of knowledge production (Lemos et al., 2018; Sletto et al., 2019; Wamsler et al., 2019; Blair et al., 2020). Some research has shown ways to decrease the costs of co-production for participants, such as funding and time to enable and sustain interactions and to build trust and legitimacy, or to create boundary organizations (Young et al., 2016; Klenk et al., 2017).

Co-production is supported by project cycles that provide for the involvement of stakeholders from the outset (Daly and Dilling, 2019; Brady and Leichenko, 2020); flexible research agendas that do not assume a climate related question (Daniels et al., 2020); support for interactivity and reflexivity (Araujo et al., 2020), and, institutionalizing incentives which address the different values, norms, perceptions and work patterns of scientists, policy-makers and civil society representatives (Cvitanovic et al., 2015; Vincent et al., 2015; Bruno Soares and Dessai, 2016; Singh et al., 2017; Djenontin and Meadow, 2018; Norström et al., 2020; Turnhout et al., 2020). Certain roles, such as policy entrepreneurs (Tanner et al., 2019), embedded researchers (Pretorius et al., 2019) and knowledge brokers (Cvitanovic et al., 2015), can facilitate co-production.

17.4.4.2.2 Climate services

Climate services (refer to CWG Box on Climate Services) can be important enablers of climate risk management, provided they are credible, relevant and usable (*high confidence*), and will become increasingly important as human influence on weather and climate extremes grows across all regions (Chapter 11; Fischer et al., 2021; IPCC, 2021). Climate services are more effective and more widely used when they are tailored to specific decisions and decision-makers (*high confidence*). Sustained iterative engagement between climate information users, producers and translators can improve the quality of the information and the decision-making and avoid maladaptation (*medium confidence*).

Historically, climate services have been organized by climate information providers, based in meteorological, hydrological, and agricultural faculties and services, serving to improve through climate risk management, including the use of historical information, monitoring, seasonal forecasts, and long-term climate projections (Hewitt et al., 2012; Blome, 2017; Bessembinder et al., 2019; Vaughan et al., 2019b).

Recent research on climate services shows that transdisciplinary knowledge co-production is a key enabler, starting to shift emphasis from the creation of climate services *products* to climate services *processes* (Vincent et al., 2018; Carter et al., 2019b; Daniels et al., 2020), potentially increasing uptake and sustainability (Norström et al., 2020). This shift is a result of the recognition of benefits which a co-production approach can offer, in addition to the provision of information; information; these additional benefits include building confidence, capacities, learning, knowledge, social capital, institutional capacity, stakeholder relationships, social networks, beneficial management practices, and strengthened institutions (Bruno Soares and Dessai, 2016; Djenontin and Meadow, 2018; Bremer et al., 2019).

Cross-Chapter Box 12.2 in WGI AR6, Climate information for climate services, shows that users are widely distributed across civil society. Relevant users of climate services include humanitarian organizations (Coughlan de Perez and Mason, 2014; Harvey et al., 2019b), government offices (Mahon et al., 2019), international agencies (Perkins and Nachmany, 2019), and the private sector (Beckett, 2016; Hudson et al., 2019). Climate services currently exist at local, national, regional, and international scales, at time scales which range from sub-seasonal to decadal and longer (White et al., 2017; Hewitt et al., 2020) and in a range of different sectors (Bruno Soares and Buontempo, 2019). Agriculture is the sector with the largest number of examples (Zebiak et al., 2015; Burke and Emerick, 2016; Cliffe et al., 2016; Haigh et al., 2018; Buontempo et al., 2020); others include health (Ghebreyesus et al., 2010; Ballester et al., 2016), forestry (Caurla and Lobianco, 2020), fisheries (Busch et al., 2016), disaster risk reduction (Street et al., 2019), and water resources management (van Vliet et al., 2015; Golding et al., 2019). Evaluations of the extent to which climate services are accessed, used, and deliver benefits to decision makers remain in an initial stage (Perrels, 2020), though studies suggest that these contributions vary widely depending on context. A review of evaluation of weather and climate agricultural services in Africa, for instance, found that most farmers use climate services when they are available , but that on-farm outcomes varied, with some farmers experiencing yield losses and others gains upward of 60% (Vaughan et al., 2019a). Other studies express concern that large climate service projects have run for decades at significant expense, without adequate evaluation at all (Gerlak et al., 2020).

Recent reviews (Carr and Onzere, 2018; Hewitt et al., 2020) provide evidence that the use of climate services is affected by (a) the quality, reliability and skill of the climate information (Zebiak, 2019); (b) the fit, tailoring and contextualization of that information with respect to the specific decision-making needs of particular users (Clarkson et al., 2019); (c) the mode and method by which the service is communicated (Golding et al., 2017); and (d) the characteristics of the users themselves – including the users' access to resources that would allow them to alter their decisions based on the information provided (Clarkson et al., 2019).

A related literature characterizes the extent to which the development, reach and effectiveness of climate services is affected by factors that can be termed 'climate service governance' (Stegmaier et al., 2020). Elements of this governance include the arrangements by which those parties engage with each other (Vaughan et al., 2016; Daniels et al., 2020) and the financial arrangements, and associated responsibilities, which support the service (Lourenço et al., 2015; Bruno Soares and Buontempo, 2019). Though governance varies by context, evidence suggests that engaging a range of experts and potential users in the co-design and co-production of climate services increases the use and utility of services (Lemos et al., 2014; Pope et al., 2017; Masuda et al., 2018; Harvey et al., 2019b). However, some studies warn that even with broad and inclusive participation, power differentials can create barriers to co-production reducing the usefulness information products (Alexander et al., 2020) and the neglect of non-meteorological sources of information which may also possess useful predictive power (Coughlan de Perez et al., 2019).

A small but growing number of papers consider the business models that support climate services, including, for instance, the role of open data (Iturbide et al., 2019; Chimani et al., 2020), the standards or institutional mandates by which users come to understand the credibility and legitimacy of certain services (Bruno Soares and Buontempo, 2019), and the role of public-private partnerships (Cortekar et al., 2020). While the commercialization of climate services holds significant promise that more and more specifically targeted services will be provided, there is not yet agreement on which business models best support this in different contexts. There is also concern that commercialization of climate services may disadvantage under-resourced actors at the expense of wealthier or more powerful ones (Webber, 2017; Webber and Donner, 2017; Cortekar et al., 2020). It has been noted that some climate services, such as weather forecasts and early warnings, are an example of a public good, best provided by public agencies (*high confidence*) (Sutter, 2013; Kitchell, 2016; Hansen et al., 2018).

17.4.4.2.3 Capacity and motivation within knowledge systems

Knowledge of climate change influences decision-making not only by providing information but also by increasing the motivation to act and by promoting behaviour change. Evidence from many sectors (including water (4.5.2), ocean and coastal ecosystems (3.6.2), and agriculture (5.4.2) and regions (including Africa (9.8.4), Asia (10.4.6), and North America (10.4.5) show that building capacity (e.g. adaptive capacity, institutional capacity, education/training in human capacity) can support adaptation and limited governance capacity can constrain it (*high confidence*). An emerging area of research examines the contribution of building capacity within public and technical organizations and agencies to draw on Indigenous knowledge and local knowledge (Adger et al., 2017; Hochman et al., 2017; Bacud, 2018). A number of factors influence the effect of knowledge on motivation and behaviour change, including values and education.

Decision-makers who shape options for managing climate risk can evaluate stakeholders' capacities and motivations to participate in the implementation process of these options. Stakeholder engagement in climate change risk management supports successful adaptation (Gray et al., 2014; Elsawah et al., 2015; Siders, 2017; Giordano et al., 2020). Research in psychology and related fields shows that the cognitive mechanisms by which individuals and organizations process climate information influence this capacity, motivation and engagement (Grothmann and Patt, 2005; Grothmann et al., 2013; Masud et al., 2016; Nelson et al., 2016; Takahashi et al., 2016; Hügel and Davies, 2020; Grothmann and Michel, 2021).

The perception of climate change as a major threat that requires action has increased since AR5, reflecting both the growth of information about climate change and the processing of that information (Lee et al., 2015; Fagan and Huang, 2019). Global social movements play an important role in raising public awareness of climate urgency (Thackeray et al., 2020). Climate change concern plays an important role in decision-making outcomes which entail public participation (Lammel, 2015; Chiang, 2018; van Valkengoed and Steg, 2019; Arıkan and Günay, 2020). Nonetheless, public risk perception varies sharply on spatial and temporal scales, reflecting environmental changes, social influences (Kousser and Tranter, 2018; Rousseau and Deschacht, 2020), economic capacities (Arıkan and Günay, 2020) and culture (Noll et al., 2020), as well as individual characteristics (van Valkengoed and Steg, 2019). The importance of values and norms is demonstrated by recent research which highlights how intrinsic motivation (altruistic, self-transcendental and ecocentric values) (Corner et al., 2014; Braito et al., 2017; Xiang et al., 2019; Bouman et al., 2020) and extrinsic social motivation (e.g., economic gains and social desirability) (van Valkengoed and Steg, 2019) can drive action.

Recent research shows the importance of education as a predictor of risk perception, motivation and action. Education level is the strongest predictor of public awareness of climate change risk in a study across 119 countries of public awareness of climate change risk (Lee, 2015), though this relationship varies in different nations, and is influenced by mediating variables (Muttarak and Chankrajang, 2015; Blennow et al., 2016) (Ballew et al., 2020). Knowledge and awareness of climate change are correlated with the motivation to undertake action on climate change (Hornsey and Fielding, 2017). The integration of climate science in educational curricula has been shown to be effective (Hess and Maki, 2019; Molthan-Hill et al., 2019), including approaches such as integration of the complex system approach (Jacobson et al., 2017), experiential climate change education (Siegner, 2018), including climate games (O'Garra et al., 2021; Pfirman et al., 2021), massive open online courses , and informal science learning centres (Geiger et al., 2017).

Attention to behavioural change of individuals has grown since AR5, including cases which address both adaptation and mitigation (e.g. dietary changes, modification of buildings, transport alternatives) (Azadi et al., 2019; Fischer, 2019; Willett et al., 2019; Sharifi, 2020; Sharifi, 2021). The interventions to promote behavioural change can be bottom-up, initiated by individuals, communities, non-governmental organizations or the private sector, or top-down, coming from governments at various levels (Robertson and Barling, 2015; Stern et al., 2016). They are supported by a number of mechanisms, including education, information strategies, and campaigns, financial incentives, regulatory processes and legislation (Rosenow et al., 2017; Creutzig et al., 2018; Carlsson et al., 2019). These behavioural changes contribute significantly to effective risk management.

17.4.5 Enabling Condition 4: Catalysing Conditions

A clear difference between enabling conditions and catalysing conditions is emerging in the climate mitigation literature (Hermwille et al., 2019; Michaelowa et al., 2021), with some examples in the adaptation literature as well (Madsen et al., 2019; Booysen et al., 2019a; Bolorinos et al., 2020). Though enabling conditions are necessary preconditions that allow response options to be formulated and implemented, their presence alone does not guarantee that these response options will occur in a timely fashion or at a scale commensurate with the risk, or even that they will occur at all. Catalysing conditions address this deficit in advancing action. They serve to overcome the inertia that often operates as a barrier to action and motivate individuals and organizations to initiate or accelerate action. Different forms of catalyzing conditions, described below, lead individuals and organizations to weigh more seriously the costs of delaying action or keeping action at low levels. Catalysing conditions focus the attention of individuals and organizations on particular risks, leading actors to augment their decision-making processes and to allocate financial and social resources to respond to those risks. This attention and deliberation can lead to more frequent and potentially substantial adaptations, whether through more extensive action on existing forms of adaptation or through the adoption of entirely new adaptations (Bolorinos et al., 2020).

The first two catalysing conditions described below address the costs of delaying action. Urgency increases the awareness of individuals and organizations of such costs, while windows of opportunity, including extreme events, are time-bound periods during which certain actions are possible, but after which they are more difficult or impossible. The other two conditions stimulate new forms or levels of action by promoting or directing step changes from one policy or management regime to another (Solecki et al., 2017). Litigation over adaptation issues, for example, can open new lines of action or close off old ones, while catalysing agents advance action through a variety of means (e.g., communicating the urgency of climate action, revising agendas for action, expanding coalitions which undertake action). As detailed below, these four catalysing conditions can operate together as well as separately to promote more prompt and extensive adaptations.

17.4.5.1 Urgency

Urgency can catalyse action for individuals and organizations. A moderate level of urgency serves as an important driver of climate action, but both high and low levels of urgency impede response (*high confidence*). Wilson and Orlove (2021) review five experimental and twenty observational papers that examine the relationship between urgency and levels of response in climate decision-making, across a range of settings: from individuals and households, to communities, managed ecosystems, sub-national regions and international river basin. Urgency in the papers is defined primarily through objective and subjective time pressure, including the recognition of the costs of delaying action and the importance of using windows of opportunity during which new forms and higher levels of response are possible. All the experimental papers and all but three of the observational papers provide support for an inverted U-shaped relationship between urgency and response intensity (including motivation and action), with higher levels of response at intermediate levels of urgency and lower levels of response at low or high levels of urgency (Figure 17.8). The general shape of this relationship also is supported for other decision domains by a well-established line of research within psychology (Heitz, 2014; Zakay, 2014; Prem et al., 2017).

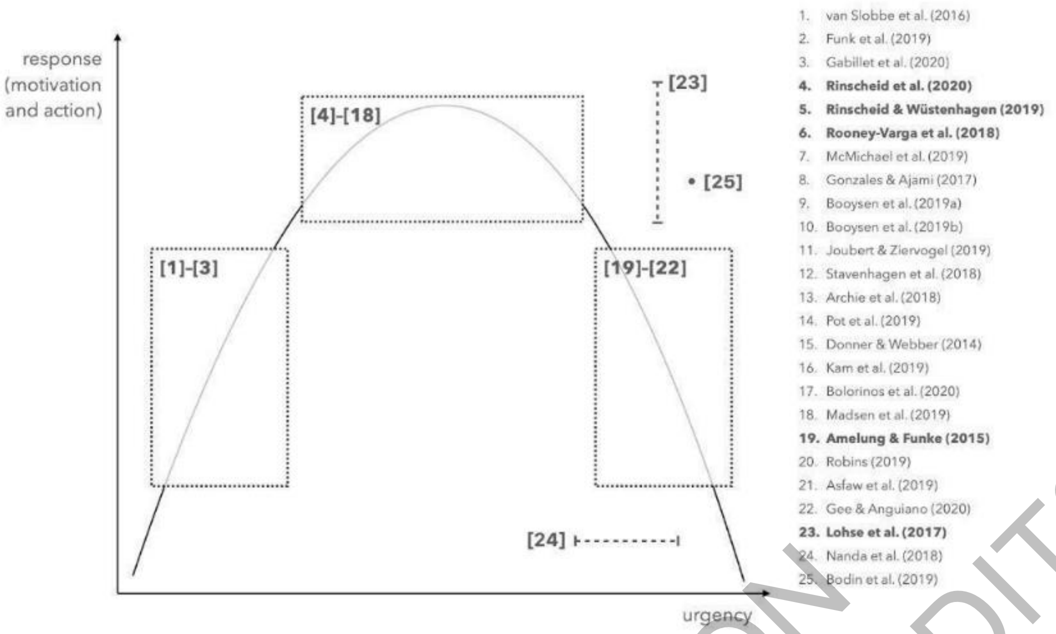

Figure 17.8: A moderate level of urgency serves as an important driver of climate action, but both high and low levels of urgency impede response [derived from Wilson and Orlove (2021)].

The synthesis of the studies on urgency offers two central lessons for policy makers, community groups, and others involved in addressing climate change. First, that greater levels of response to climate change-induced challenges can be motivated by communication strategies that move decision makers from low to moderate levels of urgency (*high confidence*). In the case of drought, a number of studies show that urgent messages promote water conservation, especially when these messages are repeated, perceived as trustworthy, and linked to concrete suggestions for action (Gonzales and Ajami, 2017; Joubert and Ziervogel, 2019; Kam et al., 2019; Booysen et al., 2019a; Booysen et al., 2019b; Bolorinos et al., 2020). These effects are also demonstrated in experimental studies of adaptation planning in contexts including European flood preparations (Madsen et al., 2019; Pot et al., 2019), and Pacific Island coastal planning (Donner and Webber, 2014).

Second, very high levels of urgency are a barrier to effective action (*medium confidence*), because last-minute actions to reduce risk during crises can create haste and panic, often leading to insufficient deliberation. In these cases, decision-makers fail to consider a full range of alternative actions, make rash choices and poorly mobilize available resources (Asfaw et al., 2019; Robins, 2019; Gee, 2020). Given that climate decision makers in many regions and sectors are experiencing greater pressure to act; this finding suggests the existence of windows for planning and action during which climate risks have led to moderate levels of urgency, but before these risks have resulted in urgency exceeding some upper threshold (see 17.4.5.2).

In addition, these studies point to potential weaknesses as well as strengths in strategic communication to modulate urgency. Such messages may instead lead to lower levels of response if they induce very high levels of urgency (Asfaw et al., 2019), though this effect may be somewhat mitigated by messages that simultaneously increase recipients' sense of self-efficacy or they are experienced in the specific risk domain discussed in the messages (Bodin et al., 2019). Future research on the relationships between urgency and effective risk management could help refine the measurement of urgency, how the relationship varies in different contexts, the role of different forms of messaging about urgency and action (Fesenfeld and Rinscheid, 2021), as well as the effects of urgency on decision-making by high-level decision-makers within polities and by climate social movements.

17.4.5.2 Windows of Opportunity

Windows of opportunity are time-bounded periods during which conditions are present for advancing and often accelerating climate adaptation strategies. They can act as significant catalysing conditions for climate action and are connected to a range of possible outcomes from small incremental shifts to larger scale more profound transformation adaptations (Novalia and Malekpour, 2020).

Windows can open because of extreme weather events (Birkmann and Fernando, 2008), political shifts, such as new institutions, new laws and regulations, and presence of a new policy entrepreneur or new policies (Haasnoot et al., 2013; Bell and Morrison, 2015), relevant and achievable policy goals, and emergence of new knowledge (Abunnasr et al., 2013), and close after the initial causes recede and become less efficacious. They also serve as focusing events whereby a coalition of groups address specific policy questions or response options (Rudel, 2019). Recognizing that windows of opportunity often catalyze action does not mean that action outside such windows is insignificant or impossible.

Extreme events such as disasters often act as proximate drivers of windows of opportunity (Birkmann and Fernando, 2008; McSweeney and Coomes, 2011). Climate disasters in a specific location become significant windows for new debate, policymaking and financing (McSweeney and Coomes, 2011). Extreme events also can facilitate change at locations distant from the most impacted site when remote actors gain perspective on their own risks (Friedman et al., 2019; Solecki et al., 2019). Factors that facilitate extreme events driving proactive as opposed to reactive responses include access to relevant risk and vulnerability data, pre-existing experience with similar events, and appropriate governance (Brown et al., 2017a). Page and Dilling (2020) find that worldview or ideology plays a central role in sense-making and in shaping what organizational decision-makers 'see' in terms of acceptable actions in response to an extreme event.

Significant variation is present across the mix and intensity of conditions that promotes action through a window of opportunity. Capacity to respond to is a function of the presence of enabling conditions as well as tools and methods to aid decision-making (Shi et al., 2015). Political activism provides windows of opportunity for climate adaptation (Lauer and Eguavoen, 2016; see also 17.4.5.3.1).

Sudden shifts in institutions and legal framework can also catalyse climate action. For example, the year 2015 included a series of international frameworks such as the Sendai Framework for Disaster Risk Reduction 2015-2030 (van Niekerk et al., 2020; Hofmann, 2021), the 2030 Agenda for Sustainable Development, which established the Sustainable Development Goals (Sanchez Rodriguez et al., 2018), and the Paris Climate Agreement, which dramatically enhanced the promotion and implementation of altered the conditions under which climate adaptation occurred.

17.4.5.3 Climate Litigation on Adaptation

Litigation for loss and damage from climate change was first noted as a potential motivator for emissions reduction in AR4 and AR5 noted that litigation was pending but not tested and that while legal systems were beginning to define the boundaries of responsibility for climate change, it was 'unclear liability exists'. The SR1.5 (IPCC, 2018a) reported, with high confidence, that litigation risks of government and business had increased and the SRCCL (IPCC, 2019b) noted that recent developments in climate attribution improve the ability to detect human influence on climate and broaden liability.

Since AR5 there has been growing recognition of the potential of litigation for failure to take measures to adapt to climate change to drive climate risk management (Banda and Fulton, 2017; Peel et al., 2017; Bouwer, 2018). Litigation cases on adaptation and loss and damage comprise about one third of those covered in the literature (Setzer and Vanhala, 2019a). Reasons for this growth are: (i) the growing gap between projected climate change impacts and current adaptation efforts (Stezer and Byrnes, 2019) and (ii) expanded legal duty of government, business, and others to manage foreseeable harms (Marjanac and Patton, 2018). Climate change litigation is expanding geographically into the Americas, Asia (and the Pacific region), and Europe with several cases brought in low- and middle-income countries (Stezer and Byrnes, 2019) (See Table 17.7).

Lawsuits against private entities contribute to articulating climate change as a legal and financial risk (*medium confidence*) (Peel and Osofsky, 2015; Ganguly et al., 2018; McCormick et al., 2018; Peel and

Osofsky, 2018). Even if unsuccessful, Estrin (2016) concludes they are important in underlining the high level of public concern.

Climate-related, legal, financial disclosure requirements are improving investment decision making of corporations as well as augmenting ex post liability for failure to consider climate change risk in decision making. Organizations are required to disclose governance around climate related risks (impact of climate change on businesses, products, services, supply or value chain, adaptation and mitigation activities, investment in research and development and operations). This functions as a vehicle for identifying climate-related risk and the organization's resilience strategy taking into consideration different climate-related scenarios including a 2˚C or lower scenario (Sarra, 2018). Institutions such as the G20 (Carney, 2019), the American Bar Association (Brammer and Chakrabarti, 2019), the European Commission (Zadek, 2018) have adopted or endorsed these standards.

Table 17.7: Examples of types of climate-related litigation

Litigation Type	Detail and Examples	Supporting Literature
Challenge government decisions for not considering climate change risks	Challenging government or administrative planning decisions for failure to consider, or adequately address, climate change in relation to developing and protecting coastal zones, water stressed regions, flood prone areas, or decisions affecting endangered species whose habitat is at risk. For example, the Victorian Civil and Administrative Tribunal in Australia rejected a planned housing project in a coastal area, citing the risks from climate change (Gippsland Coastal Bd. v. South Gippsland Sc & Ors (No2), 2008).	(Banda and Fulton, 2017; Peel et al., 2017; Bouwer, 2018; Clarke and Hussain, 2018)
Petitions to act	Constitutional petitions to force governments to take adaptation measures. As an example, in Leghari v. Pakistan a farmer initiated public interest litigation against federal and provincial governments for failure to develop climate change resilience through adaptation to floods, droughts and other impacts because it violated his rights to life and dignity. The High Court of Lahore found for Mr. Leghari and created a commission to develop and implement a wide range of adaptation actions.	(Banda and Fulton, 2017; Ashgar Leghari v. Federation of Pakistan, April 2015; Ashgar Leghari v. Federation of Pakistan, September 2015)
Regulatory proceedings	Environmental groups and city and state officials intervened in the application of the electric utility serving New York City, Consolidated Edison Company, to the New York State Public Service Commission for a rate increase. The intervenors argued that the company was not adequately preparing for flooding, heat waves and other climate-related impacts. As a result, the Commission directed the company to undertake a study of its vulnerability to climate change, and write and implement a plan to address these risks.	(Consolidated Edison Co., 2019)
Failure to act by public authorities	Liability of public authorities for failure to undertake necessary adaptation actions to avoid damage to life or property especially where statutory framework is proven ineffective or out of step with international commitments; in some areas these are class action suits. An example is private lawsuits for failure of a built environment to consider adaptation needs in a built environment (energy efficiency works, overheating because of increased temperatures).	(Banda and Fulton, 2017; Peel et al., 2017; Bouwer, 2018)
Failure by private sector to consider climate change	Examples include: (i) A citizen suit against ExxonMobil for failure to adapt Everett Terminal to the impacts of	(Benjamin, 2017; Stezer and Byrnes,

adaptation in their business practice	climate change including increased precipitation, sea level rise and storm surges occurring with increasing frequency; (ii) A citizen suit against. Shell Oil Products US alleging Shell failed to incorporate climate risks in its investment in a bulk storage and fuel terminal in Rhode Island, USA; (iii) Shareholder action against ExxonMobil for failure to report climate risks or complying with recommendations to do so and for issuing misleading corporate disclosure relied on by investors; (iv) A suit brought an NGO, the Conservation Law Foundation, against Exxon Mobil alleging that the company had taken insufficient precautions to protect a major oil tank farm near Boston, USA, from coastal storms that are worsened by climate change, creating a danger of an oil spill into Boston Harbour. The U.S. Court of Appeals for the First Circuit ruled in 2021 that the lawsuit could proceed, and that the NGO could attempt to make out its case that Exxon Mobil should take greater precautions.; (v) Government and citizen claims for public nuisance against fossil fuel companies for the costs of adaptation such as infrastructure to protect against sea level rise.	2019; Street and Jude, 2019; Wasim, 2019; Conservation Law Foundation v. Exxon Mobil Corporation, 2021)
Youth public trust claims	Government inter-generational liability for inadequate climate change mitigation and adaptation efforts. Our Children's Trust (a non-profit organization) and others brought an action against the United States and several executive branch individuals in 2015 claiming damages for their loss of the environment and the defendant's failure to preserve a habitable climate system. Similarly, a public trust claim could be brought in a coastal town for failure to adapt to climate change.	(Schneider et al., 2017; Bouwer, 2018)
Human rights claims	Human rights may be a powerful tool for organizing and unifying adaptation decision making, especially for the most vulnerable, through enforcement mechanisms of progressive realization as well as ex post liability (see Chapter 8). For example, a persons' right to food implores state parties to take necessary actions to alleviate hunger caused by climate change; during natural and other disasters rights to water, and life are impacted; sea-level rise and storm surges impact many coastal settlements and the right to adequate housing and an adequate standard of living. This is in part due to increasing acceptance of the impact of climate change on health, livelihoods, shelter and fundamental rights.	(Hall and Weiss, 2012; Peel and Osofsky, 2018; Setzer and Vanhala, 2019b; Stezer and Byrnes, 2019)

17.4.5.4 Catalysing Agents

Individuals and organizations often serve as catalysing agents of climate risk decision-making. They promote greater levels of new forms of climate action by communicating the urgency of climate action and by developing coalitions which undertake action. Agents include individuals, organisations or collectives, or multiple organizations linked together.

17.4.5.4.1 Social movements and other mobilizations

Recent studies of climate-related social movements show that they can act as catalysing agents which promote action to manage climate-related risks (*medium confidence*). However, these studies use varying definitions of climate movements within the broader context of environmental movements. A prominent topic of research is the rapidity and the large scale of the proliferation of these movements around the world, primarily in urban settings but also in rural and Indigenous contexts (Claeys and Delgado Pugley, 2017).

These movements usually focus on climate mitigation but sometimes include adaptation. Their social bases include groups which had not previously been active in climate politics, notably children and youth, as well as sectors with long traditions of environmental activism, such as women and Indigenous peoples (see Cross-Chapter Boxes GENDER and INDIG in Chapter 18). Much of the literature on youth movements traces the emergence of the movements themselves (Sanson et al., 2019; Treichel, 2020), their framings of climate change as a social justice issue (Holmberg and Alvinius, 2019) and their presence in demonstrations and on social media (Boulianne et al., 2020). Climate action catalysed by youth and other climate movements include visible international events such as the signing of Declaration on Children, Youth, and Climate Action at COP25 in Madrid 2019 (Han and Ahn, 2020), as well as national efforts, including lawsuits, and local events such as in tree-planting and waste reduction initiatives (Bandura and Cherry, 2019).

A recent review examines 2743 cases around the world of mobilizations for environmental justice causes (Scheidel et al., 2020); roughly half the cases occurred between 1970 and 2007, and half between 2008 and 2019. Of these environmental mobilizations, 17% are directly related to climate and energy, and others are related to climate-sensitive issues (15% for biomass and land use, 14% for water management). This study reports the proportion of positive outcomes for different strategies, defined as meeting the goals of the movements, which generally align with climate adaptation and sustainable resource management. These rates vary from 10% for negotiated solutions to 34% for court decisions. It notes the corresponding higher rates of failure, as well as the costs borne by the movements, which include criminalization (20% of cases), violence (18%) and assassination (13%). These costs are significantly higher for Indigenous communities that engage in these mobilizations.

At a global scale, climate movements succeeded in pressing for the greater recognition of the importance of Indigenous knowledge within international agreements (Tormos-Aponte and García-López, 2018) but did not achieve the major reforms of climate finance which they sought (Khan et al., 2019a); these differing outcomes reflect the sensitivity of the issues and the formation of coalitions which supported or opposed the movements. At national and local scales, one review of US cases reports limited effectiveness of climate movements because of the ability of governmental agencies to coopt them (Pulido et al., 2016), while another review in Pakistan shows a number of successes, because the movements were able to build alliances with other public sector and community groups (Shawoo and McDermott, 2020).

17.4.5.4.2 Policy leaders and entrepreneurs

Policy leaders, often described as policy entrepreneurs within the scholarly literature, are individuals in positions of leadership who set agendas and build coalitions to drive decision-making processes, and hence can function as catalysers of climate adaptation (Petridou and Mintrom, 2020). Political leaders who have taken on climate change as a key policy issue function as policy entrepreneurs at international, national and sub-national levels. City officials including mayors and other executives often play the role of climate policy entrepreneurs, while the absence of effective leadership negatively affects adaptation success (Becker and Kretsch, 2019). Such entrepreneurs can be important forces for change in both reactive contexts following an extreme or focusing event and in proactive context. They can be effective especially in contexts where they navigate and link together formal and informal networks of complex climate governance systems (Tanner et al., 2019). Their capacity to act has been increased when they and their institutions are embedded within partnership networks (Bellinson and Chu, 2019). It is in these contexts that the leadership and position of a policy entrepreneur becomes even more catalytic when operating at the interface of formal and informal networks (Mintrom, 2019; Stone, 2019).

Sub-national actors and city officials including mayors and other executives are among the individuals most often described and assessed as climate policy entrepreneurs (Kalafatis and Lemos, 2017). City level climate policy entrepreneurs often operate using their own experience, connections, and persistence to address issues of importance to their constituency. Climate risk concerns are often inherently local and in turn local decision-makers perceive it being appropriate to engage. Conversely, the absence of effective leadership negatively affects adaptation success (Kalafatis and Lemos, 2017; Becker and Kretsch, 2019). Urban climate policy entrepreneurs operate in four key spheres of policy development and implementation: attention and support seeking strategies; linking strategies (e.g., coalition building); relational management strategies (e.g., networking and trusting building); and arena strategies including timing (Brouwer and Huitema, 2018). The presence and operation of urban climate policy entrepreneurs is positively associated in settings with multiple jurisdictions and across differing spatial scales (Kalafatis and Lemos, 2017; Renner and Meijerink, 2018). It is these contexts that their capacity to operate simultaneously at the interface of multiple networks is particularly valuable for promoting climate action. Urban climate policy entrepreneurs can directly engage with a range of constituent groups and offer and promote climate adaptation strategies that can have direct impact on the daily lives of these residents and their interests.

[START BOX 17.3 HERE]

Box 17.3: Climate Risk Decision-Making in Settlements: From Incrementalism to Transformational Adaptation

Cities are important sites of experimentation where the integration and management of adaptation decision-making complexity often takes place. These actions provide early evidence of what aspects of complex climate risk management decision-making functions well, but also what does not work (Revi et al., 2020). Cities are seen as locales where case examples of transformative adaptation can be examined (Rosenzweig and Solecki, 2018; Vermeulen et al., 2018). Cities act as testbeds of how to integrate climate response into issues of equity, health, resource allocation, and sustainability in ways that utilize innovative use of new and emerging decision-support tools, methods and protocols.

Risk management has been an integral part of the community development and settlement building process. Three key sets of drivers influence risk management decision-making in cities (Solecki et al., 2017). These include 1) root – i.e., cultural norms and social traditions; 2) context – i.e., policy and governance conditions and 3) proximate – i.e., extreme events. Settlements have developed informal and formal strategies including climate protection levels to respond to local conditions of climate risk and hazards. In formal contexts, these strategies are contextualized in local climate change action plans (Araos et al., 2016a; Stults and Woodruff, 2017; Reckien et al., 2018a; Singh et al., 2021) and defined around a set of evaluation tools and methods and building codes, standards, and regulations (see discussion in 17.4.4).

Climate change has begun to alter the environmental baseline of cities changing their risk and hazard profiles. In recent years, national and local risk management can benefit from assessments of current decision-making strategies and from evaluations of opportunities for change in risk management policy. These changes can be adjustments of existing policies or transitions to a new policy for current (i.e., conditions already experienced by getting worse) or emerging risks (i.e., conditions not previously or widely experienced but now increasingly present).

With increasing impacts of climate change, settlements of all sizes are considering how to make their communities more resilient to climate risk (see Cross-Working Group Box URBAN in Chapter 6; Araos et al., 2016a; Araos et al., 2017; Reckien et al., 2018a). In many settlements demands for heightened resiliency are being coupled with opportunities to enhance the social and economic equity and quality of life of residents. Transformational adaptation (transformational, as being outcome-oriented; Vermeulen et al., 2018) and associated adjustments to the urban risk management decision-making requires an integration of climate resiliency pathways and conditions of sustainable development (Mendizabal et al., 2018). At the same time, growing conflict is present between requirements for greater resiliency and continued economic development, in particular in low-income environments (Ahenkan et al., 2020). Cities and their residents have the capacity to transform their own governance and decision-making systems (Birkmann et al., 2014; Chu, 2018; Romero-Lankao et al., 2018). Furthermore, cities have recognized the opportunity and demand to transform in order to be more ambitious (Mendizabal et al., 2018) and more successful, more equitable (Reckien et al., 2018b) and better able to connect the climate action to the sustainable development process (Singh et al., 2021).

In some cases, transformational adaptation is associated with large-scale, top-down, formal decision processes leading to significant policy shifts. For coastal cities this might include actions to build massive flood protection systems (as opposed to simple increase of existing structures) (Albers et al., 2015; Hinkel et al., 2018; Ajibade, 2019; see also Section 2.3.5, Cross-Chapter Paper 2) or policies to encourage managed retreat from increasing at risk locations (Hino et al., 2017; Rulleau and Rey-Valette, 2017). In more extreme instances, the relocation of cities is presented as a possibility, such as planned for the city of Jakarta

(Garschagen et al., 2018b). However, acceptability of top-down approaches to relocation are usually low and bottom-up drivers of relocation are important, especially to avoid inequitable outcomes (Mach and Siders, 2021). Intensity of extreme events and changing risk perceptions and expectations of property prices have been identified as important behavioural drivers of voluntary relocation (de Koning et al., 2019; de Koning and Filatova, 2020). Yet, when not supported by equitable public adaptation policies, the transformational adaptation left to the influence of autonomous adaptation and market institutions alone leads to climate gentrification low-income households are priced out from the hazard-free zones (de Koning and Filatova, 2020).

These circumstances also have revealed potential advances in decision-making by encouraging greater participation, more effective generation and use of information and data, and more prominent inclusion of questions of social and economic equity (Ziervogel et al., 2017; Reckien et al., 2018b; Solecki et al., In Press). Adaptation planning and decision-making, in general, within cities has increasingly focused on actively engaging residents in participatory and neighbourhood scale co-production processes (Broto et al., 2015; Sarzynski, 2015; Wamsler, 2017; Foster et al., 2019). However, engaging residents in risk management and adaptation has not always led to transformative decision-making and resiliency, but can at times also reinforce existing maladaptive systems (D'Alisa and Kallis, 2016).

Now increasing amounts of data are being collected via surveys or in participatory settings next to advanced methods, such as using citizen science, big data and AI, to integrate these social dimensions of climate adaptation decisions in cities in formal models (Abebe et al., 2019; Taberna et al., 2020). Linking to social data on individual decisions, risk perceptions, social norms, and governmental policy, advanced social models trace and quantify how adaptation in cities evolve and would cumulatively induce transformational change. Although wider application of these models is outstanding there is opportunity to simulate and learn from the integration of social and behavioural data with political and cultural norms (de Koning and Filatova, 2020).

Although non-urban areas could in many instances act in the same way as urban areas, the density of people, assets, infrastructure, and economical values drives cities to act as testbeds, implement adaptation, and strive for resiliency. Cities are showcases for the larger environmental systems of governments that also support mitigation ambition of national actors and are therefore demanding to be recognized as valuable actors in the international negotiations, highlighting their contribution in emissions reductions (Chan et al., 2015; Hale, 2016), e.g., in the preparation for the first Global Stocktake of the Paris Agreement in 2023 (see Cross-Chapter Box PROGRESS in this Chapter).

[END BOX 17.3 HERE]

17.5 Adaptation Success and Maladaptation, Monitoring, Evaluation and Learning

17.5.1 Adaptation Success and Maladaptation

17.5.1.1 The Adaptation-Maladaptation Continuum

As evidence on adaptation implementation grows (Berrang-Ford et al., 2021; Eriksen et al., 2021), there is a need to examine the outcomes of adaptation (Ford et al., 2011) for effectiveness, adequacy, justice/ equity in both outcomes and process, as well as synergies and trade-offs with mitigation, ecosystem functioning, and other societal goals. There is also a growing recognition of the observed and potential negative consequences of some adaptation interventions, often referred to as maladaptation (Juhola et al., 2016; Magnan et al., 2016; Schipper, 2020; Eriksen et al., 2021). This section advances a new framing to allow for an improved assessment of the potential positive or negative outcomes of adaptation options, therefore allowing navigation of the adaptation-maladaptation continuum.

17.5.1.1.1 Defining and assessing success in adaptation vis a vis maladaptation

The highly contextual nature of adaptation, a multitude of applied definitions of adaptation (e.g cost effectiveness versus outcomes), its overlaps with development interventions, and the long time horizons over which outcomes accrue, deter a universal definition of adaptation success (Dilling et al., 2019a; section

17.5.1.2; Owen, 2020; Singh et al., 2021). Moser and Boykoff (2013), Olazabal et al. (2019b), and Sherman and Ford (2013) suggest criteria against which successful adaptation could potentially be tracked. The literature is converging to suggest that successful adaptation broadly refers to actions and policies that effectively and substantially reduce climate vulnerability, and exposure to and/or impacts of climate risk (Noble et al., 2014; Juhola et al., 2016), while creating synergies to other climate-related goals, increasing co-benefits to non-climate-related goals (such as current and future economic, societal, and other environmental goals) and minimize trade-offs (Grafakos et al., 2019) across diverse objectives, perspectives, expectations, and values (Eriksen et al., 2015; Gajjar et al., 2019a; Owen, 2020) (*high confidence*).

Maladaptation refers to current or potential negative consequences of adaptation-related responses that lead to an increase in the climate vulnerability of a system, sector, or group (Barnett and O'Neill, 2010) by exacerbating or shifting vulnerability or exposure now or in the future (Antwi-Agyei et al., 2014; Noble et al., 2014; Juhola et al., 2016; Magnan et al., 2020) and eroding sustainable development (Juhola et al., 2016). Conceptually, maladaptation differs from 'failed' or 'unsuccessful' adaptation (Schipper, 2020), which "describes a failed adaptation initiative not producing any significant detrimental effect" (Magnan et al., 2016: 648). Several frameworks have been proposed to explain and better assess maladaptation (Hallegatte, 2009; Barnett and O'Neill, 2010; Magnan, 2014; Magnan et al., 2016; Gajjar et al., 2019b). In order to limit the risk of maladaptation, a common focus of these frameworks is on intentionally avoiding negative consequences of adaptation interventions, anticipating detrimental lock-ins and path dependence, and minimizing spatio-temporal trade-offs.

The adaptation literature challenges the simplistic dichotomy of interventions being either successful or maladaptive (e.g. Moser and Boykoff, 2013; Singh et al., 2016; Magnan et al., 2020; Schipper, 2020). There is no clear cut boundary between these two categories; rather, successful adaptation and maladaptation need to be considered the two ends of a continuum of risk management strategies (Figure 17.9) emphasising that:

- no options are "bad" or "good" *a priori* with respect to reducing climate risk/vulnerability.
- positive and negative outcomes of adaptation depend on local context specificities (including the presence/ absence of enabling conditions [1]), how adaptation is planned and implemented, who is judging the outcomes (i.e. adaptation decision-maker, planner, implementer or recipient) and when adaptation outcomes are assessed.
- *ex ante* assessment of where options fall on the continuum can help anticipate maladaptive outcomes.

Along the adaptation-maladaptation continuum, adaptation options can score high or low on different outcome criteria identified in this section as: benefits to the number of people, benefits to ecosystem services, equity outcomes (for marginalized ethnic groups, gender, low-income populations), transformational potential and contribution to GHG emission reduction (see SM 17.1 for full descriptions). Importantly, the outcome of the assessment, and consequently location of a given adaptation option along this continuum, is dynamic, depending on multiple components including changes in the characteristics of climate hazards and the effects of iterative risk management. Unfortunately, this temporal dimension is understudied in the literature (including studying thresholds or speed), preventing advances on this specific point.

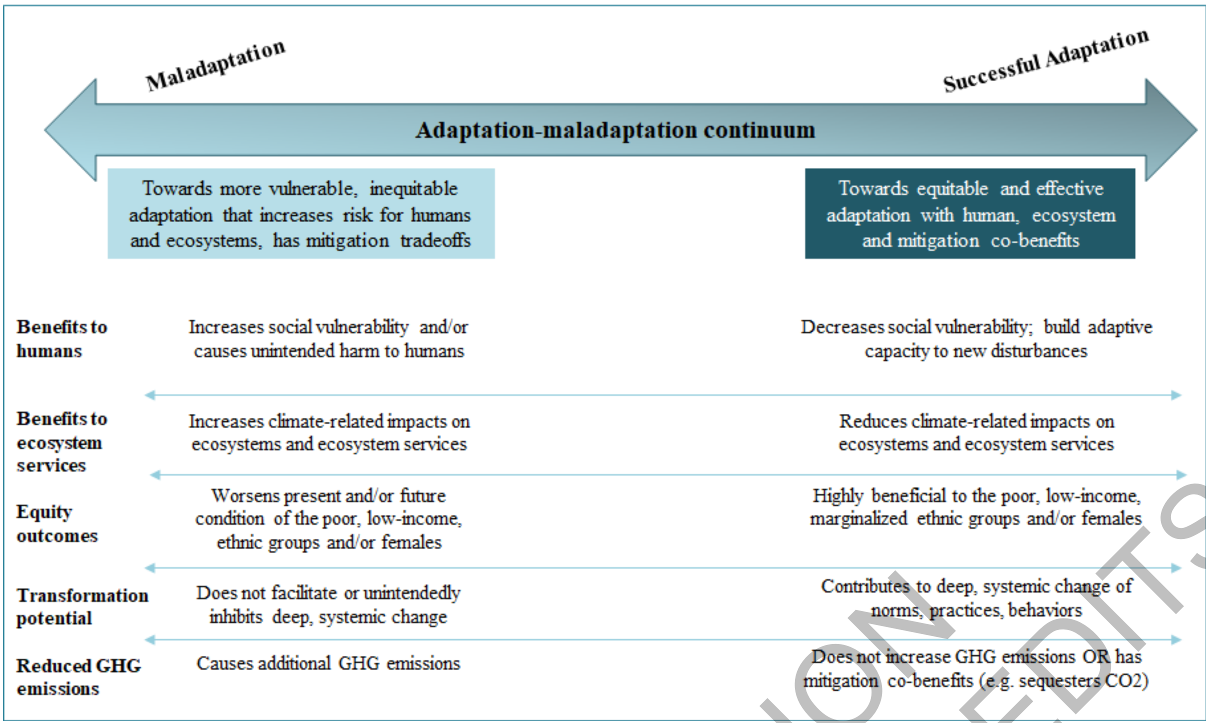

Figure 17.9: Successful adaptation and maladaptation are conceptualised as the two end points of a continuum, with adaptation options being located along the continuum based on outcome criteria (how they benefit humans and ecosystems; how they contribute to or hinder equity goals; whether they enable transformative change to climatic risks, and synergies and trade-offs with climate mitigation). As indicated in SM 17.1 and figure 17.9, adaptation options might rate largely positive and slightly negative across outcome criteria (tending towards successful adaptation), while other adaptation options might have small positive aspects and larger negative ones across different outcome criteria (tending towards maladaptation). The figure draws on Singh et al. (2016); Magnan et al. (2020), and Schipper (2020).

17.5.1.1.2 Empirical evidence on success of adaptation vis a vis maladaptation

Although the empirical evidence on current and potential successful adaptation and maladaptation remains small and fragmented (Magnan et al., 2020; Berrang-Ford et al., 2021; see Section 17.3.2 in this Chapter), the above framing allows for moving a step further in assessing the potential contribution of a wide range of adaptation-related options to success or maladaptation.

According to an assessment (Figure 17.10; see SM 17.1 for full descriptions) of maladaptation-relevant outcome dimensions, here called criteria, i.e. benefits to people, benefits to ecosystem services, benefits to equity (marginalized ethnic groups, gender, low-income populations), transformational potential, and contribution to GHG emission reduction, no option is located at one or the other end of the adaptation-maladaptation continuum (Figure 17.10, right panel), showing that all options have some maladaptation potential, i.e. trade-offs (*very high confidence*). This is also shown by the wide confidence bars of most options (right panel) signifying that most adaptation can be done in a way that involves a higher or a lower risk of maladaptation (*medium confidence*; see also Table 17.2). The option of ‘coastal infrastructure’ signifies the highest risk for maladaptation. While it can be an efficient adaptation option in highly densely populated areas (Oppenheimer et al., 2019; CCP2.3), it has potential tradeoffs for natural system functioning and human vulnerability over time. The option most widely associated with successful adaptation is ‘nature restoration’, closely followed by ‘social safety nets' and options relating to ‘farm/ fishery practices’, and ‘diets/ food waste’ (*high confidence*).

Some options show the dominant influence of certain criteria (Figure 17.10, central panel rows). For example, ‘availability of health infrastructure’ and ‘access to health care’ are dominated by the criterion ‘greenhouse gas emissions’. Similarly, ‘spatial planning’ carries a high risk of disadvantages to marginalized ethnic and low-income groups. This means that these adaptations could be transformed into successful adaptations more easily than others, if attention is paid to the dominant criterion. For example, if healthcare could be provided with low GHG emissions it would move closer towards successful adaptation (*high confidence*). For other options, the criteria’s influence is more evenly distributed, as illustrated for the 'diversification of livelihoods' and the three options to address climate risks to peace and mobility, denoting multiple entry points to reduce the risk of maladaptive outcomes for these options.

Some criteria score highly across a number of options (Figure 17.10, central panel columns), showing that many adaptations do not pay attention to different trade-offs. For example, particular attention should be paid to prioritising benefits to low-income groups and leveraging the transformational potential of adaptation (having the largest number of large circles), i.e. many evaluated options become maladaptive by exacerbating the vulnerability of low-income groups and by fortifying the status-quo (*medium confidence*). On the contrary, most evaluated adaptation options are widely applicable across populations (benefits to humans), and deliver ecosystem services, while some also respect gender equity (largest number of small bubbles across options), through these criteria a number of adaptation options contribute to a higher potential for successful adaptation (*high confidence*).

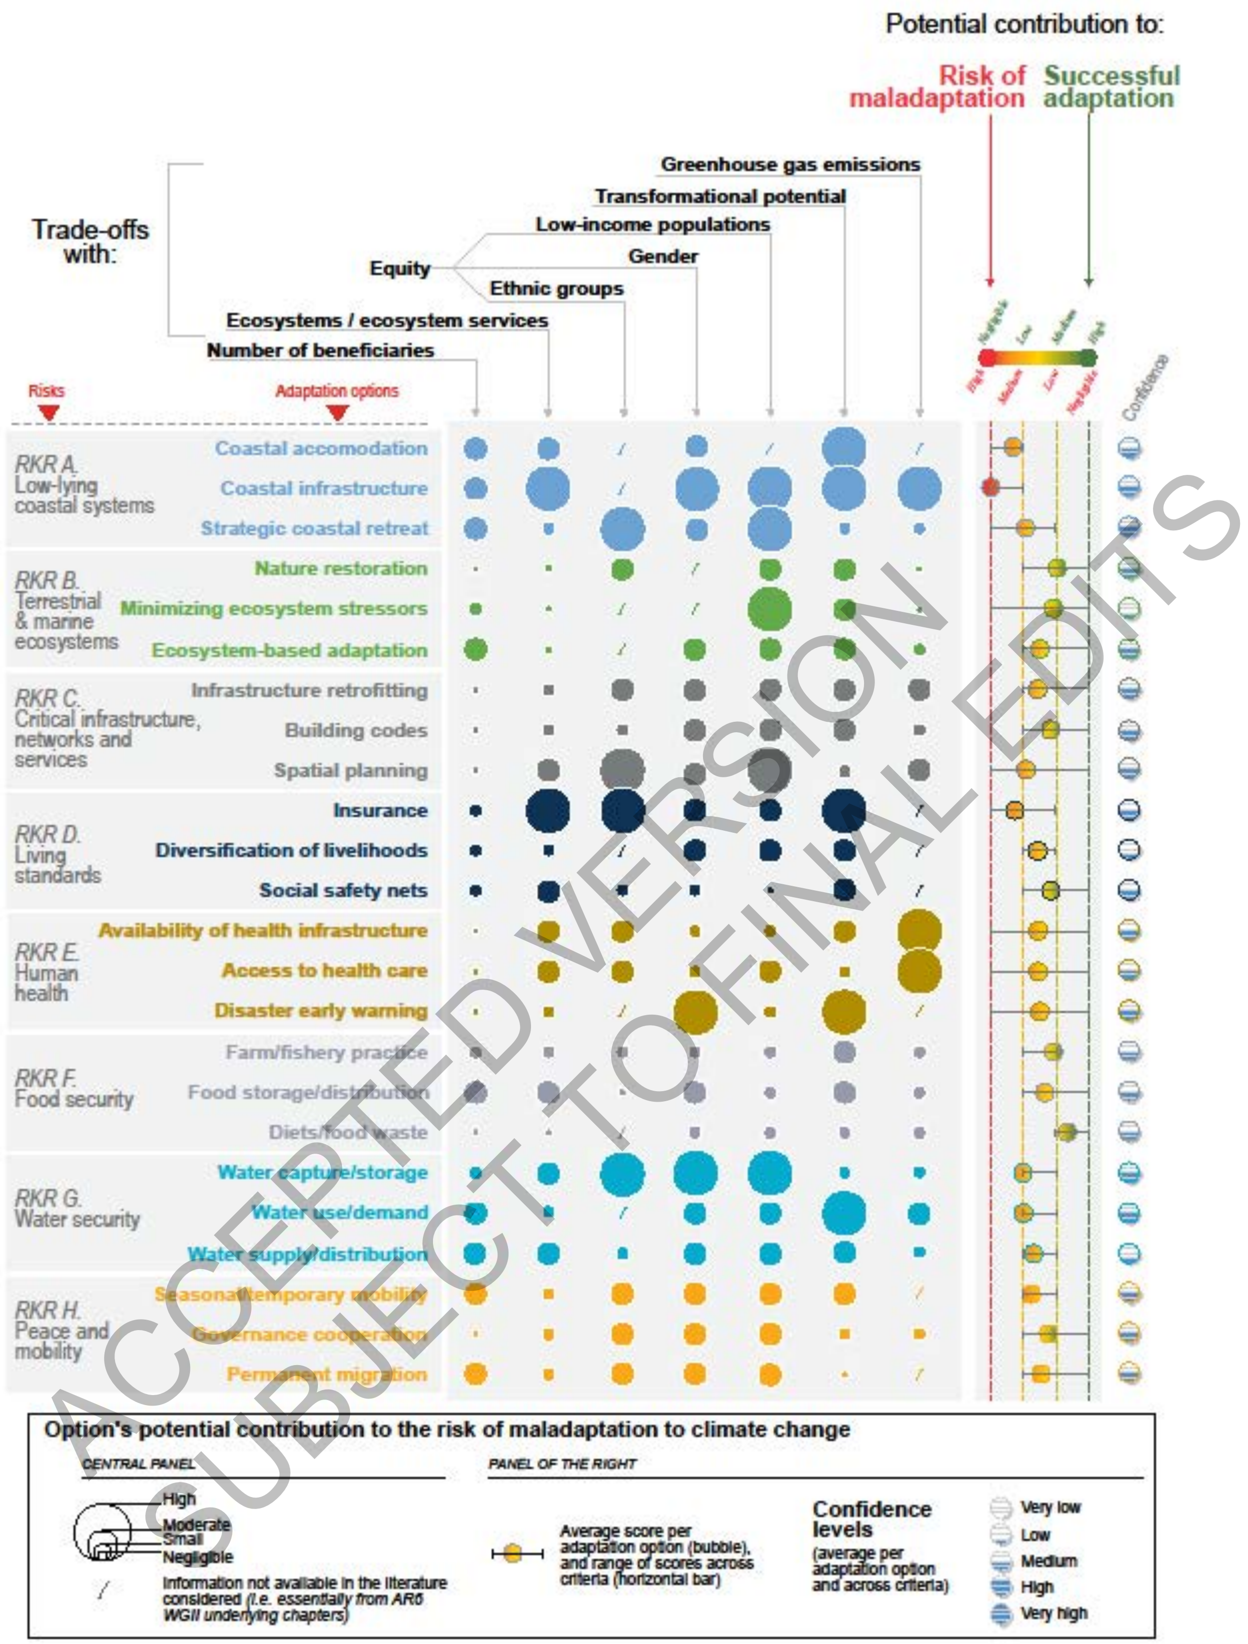

Figure 17.10: The potential contribution of 24 adaptation-related options to maladaptation and successful adaptation. The figure builds on evidence provided in the underlying sectoral and regional chapters and the Cross-Chapter Papers (SM17.1) to map 24 adaptation options identified as relevant to the eight Representative Key Risks (see Ch16.5) onto the adaptation-maladaptation continuum. It assesses the potential contribution of each of these adaptation options to successful adaptation and the risk of maladaptation. The figure permits a review of options in multiple ways: a) Looking at adaptation options (first column) one can see which adaptation options score highest across the criteria (the central rows). Results by options show which ones carry the highest risk of maladaptation (=largest circles per row). b): Looking at criteria (top centre) one can see which criteria seem to be most influential to contribute to

maladaptation outcomes (=largest circles per central column). c) The panel on the right: Merging the scores of each adaptation option across criteria helps highlighting whether the options are likely to end up as successful adaptation or maladaptation.

The results displayed in Figure 17.10 are not rigorous predictions but illustrate the maladaptive potential of options based on a synthesis of literature from underlying WGII chapters and cross-chapter papers. This leads to findings for general situations, potentially obscuring critical contextual specificities which can mediate successful adaptation or maladaptation outcomes. In a certain context, Figure 17.10 will appear different. Moreover, the analysis is based on a static interpretation of adaptation outcomes, while risk and risk reduction are dynamic. The current, underlying literature does not help understanding the temporal dimension of the options, their flexibility or risk of lock-in, and related potential contribution to long-term maladaptation or successful adaptation. The added value of the analysis lies in the approach to assess the potential contribution to maladaptation or successful adaptation (via the seven criteria at the top of the figure), rather than in the final results themselves. This overview illustrates how in a particular context and for particular groups of people, adaptation options and their location on the adaptation-maladaptation continuum can be assessed for a set of outcome dimensions, focuses on assessing potential contributions per and across criteria, as well as per and across options (critical information to support the identification of adaptation pathways; Cross-Chapter Box DEEP in this Chapter).

17.5.1.1.3 Enabling successful adaptation and pre-empting maladaptation

Considering evidence on enabling successful adaptation in the sectoral (Chapters 2-8) and regional chapters (9-15), four conditions stand out as particularly key to enabling adaptation success: recognitional equity and justice, including the integration of Indigenous and local communities and knowledge; procedural equity and justice; distributive equity and justice; and flexible and strong institutions that seek integration of climate risk management with other policies and address long-term risk reduction goals (Table 17.8). For a wider discussion of enablers for adaptation and climate risk management, see Section 17.4.

Recognitional equity and justice: Recognitional justice focuses on inclusion and agency, i.e. examining who is recognised as a legitimate actor and how their rights, needs and interests are acknowledged and incorporated into action (Singh et al., 2021).

A global assessment of 1682 papers on adaptation responses yields that low-income groups (*high agreement*, 37% of 1682 articles), women (*medium agreement*, 20% articles), Indigenous peoples (10%), the elderly (8%), youths (5%), racial and ethnic minorities (4%), and migrants (4%) were the most frequently considered groups in adaptation responses. Individuals with disabilities are the least considered, with only 1% of articles including this group. There is a category of "other" capturing characteristics of social disadvantage that are distinct from the categories above. This includes, for example, spatially marginalized populations (e.g., groups relegated to flood-prone or cyclone-prone areas) and groups marginalized due to marital status or assets (education, farm size, and land tenure) (Araos, in press).

Procedural equity and justice: Participation is employed to enable procedures that aim to redress power imbalances, which are assumed to be the root causes of vulnerability (i.e. the reasons that lead certain people and places to be differentially vulnerable to climate risks) (Tschakert and Machado, 2012; Shackleton et al., 2015; Schlosberg et al., 2017; Ziervogel et al., 2017). However, participation is often constrained by gender (Cross-Chapter Box GENDER, Ch 18), social status, unequal citizenship (as concerns education, access to information, finance and media) (Wallimann-Helmer et al., 2019), entrenched political interests (Shackleton et al., 2015; Chu et al., 2017), power dynamics (Rusca et al., 2015; Taylor and Bhasme, 2018; Kita, 2019; Omukuti, 2020; Taylor and Bhasme, 2020), or institutional shortcomings (Nightingale, 2017, in Nepal), which allow the most powerful access to funding and reinforce marginalisation of the powerless (Schipper et al., 2014; Khatri, 2018; McNamara et al., 2020). Vulnerability is also sometimes used as a pretext to exclude groups from participation, often because vulnerable groups do not own land, lack legal status, time, or the ability to commit labour or material inputs for adaptation, all drivers of vulnerability in the first place (Nyantakyi-Frimpong and Bezner Kerr, 2015; Camargo and Ojeda, 2017; Nagoda and Nightingale, 2017; Nightingale, 2017; Thomas and Warner, 2019; Mikulewicz, 2020).

Reporting from the global assessment of equity considerations in adaptation, procedural equity and justice, was slightly more often mentioned (~52%) than not (~48) (*medium agreement*). However, the robustness of the evidence on inclusion of vulnerable and marginalized groups in the planning of adaptation responses is low (63%) (*high agreement*). Only for ~6% of the articles that provide evidence for inclusion of vulnerable groups the robustness of evidence is high (*low agreement*). Globally, the category of low-income (~25%) and women (~13%) are most often included, although the robustness remains low. Most of the robust evidence comes from Africa and Asia, where adaptation responses mostly focus on low-income and women groups in the food (28%) and poverty (32%) sectors (*medium agreement*). With regards to other vulnerability categories, such as disabled populations, almost negligible evidence was found for the inclusion of this group, globally. There is also little reporting of procedural equity in community-based or ecosystem-based responses (Araos, in press).

Distributive equity and justice: Attention to distributional equity and justice aims to ensure that adaptation interventions do not exacerbate inequities (Atteridge and Remling, 2018) and that the benefits and burdens of interventions are distributed fairly (Tschakert et al., 2013; Reckien et al., 2017; Reckien et al., 2018b; Pelling and Garschagen, 2019).

A global assessment of 1682 papers on adaptation (Araos, in press) finds that about 60% of articles mentioned at least one vulnerable group being involved in the implementation of adaptation or targeted by it (*medium confidence*). Low-income groups (*high agreement*, 37% of 1682 articles) and women (*medium agreement*, 20% articles) are the most frequently mentioned. Particularly in sectors and regions that incorporated coping measures in their adaptation response (Poverty, Food, Africa, Asia, Central & South America), these groups are prevalent. In sectors where responses were more strategic or planned, such as in cities, terrestrial and water, a larger proportion of articles (51%, 47% and 47% of articles respectively) vulnerable groups were not frequently included in the response (medium agreement). There was also a stark difference in inclusion of marginalized and vulnerable groups between high-income and low-income countries regions, with the majority of the responses from Australia, Europe and North America, not including marginalized groups (*high agreement* with 70%, 69% & 55% of articles respectively), showing the need for increasing attention in particular on a cross-sectoral and cross-regional relation (Araos, in press).

Flexible and strong institutions: There is *medium confidence* that flexible institutions can enable adoption of new adaptation measures or course-correct established ones based on ongoing monitoring and evaluation, which is key to avoiding potential maladaptation (e.g. Granberg and Glover, 2014, in Australia; Magnan et al., 2016; Torabi et al., 2018; Gajjar et al., 2019a, in India). Cross-sectoral, cross-jurisdictional and cross-spatial institutional frameworks enable successful adaptation by improving the ability of societies to respond to changes in their environment in a timely manner. The latter points to the vital role of monitoring and evaluation, as the tool to detect change in risk and vulnerability, together with environmental or societal conditions determining risk and the effectiveness, efficiency, adequacy, or success of adaptation responses.

Table 17.8: Key factors that enable successful adaptation. The evidence and examples draw on the underlying sectoral and regional chapters as well as a synthesis of adaptation literature.

Enablers	What this enables	Key characteristics	Examples and traceability
Recognitional justice	Pluralising the ambit of who is 'counted' as vulnerable, drawing on multiple knowledge systems	- Focuses on inclusion and agency, i.e., who is recognised as a legitimate actor and how their rights, needs and interests are acknowledged and incorporated into adaptation (Chu and Michael, 2018; Singh et al., 2021). - Acknowledges how differential vulnerability to climate change stems from historical and structural inequalities, which can unevenly distribute adaptation benefits, especially for the poorest and the most marginalized (Tschakert and Machado, 2012; Shackleton et al., 2015; Schlosberg et al., 2017; Ziervogel et al., 2017; Eriksen et al., 2021). - Informs more equitable adaptation priorities (Ziervogel et al., 2017), legitimizes adaptation	- Co-production of knowledge and inclusion of Indigenous and local knowledge (Loboguerrero et al., 2018; Dannenberg et al., 2019, Cross-Chapter Box ILK; Ziervogel et al., 2019). - Co-production of knowledge and inclusion of marginalized groups across sectors, see e.g., in the health sector (Ch 7), food systems (Ch 5) and fire management (Ch 12).

		actions (Myers et al., 2018; Ellis and Tschakert, 2019), supports inclusion of marginalized groups (Chu and Michael, 2018) (*medium confidence)*.	
Procedural justice	Differential participation and power for more inclusive adaptation planning and implementation	- Ensures that processes of representation and participation in adaptation planning, prioritisation and implementation are inclusive (Holland, 2017; Reckien et al., 2017; Reckien et al., 2018b) (*medium confidence*). - Enable adaptations to advance more quickly and generate higher levels of wellbeing (e.g. Dannenberg et al., 2019 comparing cases of strategic retreat), while also benefiting poorer households (Chu and Michael, 2018). - Higher participation can enable more legitimate outcomes, greater awareness about societal problems addressed, larger willingness for community cooperation, and increased individual behavioural change (Burton and Mustelin, 2013). - Participation in design and implementation of adaptation projects can be a critical element for avoiding maladaptive outcomes (Taylor, 2015; Nightingale, 2017; Forsyth, 2018; Mikulewicz, 2019).	- Participation of multiple stakeholders enables co-production of adaptation strategies and devolution of decision-making (Ziervogel, 2019) and often, even if not always (D'Alisa and Kallis, 2016), a higher level of transformational adaptation (and more ambitious local mitigation goals) (Cattino and Reckien, in press). - Participatory processes can have more equitable outcomes as evidenced in informal settlements (Ziervogel, 2019, South Africa), small farmers (Loboguerrero et al., 2018, Colombia); migrants (Gajjar et al., 2019b, India), and deliberative dialogues (Ojha and et al., 2019). - But participation does not always address unequal power relations (e.g. Buggy and McNamara, 2016; Karlsson et al., 2017).
Distributive justice	Delivering adaptation for vulnerable groups and correcting structural vulnerabilities	- Ensures that adaptation interventions do not exacerbate inequities (Atteridge and Remling, 2018) and that the benefits and burdens of interventions are distributed fairly (Tschakert et al., 2013; Reckien et al., 2017; Reckien et al., 2018b; Pelling and Garschagen, 2019). - However, low levels of commitment to distributive justice, e.g. when justice is one of many goals of adaptation instead of the prime one, are insufficient to promote equitable distribution of benefits and harms (*medium evidence, high agreement*) (Anguelovski et al., 2016; Pulido et al., 2016; Weinstein et al., 2019; Shawoo and McDermott, 2020).	- Women and men have very different access to mobile phones, entailing lower responsiveness with climate services among women (Partey et al., 2020, across Africa). - Slow progress on prioritizing distributional and procedural justice limits the expansion of adaptation funding to poorest and most vulnerable social groups and nations (Khan et al., 2019a). - Focussing only on distributive justice alone is less effective than a holistic integration of recognitional and procedural justice (*limited evidence, medium agreement*); e.g., only including poor households as recipients provides benefits to wealthier households, in sectors such as insurance for herders in Mongolia (Taylor, 2016b), urban water supply in Malawi (Rusca et al., 2017), informal urban settlements in Kenya (Pelling and Garschagen, 2019), and

			forest management in Cambodia (Work et al., 2019).
Flexible and strong institutions	Seeks policy integration, dynamic risk management, and account for long-term goals	- Institutional flexibility allows a society to respond quickly to the demands of a changing environment by developing new institutions or adjusting existing ones quickly (Davis, 2010); possibly avoiding lock-ins and addressing future climate risks (*very high evidence, high agreement*) (Levi-Faur, 2012; Sherman and Ford, 2013; Boyd and Juhola, 2015; Magnan et al., 2016). - Stability (and familiarity) is often desired in governance arrangements and balancing the need for stability with goals of flexibility, without causing rigidity is key (Craig et al., 2017, in USA; Ch 11). This is possible through deliberate, consultative changes that build awareness, develop shared norms, rules, and goals, and develop inclusive decision-making processes (Ch 3).	- Capacity building of adaptation funders, planners, and implementers and reorienting existing institutions to make decisions under uncertainty, institute long-term climate risk management that goes beyond typical political/ planning cycles, and develop learning mechanisms between sectors, actors, and projects needed (Moser and Boykoff, 2013; Granberg and Glover, 2014 in Australia; Boyd and Juhola, 2015 in cities; Ziervogel, 2019 in Africa and; Olazabal et al., 2019b in India; Ch 3 Oceans; Ch 10; Ch 11; Ch 12). - Flexible institutions enable adoption of new adaptation measures or course-correct based on ongoing M&E (e.g. Granberg and Glover, 2014 in Australia; Magnan et al., 2016; Torabi et al., 2018; Gajjar et al., 2019a in India) (*medium evidence, high agreement)*. - Sectoral or spatial policy integration (Chu et al., 2017; section 17.6; Hino et al., 2017; Robinson and Wren, 2020); integration of jurisdictional frameworks of different agencies (Poesch et al., 2016; Ch 5; Ch 9); and adaptive and flexible legal systems, which disaggregate socio-ecological systems into smaller components (Arnold and Gunderson, 2013; Wenta et al., 2019) are key enablers.

17.5.2 Adaptation Monitoring, Evaluation & Learning

17.5.2.1 Purpose of Monitoring and Evaluation

Adaptation responses have been observed in every region and across a wide variety of sectors (Ch16.3), but little evidence exists of their outcomes in terms of climate risk reduction (*high confidence*) (Ch 1.4.3; Ford and Berrang-Ford, 2016; Tompkins et al., 2018; Berrang-Ford et al., 2021; Eriksen et al., 2021; UNEP, 2021a). To advance on that, the Paris Agreement is encouraging countries to engage in "Monitoring and evaluating and learning from adaptation plans, policies, programmes and actions" (UN, 2015, Article 7.9d). Monitoring and Evaluation (M&E) is the systematic process of collecting, analyzing and using information to assess the progress of adaptation and evaluate its effects--e.g., risk reduction outcomes, co-benefits and trade-offs--mostly during and after implementation (AR6 Glossary). Distinctions between monitoring and evaluation typically view monitoring as a continuous process of tracking implementation and informing management to allow for corrective action including in situations of deep uncertainty (see Cross-Chapter

Box DEEP in this Chapter) while evaluation is described as a more comprehensive assessment of achievements, unintended effects and lessons learned carried out at certain point in time (OECD, 2002). Monitoring and evaluation is an important part of the adaptation process (Figure 1.9). It can help to generate information on adaptation success or maladaptive outcomes.

M&E of adaptation is undertaken for different purposes, including: (1) understanding whether responses have achieved their intended objectives and contributed to a reduction in climate risks and vulnerability or to an increase of adaptive capacity and resilience, (2) informing ongoing implementation and future responses, and (3) providing upward and downward accountability (Preston et al., 2009; UNFCCC, 2010a; Pringle, 2011; Spearman and McGray, 2011). M&E is also commonly linked to learning (section 17.5.2.7). By continuously monitoring implementation, e.g., to assess whether adaptation is on track or needs to be accelerated— M&E can aid decision-making under uncertainty. Adaptation M&E is distinct from tracking financial flows related to adaptation since financial accounting does not provide information on implementation and outcomes (17.5.2.5; Adaptation Partnership, 2012; World Bank Independent Evaluation Group, 2012).

17.5.2.2 Adaptation M&E Approaches

Adaptation M&E can be conducted for various purposes and in a wide variety of different contexts ranging from the local to the global level (McKenzie Hedger et al., 2008; UNFCCC, 2010a; Spearman and McGray, 2011). The context and specific purpose of M&E determine what information needs to be generated, and together with the available resources also determine the suitability of particular approaches and methods (Leiter, 2016; Leiter, 2017). Several frameworks and approaches have been proposed for M&E of adaptation and climate resilience (Bours et al., 2014d; Schipper and Langston, 2015; Adaptation Committee, 2016; ODI, 2016; Cai et al., 2018; Gregorowski et al., 2018) including sector-specific ones for agriculture (FAO, 2017; FAO, 2019a; FAO, 2019b), health (Ebi et al., 2018), ecosystem-based adaptation (Donatti et al., 2018; Donatti et al., 2020; GIZ, 2020a) and cities (section 6.4.6).

Adaptation M&E generally seeks to answer whether implementation is taking place and what effects it has (figure 17.11). Accordingly, M&E can focus on the processes, activities and outputs or on their outcomes and ultimate impacts (Harley et al., 2008; Pringle, 2011; Ford et al., 2013). Most of the available guidance for the development of adaptation M&E systems is aimed at the household, local or project level (Pringle, 2011; Villanueva, 2012; Olivier et al., 2013; CARE, 2014; BRACED, 2015; Leiter, 2016; Jones, 2019b) with only limited guidance for national or cross-sectoral M&E systems (Price-Kelly et al., 2015) or frameworks that are applicable at different scales (Brooks et al., 2014). The available guidebooks take users through a series of steps which are synthesized in Figure 17.11.

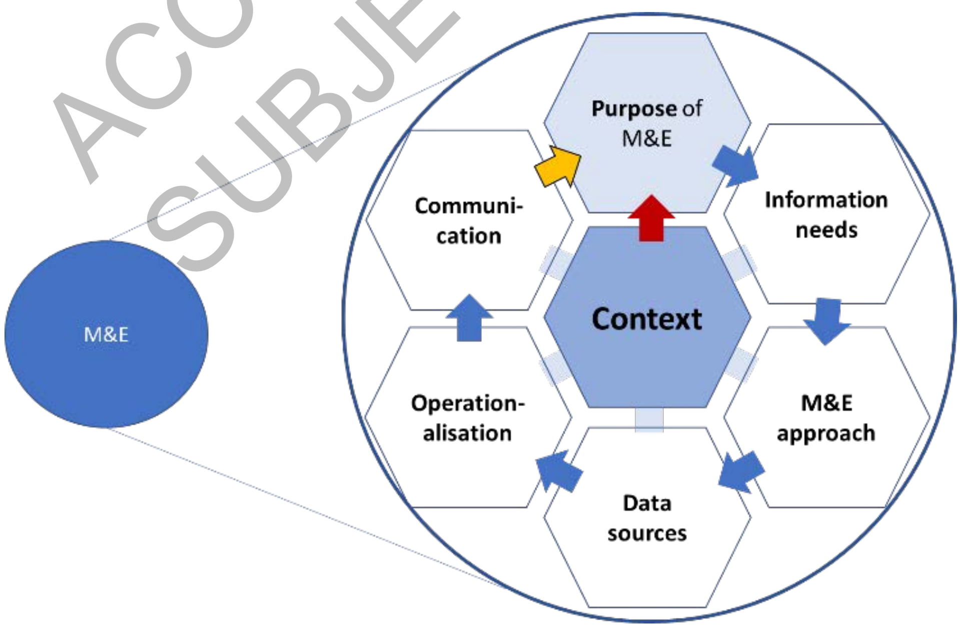

Figure 17.11: Adaptation M&E and learning as part of the adaptation process (based on Hammill et al., 2014a; Price-Kelly et al., 2015; Leiter, 2016). This figure shows the main steps involved in developing an adaptation M&E system where the context informs the purpose of M&E which in turn determines the information needs. To achieve the M&E purposes, the chosen approach and data sources need to be able to generate the needed information which needs to be communicated in a suitable way to the target audiences.

The majority of adaptation M&E efforts have so far focused on processes and outputs rather than on achieved outcomes, e.g. climate risks, vulnerability, well-being or development (Droesch et al., 2008; GIZ and Adelphi, 2014; UNDP Cambodia, 2014; Fawcett et al., 2017) (*high confidenc*e) or use a combination thereof (Brooks et al., 2011; Brooks et al., 2014). Newly emerging approaches include perception-based measurements and the use of data collected via mobile phones (Jones et al., 2018; Jones, 2019a), which can be collected frequently (Clare et al., 2017a; Knippenberg et al., 2019; Jones and Ballon, 2020). Such advances call into question the common reliance on "objective" indicators defined from an external perspective. Instead, they suggest that multiple complementary approaches combined with higher frequency data collection produce a more elaborate picture of the effects of adaptation and resilience responses (Jones and d'Errico, 2019; Knippenberg et al., 2019; Singh et al., 2019; Jones, 2019a; see Cross-Chapter Box PROGRESS in this Chapter) (*medium confidence*).

Central to designing, monitoring and evaluating adaptation responses is outlining how activities are expected to lead to intended objectives, e.g., via a theory of change (Bours et al., 2014c; Oberlack and al., 2019). Theories of change or similar change models provide a basis to decide what to measure but more attention needs to be paid to how theories of change are constructed and who is involved (Mason and Barnes, 2007; Forsyth, 2018). Participatory approaches can support understanding how climate risks affect the respective population, how these risks interact with social and cultural processes, and how responses could most effectively address climate risks (Conway et al., 2019). Inclusive M&E systems can facilitate ownership and enhance the meaningfulness and usability of the generated information (CARE, 2014; Faulkner et al., 2015). Meaningfulness is not associated with a particular approach or method but depends on whether the chosen M&E design fits the M&E purpose and the information needs of the intended audience (Fisher et al., 2015; Leiter, 2017). Effective communication of M&E findings and feedback into decision making processes is essential to achieve the respective M&E purpose and facilitate learning (section 17.5.2.7).

17.5.2.3 Adaptation Indicators and Indices

A set of all-purpose and globally applicable standard indicators that could comprehensively measure adaptation does not exist (*high confidence*) (IPCC, 2014a; Leiter and Pringle, 2018). A wide variety of indicators have been used to assess adaptation and its results (CARE, 2010; Harvey et al., 2011; Lamhauge et al., 2013; Brooks et al., 2014; Hammill et al., 2014b; Mäkinen et al., 2018; HM Government, 2019). Literature has also noted unrealistic expectations of what indicators can accomplish. For instance, decisions involving competing political interests would not be adequately informed through simple indicators; and learning requires knowledge of how and why change has happened, something that indicators often do not capture (Hinkel, 2011; Bours et al., 2014d). Indicators can also become misguided incentives and might steer attention away from what matters (Leiter and Pringle, 2018; Hallegatte and Engle, 2019; Klonschinski, 2021). Surveys, scorecards, interviews and focus groups are alternative methods of gaining insights on adaptation progress (Brooks et al., 2014; Porter et al., 2015; Das, 2019; McNamara et al., 2020).

The difficulties of assessing adaptation and an emphasis on short-term results have contributed to the common practice of relying on easily quantifiable indicators rather than assessing actual changes, i.e. outcomes and impacts (World Bank Independent Evaluation Group, 2012; Fisher et al., 2015). In fact, indicators used by international climate funds largely measure outputs which provide little evidence of the actual effectiveness of adaptation, i.e. its outcomes and impacts (GCF Independent Evaluation Unit, 2018; Leiter et al., 2019; Pauw et al., 2020).

Indices, the combination of multiple indicators into a single score, are common products of risk and vulnerability assessments to compare countries or other entities, often in the form of rankings or maps (Preston et al., 2011; Reckien, 2018; de Sherbinin and et al., 2019). They can indicate changes in vulnerability over time within their respective conceptualisation of vulnerability or risk. The construction of indices including indicator selection, their weighting, normalisation and data sources have a profound impact on their scores (Reckien, 2018). Research has consistently found large discrepancies between country vulnerability rankings (Brooks et al., 2005; Eriksen and Kelly, 2007; Leiter et al., 2017b; Visser et al., 2020). Reviews of vulnerability and resilience indices identified "substantial conceptual, methodological and empirical weaknesses" (Füssel, 2010: 8) and a widespread lack of validation (Cai et al., 2018). Using countries as a unit of analysis also masks significant subnational variation (Otto et al., 2015; Mohammadpour et al., 2019). Individual indices therefore "fail to convene a robust guidance for policy makers" (Muccione et al., 2017: 4) and should not present the sole basis for policy decisions (Brooks et al., 2005; Leiter and Pringle, 2018). Due to their limitations (Singh et al., 2017), the OECD suggests that indices are primarily used for "initiating discussion and stimulating public interest" (OECD, 2008: 13).

17.5.2.4 Empirical Evidence of National Adaptation M&E Systems

Tracking the implementation of national adaptation plans is essential for understanding their effectiveness, i.e. the progress made in addressing climate risks, and can support assessing the success of adaptation and the risk of maladaptation. Over 60 countries have developed or started developing national adaptation M&E systems, although less than half are yet reporting on implementation (Leiter, 2021b; Table 17.9). Country-specific adaptation M&E systems vary considerably regarding their legal mandate, purpose, content, involved actors and types of reporting (Hammill et al., 2014a; EEA, 2015; Leiter, 2015; Leiter et al., 2017a; EEA, 2020). In most cases, they focus primarily on monitoring implementation rather than assessing outcomes, although some are linked to national climate risk or vulnerability assessments (e.g. in Germany and the United Kingdom) (EEA, 2018). At least 15 countries have published evaluations of national adaptation plans which help inform the development of successive adaptation plans or strategies (Table 17.9). Nevertheless, there is only limited empirical evidence of the ability of M&E systems to facilitate action or increase the level of ambition of revised policies. More research is needed to determine the quality of national adaptation M&E systems and how well they support the policy cycle.

Under the Paris Agreement countries are encouraged to provide information on adaptation including its adequacy and effectiveness (Möhner et al., 2017; Adaptation Committee, 2021). National adaptation M&E systems can inform both national as well as international reporting and contribute to the global stocktake (see Cross-Chapter Box PROGRESS in this Chapter; Craft and Fisher, 2015; Leiter et al., 2017a). Guidance for and examples of national adaptation progress assessments are provided by Price-Kelly et al. (2015); Brooks et al. (2014); Brooks et al. (2019); EEA (2015); GIZ (2017); Karani (2018); and van Rüth and Schönthaler (2018). Global assessments of adaptation progress have so far often focused on adaptation planning and, to a lesser extent, implementation whilst evidence of the collective effect of adaptation globally remains limited (*high confidence*) (UNEP, 2021a; Cross-Chapter Box PROGRESS in this Chapter).

Table 17.9: Countries in different stages of developing or operating a national adaptation M&E system as of 1 August 2021 (Source: Leiter (2021b). Countries can appear twice if they have published both a progress report and an evaluation.

	National adaptation M&E system		
	Stage	Definition	Country
Under develop-ment	Early stage	Tangible steps have been undertaken to develop a national adaptation M&E system, for example a stocktake of relevant existing data sources and engagement with stakeholders on the objectives of the M&E system	Benin, Cook Islands, Jordan, Paraguay, Sri Lanka, Uganda
	Advanced stage	Details of the adaptation M&E system have been developed, including, for instance, institutional arrangements, indicators and data sources, but it has not yet been applied	Albania, Bulgaria, Cameroon, Canada, Colombia, Ethiopia, Fiji, Grenada, Indonesia, Moldova, Morocco, Mozambique, Nauru, Peru, Rwanda, Senegal, St.Lucia, St. Vincent and the Grenadines, Suriname, Thailand, Togo, Tonga, Turkey, Vietnam

In operation	Adaptation progress report published	A progress report on the implementation of the national adaptation plan or strategy has been published	Austria, Belgium (Flanders), Brazil, Burkina Faso, Cambodia, Chile, Cyprus, France, Germany, Japan, Kenya, Kiribati, Lithuania, Mexico, Netherlands (Delta Programme), Norway, Portugal, Slovakia, Spain, South Africa, South Korea, Switzerland, United Kingdom
	Evaluation published	An evaluation of the implementation of the national adaptation plan or strategy has been undertaken and published.	Belgium, Cambodia, Chile, Czech Republic, Finland, France, Germany, Ireland, Mexico, Netherlands, Philippines, South Korea, Spain, Switzerland, United Kingdom

17.5.2.5 Challenges of Assessing Adaptation

To date, literature has largely focused on aspects prior to implementation such as assessments of climate vulnerability and risks or appraisals of adaptation options (Sietsma et al., 2021; Cross-Chapter Box Adaptation). To understand adaptation progress, the assessment of implemented adaptation actions and their outcomes requires more attention (*very high confidence*) (Cross-Chapter Box PROGRESS in this Chapter).

Outcomes on risk reduction are typically expressed in ways that are specific to the respective sector or context (e.g., as agricultural yields, health benefits or reduced water stress) highlighting that "adaptation has no common reference metrics in the same way that tonnes of GHGs or radiative forcing values are for mitigation" (IPCC, 2014a: 856). Assessments of adaptation progress therefore need to specify what they are measuring and how they are measuring it. The way adaptation is conceptualised, e.g. as a continuum between successful adaptation and maladaptation (Section 17.1.1) and the way adaptation is framed, e.g. as a technical challenge or a political process (Juhola et al., 2011; Bassett and Fogelman, 2013; Eriksen et al., 2015), shape the understanding of progress and its subsequent measurement (Singh et al., 2021).

Furthermore, people can be differently affected even in the same location due to, amongst others, differential vulnerability amongst the population (Reckien and Petkova, 2019; Thomas et al., 2019). Different views and values can also affect what it means to adapt (Few et al., 2021). Assessments of adaptation progress therefore need to be transparent and reflective about how they define and measure adaptation and account for culturally and geographic contingent concepts of what it means to adapt in light of the global diversity of livelihoods and concepts.

The lack of knowledge on adaptation progress is associated with further measurement challenges including that avoided impacts are difficult to measure and that risk levels change over time, meaning what is effective today may not be effective in the future (Brooks et al., 2011; Pringle, 2011; Spearman and McGray, 2011; Villanueva, 2012; Bours et al., 2014a). Moreover, adaptation is embedded in complex political and social realities where power and politics shape outcomes and where simplistic views of how adaptation would take place may be ill-conceived (Nightingale, 2017; Mikulewicz, 2018; Mikulewicz, 2020). In practice this means that theories of change of adaptation projects may miss important causes of risks and could subsequently lead to inaccurate assessments (Forsyth, 2018). Measuring adaptation is therefore a matter of understanding drivers of vulnerability and risk and of designing responses and M&E systems accordingly (UNFCCC, 2019a, section V).

The importance of context and the dependence on viewpoints make comparative assessments of adaptation across nations, regions or responses challenging. Comparison requires a consistent conceptualisation of adaptation, comparable units of analysis and access to relevant datasets (Ford et al., 2015; Ford and Berrang-Ford, 2016). Comparative adaptation policy assessments to date often lack clarity in concepts and explanatory variables (Dupuis and Biesbroek, 2013; Biesbroek R, 2018a). The trade-off between standardisation and context-specificity also complicates attempts to aggregate adaptation progress across scales to the national or global level (Leiter and Pringle, 2018; Cross-Chapter Box PROGRESS in this Chapter).

[START CROSS-CHAPTER BOX PROGRESS HERE]

Cross-Chapter Box PROGRESS: Approaches and Challenges to Assess Adaptation Progress at the Global Level

Authors: Matthias Garschagen, Timo Leiter, Robbert Biesbroek, Alexandre K. Magnan, Diana Reckien, Mark New, Lea Berrang-Ford, So Min Cheong, Lisa Schipper, Robert Lempert

This Cross-Chapter Box responds to a growing demand for assessing global climate change adaptation progress, which currently faces the challenge of lacking consensus on how adaptation progress at this level can be tracked (*high confidence*). The box therefore assesses the rationale and methodological approaches for understanding adaptation progress globally across sectors and regions. It discusses strengths and weaknesses of existing approaches and sources of information, with a view towards informing the first Global Stocktake of the Paris Agreement in 2023.

Rationale for assessing adaptation progress at the global level

Global assessments of adaptation are expected to help answer key questions of climate policy (Ford et al., 2015; UNEP, 2017; Adaptation Committee, 2021) (*low evidence, high agreement,*), including: Do the observed, collective investments in adaptation lead humanity to being better able to avoid or reduce the negative consequences from climate change? Where is progress being made and what gaps remain in the global adaptation response to climate risks?

Whilst more than 170 countries have policies that address adaptation (Nachmany et al., 2019b; 17.4.2), very few have operational frameworks to track and evaluate implementation and results (Leiter, 2021a; 17.5.2.4). In Europe, for example, most countries have adopted a national adaptation plan or strategy, but only few are tracking whether ambitions are realised (EEA, 2020; 13.11.2). Moreover, climate risks are interconnected across scales, regions and sectors (Eakin et al., 2009; Challinor et al., 2017; Cross-Chapter Box INTERREG in Chapter 16; Hedlund et al., 2018) (*high confidence*), complicating causal attribution. National assessments of progress usually do not assess private sector and non-governmental adaptation and barely account for climate risks that transcend across borders, for example through supply chains or shared ecosystems (EEA, 2018; Benzie and Persson, 2019). In addition, adaptation action in one place or time can potentially lead to negative effects elsewhere (externalities) (Magnan and Ribera, 2016; Atteridge and Remling, 2018; 17.5.1). Hence, determining the collective adequacy and effectiveness (see Figure 1.7 in Chapter 1) of adaptation responses is different from simple aggregates of national and sub-national information (UNEP, 2017).

Assessing global progress on adaptation is therefore of high relevance to the scientific community, to policy makers and other actors. Global assessments serve different information needs than local assessments and their meaningfulness depends on the chosen approaches and their limitations. Aggregated global assessments of adaptation progress are therefore not meant to substitute place-specific ones but to complement them to enhance the knowledge base on adaptation beyond actions by or within individual countries. The Paris Agreement stipulates a Global Stocktake to be undertaken every five years to assess the collective progress towards its long-term goals including on adaptation (UNFCCC, 2015, Article 14). Yet very few scientific studies have addressed the adaptation-specific aspects of the Global Stocktake (Craft and Fisher, 2018; Tompkins et al., 2018) and there are different views and options on how assessing global progress could take place (*high confidence*).

Considerations in designing global adaptation assessments

A number of key considerations for the design of global adaptation assessment approaches are discussed in the literature (Ford and Berrang-Ford, 2016; Berrang-Ford et al., 2017). Some of these involve trade-offs, e.g. global applicability vs. context-specificity, for which there is no simple solution. Design considerations directly depend on the objectives of global adaptation assessments, which can differ between actors and can include e.g. providing transparency, enabling accountability, understanding effectiveness, or guiding policy development (Section 17.5.2.1). The underlying objectives determine the suitability of approaches and the data requirements.

Comparability

Global assessments may have the objective to compare adaptation over time and across sectors and regions (Ford et al., 2015). Such comparison requires a consistent definition of concepts (Hall, 2017; Berrang-Ford et al., 2019) and the identification of variables that are both generic enough to be applicable from one context to another and specific enough to illustrate national circumstances. To date, finding such balance has proven to be challenging (Dupuis and Biesbroek, 2013). The context-dependence of adaptation outcomes poses limits for meaningful comparisons. Even people exposed to the same climate hazard may be differentially affected due to varying levels of vulnerability and resilience (Jones et al., 2018; Thomas et al., 2019), meaning that perceptions on adaptation outcomes can also differ (Jones and d'Errico, 2019).

Aggregation

The aggregation of data from local or regional to global scales can take different forms ranging from qualitative synthesis to quantitative aggregation which may involve condensing a diverse set of variables into a single score (Leiter, 2015; 17.5.2.3). In contrast to climate change mitigation, adaptation does not have a global reference metric against which adaptation levels could be assessed to identify progress or gaps. Experience from the Global Environment Facility, for example, has shown that mechanical aggregation based on standardized indicators fails to capture what makes the greatest difference on the ground (Chen and Uitto, 2014).

Results: Input, process, output or outcome

Adaptation progress at any spatial scale can in principle be assessed in terms of input (e.g. resources spent), process (i.e. the way adaptation is organized), output (i.e. adaptation capacities and actions) and outcomes (i.e. actual changes induced) (Section 17.5.2.2). Due to the challenges inherent in measuring adaptation outcomes (Sections 16.3, 17.5.1 and 17.5.2.5), most global assessments to date have focused on outputs, e.g. whether countries have adopted adaptation plans (Berrang-Ford et al., 2021; UNEP, 2021a) (*high confidence*). Understanding the effectiveness of adaptation responses globally requires a way to conceptualize and capture outcomes, for example in terms of effective climate risk reduction, whilst avoiding simplifications that mask maladaptation at the global level, e.g. where climate risks are shifted to other countries, sectors or population groups (Cross-Chapter Box INTERREG in Chapter 16, Section 17.5.1).

Data

Global assessments typically require global availability of consistent data, be it quantitative or qualitative, which has proven to be a constraining factor for attempts to assess global adaptation (*high confidence*). For example, many countries face difficulties in reporting adequately on progress in implementing the Sendai Framework and risk-related SDGs (UNDRR, 2019: vi). The availability of data also influences which variables can be eventually selected in an assessment. This limitation can affect the ability to meet the initial objectives and lead to biases in the framing and interpretation of assessment outcomes. For some variables, an alternative to relying on nationally provided data can be to develop new global datasets (Magnan and Chalastani, 2019), or utilising data from Earth Observation (Andries et al., 2018). Adaptation is hence faced with a dilemma between globally available yet generic data and regionally or locally more detailed yet patchy data (*high confidence*).

Assessment of existing approaches to assess adaptation progress at the global level

Only few global assessments of adaptation progress across sectors have been undertaken to date (*high confidence*). They focus, for example, on whether countries have progressed their adaptation policies and actions over time (Lesnikowski et al., 2015; Nachmany et al., 2019b), the extent of implemented adaptation globally (Leiter, 2021a; Leiter, 2021b), and the type and actors of responses (Berrang-Ford et al., 2021), evidence for reduced vulnerability to climate-related hazards (Formetta and Feyen, 2019; UNDRR, 2019) or adaptation planning in cities across the globe (Araos et al., 2016a; Reckien et al., 2018a; Olazabal et al., 2019a). Each of these assessments draw on different approaches and data, and all have particular potential but also limitations (Table Cross-Chapter Box PROGRESS.1) (*high confidence*). The application of differing approaches shows that there is no single 'best' approach or data source to assess global progress on adaptation (*high confidence*). Existing global assessments have provided valuable insights into the extent and types of responses and their level of planning and implementation (16.3.2.4). They do, however, not provide comprehensive and robust answers so far on whether climate risk and vulnerability have been reduced

(Berrang-Ford et al., 2021) (*high confidence*). As a result, combining different approaches and integrating data on climate risk levels, policy measures, implemented actions and their effects on climate risk reduction is currently regarded the most robust approach (Berrang-Ford et al., 2019) (*medium evidence, high agreement*).

Table Cross-Chapter Box PROGRESS.1: Key approaches and data sources used for global adaptation assessments.

Approach / Data source	Potential added-value	Limitations
Systematic assessment of adaptation responses reported in academic literature (e.g. systematic reviews, evidence synthesis, meta-analysis, large-n comparative studies) Examples: Berrang-Ford, 2011 #188}, Global Adaptation Mapping Initiative (Berrang-Ford et al., 2021)	Provides an indication of the status, trends and gaps in adaptation responses	Not a representative sample; biased towards responses published in scientific literature; excludes grey literature; some topics and regions not well covered; challenges in terms of comparability and aggregation; inconsistency in definitions and use of concepts; English language bias
Self-reported progress documents by countries (e.g. National Communications, Biennial Transparency Reports or domestic progress and evaluation) Examples: (Gagnon-Lebrun and Agrawala, 2007; Lesnikowski et al., 2015; Lesnikowski et al., 2016; Leiter, 2021a)	Context-specific information; official government documents enable assessments of national progress	May only be available every few years; content is sensitive to political and policy changes; possible bias towards positive examples; challenges in terms of comparability and aggregation; inconsistency in definitions and use of concepts
Self-reported information from the private sector (e.g. information on actions taken in response to climate risks within the context of climate-related financial disclosure or in company reports). Examples: (Committee on Climate Change, 2017; Street and Jude, 2019; UNFCCC, 2021), responses reported under Climate-related Financial Disclosure	Provides an indication of the status, trends and gaps in adaptation responses by the private sector; complements information published in the scientific literature; could enable better understanding of supply chain risks	Sample biased towards larger companies; challenges in terms of comparability and aggregation; potential inconsistencies in definitions and use of concepts
Project documents and evaluations (e.g. from climate funds or implementing organisations) Examples: (Leiter, 2021b); (Eriksen et al., 2021)	Detailed information on context, intended or achieved results and activities	Actual implementation can differ from what was proposed; fragmented picture of local/regional actions; results may be challenging to aggregate; challenges in terms of comparability and aggregation; inconsistency in definitions and use of concepts
Existing global data sets of mostly quantitative indicators Examples: United Nations (UN, 2016a; UN, 2016b; UN, 2019; UNDRR, 2019)	Comparable information based on globally defined indicators	Global data availability constrains indicator choice; reporting burden for new indicators; trade-off between global applicability and national circumstances; usefulness and meaningfulness of global indicators is contested (Leiter and Pringle, 2018; Lyytimäki et al., 2020; Pauw et al., 2020).
Tracking financial flows Examples: (CPI, 2019), (OECD, 2018a), (MDBs, 2019)	Comparable data on financial flows directed at adaptation; standardised methodologies (e.g. OECD RIO markers; climate	No information about implementation of measures and their adaptation effect (Eriksen et al, 2021), i.e. it tracks inputs, not

	finance tracking method of multilateral development banks; chapter 17.5.2.6; Cross-Chapter Box FINANCE in this Chapter)	outputs or outcomes; inconsistency in what gets counted as adaptation finance (Donner et al., 2016; Doshi and Garschagen, 2020); evidence of over-reporting (Michaelowa and Michaelowa, 2011; Weikmans et al., 2017)

Conclusion -- Combining approaches for assessing adaptation progress at the global level

Understanding to what extent the world is on track to adapt to climate change impacts and risks globally is a pressing question in scientific and policy communities, especially in light of the Global Stocktake under the Paris Agreement. Important considerations for a robust assessment framework (e.g. consistency), as well as the associated scientific challenges (e.g. aggregation, externalities, breath vs. depth of data) and the role of underlying objectives (e.g. on the contested issue of comparability) are increasingly understood (*high confidence*). There is also a growing and diverse body of information on adaptation progress, although most assessments of global progress undertaken to date focus on processes and outputs (e.g. policies and plans) rather than outcomes (i.e. risk reduction). A variety of approaches and data sources are employed, such as systematic reviews of observed adaptation, formal communications by Parties to the UNFCCC, and project documents to international funding agencies. Novel approaches, including big data tools (Ford et al., 2016; Biesbroek et al., 2020), are also being explored but still have to prove their practical value. Each approach and source of information can contribute additional knowledge, but also demonstrates limitations, so that there is no single 'best' approach (*high confidence*). Yet to date, the international community has not sufficiently explored the relative strengths and weaknesses of different approaches and their applicability, and therefore their potential synergies in complementing each other. Triangulated assessments have only rarely been applied (*high confidence*) due to multiple conceptual and methodological challenges, despite their potential for increasing the robustness of knowledge. One overarching conclusion of this Cross-Chapter Box therefore is that the combination of different approaches will provide a more comprehensive picture of global adaptation progress than is currently available from individual approaches (*low evidence, high agreement*).

[END CROSS-CHAPTER BOX PROGRESS HERE]

17.5.2.6 Tracking Adaptation Finance

Adaptation finance tracking is capturing the financial flows associated with adaptation. It can indicate how much is being spent on adaptation, where funds are going to, and whether spending matches allocated budgets. Thus, adaptation finance tracking can provide useful information for decision making, but it does not provide information on the achievements resulting from the invested funds. Accordingly, it can complement, but not substitute, M&E of actions and outcomes. Adaptation finance tracking can be applied domestically (Guzmán et al., 2017; Guzmán et al., 2018) as well as internationally, for instance by developed countries to report on the goal to mobilize US$100 billion a year by 2020 in climate finance (UNFCCC SCF, 2018). Data on adaptation finance can be used alongside information on planning and implementation to assess adaptation progress (UNEP, 2021a).

Tracking adaptation finance requires defining what counts as adaptation. Different definitions can lead to large variations in the estimated amount of adaptation finance (Donner et al., 2016; Hall, 2017). A further challenge is how to account for adaptation that is mainstreamed, i.e. where adaptation-specific investments form only part of a larger programme or budget line, or where actions contribute to adaptation without being labelled as adaptation. These challenges limit the direct comparability between adaptation and mitigation finance (UNFCCC, 2019a). In fact, tracking adaptation finance differs from tracking mitigation finance since activities cannot be a-priori assumed to constitute adaptation but instead have to be assessed for their linkage to climate risks in a particular context (MDBs & IDFC, 2018). Methods for adaptation finance tracking continue to be further developed aiming at better comparability and completeness (Richmond and Hallmeyer, 2019; Richmond et al., 2021).

Various methods are used to track adaptation finance, which makes comparisons between adaptation finance figures challenging (UNFCCC SCF, 2018; Weikmans and Roberts, 2019). For example, multilateral development banks use a different methodology than countries do under the OECD Development Assistance Committee (DAC) (see Box 17.4; MDBs, 2019). One of the differences concerns the treatment of partially adaptation-relevant projects, namely whether only parts or the full amount of a given project volume are counted as adaptation finance (see e.g. MDBs, 2019). Under the OECD DAC methodology, countries often use a fixed percentage (e.g., 50% of the total project value) whereas the MDB methodology attempts for a project-specific estimation of the adaptation-relevant proportion (MDBs & IDFC, 2018). Another aspect is whether tracking distinguishes between financial instruments, e.g., grants or loans. Different accounting rules can lead to large differences in reported amounts of adaptation finance and to a lack of comparability between providers (Weikmans and Roberts, 2019). Studies identified an over-reporting (i.e., counting non-adaptation related finance) by a factor of two to three, which suggests the need for a more consistent and transparent accounting system (Weikmans et al., 2017; CARE, 2021).

Good coverage of adaptation finance data exists around international public finance flows, predominantly official development assistance flows from OECD DAC members and from multilateral development banks. Less data exists around domestic public finance and private finance flows to adaptation activities, but data sources continue to be further expanded e.g. through climate change expenditure tagging and city-level data (Weikmans et al., 2017; UNFCCC SCF, 2018; Richmond et al., 2021). Recent estimates of adaptation finance are provided in UNFCCC SCF (2018); Macquarie et al. (2020); and in Cross-Chapter Box FAR.

[START BOX 17.4 HERE]

BOX 17.4: The Rio Markers Methodology to Track Climate Finance

The OECD Development Assistance Committee (DAC) introduced a methodology to track the amount of bilateral official development assistance (ODA) that is targeting climate change mitigation and/or adaptation. It distinguishes whether activities have adaptation as a "principal" objective (score "2"), as a "significant" objective (score "1"), or as not targeting it (score "0") (OECD, 2016). The associated project value is counted in full, in part, or not counted as adaptation finance, respectively. Countries count the volume of partial adaptation projects (score "1") to a different extent which limits comparability and can lead to over-reporting (OECD, 2019a). The first data on this "adaptation marker" became available in 2012 for the financial flows of 2010. It forms the basis for developed countries' reporting to the UNFCCC Secretariat on their financial commitments towards developing countries (Weikmans and Roberts, 2019).

While a guidebook with requirements for adaptation as a principle or significant objective has been developed (OECD, 2016), several studies have shown that OECD DAC donors tend to overestimate the number of activities in their portfolio that genuinely have adaptation objectives (Michaelowa and Michaelowa, 2011; Weikmans et al., 2017; CARE, 2021). Hence, the amount of adaptation finance from public sources may be lower than reported. The use of just three categories leads to a broad range of the extent of adaptation being concentrated in the middle category ("significant objective"). Accordingly, the category "principle objective adaptation" provides a more robust predictor of the relevance of an activity to adaptation (Donner et al., 2016).

[END BOX 17.4 HERE]

17.5.2.7 Evaluation and Learning

Most adaptation M&E frameworks and tools proposed to date refer to monitoring rather than evaluation (*high confidence*) (Adaptation Committee, 2016). Evaluations are envisioned to go beyond monitoring by examining how and why results have been achieved and what could be improved (Brousselle and Buregeya, 2018; Vähämäki and Verger, 2019). Evaluations of adaptation outcomes are still rare, particularly quantitative impact evaluations (Weldegebriel and Prowse, 2013; Das, 2019; Béné et al., 2020). Impact evaluations of adaptation need to address several methodological as well as practical challenges (Dinshaw et al., 2014; Fisher et al., 2015; Béné et al., 2017; Puri et al., 2020). Different types of evaluations are appropriate for different evaluation questions (Silvestrini et al., 2015). Evaluations of the available evidence of effective adaptation in particular topics or sectors have emerged more recently, for instance on mainstreaming (Runhaar et al., 2018) and agricultural climate services (Vaughan et al., 2019a). Impact evaluations of capacity building measures are important because capacity building is assumed to lead to adaptation, but its actual effects are seldom examined (Mortreux and Barnett, 2017; Alpizar F and Meiselman, 2019). If well designed and utilised for learning, evaluations can play an important role in improving adaptation responses (Hildén, 2011).

Learning requires information about how and why change occurred and what experiences have been made (Feinstein, 2012). M&E is frequently associated with learning, but it is rarely made explicit how learning is supposed to take place (Armitage et al., 2008; Baird et al., 2015; Borras and Hølund, 2015). The design of adaptation M&E systems can support learning by gathering relevant information and disseminating it in a way that is accessible and effectively linked to decision making processes (Spearman and McGray, 2011; Villanueva, 2012; Fisher et al., 2015). Options include institutionalised feedback mechanisms, peer learning and knowledge sharing events, a learning culture and ways to gather in-depth insights beyond indicators (ibid; Oswald and Taylor, 2010). Since AR5, adaptation programmes and funds such as the BRACED programme, the Adaptation Fund, the Climate Investment Funds and the Green Climate Fund have created knowledge-sharing units and provide resources to support learning activities(BRACED, 2015; Roehrer and Kouadio, 2015; Adaptation Fund, 2016; Leavy et al., 2018; CIF, 2020; Puri et al., 2020), but there is little information about their longer-term effectiveness.

17.6 Managing and Adapting to Climate Risks for Climate Resilient Development

Actions to ameliorate a climate risk have consequences beyond the immediate effects on exposure or vulnerability to a hazard. They may aim to combat many risks, could adversely interact with other risks and actions, or may be nested within a suite of actions across many risks. Some actions may have negative consequences for climate resilient development. In this broader context, the effectiveness of adaptations for supporting climate resilient development is now better articulated (Box 17.1). Importantly, adaptations need to be designed to not only combat current and future climate risks, but also ensuring that they do not lock in undesirable pathways in the future as risks develop and change (*very high confidence*) (17.2, 17.3.1, 17.5). Effective management of climate risks will therefore be dependent on satisfactorily managing current climate risks (Box 17.1, 17.2, 17.5), coupled with assessing prognoses for future climate risks, and developing responses in advance for reducing those risks to tolerable residual levels (*very high confidence*) (1.4, 1.6, 16.6, 17.2, Box 16.1; e.g. water risks - 4.7.1). The dynamic nature of risk (Viner et al., 2019; Simpson et al., 2021; 16.3, 16.6) also means that the contribution of current adaptations to ameliorating future risks needs to be regularly reviewed (*high confidence*) (17.5.2). Across the Working Group II report are examples of how managing adaptations to ameliorate climate risks can negatively or positively affect sustainable development, thereby impacting the potential for climate resilient development discussed in Chapter 18. Drawing on the assessment of sectoral and regional chapters in this report, this section examines three broad components for orienting decision-making for climate adaptation towards climate resilient development.

17.6.1 Need for Integrated Risk Management

The complex, interacting and compounding nature of climate risks means that single risks cannot be managed in isolation (*very high confidence*) (16.5, Figure 16.11; 17.3.2; Nhamo et al., 2018), including accounting for potential risks arising from adaptations (Simpson et al., 2021). Regional examples of needs for cross-sectoral integrated management include the water-energy-food nexus in Africa (10.5.1), Asia (10.6.3), Australasia (11.6), Europe (13.2.2) and North America (Table 14.8), and ecosystem-oriented adaptations and/or nature-based solutions, in Africa (9.6.5), Asia (10.4.2), Australasia (Box 11.4, 11.3.5), Central and South America (12.5.1), Europe (13.3.2), North America (14.6.1, Box14.3) and Small Islands (15.5.4). The cross-sectoral interactions within humans systems, including impacts on cities, settlements and infrastructure, are reflected in those subjects as well as for health in Africa (9.10.2), Asia (10.4.5), Australasia (11.3.6), Central & South America (12.5.6), Europe (13.7.2), North America (14.6.1), and Small

Islands (15.6.2), and poverty and livelihoods in Africa (9.11.3), Asia (10.4.5, 10.5), Australasia (11.4), Central & South America (12.5.7), Europe (13.8.2), North America (14.6.1), and Small Islands (15.3.4). These examples demonstrate that the emergence of climate risks can be at different rates, different time horizons, and the interactions between risks vary from region to region (*very high confidence*). The need to manage these risks in an integrated manner is readily identified in the Water-Energy-Food nexus (Box 9.5). However, in terms of climate resilient development, the need for integration is demonstrated by the diverse and interacting impacts of climate risks on ecosystems (2.7, 3.6), cities (6.2.3, 6.2.4, Box 6.2, 6.3), health (7.4), and poverty and livelihoods (8.6).

17.6.2 Strategies for Managing a Portfolio of Climate Risks

Since WG2 AR5, new methods for simultaneously considering multiple societal and sectoral objectives, climate risks and adaptation options have emerged (17.3.2; Adam et al., 2014; Hadka et al., 2015; Garner et al., 2016; Rosenzweig et al., 2017; Giupponi and Gain, 2017a; Stelzenmuller et al., 2018; Marchau et al., 2019), including methods for accounting for different sources of uncertainty and types of risk (17.3.1; Giupponi and Gain, 2017a). Different decision-making approaches can be complementary (*high confidence*) (17.3.1; Kwakkel et al., 2016) and multiple approaches will likely be necessary in managing the risks across sectors, over different spatial scales, and over short to long time scales (*medium confidence*) (Cross-Chapter Box PROGRESS in this Chapter; Girard et al., 2015; Rouillard and Spray, 2016).

Deciding on which adaptations to adopt when managing climate risks inevitably needs examination of trade-offs in outcomes *(very high confidence*) (17.3.1, 17.5.1; Cross-Chapter Box FEASIB in Chapter 18). A current difficulty with integrated assessments is to develop a set of metrics that are appropriately scaled for the different sectors or outcomes to be compared (e.g., 12.5.2.6; 17.3.1; 17.5.2; Cross-Chapter Box PROGRESS in this Chapter). For climate resilient development, dimensions of poverty, equity, justice, and health need to be factored into analyses (Box 17.1, 17.5), many of which are difficult to quantify (*high confidence*) (18.2.4). Moreover, uncertainties on the interactions within and between sectors can make trade-off analyses uneven in their precision across sectors and uncertain as to the outcome of an implemented adaptation (*medium confidence*) (4.7.2, 17.4, 17.5).

Expertise and resources for using tools and approaches for integrated risk management varies between the developed and developing countries (*high confidence*) (e.g. 4.7.2). Exploration of adaptation scenarios can be derived from Earth System Models (high confidence) (e.g. 4.7.1.2, 11.7.3.1). However, the feasibility of possible adaptations and the degree to which they are likely to be effective (Box 17.1) will require further exploration as success will depend on appropriate enabling conditions including institutional support and capacity, available financial resources and knowledge, and suitable conditions for stakeholder participation (*high confidence*) (17.4). The current levels of uncertainty surrounding the effectiveness of many adaptation options (17.5.2; Cross-Chapter Box PROGRESS in this Chapter) means that decision-making approaches applicable to deep uncertainty (Cross-Chapter Box DEEP in this Chapter; 17.3.1) will apply in many if not most cases (*medium confidence*). An early step in identifying suitable integrated pathways for managing climate risks, establish 'no regrets' anticipatory options in a timely manner, and avoiding path dependencies, is to jointly map the steps for adapting to sectoral risks, and determine suitable ways to avoid maladaptations arising (*high confidence*) (17.3.1, Cross-Working Group Box URBAN in Chapter 6 and Cross-Chapter Boxes DEEP in this Chapter). The application of Dynamic Adaptive Pathway planning has been successfully used in this way in Australasia (11.7.3) and Europe (13.6.2.2, 13.10.2) (Lawrence et al., 2019a; Haasnoot et al., 2020a). Current experience suggests that synergies between sectors can save resources and effort (*limited evidence*) (13.11.2). Iterative processes can then enhance adaptation programs by including more detailed modelling and updated knowledge as the experience is acquired (17.3.1).

17.6.3 Mainstreaming Climate Risk Management in Support of Climate Resilient Development

This chapter has assessed and detailed a number of decision-making tools (17.3) and enabling mechanisms and catalysing conditions (17.4) that could be used in mainstreaming the management of climate risk and adaptation in the sustainable development of communities, different sectors and nations. Since AR5, the challenges facing the management of climate risks have been articulated (Adger et al., 2018; Balasubramanian, 2018) and greater clarity on the steps that could be taken to better mainstream adaptation has been developed (*high confidence*) (Cuevas, 2016; Giupponi and Gain, 2017a; Gomez-Echeverri, 2018;

Sanchez Rodriguez et al., 2018). Nevertheless, the choice of decision processes is recognized as being dependent on a variety of local factors influencing development (Ayers et al., 2014; Szabo et al., 2016).

Adaptation strategies or plans, some of which incorporate elements of climate resilient development, have been developed in many jurisdictions from local (Cuevas, 2016; Araos et al., 2016a; Reckien et al., 2018a; Göpfert et al., 2019) to provincial/state (Warnken and Mosadeghi, 2018) to national governments (Markolf et al., 2015; CSIRO, 2018; Warnken and Mosadeghi, 2018; Brown et al., 2018a; Table 17.9). National Adaptation Plans have been a requirement under the UNFCCC and establish the general approach taken by nations for adapting to climate change (Woodruff and Regan, 2019). Integrated risk assessments and adaptation processes are being developed but with much less experience evident in their implementation (*high confidence*) (Wise et al., 2014; Woodruff and Stults, 2016; Brown et al., 2018a).

National Adaptation Plans (NAPs) submitted to the UNFCCC have been reviewed for quality by Woodruff and Regan (2019). In their review, Woodruff & Regan used a number of indicators grouped within established "quality principles". They found that the plans were more oriented at the strategic level or at the level of specific projects rather than identifying methods for resolving cross-sectoral or cross-jurisdictional interactions or issues (*medium confidence*). A key recommendation from their review and supported by other studies (e.g. Abutaleb et al., 2018) is that plans would be improved greatly by having inputs from multiple government agencies and multiple sectors (*medium confidence*), which could provide the basis for planning and review of integrated adaptation. Also, the plans need greater attention to implementation (9.4.1, 11.8, 13.11.2), and the identification of metrics by which success (17.5.1) and performance can be measured (Cross-Chapter Box PROGRESS in this Chapter), a common issue for adaptation planning generally (e.g. 12.5.2.6, 17.5).

Hence, satisfactorily managing intersecting climate risks in different settings, of which RKRs provide examples, is central to achieving sustainable development (*high confidence*) (16.6.4), requiring integrated risk management within and across regions, jurisdictions, sectors and ecosystems (*high confidence*) (more cross references please CCP5.4.2; CCP5.4.3). Iterative processes will enable measuring progress and updating adaptation at a satisfactory rate, in order to account for the different needs within regions and across sectors at different times (*high confidence*). The degree to which equity and justice will be achieved will be determined by the participatory processes in deciding on suitable adaptation options, the investment in the adaptation processes and the coordination and collaboration built amongst institutions and people across regions (*high confidence*).

[START FAQ17.1 HERE]

FAQ17.1: Which guidelines, instruments and resources are available for decision-makers to recognize climate risks and decide on the best course of action?

Guidelines, instruments, and resources to identify options for managing risks, and support decisions on the most suitable course of actions to take, can be collectively referred to as decision-support frameworks. These can include data services, decision-support tools, processes for making decisions and methods for monitoring and evaluating progress and success. Data services enable the identification, location and timing of risks that could manifest with negative impacts, as well as potential opportunities. Often, these are termed 'climate services' and assist with mapping hazards and how they are changing. Decision-support tools range from qualitative approaches to determine overlap of areas of concern with those hazards in the future, to more quantitative and dynamic simulation approaches that enable dynamic stress-testing of adaptation options and strategies to determine if proposed plans for adapting to the future could be successful. An important consideration is whether options for risk management or capitalisation on opportunities will limit options and flexibility for responding to unforeseen events in the future. If these options have a negative effect on other areas of concern, then they could be identified in these planning scenarios as maladaptations, and therefore avoided.

A great challenge for decision-makers is how to choose effective options when the future is uncertain. Uncertainty can arise not just in the statistical error of the magnitude of risk but also in the nature and consequence of risk from uncertainty about mechanisms that link areas of concern to hazards, uncertainty in the decision processes itself and so on. Methods are available to help develop no-regret options, commonly referred to as "decision making under conditions of deep uncertainty". Decision-support frameworks are most successful when they are iterative, integrative, and consultative. Rather than a single decision be made, and an action taken, there are processes for making the best decision possible then monitoring progress toward delivering a successful outcome. Given a set of suitable indicators with regular monitoring, decisions can be revised, updated, or changed as the future unfolds and foundations for the original decision tested. This is important because climate responses need to be initiated well in advance of them being needed due to the time required to implement suitable responses. These forward-looking approaches allow errors to occur and corrections made before problems arise. They also enable action to be taken without having to wait for the circumstances to arise, which if this were to occur could result in only limited reactions being available and the outcomes then dependent upon recovery from events rather than proactive planning and avoidance of events. Integrated approaches to risk management are available to help manage portfolios of interacting risks, including the potential for compounding and cascading risks when climate-related events arise.

Managing uncertainty with forward-looking processes needs to be more deliberative and oriented towards building trust in a collaborative process. Building relationships through informal, bottom-up processes enables this to occur. Top-down planning processes are important for ensuring the management of risks and opportunities do not end up with maladaptations and that the approaches are equitable and proportional to that which is needed to manage the risks.

[START FAQ17.2 HERE]

FAQ17.2: What financing options are available to support adaptation and climate resilience?

What do we mean by "climate finance"?
The UNFCCC has no formally agreed definition of climate finance. The current IPCC definition is: "*the financial resources devoted to addressing climate change by all public and private actors from global to local scales, ~~i~~including international financial flows to developing countries to assist them in addressing climate change"* (see Annex I: Glossary).

What needs to be financed?
Financial resources might be needed for a range of adaptation and resilience building activities. These include research, education and capacity building; development of laws, regulations, and standards; provision of climate services and other information; reducing the vulnerability of existing assets, activities, and services; and ensuring future development - such as new infrastructure, settlements, health services and business activities - is climate resilient. Finance is also needed to recover and rebuild from the damage of climate hazards that cannot be completely avoided through adaptation. Adaptation actions can be undertaken by many different actors, alone or in partnership, including national and sub-national governments, public and private utilities, businesses of varying size, communities, households, and individuals.

Table FAQ17.2.1 Examples of adaptation and resilience activities that might need to be financed

Training of agricultural extension officers so that their advice to small-holder farmers can support implementation of climate adapted agriculture. Additional financial support is needed for the costs of farmers transitioning to climate resilient agricultural practices.	A new urban development requires higher standards (and up-front costs) for buildings, roads, stormwater systems, water re-use and to be resilient to expected changes in heavy rainfall, runoff, temperature, and water supply reliability.
A water utility requires capital expenditure to increase supply through a desalination plant and to reduce leakage from its reticulation system in response to a scenario of	A catastrophe risk insurance facility is established to provide post-disaster (drought, hurricane, flooding, pest outbreaks) recovery finance to national governments.

reduced surface water availability and an increase in customers.	The facility requires capital to be able to underwrite the insurance products it offers.

How much finance is needed?

The amount of adaptation finance depends on global, regional, and local factors, including: the amount and timing of global warming, how this translates into impacts and adaptation needs across the world; the levels of adaptation already in place; the type of risk being adapted to; and the adaptation options being chosen, including whether the adaptation required is incremental or transformational.

The most mentioned figure for finance need is the developed countries commitment to provide USD 100 billion per year by 2020 to support developing countries efforts in mitigation and adaptation. Negotiations will start in 2021 on updating this amount for 2025. While sometimes thought to represent the actual cost of responding to climate change in developing countries, this is not the case. More recent estimates of the global cost of adaptation by 2030 across developed and developing countries range between about USD 80-300 billion per year.

What types of finance are available?

Four main types (or instruments) of finance are currently being used to support adaptation. These different types are not mutually exclusive; grants can be combined with loans to provide blended finance.

Table FAQ17.2.2 The main instruments through which adaptation is being financed

Grants provide finance without any repayment requirements. Most grants for adaptation have been provided by multilateral funds such as the Green Climate Fund or a fund managed by a single OECD country such as Germany's International Climate Initiative. Some countries have national climate or environment funds that provide grants for their own climate adaptation actions. Grants are also provided by philanthropic foundations and sometimes by companies as part of their environmental and social responsiveness mandate.	**Concessional loans** require partial repayment of the finance provided. These involve either capital repayment coupled to below market interest rates or capital repayment only. Concessional finance is almost entirely provided through multilateral development banks such as the World Bank. This finance is particularly important for developing countries where market interests are high due to poor credit ratings or other risk factors, or where the return on investment is too low make a commercial loan viable.
Non-concessional loans (or debts) are commercial instruments, where capital repayment and market interest rates apply. These may be provided through development banks or private banks. Green bonds are a relatively new form of market loan, designed to meet climate and other environmental sustainability criteria in terms of how the proceeds are used. In recent years green bonds have offered better interest than ordinary bonds due to oversubscription by investors who are looking to move towards environmentally sustainable investment portfolios.	**Budget reallocation** does not require raising of new finance; rather it involves moving funds already secured away from other purposes towards adaptation. In government, this might involve reallocation towards flood defence. In the private sector a company might move budget from marketing, research and development, or perhaps dividends, towards increasing the climate resilience of operation, infrastructure or their value chain.

Where are different types of finance most useful?

Grants are useful for a range of adaptation actions where it is hard to generate a financial return. These include capacity building activities, piloting new adaptation innovations, high risk investment settings, or projects where there are considerable non-financial benefits. In contrast loans and other debt instruments can often support larger investments, for example for scaling out of successful pilot projects or for building adaptation and resilience into general development investment. To date, a large proportion of international climate finance for adaptation in developing countries, especially in sub-Saharan Africa and Oceania has been grant led, sourced from OECD public funds, indicating that in many instances financing via loans is either considered too risky by the commercial investment sector or it has been hard to demonstrate sufficient return on investment.

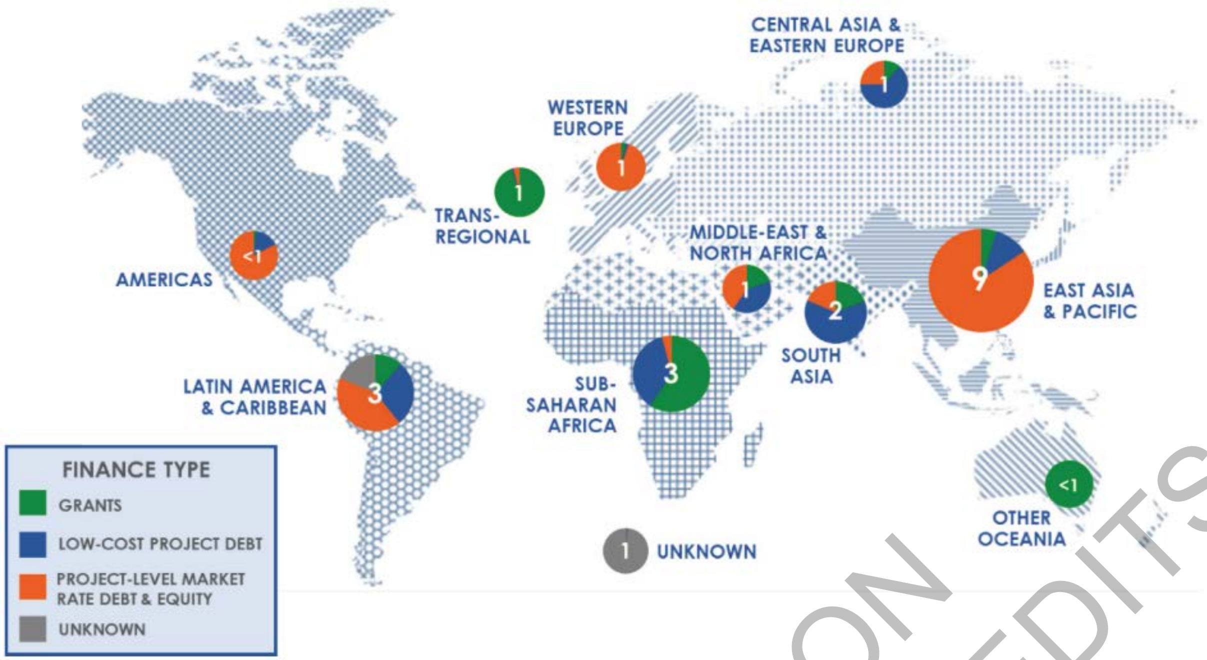

Figure FAQ17.2.1. The distribution of adaptation finance across different regions and different types of finance in 2015-2016, as tracked the Climate Policy Initiative. The size of each circle represents the amount of finance, with amount in billions USD superimposed. Based on data tracked by the Climate Policy Initiative.

[END FAQ17.2 HERE]

[START FAQ17.3 HERE]

FAQ17.3: Why is adaptation planning along a spectrum from incremental to transformational adaptation important in a warming world?

In a warming world, incremental adaptation, i.e. proven standard measures of adaptation, will not always suffice to adjust to the negative impacts from climate change leading to substantial residual risks and, in some cases, the breaching of adaptation limits; transformational adaptation, involving larger system-wide change (as compared to in system change), will increasingly be necessary as a complement for helping individuals and communities to cope with climate change. As an example of incremental adaptation, a farmer may decide to use drought-tolerant crops to deal with increasing occurrences of heatwaves. With further warming and increases in heat waves and drought, however, the impacts of climate change may necessitate the consideration of system-wide change, such as moving to an entirely new agricultural system in areas where the climate is no longer suitable for current practices; or switching to livestock rearing. Where on-site adaptation becomes infeasible and pull factors exist, the farming households may decide to seek employment in other sectors, which may also lead to migration for work. As another example, physical protection through sea walls to stop coastal flooding is a proven adaptation measure. With further projected flooding due to increasing sea level rise attributable to climate change transformational city planning, that would systemically change how flood water is managed throughout the whole city requiring deeper institutional, structural, and financial support, may become necessary. Also, the deliberate relocation of settlements (managed retreat) is seeing attention in the face of increasingly severe coastal or riverine flooding in some regions. While transformational adaptation is increasingly being considered in theory and planning, implementation is only beginning to see attention.

[END FAQ17.3 HERE]

[START FAQ17.4 HERE]

FAQ17.4: Given the existing state of adaptation, and the remaining risks that are not being managed, who bears the burden of these residual risks around the world?

A warming climate brings along increasing risks, part of which can be reduced or insured. What remains is called residual risks and needs to be retained by households, the private and public sectors. People living in conflict-affected areas benefit only marginally from adaptation investments by governments, private sector, or other institutions. These people bear most of the changing climate risks themselves. Higher-income countries generally have invested heavily in structural adaptation to make sure people are not exposed to extreme events (e.g. dykes) and have developed a variety of private or public insurance systems to finance the risk of the most rare or extreme events. In other, middle or lower-income countries, these very extreme events are less likely to be insured, and the impacts are borne by the most vulnerable people. Absent risk reduction or insurance, coping with residual risks generally means reducing consumption (e.g. food) or drawing down assets (selling machinery, houses etc), which all can bring along longer-term adverse developmental implications. Adaptation investments in low-income countries tend to focus more heavily on increasing capacity and reducing vulnerability; people remain exposed to the changing climate risks, and bear the burden of reacting and responding.

[END FAQ17.4 HERE]

[START FAQ17.5 HERE]

FAQ17.5: How do we know whether adaptation is successful?

Adaptation aims to reduce exposure and vulnerability to climate change by responding to dynamic and multi-scalar combinations of climatic risks. What might be seen as successful at one scale or at one point in time might not be at another, particularly if climate risks continue to rise. Moreover, the benefits of adaptation interventions may not reach all intended beneficiaries or everyone affected by climate impact and risk, causing different people to have different views on how successful adaptation has been.

There is, therefore, no universal way to measure adaptation success, but there is high agreement that success is associated with a reduction of climate risks and vulnerabilities (for humans and ecosystems) and an equitable balancing of synergies and trade-offs across diverse objectives, perspectives, expectations, and values. Adaptation that is successful is also commonly expected to be inclusive of different socio-economic groups, especially the most vulnerable, and to be based on flexible and integrative planning processes that take into account different climate scenarios.

Conceptually, the opposite of successful adaptation is maladaptation, i.e. when adaptation responses produce unintended negative side effects such as exacerbating or shifting vulnerability, increasing risk for certain people or ecosystems, or increasing greenhouse gas emissions. Among the adaptation options assessed in this report (Figure FAQ 17.5.1), physical infrastructure along coasts (e.g., sea walls) has the highest risk for maladaptation over time through negative side-effects on ecosystem functioning and coastal livelihood opportunities. However, such adaptations may appear valuable in the short and even longer term for already densely populated urban coasts, demonstrating that an adaptation can be differently judged based on the context it is implemented in (Figure FAQ 17.5.1). Many other adaptation options have a larger potential to contribute to successful adaptation (Figure FAQ17.5.1), such as nature restoration, providing social safety nets, and changing diets/ minimizing food waste.

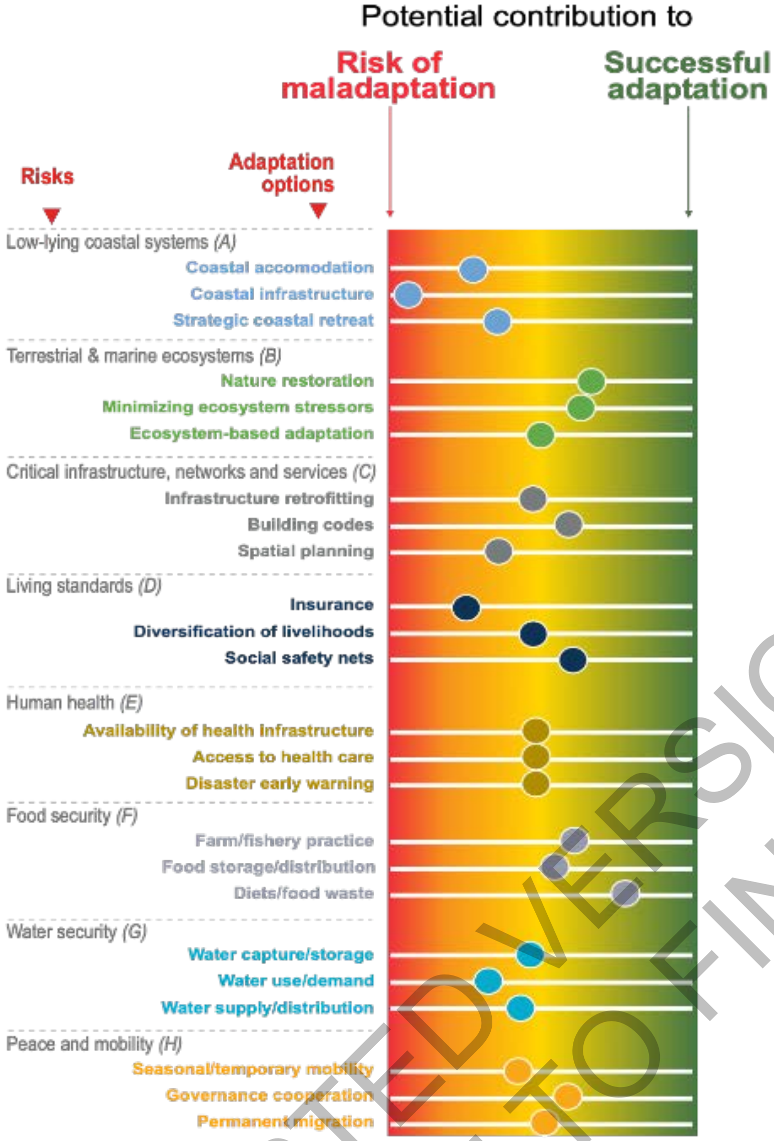

Figure FAQ17.5.1: Contribution of adaptation options to potentially successful adaptation and to the risk of maladaptation. Note: A similar figure is part of Ch17.5.2.

Assessments of adaptation need to be transparent about how they are measuring success. Monitoring and Evaluation (M&E) can be used to track progress and evaluate success and to identify if course corrections during adaptation implementation are needed to achieve the envisaged objectives. Given the diversity of adaptation actions and contexts, no one-size-fits-all approach to M&E and no common reference metrics for adaptation exist. To date, assessments of progress of adaptation have often focused on processes and outputs (i.e. actions taken, such as adaptation plans adopted) that are easier to measure than the effects of these actions in terms of long-term reduction of risks and vulnerabilities. However, knowledge about the outcomes in terms of reducing climate risk, impact and vulnerability is critically required to know if adaptation has been successful.

Tracking progress, in particular outcomes and impacts of adaptation, involves a number of challenges. First, in order to determine progress over time, risk and vulnerability assessments need to be repeated at least once after starting an adaptation process. This is rarely done, as it demands resources that are usually not factored into the adaptation response. Second, attributing changes in climate risks and vulnerabilities to the adaptation response is often difficult due to other influencing factors, such as socio-economic development over time. Expected causal relationships between responses and their outcomes should already be outlined during the adaptation planning phase, for example by mapping the way from activities to outcomes, and they should be monitored during implementation. Third, as adaptation can occur in multiple forms and target multiple temporal and spatial scales, the engagement of a diversity of stakeholders is vital to understand how responses enable adaptation and adaptation success across vulnerable groups. Though, stakeholder engagement can be time intensive and costly, in particular when reaching out to populations that are usually not part of policy and planning processes it can support evaluating co-benefits and trade-offs of adaptation responses. Consideration and analysis of co-benefits and trade-offs along with a focus on short, medium, and long time horizons of adaptation goals, which is usually possible through flexible and strong institutions, facilitate successful adaptation and reduce the likelihood of maladaptation.

Executive Summary

Climate resilient development (CRD) is a process of implementing greenhouse gas mitigation and adaptation options to support sustainable development for all (18.1). Climate action and sustainable development are interdependent processes and climate resilient development is possible when this interdependence is leveraged. Pursuing these goals in an integrated manner increases their effectiveness in enhancing human and ecological well-being. Climate resilient development can help build capacity for climate action, including contributing to reductions in greenhouse gas emissions while enabling the implementation of adaptation options that enhance social, economic and ecological resilience to climate change as the prospect of crossing the 1.5°C global warming level in the early 2030s approaches (WG1 Table SPM1). For example, incorporating clean energy generation, healthy diets from sustainable food systems, appropriate urban planning and transport, universal health coverage and social protection, can generate substantial health and wellbeing co-benefits (*very high confidence*[1]) (7.4.4, Cross-Chapter Box HEALTH in Chapter 7). Similarly, universal water and energy access can help to reduce poverty and improve well-being while making populations less vulnerable and more resilient to adverse climate impacts (*very high confidence*) (18.1, Box 4.7).

Current development pathways combined with the observed impacts of climate change, are leading away from, rather than toward, sustainable development, as reported in recent literature (*moderate agreement, robust evidence*). While demonstrable progress has been made on some of the SDGs, significant gains across a range of targets are still necessary, as is enhancing synergies and balancing and managing trade-offs. Severe risks to natural and human systems are already observed in some places (high confidence), and could occur in many more systems, worldwide before mid-century (*medium confidence*), by end-century at all scales, from the local to the global, and at all latitudes and altitudes (*high confidence*). The COVID-19 pandemic revealed the vulnerability of development progress to shocks and stresses, potentially delaying the implementation of the 2030 Agenda for all (8.1, Cross-Chapter Box COVID in Chapter 7). Various global trends including rising income inequality, continued growth in greenhouse gas emissions, land use change, food and water insecurity, human displacement, and reversals of long-term increasing life expectancy trends in some nations run counter to the SDGs (*very high confidence*) as well as efforts to mitigate greenhouse gas emissions and adapt to a changing climate (18.2). These development trends contribute to worsening poverty, injustice and inequity, and environmental degradation. Climate change can exacerbate these conditions by undermining human and ecological well-being (18.2).

Social and economic inequities linked to gender, poverty, race/ethnicity, religion, age, or geographic location compound vulnerability to climate change and have created and could further exacerbate injustices, and constrain the implementation of CRD for all (*very high confidence*). Climate change intensifies existing vulnerability and inequality, with adverse impacts of climate change on the most vulnerable groups, including women and children in low-income households, Indigenous or other minority groups, small-scale producers and fishing communities, and low-income countries (*high confidence*). Most vulnerable regions and population groups, such as in East, Central and West Africa, South Asia, Micronesia and Melanesia and in Central America, present the most urgent need for adaptation (*high confidence*) (Ch 10, 12, 15). Climate justice initiatives explicitly address these multi-dimensional distributional issues as part of climate change adaptation. However, adaptation strategies can worsen social inequities, including gender, unless explicit efforts are made to change those unequal power dynamics, including spaces to foster inclusive decision-making. Drawing upon Indigenous knowledge and local knowledge can contribute to overcoming the combined challenges of climate change, food security, biodiversity conservation, and combating desertification and land degradation. (18.2; Cross-Chapter Box GENDER; Cross-Chapter Box INDIG}

Opportunities for climate resilient development vary by location (*very high confidence*). Over 3.3 billion people live in regions that are very high and highly vulnerable to climate change, while 2 billion people live in regions with low and very low vulnerability. Response to global greenhouse gas emissions

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

trajectories, regional and local development pathways, climate risk exposure, socio-economic and ecological vulnerability, and the local capacity to implement effective adaptation and greenhouse gas mitigation options, differ depending on local contexts and conditions (Table 18.3). As an example, underlying social and economic vulnerabilities in Australasia, exacerbate disadvantage among particular social groups and there is deep underinvestment in adaptation, given current and projected risks (Ch 11). There is also significant regional heterogeneity in climate change, exposure, and vulnerability, indicating different starting points for CRD, as well as mitigation, adaptation, and sustainable development opportunities, synergies, and trade-offs (18.5).

There are multiple possible pathways by which communities, nations and the world can pursue climate resilient development. Moving toward different pathways involves confronting complex synergies and trade-offs between development pathways, and the options, contested values, and interests that underpin climate mitigation and adaptation choices (*very high confidence*). Climate resilient development pathways are trajectories for the pursuit of climate resilient development and navigating its complexities. Different actors, the private sector, and civil society, influenced by science, local and Indigenous knowledges, and the media are both active and passive in designing and navigating CRD pathways (18.1, 18.4). Increasing levels of warming may narrow the options and choices available for local survival and sustainable development for human societies and ecosystems. Limiting warming to Paris Agreement goals will reduce the magnitude of climate risks to which people, places, the economy and ecosystems will have to adapt. Reconciling the costs, benefits, and trade-offs associated with adaptation, mitigation, and sustainable development interventions and how they are distributed among different populations and geographies is essential and challenging, but also creates the potential to pursue synergies that benefit human and ecological well-being. For example, in parts of Asia sustainable development pathways that connect climate change adaptation and disaster risk reduction can reduce climate vulnerability and increase resilience (Table 18.3. 10.6.2). Different actors and stakeholders have different priorities regarding these opportunities, which can exacerbate or diminish existing social, economic and ecological vulnerabilities and inequities. For example, in parts of Africa, intensive irrigation contributes to the development of agriculture but has come at a cost to ecosystem integrity and human well-being (Table 18.3., 9.15.2). Careful and explicit consideration for the ethical and equity dimensions of policies and practices associated with a climate resilient development pathway can help limit these negative externalities.

Prevailing development pathways are not advancing climate resilient development *(very high confidence)*. Societal choices in the near-term will determine future pathways. Some low-emissions pathways and climate outcomes are *unlikely*[2] to be realized (*very high confidence*). Rapid climate change is affecting every region across the globe and affecting natural and human systems relevant to the pursuit of the SDGs (18.1, 18.2, Fig. 18.1). Even the most ambitious greenhouse gas mitigation scenarios indicate climate change will continue for decades to centuries (WGI, 18.2). Increasing mitigation effort across multiple sectors exhibits opportunities for synergies with sustainable development, but also trade-offs that increase with mitigation effort that need to be balanced and managed (*high confidence*). The uncertainty associated with achieving specific pathways and climate outcomes is a risk factor to consider in planning, with plausibility and transformational challenges, as well as trade-offs and synergies, affected by technology, policy design, and societal choices (18.2). For instance, restrictions on utilization of individual mitigation options to manage trade-offs (e.g., bioenergy with CCS, afforestation, nuclear power) can also affect the mitigation cost to households (e.g., energy security, commodity prices) and the likelihood of a desired climate outcome being realized. Developing and transitional economies are estimated as low-cost mitigation opportunities, but are often at high risk from climate change due to their regional and development context (*high confidence*) (18.2,18.5). For example in Africa, competing uses for water such as hydropower generation, irrigation, and ecosystem requirements can create trade-offs among different management and development objectives (9.7.3). In Asia, intensive irrigation and other forms of water consumption can have a negative effect on water quality and aquatic ecosystems (Ch 10.6.3). Developed countries also,

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

face trade-offs, including in Australasia where adapting to fire risk in peri-urban zones introduces potential trade-offs among ecological values and fuel reduction in treed landscapes (Ch 11.3.5) and in North America where new coastal and alpine developments generate economic activity but enhance local social inequalities (15.4.10).

Systems transitions can enable climate resilient development, when accompanied by appropriate enabling conditions and inclusive arenas of engagement (*very high confidence*). Five systems transitions are considered: energy, industry, urban and infrastructure, land and ecosystems, and societal. Advancing climate resilient development in specific contexts may necessitate simultaneous progress on all five transitions. Collectively, these system transitions can widen the solution space and accelerate and deepen the implementation of sustainable development, adaptation, and mitigation actions by equipping actors and decision-makers with more effective options. For example, urban ecological infrastructure linked to an appropriate land use mix, street connectivity, open and green spaces, and job-housing proximity provides adaptation and mitigation benefits that can aid urban transformation. (Table 18.4, Cross-Working Group Box URBAN in Chapter 6) These system transitions are necessary precursors for more fundamental climate and sustainable-development transformations; but can simultaneously be outcomes of transformative actions. However, the way they are pursued may not necessarily be perceived as ethical or desirable to all actors. Hence, enhancing equity and agency are cross-cutting considerations for all five transitions. Such transitions can generate benefits across different sectors and regions, provided they are facilitated by appropriate enabling conditions including effective governance, policy implementation, innovation, and climate and development finance, which are currently insufficient (18.3, 18.4).

There is a rapidly narrowing window of opportunity to implement system transitions needed to enable CRD. Past choices have already eliminated some development pathways, but other pathways for climate-resilient development remain (*very high confidence*). In spite of a growth in national net-zero commitments, the current prospects of surpassing 1.5°C global mean temperatures by the 2030s are high (WG1 Table SPM1). There is strong evidence of the worsening of multiple climate impact drivers in all regions, that will place additional pressures on ecosystem services that support food and water systems, increasing the risks of malnutrition, ill-health and poverty in many regions (WG1 Fig SPM9, Table 18.4). This implies that significant additional adaptation will be needed. Over the near-term, implementing such transformational change could be disruptive to various economic and social systems. Over the long-term, however, they could generate benefits to human well-being and planetary health. Strengthening coordinated adaptation and mitigation actions can enhance the potential of local and regional development pathways to support CRD. Planning for CRD can support both adaptation and decarbonization via effective land-use, promoting resilient and low-carbon infrastructure; protecting biodiversity and integrating ecosystem services (Table 18.4), assuming advancing just and equitable development processes.

Prospects for transformation towards climate resilient development increase when key governance actors work together in inclusive and constructive ways to create a set of appropriate enabling conditions (18.4.2) (*high confidence*). These enabling conditions include effective governance and information flow, policy frameworks that incentivize sustainability solutions; adequate financing for adaptation, mitigation, and sustainable development; institutional capacity; science, technology and innovation; monitoring and evaluation of climate resilient development policies, programs, and practices; and international cooperation. Investment in social and technological innovation, could generate the knowledge and entrepreneurship needed to catalyze system transitions, and their transfer. The implementation of policies that incentivize the deployment of low-carbon technologies and practices within specific sectors such as energy, buildings, and agriculture could accelerate greenhouse gas mitigation and deployment of climate resilient infrastructure, in urban and rural areas. Civic engagement is an important element of building societal consensus and reducing barriers to action on adaptation, mitigation, and sustainable development. (18.4)

CRD pathways are determined through engagement in different arenas degree to which the emergent pathways foster just, and climate resilient development depends on how contending societal interests, values and worldviews are reconciled through inclusive and participatory interactions between governance actors in these arenas of engagement (18.4.3) (*high confidence*). These interactions occur in many different arenas (e.g., governmental, economic and financial, political, knowledge, science & technology, and community) that represent the settings, places, and spaces in which societal actors interact to influence the nature and course of development. For instance, the Agenda 2030 highlights the importance of multi-level adaptation governance, including non-state actors from civil society and the private sector. This implies the need for wider arenas and modes of engagement around adaptation that facilitate coordination, convergence, and productive contestation among these diverse actors to collectively solve problems and to unlock the synergies between adaptation and mitigation and sustainable development.

Regional and national differences mean different capacities for pursuing climate resilient development pathways. Economic sectors and global regions are exposed to different opportunities and challenges in facilitating climate resilient development, suggesting adaptation and mitigation options should be aligned to local and regional context and development pathways (*very high confidence*). Given their current state of development, some regions may prioritize poverty and inequality reduction, and economic development over the near-term as a means of building capacity for climate action and low-carbon development over the long-term. For example, Africa, South Asia, and Central and South America are highly exposed, vulnerable and impacted by climate change, which is amplified by poverty, population growth, land use change and high dependence on natural resources for commodity production. In contrast, developed economies with mature economies and high levels of resilience may prioritize climate action to transition their energy systems and reduce greenhouse gas emissions. Some interventions may be robust in that they are relevant to a broad range of potential development trajectories and could be deployed in a flexible manner. For example, conservation of land and water could be achieved through a variety of means and offer benefits to populations in the global North and South alike. However, other types of interventions, such as those that are dependent upon emerging technologies, may require a specific set of enhanced enabling conditions or factors including infrastructure, supply chains, international cooperation, and education and training that currently limit their implementation to certain settings (18.5). Notwithstanding national and regional differences, development practices that are aligned to people, prosperity, partnerships, peace and the planet as defined in Agenda 2030, could enable more climate resilient development (see Figure 18.1).

People, acting through enabling social, economic and political institutions, are the agents of system transitions and societal transformations that facilitate climate resilient development founded on the principles of inclusion, equity, climate justice, ecosystem health, and human well-being (*very high confidence*). While much literature on climate action has focused on the role of technology and policy as the factors that drive change, recent literature has focused on the role of specific actors – citizens, civil society, knowledge institutions (including local and Indigenous Peoples and science), governments, investors and businesses. Greater attention to, and transparency of, which actors' benefit, fail to benefit, or are impacted by mitigation and adaptation choices actions could better support climate-resilient and sustainable development. For example, grounding adaptation actions in local realities could help to ensure that adaptive actions do not worsen existing gender and other inequities within society (e.g., leading to maladaptation practices) *(high confidence)*. Differences in the ability of different actors to effect change ultimately influence which interventions for sustainable development or climate action are implemented and thus what development outcomes are achieved. Recent literature has focused on the social, political, and economic arenas of engagement, in which these different actors interact. More focused attention on these arenas of engagement could prove beneficial to reconciling divergent views on climate action, integrating Indigenous knowledge and local knowledges, elevating diverse voices that have historically been marginalized from the policy discourse, thereby reducing vulnerability, deepening adaptive capacity and the ability to implement CRD (18.4; Cross-Chapter Box GENDER; Cross-Chapter Box INDIG)

Pursuing climate resilient development involves considering a broader range of sustainable development priorities, policies and practices, as well as enabling societal choices to accelerate and deepen their implementation *(very high confidence)*. Scientific assessments of climate change have traditionally framed solutions around the implementation of specific adaptation and mitigation options as mechanisms for reducing climate-related risks. They have given less attention to a fuller set of societal priorities and the role of non-climate policies, social norms, lifestyles, power relationships and worldviews in enabling climate action and sustainable development. Because climate resilient development involves different actors pursuing plural development trajectories in diverse contexts, the pursuit of solutions that are equitable for all requires opening the space for engagement and action to a diversity of people, institutions, forms of knowledge, and worldviews. Through inclusive modes of engagement that enhance knowledge sharing and realize the productive potential of diverse perspectives and worldviews, societies could alter institutional structures and arrangements, development processes, choices and actions that have precipitated dangerous climate change, constrained the achievement of SDGs, and thus limited pathways to achieving CRD (Box 18.1, 18.4). There are only a few decades remaining to chart CRD pathways that catalyze the transformation of prevailing development practices and offer the greatest promise and potential for human well-being and planetary health.

18.1 Ways Forward for Climate Resilient Development

The links between climate change and development have been long recognized by various research communities (Nagoda, 2015; Winkler et al., 2015; Webber, 2016; Carr, 2019) and have been assessed by Working Group II in every IPCC Assessment Report since AR3 (Smit et al., 2001; Yohe et al., 2007; Denton et al., 2014). For the AR1-3 reports, these links were largely framed in the context of sustainable development, a concept that has been well described in the literature for decades (Brundtland, 1987). The AR5 introduced the framing of climate resilient pathways, which narrowed the discussion around sustainable development to specifically address the contributions of mitigation and adaptation actions to the reduction of risk to development and the various institutions, strategies, and choices involved in risk management (Denton et al., 2014). That assessment concluded that identifying and implementing appropriate technical and governance options for mitigation and adaptation as well as development strategies and choices that contribute to climate resilience are central to the successful implementation of such strategies. The AR5 also recognized that transformation of current development pathways in terms of wider political, economic and social systems may be necessary (Denton et al., 2014).

The literature presenting research findings on climate resilient development (CRD) and pathways and processes for successfully achieving CRD has expanded significantly in the several years since the AR5 (*very high confidence*). This includes both qualitative studies of development as well as illustrative, quantitative analyses of development trajectories linked to specific scenarios, such as the Shared Socioeconomic Pathways (SSPs) (18.2.2). Furthermore, the literature describing the role of system transitions and societal transformation in enabling climate action (Box 18.1, 18.3), compliance with the Paris Agreement (18.1.3, 18.2.1), and achievement of the Sustainable Development Goals (18.1.3; Box 18.4) has expanded significantly (*very high confidence*). This expansion is comprised of studies spanning a broad range of disciplinary perspectives, some of which have been underrepresented in prior IPCC assessments (*high agreement, limited evidence)* (Minx et al., 2017; Pearce et al., 2018b)).

This chapter therefore focuses on assessing this more recent literature and the diverse scientific understandings of CRD and the pathways for pursuing it. Notably, this chapter takes off where Chapters 16 and 17 end: recognizing the decision-making context to address the representative key risks and their intersections with development, among others. This chapter therefore highlights not only how climate risk undermines CRD, but also how current patterns of development contribute to climate risk, both generally and in different sectoral and regional contexts. In particular, the chapter focuses on achieving CRD through systems transitions, discussing these in relation to societal transformation, and how different actors engage one another in order to pursue policy and practice consistent with CRD.

18.1.1 Understanding Climate Resilient Development

Past IPCC Assessment Reports have consistently examined an extensive literature on the links between climate change, adaptation, and sustainable development (Smit et al., 2001; Klein et al., 2007; Yohe et al., 2007). However, studies that explicitly refer to CRD as a concept or a guide for policy and practice remain modest (*very high confidence*). The concept of CRD appeared in scholarly literature as well as development program documents over a decade ago (Kamal Uddin et al., 2006; Garg and Halsnæs, 2007) and has been used in more recent IPCC assessment reports and special reports (e.g., Denton et al., 2014; Roy et al., 2018). Similarly, the use of the term climate resilient development pathways dates to 2009 (Ayers and Huq, 2009), but its use accelerated after appearing in UNFCCC publications around the launch of the Green Climate Fund (UNFCCC, 2011). While this chapter prioritizes the CRD literature, it also recognizes a broad range of literature, disciplinary expertise, and development practice is relevant to the concept of CRD.

Much of this literature is assessed in recent IPCC Special Reports (Rogelj et al., 2018; Roy et al., 2018; Bindoff et al., 2019; Hurlbert et al., 2019; Oppenheimer et al., 2019), but new studies have continued to emerge. More specific uses of CRD found in the literature describe development that seeks to achieve poverty reduction and adaptation to climate change simultaneously without explicit mention of mitigation (USAID, 2014)), as well as mitigation and poverty reduction, described as 'low-carbon development,' without explicit mention of adaptation (Alam et al., 2011; Fankhauser and McDermott, 2016). Other similar terms include 'climate safe', 'climate compatible' and 'climate smart' development (Huxham et al., 2015; Kim et al., 2017b; Ficklin et al., 2018; Mcleod et al., 2018), each with varying nuances. Climate-compatible development coined by Mitchell and Maxwell (2010) specifically describes a 'triple win' of adaptation, mitigation and development (Antwi-Agyei et al., 2017; Favretto et al., 2018) (see also 8.6). In this spirit, AR5 specifically referred to climate-resilient development as "*development trajectories that combine adaptation and mitigation to realize the goal of sustainable development*" (Denton et al., 2014). This chapter builds on the AR5 and, for the purposes of assessment, formally defines CRD as *a process of implementing greenhouse gas mitigation and adaptation measures to support sustainable development for all.* This extension of the earlier definition reflects the emphasis in recent literature on equity as a core element of sustainable development as well as the objective of the SDGs to "*create conditions for sustainable, inclusive and sustained economic growth, shared prosperity and decent work for all, taking into account different levels of national development and capacities*" (United Nations, 2015: 3/35).

Past, present, and future concentrations of greenhouse gases in the atmosphere are the direct result of both natural and anthropogenic greenhouse gas emissions which are, in turn, a function of past and current patterns of human and economic development (*very high confidence*, WGI SPM). This includes development processes that drive land use change, extractive industries, manufacturing and trade, energy production, food production, infrastructure development, and transportation. These patterns of development are therefore drivers of current and future climate risk to specific sectors, regions, and populations (Byers et al., 2018), as well as the demand for both mitigation and adaptation as a means of preventing climate change from undermining development goals. The Sustainable Development Goals (SDGs) represent targets for supporting human and ecological well-being in a sustainable manner. Yet, while progress is being made toward a number of the Sustainable Development Goals (SDGs), success in achieving all of the SDGs by 2030 across all global regions remains uncertain (*high agreement, medium evidence*) (United Nations, 2021). Moreover, current commitments to reduce greenhouse gas emissions are not yet consistent with limiting changes in global mean temperature elevation to less than 2°C or 1.5°C (*very high confidence*) (IPCC, 2018a) (see also 18.2).

Atmospheric concentrations of greenhouse gases are just one of a number of planetary boundaries which define safe operating spaces for humanity and therefore opportunities for achieving sustainable and climate-resilient development. Exceeding these boundaries poses increased risk of large-scale abrupt or irreversible environmental changes that would threaten human and ecological well-being (*very high confidence*) (Rockström et al., 2009a; Rockström et al., 2009b; Butler, 2017; Schleussner et al., 2021). Other planetary boundaries reported in the literature such as biodiversity loss, changes in land systems, and freshwater use are also directly influenced by patterns of development as well as climate change (18.2; 18.5). Current rates of species extinction, conversion of land for crop production, and exploitation of water resources exceed planetary boundaries, thereby undermining CRD. Moreover, studies indicate that achievement of the sustainable development goals, while consistent with maintaining some planetary boundaries, could undermine others (O'Neill et al., 2018; Hickel, 2019; Randers et al., 2019) (18.2), suggesting significant shifts in current patterns of development are necessary to maintain development within planetary boundaries.

Exceedance of planetary boundaries contributes to human and ecological vulnerability to climate change and other shocks and stressors. People and regions that already face high rates of natural resource use, ecosystem degradation, and poverty are more vulnerable to climate change impacts, compounding existing development challenges in regions that are already strained (IPCC, 2014a; Hallegatte et al., 2019). The International Monetary Fund, for example, found that for a medium and low-income developing country with an annual average temperature of 25°C, the effect of a 1°C increase in temperature is a reduction in economic growth by 1.2% (Acevedo et al., 2018). Countries whose economies are projected to be hard hit by an increase in temperature account for only about 20% of global Gross Domestic Product (GDP) in 2016, but are home to nearly 60% of the global population. This is expected to rise to more than 75% by the end of the century. These economic impacts are a function of the underlying vulnerability of low- and middle-income developing economies to the impacts of climate change (see 18.5). Such vulnerability was also evidenced and enhanced by the COVID-19 pandemic which slowed progress on the SDGs in multiple nations (Naidoo and Fisher, 2020; Srivastava et al., 2020; Bherwani et al., 2021).

18.1.2 Pathways for Climate Resilient Development

One approach for operationalizing the concept of climate-resilient development in a decision-making context is to link the concept of CRD to that of pathways (Figure 18.1). A pathway can be defined as *"a trajectory in* *time, reflecting a particular sequence of actions and consequences against a background of autonomous developments, leading to a specific future situation"* (Haasnoot et al., 2013; Bourgeois, 2015). As such, a pathway represents changes over time in response to policies and practices as well spontaneous and exogenous events. For example, the SR1.5 report suggested that CRD pathways are "*a conceptual and aspirational idea for steering societies towards low-carbon, prosperous and ecologically safe futures*" (Roy et al., 2018: 468), and a way to highlight the complexity of decision-making processes at different levels. Here, consistent with the aforementioned definition of CRD, we define CRD pathways as *development trajectories that successfully integrate mitigation, adaptation, and sustainable development to achieve development goals*.

As illustrated in Figure 18.1, the ultimate aim of CRD pathways is to support sustainable development for ensuring planetary health and human well-being. CRD is both an outcome at a point in space and time, as observed through SDG achievement indicators, but also a process consisting of actions and social choices made by multiple actors—government, industry, media, civil society, and science (18.4). These actions and social choices are performed within different dimensions of governance—politics, institutions (norms, rules), and practice, and bounded by ethics, values and worldviews. The development outcomes and processes pertain to political, economic, ecological, socio-cultural, knowledge-technology, and community arenas (Figure 18.2). A CRDP will, for example, aspire to achieve ecological outcomes in terms of planetary health and achievement of Paris Agreement goals as well as human well-being, solidarity and social justice, in addition to political, economic, and science-technology outcomes. These outcomes are enabled by achieving progress in core system transitions that catalyze broader societal transformations (Figure 18.3).

While there are many possible successful pathways to future development in the context of climate change, history has shown that pathways that are positive for the vast majority, often induce notable impacts and costs, especially on marginal and vulnerable people (Hickel, 2017; Ramalho, 2019), placing them in direct contradiction with the commitment to 'leave no one behind' (United Nations, 2015). Similarly, contemporary scenario analyses find that there are plausible development trajectories that lead toward sustainability (Figure 18.1, 18.2.2). Yet, a number of plausible trajectories that perpetuate or exacerbate unstainable forms of development also appear in the literature (Figure 18.1, 18.2.2). A significant challenge lies in identifying pathways that address current climate variability and change, while allowing for improvements in human well-being. Furthermore, while a given pathway might lead to a set of desired outcomes for one region or set of actors, the process of getting there may come at high environmental, socio- and economic cost to others *(very high confidence*) (Raworth, 2017; Faist, 2018). Frequently, considerations of social difference and equity are not prioritized in the evaluation of different development choices. The assumption that a growing economy lifts opportunity for all, could for example, further marginalize those who are the most vulnerable to climate change (Matin et al., 2018; Diffenbaugh and Burke, 2019; Hickel et al., 2021).

Placing pathways and climate actions within development processes implies a broadening of enablers to include the ethical-political quality of socio-environmental processes that are required to shift such processes in directions that support CRD and the pursuit of sustainability outcomes. This chapter therefore departs from the AR5s alignment of CRD with adaptation pathways and the emphasis on decision points that enable one to manage (or fail to manage) climate risk towards a framing that integrates a range of possible futures each offering different opportunities, risks, and trade-offs to different actors and stakeholders (see WGII AR5, IPCC, 2014b, Figure SPM.9). Instead, CRD emerges from everyday formal and informal decisions, actions, and adaptation or mitigation policy interventions. This is inclusive of system transitions, increased resilience, environmental integrity, social justice, equity, and reduced poverty and vulnerability, all facets of human well-being and planetary health. Rather than encompassing a formula or blueprint for particular actions, sustainable development is a process that provides a compass for the direction that these multiple actions should take (Anders, 2016). This creates opportunities for actors to apply a diverse toolkit of adaptation, mitigation, and sustainable development interventions, thereby opening up the solution space.

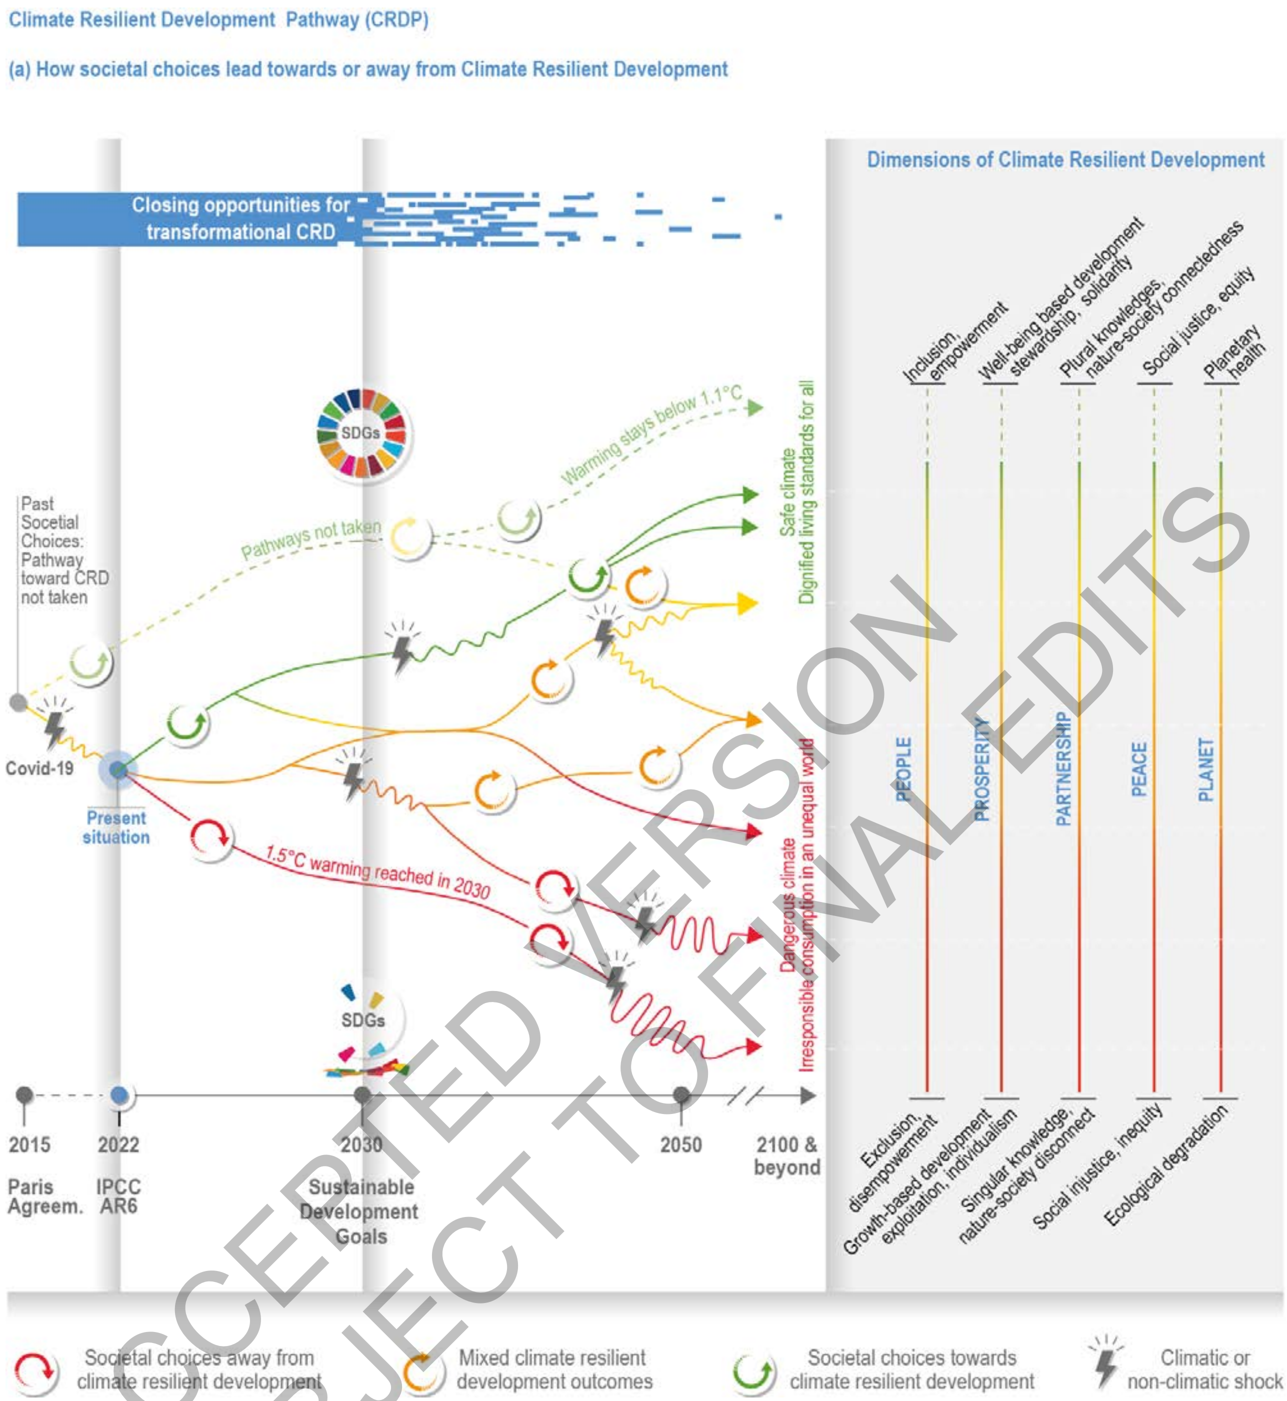

Figure 18.1: Climate Resilient Development Pathways. Climate resilient development is a process that takes place through societal choices towards (green pathways) or away from (red pathways) five development dimensions (people, prosperity, partnership, peace, planet) on which the SDGs build. Some societal choices have mixed outcomes for CRD (orange pathways). This figure builds on figure SPM.9 in AR5 WGII depicting climate resilient pathways) by describing how CRDPs emerge from societal choices within multiple arenas – rather than solely from discrete decision points. Societal choices, often contested, are made in these arenas through interactions between key actors in civil society, the private sector and government (see Figure 18.2). The quality of interactions between these actors in these arenas determine whether societal choices shift development towards or away from CRD. For example, inclusion vs exclusion and influence over choices shapes the quality of these interactions, and the outcomes of emergent societal choices. These qualities thus also characterize alternative futures resulting from different pathways, along five development dimensions (people, prosperity, partnership, peace, planet) on which the SDGs build. five CRD dimensions underline the close interconnectedness between the biosphere and humans, the two necessarily intertwined in interactions, actions, transitions, and futures (Figure 18.3). There is a narrow and closing window of opportunity to make transformational changes to move towards and not away from development futures that are more climate-resilient and sustainable. Pathways not taken (dotted line) show that the pathways towards the highest CRD futures are no longer available due to past societal choices and increasing temperatures. Present societal choices determine whether we shift towards CRD in future or whether pathways will be limited to less CRD.

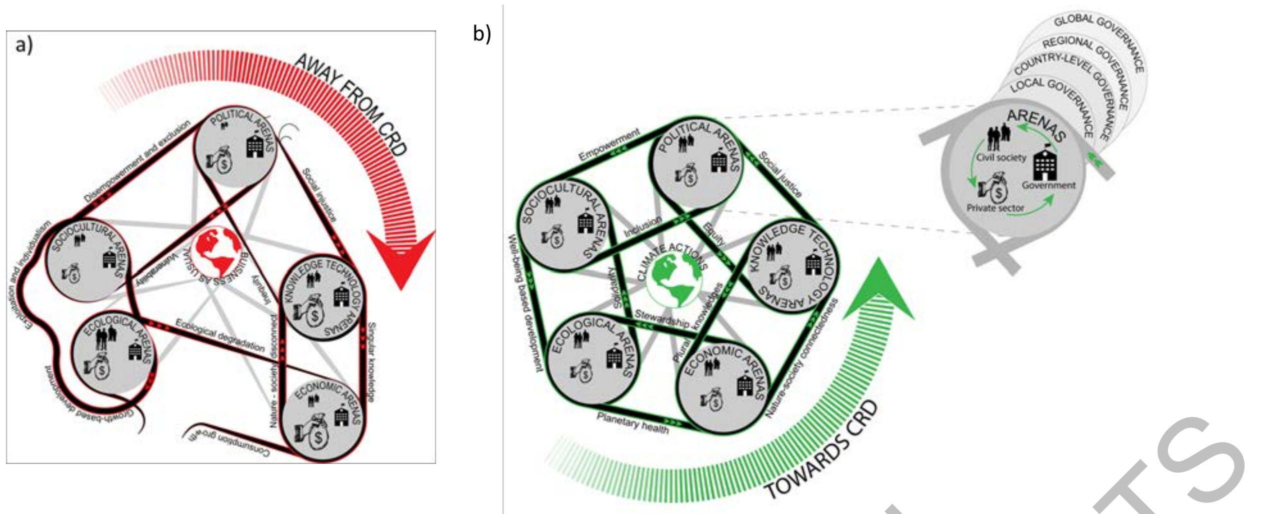

Figure 18.2: Societal choices in arenas of engagement shaping actions and systems. The settings, places and spaces in which key actors from government, civil society and the private sector interact to influence the nature and course of development can be called arenas of engagement, including political, economic, socio-cultural, ecological, knowledge-technology and community arenas. For instance, political arenas include formal political settings such as voting procedures to elect local representatives as well as less formal and transparent political arenas. Streets, town squares and post-disaster landscapes can become sites of interaction and political struggle as citizens strive to have their voices heard. Arenas exist across scales from the local to national level, and beyond. Arenas of engagement can take the form of "struggle arenas" – in which power and influence are used to include/exclude, set agendas, and make and implement decisions – with inevitable winners and losers. The quality of interactions in these arenas leads to development outcomes that can be characterized as CRD dimensions that underpin the SDGs – people, prosperity, partnership, peace, planet (see Figure 18.1). a) Interactions characterized by inequitable relations and domination of some actors over others may lead to societal choices away from CRD, including exacerbating disempowerment and vulnerability among marginalized groups. b) Prospects for moving towards CRD increase when governance actors work together constructively in these different arenas. Interactions and actions that are inclusive and synchronous, as opposed to fragmented or contradictory, enable system transitions and transformational change towards CRD (Figure 18.3b, Box 18.3). b) Well-intentioned efforts often fail to be transformative, but instead entrench inequities. Instead, marginalized groups and future trends in vulnerability need to be placed at the center of efforts to chart CRDPs. Unlocking the productive potential of conflict that often characterizes interactions in these arenas of engagement is central to advancing human well-being and planetary health. Moreover, the window for doing so is closing rapidly to avert dangerous climate change and unsustainable development.

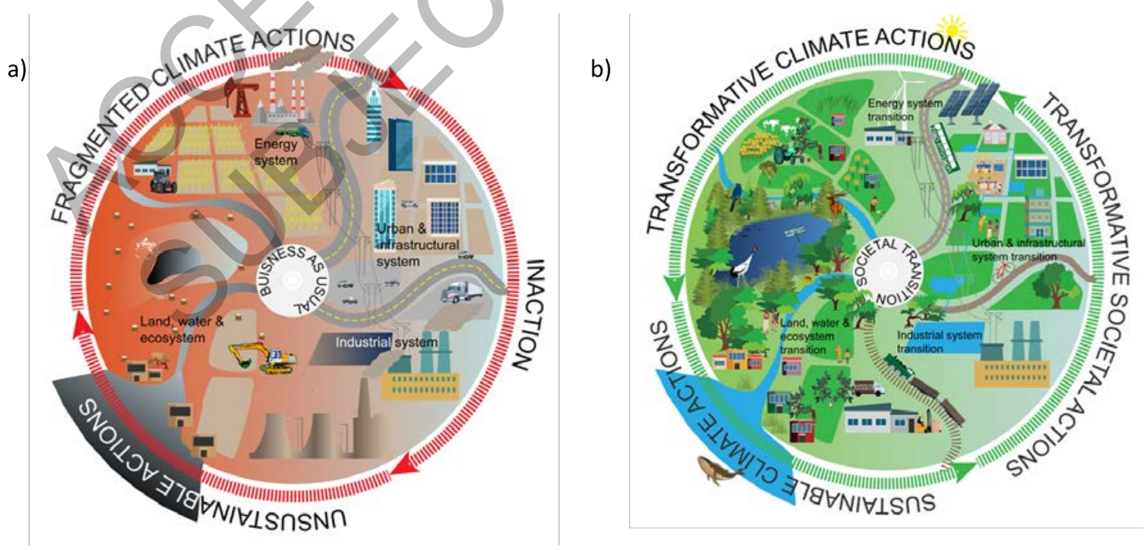

Figure 18.3: Transformative actions and system transitions a) Societal choices that generate fragmented climate action or inaction and unsustainable development perpetuate business as usual development. b) Societal choices that support CRD involve transformative actions that drive five systems transitions (energy, land and other ecosystems, urban and infrastructure, industrial and societal). There is close interdependence between these systems. The system transition

framework allows for a comprehensive assessment of the synergies and trade-offs between mitigation, adaptation and sustainable development. For example, land and water use in one system impacts the other systems and their surrounding ecosystems, thus reflecting how agricultural practices can have an impact on energy usage in urban centers. Finally, societal system transitions within each of the other systems enable the transitions to occur

This understanding of CRD implies that different actors – governments, businesses, and civic organizations – will have to design and navigate their own CRD pathways toward climate resilient and sustainable development. This includes determining the appropriate balance of adaptation, mitigation, and sustainable development actions and investments that are consistent with individual actors' development circumstances and goals while also ensuring that the collective actions remain consistent with global agreements and goals (such as the SDGs, Sendai Framework, and the Paris Agreement; 18.1.3), planetary boundaries, and other principles of CRD including social justice and equity (Roy et al., 2018). Empowering individual actors to pursue CRD in context-specific manner while coordinating action among actors and a diversity of scales, local to global, is a key challenge associated with achieving CRD (*high agreement, limited evidence*).

18.1.3 Policy Context for Climate Resilient Development

As reflected in Chapter 1 of the AR6 WGII report, CRD is emerging as one of the guiding principles for climate policy, both at the international level (Denton et al., 2014; Segger, 2016), as reflected in the Paris Agreement (Article 2, UNFCCC, 2015), and within specific countries (Simonet and Jobbins, 2016; Kim et al., 2017b; Vincent and Colenbrander, 2018; Yalew, 2020). This framing of development recognizes the risks posed by climate change to development objectives (18.2; see also Chapter 16); the opportunities, constraints and limits associated with reducing risk through adaptation; synergies and trade-offs between mitigation, adaptation, and sustainable development (18.2.5, 18.5, Box 18.4); and the role of system transitions in enabling large-scale transformations that limit future global warming to less than 1.5°C while boosting resilience (IPCC, 2018a) (18.3, Box 18.1).

Since the AR5, the volume of research at the nexus of climate action and sustainable development has changed markedly (*very high confidence*). A rapidly growing, multi-disciplinary literature has emerged on climate resilient development (Mitchell et al., 2015; Clapp and Sillmann, 2019; Hardoy et al., 2019; Yalew, 2020) and associated pathways (Naess et al., 2015; Winkler and Dubash, 2016; Brechin and Espinoza, 2017; Solecki et al., 2017; Ellis and Tschakert, 2019) (18.2.2). Nevertheless, the concept of resilience generally, and climate resilient development specifically, has come under increasing criticism in recent years (*very high confidence*) (Joakim et al., 2015; Schlosberg et al., 2017; Mikulewicz, 2018; Mikulewicz, 2019), suggesting the need to enhance understanding of how resilience is being operationalized at the program and project level and the net implications for human and ecological well-being.

This expansion of research has been accompanied by a shift in the policy context for climate action including an increasingly strong link between climate actions and sustainable development. In particular, the SDGs represent a near-term framework linking sustainability and human development in a manner that not only addresses planetary health and human wellbeing, but also help better plan and implement mitigation and adaptation actions to achieve these linked goals (Conway et al., 2015; Griscom et al., 2017; Allen et al., 2018b; Roy et al., 2018; P.R. Shukla E. Calvo Buendia, 2019). The SDGs explicitly identify climate action (SDG 13) among the goals needed to achieve sustainable development. Meanwhile, the text of the Paris Agreement makes explicit mention of the importance of considering climate "in the context of sustainable development" (Articles 2, 4, 6) or as "contributing to sustainable development" (Article 7) (Article 7, UNFCCC, 2015). Similarly, sustainable development appears prominently within the text of the Sendai Framework for Disaster Risk Reduction (UNDRR, 2015), and the Global Assessment Reports on Disaster Risk Reduction (Undrr, 2019). At the micro-level, a growing literature recognizes that climate impacts tend to exacerbate existing inequalities within societies, even at the level of gender inequalities within households (Sultana, 2010; Arora-Jonsson, 2011; Carr, 2013). Thus, climate change impacts threaten even short-term gains in sustainable development, which could be rolled back over longer adaptation and mitigation horizons. For example, the COVID-19 pandemic is estimated to have reversed gains over the past several years in terms of global poverty reduction (*very high confidence*) (Phillips et al., 2020; Sultana, 2021; Wilhelmi et al., 2021) (Cross-Chapter Box COVID in Chapter 7), reflecting the risks posed by global, systemic threats to development.

The WGII AR5 Report noted that adapting to the risks associated with climate change becomes more challenging at higher levels of global warming (IPCC, 2014a). This was evidenced by contrasting impacts and adaptive capacity for 2° and 4°C of warming. This relationship between levels of warming, climate risk, and reasons for concern (see Chapter 16) is also relevant to the concept of CRD. For example, recent literature on CRD emphasizes the urgency of climate action that achieve significant reduction in greenhouse gas emissions as well as the implementation of adaptation options that result in significant gains in human and natural system resilience (*very high confidence*) (Haines et al., 2017; Shindell et al., 2017; Xu and Ramanathan, 2017; Fuso Nerini et al., 2018). This was explored extensively in the IPCC's SR1.5 report in its comparison of impacts associated with 1.5°C versus 2°C climate objectives and synergies and trade-offs with the SDGs (IPCC, 2018a). However, the SR1.5 report and other literature also identified potential trade-offs between aggressive mitigation and the SDGs (see also Frank et al., 2017; Hasegawa et al., 2018). This indicates that while future magnitudes of warming are a fundamental consideration in climate-resilient development, such development involves more than just achieving temperature targets. Rather, CRD considers the possible transitions that enable those targets to be achieved including the evaluation of different adaptation and mitigation options and how the implementation of these strategies interacts with broader sustainable development efforts and goals. This interdependence between patterns of development, climate risk, and the demand for mitigation and adaptation action is fundamental to the concept of CRD (Fankhauser and McDermott, 2016). Therefore, climate change and sustainable development cannot be assessed or planned in isolation of one another.

18.1.4 Assessing Climate Resilient Development

In operationalizing the aforementioned definitions of CRD and CRD pathways this chapter builds its assessment around five core elements that provide insights relevant to policymakers actively pursuing the integration of climate resilience into development. First, as noted above, climate change poses a potential risk to the achievement of development goals, including global goals such as the SDGs, as well as nationally- or locally-specific goals. Accordingly, Chapter 16's discussion of key risks, their implications for the SDGs, and the options for risk management are fundamental to the pursuit of CRD. This includes the opportunities for implementing adaptation, mitigation, or other risk management options. Yet, the management of climate risk must be accompanied by interventions that address social and ecological vulnerabilities that enhance climate risk.

Second, CRD is dependent on achieving transitions in key systems including energy, land and ecosystem, urban and infrastructure, and industrial systems (*very high confidence*) (Box 18.1, Figure 18.3). In this context, CRD links to the discussion of system transitions in the SR1.5 report (IPCC, 2018b; IPCC, 2018a). However, in building on the SR1.5, here the assessment of CRD also recognizes the importance of transitions in societal systems that drive innovation, preferences for alternative patterns of consumption and development, and the power relationships among different actors that engage in CRD. In particular, the rate at which actors can achieve system transitions has important implications for the pursuit of CRD. Transitions that are slow to evolve or that are more incremental in nature may not be sufficient to enable CRD in comparison with faster transitions that contribute to more fundamental system transformations.

Third, equity and social justice are consistently identified in the literature as being central to climate resilient development (*very high confidence*; 18.1.1, 18.3.1.5, 18.4, 18.5). This includes designing and implementing adaptation, resilience, and climate risk management options in a manner that promotes equity in the allocation of the costs and benefits of those options. Similarly, the literature on CRD emphasizes equity should be pursued in the implementation of options for greenhouse gas mitigation, transitions in energy systems, and low-carbon development. This emphasis on equity is consistent with the SDGs which place an emphasis on reducing inequality and achieving sustainable development for all.

Fourth, success in CRD and alignment of development interventions to CRD pathways (CRDPs) is contingent on the presence of multiple enabling conditions (*very high confidence*, 18.4.2), that operate at different scales ranging from those that provide capacity to implement specific adaptation options to those that enable large-scale transformational change (Box 18.1). The qualities that describe sustainable development processes (e.g., social justice, alternative development models, equity and solidarity as described above and in Figure 18.1) lead to short-term outcomes and conditions, such as those represented by SDGs, that in an iterative fashion enable or constraint subsequent efforts toward CRD. For example, success or failure in achieving the SDGs or the Paris Agreement would shape future efforts in pursuit of CRD and the options available to different actors.

Fifth, CRD involves processes involving diverse actors, at different scales operating within an environmental, developmental, socio-economic, cultural, and political context, as typified in the SDG and the Paris Agreement negotiations *(very high confidence*) (Kamau et al., 2018) (18.4). The dependence of CRD on processes of negotiation and reconciliation among diverse actors and interests leads to the dismissal of the notion that there is a single, optimal pathway that captures the objectives, values, and development contexts of all actors, even for a particular sector, country or region. Rather, preferences for different pathways and specific actions in pursuit of those pathways will be subjected to intense scrutiny and debate among diverse actors within various arenas of engagement (18.4), meaning the settings, places and spaces in which key actors from government, civil society and the private sector interact to influence the nature and course of development.

18.1.5 Chapter Roadmap

This chapter engages with understanding CRD and the pathways to achieving it by building on the concepts introduced in Chapter 1 of this Working Group II report as well as the regional and sectoral context presented in other chapters (18.5). Notably, this chapter takes off where Chapters 16 and 17 end: recognizing the significance of the representative key risks for CRD as well as the decision-making context of different actors who are implementing policies and practices to pursue different CRD pathways and manage climate risk. Therefore, the chapter assesses options for pursuing CRD as well as the broader system transitions and enabling conditions in support of CRD.

This chapter hosts three Cross-Chapter Boxes, which have their natural home here. The Cross-Chapter Box on Gender, Justice and Transformative Pathways (Cross-Chapter Box GENDER) assesses literature specifically on gender and climate change to uncover the importance of a justice focus to facilitate transformative pathways, both toward CRD, as well as a means to achieving gender equity and social justice. The Cross-Chapter Box on The Role of Indigenous Knowledge in Understanding and Adapting to Climate Change (Cross-Chapter Box INDIG) highlights that achieving CRD requires confronting the uncertainty of a climate change future. There are many perspectives about what future is desired and how to reach it. Integrating multiple forms of knowledge is a strategy to build resilience and develop institutional arrangements that provide temporary solutions able to satisfy competing interests (Grove, 2018). Indigenous knowledge is proven to enhance resilience in multiple contexts (e.g., Chowdhooree, 2019; Inaotombi and Mahanta, 2019). Meanwhile, Cross-Chapter Box FEASIB acts as an appendix to the WGII report, synthesizing information on the feasibility associated with different adaptation options for reducing risk.

In assessing the opportunities and constraints associated with the pursuit of sustainable development, this chapter proceeds in Section 18.2 to assess the links between sustainable development and climate action, including examination of current patterns of development and consideration for synergies and trade-offs among different strategies and options. Then, in Section 18.3, the chapter assesses five systems transitions to identify the shifts in development that would enable CRD. Section 18.4 assesses the role of different actors in the pursuit of CRD as well as the public and private arenas in which they engage. Section 18.5 synthesizes CRD assessments from different WGII sectoral and regional chapters to identify commonalities and differences. The chapter concludes in Section 18.6 with a summary of key opportunities for enhancing the knowledge needed to enable different actors to pursue CRD.

[START BOX 18.1 HERE]

Box 18.1: Transformations in Support of Climate Resilient Development Pathways

Transformational changes in the pursuit of CRDPs involve interactions between individual, collective, and systems change (see Figures 18.1–18.3). There are complex interconnections between transformation and transition (Feola, 2015; Hölscher et al., 2018), and they are sometimes used as synonyms in the literature (Hölscher et al., 2018). Much of the transitions literature focuses on how societal change occurs within existing political and economic systems. Transformations are often considered to involve deeper and more fundamental changes than transitions, including changes to underlying values, worldviews, ideologies, structures, and power relationships (Göpel, 2016; O'Brien, 2016; Kuenkel, 2019; Waddock, 2019). Systems transitions alone are insufficient to achieve the rapid, fundamental and comprehensive changes required for humanity and planetary health in the face of climate change (*high confidence)*. Transformative action is increasingly urgent across all sectors, systems and scales to avert dangerous climate change and meet the SDGs (Pelling et al., 2015; IPCC, 2018a; IPCC, 2021b; Shi and Moser, 2021; Vogel and O'Brien, 2021) (*high confidence*). The SR1.5 identified transformative change as necessary to achieve transitions within land, water and ecosystems systems; urban and infrastructural systems; energy systems; and industrial systems. This box summarises key points in the transformations literature relevant to climate resilient development.

Transformative actions aimed at 'deliberately and fundamentally changing systems to achieve more just and equitable outcomes', (Shi and Moser, 2021: 2) shift pathways towards CRD (*high confidence)*. Transformative action in the context of CRD specifically concerns leveraging change in the five dimensions of development (people, prosperity, partnership, peace, planet) that drive societal choices and climate actions towards sustainability (18.2.2; Figure 18.1). Climate actions that support CRD are embedded in these dimensions of development; for example, social cohesion and equity, individual and collective agency, and democratising knowledge processes have been identified as steps to transform practices and governance systems for increased resilience (Ziervogel et al., 2016b; Nightingale et al., 2020; Colloff et al., 2021; Vogel and O'Brien, 2021) (*high confidence)*. Transformative actions toward sustainability and increased well-being, which are dominant components of climate resilient development, include those that explicitly redress social drivers of vulnerability, shift dominant worldviews, decolonialise knowledge systems, activate human agency, contest political arrangements, and insert a plurality of knowledges and ways of knowing (Görg et al., 2017; Fazey et al., 2018a; Brand et al., 2020; Gram-Hanssen et al., 2021; Shi and Moser, 2021). They alter the governance and political economic arrangements through which unsustainable and unjust development logics and knowledges are implemented (Patterson et al., 2017; Shi and Moser, 2021) by shifting the goals of a system or altering the mindset or paradigm from which a system arises, e.g from individualism and nature-society disconnect to solidarity and nature-society connectedness along the CRD dimensions in figure 18.1, and connecting inner and external dimensions of sustainability, (Göpel, 2016; Abson et al., 2017; Wamsler and Brink, 2018; Fischer and Riechers, 2019; Horcea-Milcu et al., 2019; Wamsler, 2019).

There is no blueprint for how transformation is generated. An expanding literature suggests that transformation takes place through diverse modalities and context-dependent actions (O'Brien, 2021). Transformation may require actions that disrupt moral or social boundaries and structures that are perpetuating unsustainable systems and pathways (Vogel and O'Brien, 2021) (*high confidence*). Extreme events and long-term climatic changes can trigger a realigning of practices, politics and knowledges (Carr, 2019; Schipper et al., 2020b) (*high confidence*). While some see opportunities for generating social and political conditions needed for CRD in such actions and events (Beck, 2015; Han, 2015; Shim, 2015; Mythen and Walklate, 2016; Domingo, 2018), this is not guaranteed. Climate shocks, when managed within socio-political systems in ways that safeguard rather than alter practices and structures, can also reinforce rather than shift the status quo (Mosberg et al., 2017; Carr, 2019; Marmot and Allen, 2020; Arifeen and Nyborg, 2021) (*high confidence*). Further, in the absence of equitable and inclusive decision-making and planning, realignments resulting from disruptive actions and events can limit inclusiveness and lead to poor or coercive decision-making processes that undermine the equity and justice foundations of sustainable development (Orlove et al., 2020; Shi and Moser, 2021) and lead to adverse socio-environmental outcomes that generate transformations away from CRD (Vogel and O'Brien, 2021) *(high confidence*, see also CCP2).

Evidence for transformative actions largely exists at the community or city level. While identifying how to rapidly and equitably generate transformations at a global scale has remained elusive, there is *high agreement* but *limited evidence* from studies of ecosystem services that suggest facilitating a wide range of locally-appropriate management decisions and actions can bring about positive global-scale outcomes (Millennium Ecosystem, 2005). Diverse local efforts to transform towards sustainability in the face of climate change have been observed, such as community mobilization for equitable and just adaptation actions and alternative visions of societal well-being (Shi, 2020b) and farmer-led shifts in agricultural production systems (Rosenberg, 2021). There has been an increase in transformative actions taking place through city-level resilience building aimed at shifting inequitable relations and opening up space for a plurality of actors (Rosenzweig and Solecki, 2018; Ziervogel et al., 2021) (*high confidence)*.

Prospects for transformation towards climate resilient development increase when key governance actors work together in inclusive and constructive ways through engagement in political, knowledge-technology, ecological, economic, and socio-cultural arenas (*high confidence*,18.4.3). Yet, the interactions between key governance actors involve struggles and negotiations in addition to collaborations (Kakenmaster, 2019; Muok et al., 2021). Transformative actions meet resistance by precisely the political, social, knowledge and technical systems and structures they are attempting to transform (Blythe et al., 2018; Shi and Moser, 2021) (*high confidence*). There is expanding evidence that many adaptation efforts have failed to be transformative, but instead entrenched inequities, exacerbated power imbalances and reinforced vulnerability among marginalized groups, and that, instead, marginalized groups and future trends in vulnerability need to be placed at the center of adaptation planning (Atteridge and Remling, 2018; Mikulewicz, 2019; Owen, 2020; Eriksen et al., 2021a; Eriksen et al., 2021b; Garschagen et al., 2021) (*high confidence*). Beyond the enablers, drivers, or modalities, another question tackled in the literature is how to evaluate transformation by establishing criteria for transformation assessments (Ofir, 2021; Patton, 2021; Williams et al., 2021), experience-based lessons on managing transformative adaptation processes (Vermeulen et al., 2018), climate policy integration (Plank et al., 2021), investment criteria (Kasdan et al., 2021), political economy analysis frameworks for climate governance (Price, 2021).

[START BOX 18.2 HERE]

Box 18.2: Visions of Climate Resilient Development in Kenya

The Government of Kenya's (GoK) ambition is to transform Kenya into a 'newly industrializing, middle-income country providing a high-quality life to all its citizens by 2030 in a clean and secure environment' (Government of Kenya, 2008). Dryland regions in Kenya occupy 80-90 per cent of the land mass, are home to 36% of the population (Government of Kenya, 2012) and contribute about 10 per cent of Kenya's Gross Domestic Product (GDP) (Government of Kenya, 2012) which includes half of its agricultural GDP (Kabubo-Mariara, 2009). In dryland regions, pastoralism has long been the predominant form of livelihood and subsistence (Catley et al., 2013; Nyariki and Amwata, 2019). The GoK seeks to improve connectivity and communication infrastructure within the drylands to better exploit and develop livestock, agriculture, tourism, energy, and extractive sectors (Government of Kenya, 2018). It argues that the transformation of dryland regions is crucial to enhance the development outcomes for the more than 15 million people who inhabit these areas (Government of Kenya, 2016: 17) and to help the country to realize its wider national ambitions including a 10 percent year on year growth in GDP (Government of Kenya, 2012). A key element within this vision is the promotion and implementation of the Lamu Port South Sudan Ethiopia (LAPSSET) project, a 2,000km long, 100 km wide economic and development corridor extending from Mombasa to Sudan and Ethiopia (Enns, 2018). Supporters of the LAPSSET project argue that it will help achieve priorities laid out in the Vision 2030 by opening up poorly connected regions, enabling the development of pertinent economic sectors such as agriculture, livestock and energy, and supporting the attainment of a range of social goals made possible as the economy grows (Stein and Kalina, 2019).

However, the development narrative surrounding LAPSSET remains controversial in its assumptions, not least because it is being promoted in the context of a highly complex and dynamic social, economic and biophysical setting (Cervigni and Morris, 2016; Atsiaya et al., 2019; Chome, 2020; Lesutis, 2020). Some of the key trends driving contemporary and likely future change in dryland regions are changing household organization, evolving customary rules and institutions at local and community levels, and shifting cultures and aspirations (Catley et al., 2013; Washington-Ottombre and Pijanowski, 2013; Tari and Pattison, 2014; Cormack, 2016; Rao, 2019). Dryland regions are also witnessing demographic growth and change in land-use patterns linked to shifts in the composition of livestock (for example from grazers to browsers), a decrease in nomadic and increase in semi-nomadic pastoralism, and transition to more urban and sedentary livelihoods (Mganga et al., 2015; Cervigni et al., 2016; Greiner, 2016; Watson et al., 2016). At a landscape level, land is becoming more fragmented and enclosed, often associated with increases in subsistence and commercial agriculture, and the establishment of conservancies and other group or private land holdings (Reid et al., 2014; Carabine et al., 2015; Nyberg et al., 2015; Greiner, 2016; Mosley and Watson, 2016). In addition, there are political dynamics associated with Kenya Vision 2030 and decentralization, the influence of international capital, foreign investors and incorporation into global markets (Cormack, 2016; Kochore, 2016; Mosley and Watson, 2016; Enns and Bersaglio, 2020), as well as increasing militarization and conflict in the drylands (Lind, 2018). Allied to these social and political dynamics are ongoing processes of habitat modification and degradation and biophysical changes linked in part to climate variability (Galvin, 2009; Mganga et al., 2015). The interconnected nature of these drivers will intersect with LAPSSET in myriad ways. For example, the implementation of LAPSSET may accentuate some trends, such as increases in land enclosure and a shift towards more urban and sedentary livelihoods (Lesutis, 2020). Conversely, the perceived threat LAPSSET could pose to pastoral lifestyles may lead to greater visibility, solidarity and strength of pastoralist institutions (Cormack, 2016).

There is a recognized need to adapt and chose development pathways that are resilient to climate change whilst addressing key developmental challenges within dryland regions, notably, poverty, water and food insecurity, and a highly dispersed population with poor access to services (Government of Kenya, 2012; Bizikova et al., 2015; Herrero et al., 2016). The current vision for development of dryland regions comes with both opportunities and threats to achieve a more climate resilient future. For example, the growth in and exploitation of renewable energy resources, made possible through increased connectivity, brings climate mitigation gains but also risks. These risks include the uneven distribution of costs in terms of where the industry is sited compared with where benefits primarily accrue, and may exacerbate issues around water and food insecurity as strategic areas of land become harder to access (Opiyo et al., 2016; Cormack and Kurewa, 2018; Enns, 2018; Lind, 2018). Whilst LAPSSET will bring greater freedom of movement for commodities, benefitting investors, improving access to markets and urban centers, supporting trade, or ease of movement for tourists supporting economic goals, it can also result in the relocation of people and impede access to certain locations for the resident populations. Mobility is a key adaptation behavior employed in the short and long term to address issues linked with climatic variability (Opiyo et al., 2014; Muricho et al., 2019). With modelled changes in the climate suggesting decreases in income associated with agricultural staples and livestock-dependent livelihoods, development that constrains mobility of local populations could retard resilience gains (Ochieng et al., 2017; ASSAR, 2018; Enns, 2018; Nkemelang et al., 2018). The likely increase in urban populations and the growth in tourism and agriculture may lead to increases in water demand at a time when water availability could become more constrained owing to the reliance on surface water sources and the modelled increases in evapotranspiration due to rising mean temperature, more heatwave days and greater percentage of precipitation falling as storms (ASSAR, 2018; Nkemelang et al., 2018; USAID, 2018). These pressures could make it harder to meet basic health and sanitation goals for rural and poorer urban populations, issues compounded further by likely increases in child malnutrition and diarrheal deaths linked to climate change (WHO, 2016; ASSAR, 2018; Hirpa et al., 2018; Nkemelang et al., 2018; Lesutis, 2020). Development must pay adequate attention to these interconnections to ensure that costs and benefits of achieving climate mitigation and adaptation goals are distributed fairly within a population.

[END BOX 18.2. HERE]

18.2 Linking Development and Climate Action

The AR5 examined the relationship between climate and sustainable development in Chapter 13 (Olsson et al., 2014) and Chapter 20 (Denton et al., 2014) in Working Group II and Chapter 4 (Fleurbaey et al., 2014) in Working Group III. It concluded that dangerous levels of climate change would limit efforts to reduce poverty (Denton et al., 2014; Fleurbaey et al., 2014). Since the AR5, the adoption of the Paris Agreement and Agenda 2030 have demonstrated increased international consensus regarding the need to pursue climate change as a component of sustainable development. For example, climate change impacts *"undermine the ability of all countries to achieve sustainable development"* (United Nations, 2015) and can reverse or erase improvements in living conditions and decades of development (Hallegatte and Rozenberg, 2017). However, recent analysis shows that actions to meet the goals of the Paris Agreement can undermine progress toward some SDGs (*high agreement, medium evidence*) (Pearce et al., 2018b; Liu et al., 2019; Hegre et al., 2020) (18.2.5.3). Meanwhile efforts to achieve the SDGs can contribute to worsening climate change (*high agreement, medium evidence*) (Fuso Nerini et al., 2018). These findings in the literature highlight the importance of identifying clear goals and priorities for both climate action and sustainable development as well as mechanisms for capitalizing on potential synergies between them and for managing trade-offs. In assessing literature relevant to the intersection between climate action and development, we first explore the implications of different patterns of development and development trajectories followed by more focused assessment of the links between development and climate risk.

18.2.1 Implications of Current Development Trends

Understanding the interactions between climate change, climate action, and sustainable development necessitates consideration for the current development context in which different communities, nations, and regions find themselves. For example, wealthy economies of the global North will encounter different opportunities and challenges vis-à-vis climate change and sustainable development than developing economies of the global South. Moreover, all economies are already following an existing development trajectory that has implications for the type and scale of interventions associated with pursuing CRD and managing climate risk. Some nations may experience particular challenges with reducing greenhouse gas emissions due to the carbon-intensive nature of their energy systems *(very high confidence)* (18.3.1.1). Others may experience acute challenges with adaptation due to existing vulnerability associated with poverty and social inequality *(very high confidence*) (18.2.5.1). Overcoming such challenges is fundamental to the pursuit of CRD.

While demonstrable progress has been made toward the SDGs and improving human well-being, globally and in specific nations, some observed patterns of development are inconsistent with sustainable development and the principles of CRD *(very high confidence*) (van Dooren et al., 2018; Eisenmenger et al., 2020; Leal Filho et al., 2020). A significant literature, for example, links development to the loss of biodiversity and the extinction crisis (Ceballos et al., 2017; Gonçalves-Souza et al., 2020; Oke et al., 2021). Meanwhile, in human systems, indicators such as the limited convergence in income, life expectancy, and other measures of well-being between poor and wealthy countries (with notable outliers such as China) (Bangura, 2019), and the increase in income inequality and the decline in life expectancy and well-being in rich countries (Rougoor and van Marrewijk, 2015; Alvaredo et al., 2017; Goda et al., 2017; Harper et al., 2017; Goldman et al., 2018), suggest limitations of the current development paradigm to successfully deliver universal human and ecological well-being, by the 2030s or even mid-century (TWI, 2019).

18.2.2 Understanding Development in Climate Resilient Development

Development in this report is defined as efforts, both formal and informal, to improve standards of human well-being, particularly in places historically disadvantaged by colonialism and other features of early global integration. Development is not limited to the SDGs, however these represent an internationally agreed sub-set of goals. Prior IPCC reports employed development as a typological framing of the current state of a given country or population (IPCC, 2014a) (Section 1.1.4). Such framings frequently rest upon measures of economic activity, using them as proxies for the wider well-being of the population whose activity is measured. For example, the level of gross domestic product (GDP) is often equated with levels of social welfare, even though as a measure of market output it can be an inadequate metric for gauging well-being over time particularly in its environmental and social dimensions (Van den Bergh, 2007; Stiglitz et al., 2009).

The result of this broad framing linking economic growth to human well-being has been decades of policies, programs, and projects aimed at growing economies at scales from the household to regional and global. However, linking development to past and current modes of economic growth creates significant challenges for CRD, as it implies that the very processes that have contributed to current climate challenges, including economic growth and the resource use and energy regimes it relies upon, are also the pathways to improvements in human well-being. This places climate resilience and development in opposition to one another.

While there are many possible successful pathways to future development in the context of climate change, history shows that pathways positive for the vast majority of people, typically induce significant impacts and costs, especially on marginal and vulnerable people (Hickel, 2017). Frequently, considerations for social difference and equity are side-lined in these processes, for example through the assumption that a growing economy lifts opportunity for all, further marginalizing those who are the most vulnerable to climate change (Matin et al., 2018; Diffenbaugh and Burke, 2019).

The Agenda 2030 and its 17 SDGs and 169 targets seeks to 'leave no one behind' through five pillars (5Ps): People, Planet, Prosperity, Peace and Partnership (United Nations, 2015). The five pillars align with the dimensions of development that influence motion toward or away from CRD. The focus on **people** refers to inclusion rather than exclusion, and the extent to which people are empowered or disempowered to make decisions about their well-being, determine their futures and be in a position to assert their rights. This means being able to make decisions that determine whether people are on a pathway toward or away from CRD (Figures 18.1–18.3. The focus on **planet** refers to protecting the planet, ensuring a balance of ecosystems, biodiversity and human activities, and giving equal space and respect for its integrity. The focus on **prosperity** refers to equity in well-being grounded in unanimity over shared goals and resources, rather than individualism, and economic, social and technological progress grounded in stewardship and care, rather than exploitation. The focus on **partnership** refers to mutual respect embedded in solidarity that recognizes multiple worldviews and their respective knowledges, rather than singular or hierarchy of knowledge, and acknowledges inherent nature-society connections, rather than posing nature as opposites or competitors. The focus on **peace** emphasizes the need for just and equitable societies. These five pillars are interrelated but local and national contexts situate current status differently around the world. Successful achievement of Agenda 2030 is aligned with a safe climate with adequate mitigation and adaptation, and effective and inclusive systems transitions. With these conditions, a high CRD world can be attained, noting that when approached individually, the transformative potential of the SDGs is limited (Veland et al., 2021).

The need for transformational changes across sectors and scales to address the urgency and scope of action needed to enable a climate resilient future in which goals like the SDGs might be realized requires attention to the specific ways in which development action is defined and enacted (Box 18.1).

18.2.2.1 Development Perspectives

Development is about 'improvement'. However there have been different and oftentimes conflicting viewpoints on the improvement of 'what' and 'how' to improve. The diversity of positions has resulted in a multitude of metrics to track development, some more influential than others on policy. Alternative measures of development, while numerous, generally seek to nuance the connection between economic growth and human well-being. Because they maintain core notions of progress and, in some cases, economic growth seen in more mainstream models of development, they are less vehicles for transformation than continuations of thinking and action fundamentally at odds with the needs of climate resilient development. These include the Measure of Economic Welfare (Nordhaus and Tobin, 1973), the Index of Sustainable Economic Welfare (Cobb and Daly, 1989), the Genuine Progress Indicator (Escobar, 1995), the Adjusted Net Saving Index or the Genuine Savings Index (GSI), The Human Development Index (HDI), the Inequality-adjusted Human Development Index (UNDP, 2016a), the Gender Development Index, the Gender Inequality Index, and the Multidimensional Poverty Index, the Index of Sustainable Economic Welfare (ISEW) (Daly and Cobb, 1989), the Genuine Progress Indicator (GPI) (Kubiszewski et al., 2013), Gross National Happiness (GNH) (Ura and Galay, 2004), Measures of Australia's Progress (MAP) (Trewin and Hall, 2004), the OECD Better Life Index (OECD, 2019a), and the Happy Planet Index (NEF, 2016).

In terms of their historical trajectory, different perspectives on development can be broadly divided into five categories.

a) *Development as economic growth (1950s onwards)*: Equating development with economic growth was a natural outcome of the dominance of economics as the major discipline to study problems of newly independent countries in the 1950s (Escobar, 1995), measured through GDP. Environment was not a policy concern in the immediate period after decolonization. The GDP measure has withstood the test of time, in spite of being an inexact measure of human well-being, and is the widely used metric globally to track development. Recent improvements to GDP have tried to account for environmental factors (Gundimeda et al., 2007; United Nations, 2021).

b) *Development as distributional improvements (1970s onwards)*: That economic growth does not automatically result in decline in poverty and improved distribution of income became apparent in the 1970s. Welfare measures were thus promoted that involved 'redistribution with growth' (Chenery, 1974). These distributional concerns have re-emerged in the last two decades with the widening gap between the richer and poorer groups of the population (Chancel and Piketty, 2019) and also the increased attention to 'ecological distribution conflicts' (Martinez-Alier, 2021). The political economy perspective, highlighting continued dependencies of countries in the Global South on the Global North, now evolved into political ecology highlighting environmental concerns between and within countries. Environment was not yet a policy priority, despite that the links between development and environment were becoming clearer.

c) *Development as participation (1980s onwards)*: Bottom-up responses emphasizing sustainable livelihoods and local-level development emerged in the 1980s. The movement which involved independent and uncoordinated efforts by grassroots activists, social movements and NGOs became 'mainstreamed' into development in the 1990s (Chambers, 2012). The multidimensional nature of poverty was acknowledged at the global policy level (World Bank, 2000) and there was wider acceptance of the role of non-economics social sciences as well as critical approaches in research on development and poverty (Thomas, 2008). Participatory development involved decentralization and local planning, emphasizing protection of local natural resources in addition to improving living standards.

d) *Development as expansion of human capabilities (1980s onwards)*: The human development and capabilities approach was the first formidable response to the GDP-centric view of development (Sen, 2000; Deneulin and Shahani, 2009). Studies showed that improvements in income did not necessarily improve human well-being in other dimensions such as health and education, or more broadly put, 'freedoms' (Ruggeri Laderchi et al., 2003). The capabilities idea was influential in global policy making through Human Development Reports and metrics such as Human Development Index (HDI) and Multidimensional Poverty Index (MPI). However, environmental sustainability was not a major component in this approach until much later (Alkire and Jahan, 2018). Recent improvements to HDI such as the Planetary pressures-adjusted HDI (United Nations, 2020) is a step in this direction.

e) *Development as post-growth (2010 onwards)*: The late 1980s saw a big push towards taking the environment to the center of the global policy agenda (World Commission on Environment and Development, 1987). However, progress in addressing environmental questions has been slow. As compared to Millennium Development Goals (MDGs), SDGs aim to tackle environmental concerns by explicitly tracking progress on multiple indicators. Nevertheless, the approach in these policy propositions sits largely within the economic growth framework itself. The climate change challenge and the financial crisis of 2008 led many scholars, ecological economists and environmental social scientists in particular, to argue for a post-growth world. Post-growth (Jackson, 2021), degrowth (Kallis, 2018; Hickel et al., 2021) and other environmentalist scholarship takes inspiration from critiques of development such as post-development (Escobar, 1995). The argument here is not for better metrics but for imagining and working towards systemic change in the wake of the climate crisis. The challenge however is how to account for historical differences in economic growth and living standards between Global North and Global South and to protect the interests of Global South in the spirit of 'common but differentiated responsibilities' to climate change adaptation and mitigation. As empirical studies in Global South have demonstrated (Lele et al., 2018), developing countries face multiple stressors, climate change being just one among them, and there are multiple normative concerns in developing country contexts, such as equity and justice, and not merely resilience (*very high confidence)*.

To achieve climate resilient development requires framings of development that move away from linear paradigms of development as material progress by focusing on diversity and heterogeneity, wellbeing and equality, not only in contemporary practices, but also pathways of change over time (Gibson-Graham, 2005; Gibson-Graham, 2006). Such approaches, which are fundamentally aligned with ecological and ecosystem-based environmental assessments which identified heterogeneity of approaches and actions as the most effective path to a sustainable world (Millennium Ecosystem Assessment, 2005), emphasize the importance of cultural, linguistic and religious diversity, not merely as alternative sources of information about the world, but as different paradigms of well-being (Kallis, 2018). These include indigenous and local knowledges that provide alternatives to these framings of the world (Cross-Chapter Box INDIG). This broad reframing of development includes a focus on visions such as 'buen vivir' (Cubillo-Guevara et al., 2014; Walsh, 2018; Acosta et al., 2019), ecological Swaraj (Kothari et al., 2014; Demaria and Kothari, 2017; Shiva, 2017), and Ubuntu (Dreyer, 2015; Ewuoso and Hall, 2019), among others. All are linked by relationships with nature radically different from the Western mechanistic vision, presenting not only framings of development and the environment that yield locally-appropriate climate resilient development pathways, but serve as examples of alternative ways of living in balance with nature that might inform similar thinking in other places.

18.2.2.2. Complexity of Development and Climate Action

Differing perspectives on development are in part determined by the multiple diverse priorities held by different actors and nations. Another reason is that development is not a linear process with a single goal, and active development planning requires simultaneously taking multiple processes and factors into account. This is well illustrated by growing attention to climate security. The AR5 delivered conflicting messages regarding climate change and security (Gleditsch and Nordås, 2014), yet the understanding of climate-related security risks has made substantial progress in recent years (von Uexkull and Buhaug, 2021). Although there remains a considerable research gaps in certain regions (Adams et al., 2018), a large body of qualitative and quantitative studies from different disciplines provides new insight into the relationship of climate change and security (Buhaug, 2015; De Juan, 2015; Brzoska and Fröhlich, 2016; Abrahams and Carr, 2017; Sakaguchi et al., 2017; Moran et al, 2018; Scheffran, 2020). Though not the only cause (Sakaguchi et al., 2017; Mach et al., 2019), climate change undermines human livelihoods and security, because it increases the populations vulnerabilities, grievances, and political tensions through an array of indirect – at times non-linear – pathways, thereby increasing human insecurity and the risk of violent conflict (van Baalen and Mobjörk, 2018; Koubi, 2019; von Uexkull and Buhaug, 2021). Indeed, context, as well as timing and spatial distribution matter and need to be accounted for (Abrahams, 2020).

In line with this better understanding, climate change and security have been reframed in the political space, to focus more on human security. The solutions to climate-related security risks cannot be military, but are linked to development and people's vulnerabilities in complex social and politically fragile settings (Abrahams, 2020). This has resulted in integration of climate-related security risk into institutional and national frameworks (Dellmuth et al., 2018; Scott and Ku, 2018; Aminga and Krampe, 2020), including several NDCs (Jernnäs and Linnér, 2019; Remling, 2021). One example is the UN Climate Security Mechanism – set up in 2018 between UNDP, UNEP and UN DPPA to help the UN more systematically address climate-related security risks and devise prevention and management strategies. Yet, work remains in bridging these concerns with practical responses on the ground (Busby, 2021). Especially since emerging research building on the maladaptation literature, shows that this practice cannot just mean adding adaptation and mitigation to the mix of development strategies in a given location, as this may have unintended and unanticipated effects and might even backfire completely (Dabelko et al., 2013; Magnan et al., 2020; Mirumachi et al., 2020; Schipper, 2020; Swatuk et al., 2021). In extremely underdeveloped, fragile contexts such as Afghanistan, the local-level side effects of climate adaptation and mitigation projects might result in different development outcomes and question the potential for sustainable peace (Krampe et al., 2021). Given the clearer understanding of the intertwined nature of climate change, security, and development – especially in fragile and conflict affected regions – a rethinking of how to transfer this knowledge into policy solutions is necessary for the formulation of climate resilient development.

18.2.3 Scenarios as a Method for Representing Future Development Trajectories

Sustainable development represents specific development processes and priorities that can affect climate risk. As a result, sustainable development both shapes the context in which different actors experience climate change and represents a potential opportunity, particularly by reducing climate risk by addressing vulnerability, inequity, and shifting development toward more sustainable trajectories (IPCC, 2012; Denton et al., 2014; IPCC, 2014b; IPCC, 2014a; IPCC, 2018a; IPCC, 2019b). As assessed in past IPCC special reports and assessment reports, this same literature has also illustrated how different socioeconomic conditions affect mitigation options and costs. For example, variations in future economic growth, population size and composition, technology availability and cost, energy efficiency, resource availability, demand for goods and services, and non-climate-related policies (e.g., air quality, trade) individually and collectively have all been shown to result in different climates and contexts for mitigation and adaptation.

One common approach for exploring the implications of different development trajectories is the use of scenarios of future socioeconomic conditions, such as the Shared Socioeconomic Pathways (SSPs) (O'Neill et al., 2017). The SSPs represent sets of future global societal assumptions based on different societal, technological, and economic assumptions that result in different development trajectories. Such scenarios often correspond to a small set of scenario archetypes (Harrison et al., 2019; Sitas et al., 2019; Fergnani and Song, 2020) in that they reflect core themes regarding the future of development such as sustainability versus rapid growth. Scenarios with assumptions more closely aligned with sustainability agendas (e.g., SSP1-Sustainability) commonly imply lower greenhouse gas emissions and projected climate change (see WGIII

AR6 Chapter 3), lower mitigation costs for ambitious climate goals (see WGIII AR6 Chapter 3), lower climate exposure due in large part to the size of society (see Chapter 16), and greater adaptive capacity (Roy et al., 2018) (see also Chapter 16). In contrast, scenarios with rapid global economic and fossil energy growth (e.g., SSP5-Fossil-Fueld Development) imply higher emissions and project climate change, higher mitigation costs, as well as greater social and economic capacity to adapt to climate change impacts (Hunt et al., 2012) (Table 18.1).

The SSPs incorporate various assumptions regarding population, GDP, and greenhouse gas emissions, for example, that are relevant to development and climate resilience. In addition, the SSPs have been used to explore a broad range of development outcomes for human and ecological systems (Table 18.1), including multiple studies explore futures for food systems, water resources, human health, and income inequality. Limited, top-down modelling studies have used the SSPs to explore issues such as societal resilience (Schleussner et al., 2021) or gender equity (Andrijevic et al., 2020a). Such studies indicate that different development trajectories have different implications for future development outcomes, but results vary significantly among different climate (e.g., representative concentration pathways [RCPs]) and development contexts, resulting in *limited agreement* among different SSPs (Table 18.1). Nevertheless, for some outcomes, SSPs are associated with generally similar outcomes. Over the near-term (e.g., 2030), those outcomes are strongly influenced by development inertia and path dependence, reducing differences among SSPs. Outcomes diverge later in the century, but fewer studies explore futures beyond 2050. Collectively, the scenarios reflect trade-offs associated with different development trajectories (Roy et al., 2018), with some SSPs foreshadowing outcomes that are positive in some contexts, but negative in others (Table 18.1). For example, pathways that lead to poverty reduction can have synergies with food security, water, gender, terrestrial and ocean ecosystems that support climate risk management, but also poverty alleviation projects with unintended negative consequences that increase vulnerability (e.g., Ley, 2017; Ley et al., 2020).

Table 18.1: Implications of different socioeconomic development pathways for CRD indicators. Studies presented in the above table include qualitative storylines and quantitative scenarios for two or more SSPs. Arrows and color coding reflect the positive or negative impacts on sustainability based on aggregation of results for the 2030-2050 time horizon across the identified studies. Confidence language reflects the number of studies upon which results are based (evidence) and the agreement among studies regarding the direction of change (agreement).

Development Indicator	Relevant SDG	Shared Socioeconomic Pathway					Confidence Evidence/ Agreement	References
		Sustainability (SSP1)	Middle of the Road (SSP2)	Regional Rialry (SSP3)	Inequality (SSP4)	Fossil-fueled Development (SSP5)		
Agriculture, Food, & Forestry • *Agriculture production* • *Forestry production* • *Food security* • *Hunger*	SDG 2	↗	↔	↘	↘	↘	*Low Agreement/ Robust Evidence*	(Hasegawa et al., 2015; Palazzo et al., 2017; Riahi et al., 2017; Duku et al., 2018; Chen et al., 2019; Daigneault et al., 2019; Mitter et al., 2020; Mora et al., 2020)
Health & Well-Being • *Excess mortality* • *Air quality*	SDG 3	↔	↔	↔	↘	↘	*Medium Agreement/ Robust Evidence*	(Chen et al., 2017; Mora et al., 2017; Aleluia Reis et al., 2018; Asefi-Najafabady

Water & Sanitation • *Water use* • *Sanitation access* • *Sewage discharge*	SDG 6	↗	↘	↘	↔	↔	*High Agreement/ Medium Evidence*	(Wada et al., 2016) (van Puijenbroek et al., 2014; Yao et al., 2017) (Mouratiadou et al., 2016; Graham et al., 2018)
Inequality • *Gini coefficient*	SDG 10	↗	↗	↗	↔	↗	*Medium Agreement/ Limited Evidence*	(Rao et al., 2019b; Emmerling and Tavoni, 2021; Gazzotti et al., 2021)
Ecosystems and Ecosystem Services • *Aquatic resources* • *Urban expansion* • *Habitat provision* • *Carbon sequestration* • *Biodiversity*	SDG 14 SDG 15	↘	↘	↘	↘	↘	*High Agreement/ Medium Evidence*	(Li et al., 2017; Chen et al., 2019; Li et al., 2019b; Chen et al., 2020b; Song et al., 2020b; McManamay et al., 2021; Pinnegar et al., 2021)

Legend
↓ Balance of studies suggest large increasing threat to sustainable development
↘ Balance of studies suggest moderate increasing threat to sustainable development
↔Studies suggest both threats and benefits to sustainable development
↗ Balance of studies suggest moderate increasing benefit to sustainable development
↑ Balance of studies suggest large increasing benefit to sustainable development

Table Notes:
Studies presented in the above table include qualitative storylines and quantitative scenarios for two or more SSPs. Arrows and color coding reflect the positive or negative impacts on sustainability based on aggregation of results for

the 2030-2050 time horizon across the identified studies. Confidence language reflects the number of studies upon which results are based (evidence) and the agreement among studies regarding the direction of change (agreement).

While the scenarios literature is useful for characterizing the potential climate risk implications of different global societal futures, important limitations impact their use in climate risk management planning *(very high confidence*). The first is the often highly geographically aggregated nature of the SSPs and other scenarios, which, in the absence of application of nesting or downscaling methods, often lack regional, national, or sub-national context, particularly regarding social and cultural determinants of vulnerability (van Ruijven et al., 2014). Furthermore, there is limited understanding of the cost and what is required to transform from today into each socioeconomic future, or the opportunity to shift from one pathway to another (18.3). Furthermore, the characteristics of the pathways suggest that they are not equally likely, there are relationships implied in assumptions that are uncertainties to consider (e.g., land productivity improvements are land saving), it is difficult to identify the role of different development characteristics, and policy implementation is stylized. In general, global assessments are not designed to inform local planning given that there are many local circumstances consistent with a global future and unique local development context and uncertainties to manage—demographic, economic, technological, cultural, policy.

Overall, pursuing sustainable development in the future is shown to have synergies and trade-offs in its relationships with every element of climate risk: the emissions and mitigation determining hazard, the size, location, and composition of development determining exposure; and the adaptive capacity determining vulnerability. Importantly, the scenarios literature overall has found trade-offs such that none of the global societal projections achieve all the sustainable development goals *(very high confidence*) (Roy et al., 2018) (18.2.5.3). Historical evidence supports this as well, for example, finding low-cost energy and food access historically associated with higher emissions but greater adaptive capacity, and energy efficiency innovation contributing to lower emissions and greater adaptive capacity (e.g., Blanford et al., 2012; Blanco et al., 2014; Mbow et al., 2019; USEPA, 2019). The literature suggests that trade-offs in the pursuit of sustainable development are inevitable. Managing those trade-offs, as well as capitalizing on the synergies, will be important for CRD, particularly given trade-offs have distributional implications that could contribute to inequities (18.2.5.3).

18.2.4 Climate Change Risks to Development

Over the next decade, additional climate change is expected regardless of the scale of greenhouse gas mitigation efforts (IPCC, 2021a). Across the global scenarios analyzed in the AR6, global average temperature changes relative to the reference period 1850-1900 range from 1.2˚C to 1.9˚C for the period 2021–2040 and 1.2˚C to 3.0˚C for the period 2041-2060 (WGI AR6 SPM *very likely* range). However, the feasibility of emissions pathways (particularly, RCP8.5) affect the plausibility of the associated climate projections, potentially lowering the upper end of these ranges (see WGIII AR6 Chapter 3). There is significant overlap between climate scenario ensemble ranges from different emissions scenarios through 2050, more so than through 2100 (Lee et al., 2021). There is also overlap between emissions scenario ensembles consistent with different temperature outcomes (see WGIII AR6 Chapter 3). Emissions pathway ranges represent uncertainties for policy-makers and organizations to consider and manage (Rose and Scott, 2018, 2020) regarding, among other things, economic growth and structure, available technologies, markets, behavioral dynamics, policies, and non-CO_2 climate forcings (see WGIII AR6 Chapter 3), while climate pathway ranges represent bio-physical climate system and carbon cycle uncertainties (Lee et al., 2021). For all climate projections and variables, there is significant regional heterogeneity and uncertainty in projected climate change *(very high confidence*) (IPCC, 2021a). Figure 18.4 (left panel) presents examples for average and extreme temperature precipitation change (see also 18.5 and Tables 18.4−18.5 for more regional detail). Similarly, for all emissions projections, there is significant regional, sectoral, and local heterogeneity and uncertainty regarding potential pathways for climate action (see WGIII AR6 Chapter 3 and Chapter 4). Not all uncertainties are represented in projected emissions pathway ensembles, such as policy timing and design (e.g., Rose and Scott, 2018) or climate projection ensembles.

The projected ranges for near-term and mid-term global average warming levels are estimated to result in increasing key risks and reasons for concern (Chapter 16). Chapter 16 developed aggregate "Representative Key Risks" (RKRs) as indicators for subsets of approximately one hundred sectoral and regional key risks indicators. The RKRs include risks to coastal socio-ecological systems, terrestrial and ocean ecosystems, critical physical infrastructure, networks and services, living standards and equity, human health, food security, water security, and peace and migration. The majority of these risks are directly linked to sustainable development priorities and the SDGs (Chapter 16, WGII AR6 sectoral and regional chapters; (Roy et al., 2018; IPCC, 2019d; IPCC, 2019b). Therefore, climate risks represent a potential additional challenge to pursuing sustainable development priorities, but also potential opportunities due to geographic variation in climate impacts. In addition, positive synergies have been found between sustainable development and adaptation, but trade-offs are also possible (e.g., Roy et al., 2018).

For all RKRs, additional global average warming is expected to increase risk. However, the increases vary significantly by RKR, and across the underlying key risks represented within each RKR. Geographic variation in key risk implications is only partially assessed in Chapter 16, but evidence can be drawn from the WGII individual regional chapters. Regionally, key risks are found to be potentially greatest in developing and transition economies (Chapter 16 and sectoral chapters), which is also where the least-cost emissions reductions are shown to be (see WGIII AR6 Chapter 3). See Figure 18.4 for an example of key risk geographic heterogeneity (see also 18.5 for regional detail). Chapter 16 also maps the RKRs to an updated aggregate "Reasons for Concern" (RFC) framing. Thus, increasing RKR risk implies increasing RFC associated with unique and threatened systems, extreme weather events, distribution of impacts, global aggregate impacts, and large-scale singular events.

Climate risks are found to vary with future warming levels, the development context and trajectory, as well as by the level of investment in adaptation. Together, these three dimensions define risk – with projected climate changes defining the hazard, development defining the exposure, and development and adaptation defining vulnerability. However, how these different dimensions interact and the level of scientific understanding vary significantly among different types of risk. For human systems, in general, the poor and marginalized are found to have greater vulnerability for a given hazard and exposure level. With some level of global average warming expected regardless of mitigation efforts, human and natural systems will be exposed to new conditions, but some level of adaptation should also be expected.

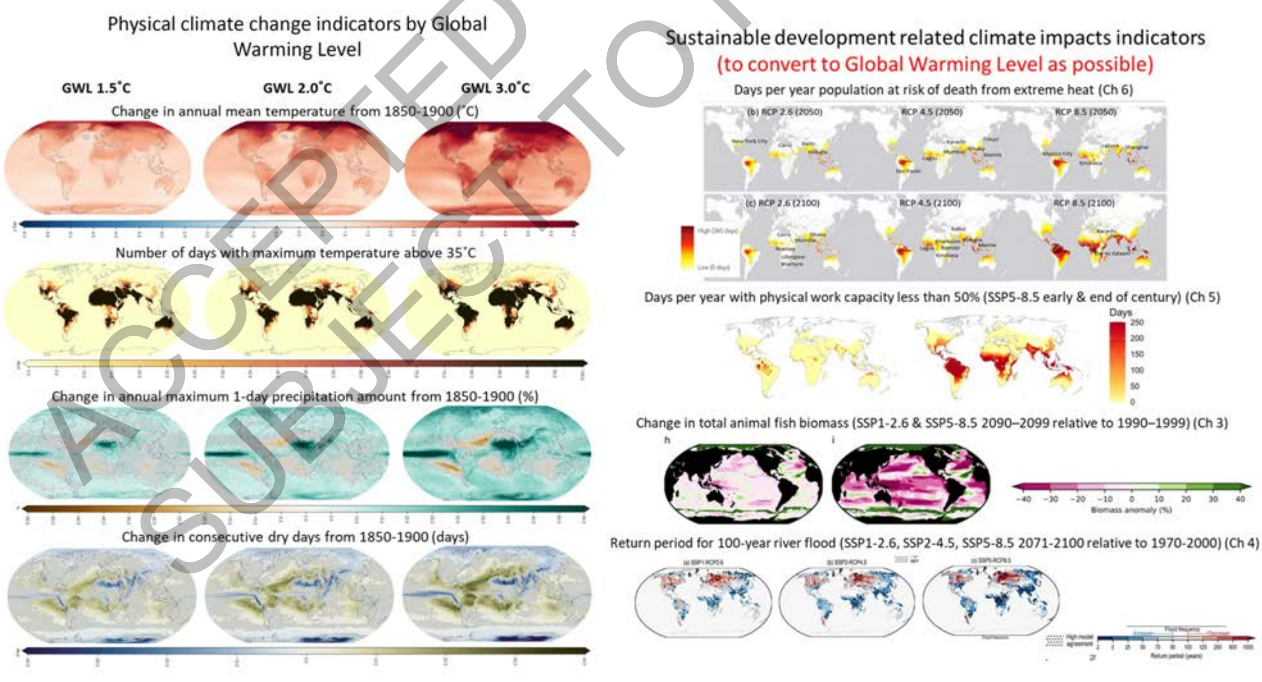

Figure 18.4: Regional projected select climate change and sustainable-development-related climate impact variables by global warming level. Sources: WGI and WGII AR6 reports.

18.2.5 Options for Managing Future Risks to Climate Resilient Development

The pursuit of CRD requires not only the implementation of individual adaptation, mitigation, and sustainable development initiatives, but also their careful coordination and integration. This section assesses the literature on CRD in the context of key climate change risks (Chapter 16); gaps in adaptation that contribute to risk; potential synergies and trade-offs among mitigation, adaptation and sustainable development; and the mechanisms for managing those trade-offs.

18.2.5.1 Adaptation

18.2.5.1.1 Adaptation and climate-resilient development

Given adaptation is recognized as a key element of addressing climate risk and CRD, the capacity for adaptation implementation is an important consideration for CRD. The AR5 noted a significant overlap between indicators of sustainable development and the determinants of adaptive capacity, and suggested that adaptation presents an opportunity to reduce stresses on development processes and the socio-ecological foundations upon which they depend (Denton et al., 2014). At the same time, it also noted that building adaptive capacity for sustainable development might require transformational changes that shift impacted systems to new patterns, dynamics, or places (Denton et al., 2014). Thus, adaptation interventions and pathways can further the achievement of development goals such as food security (Campbell et al., 2016; Douxchamps et al., 2016; Richardson et al., 2018; Bezner Kerr et al., 2019) and improvements in human health (Watts et al., 2019) including in systems where animals and humans live in close proximity *(very high confidence*) (Zinsstag et al., 2018). However, to do so requires not only the avoidance of incremental adaptation actions that extend current unsustainable practices, but also the ability to manage and overcome the barriers which arise when the limits of incremental adaptation are reached (*high agreement; medium evidence)* (Few et al., 2017; Vermeulen et al., 2018; Fedele et al., 2019).

Since AR5, the scientific community has deepened its understanding of the relationship between adaptation and sustainable development *(very high confidence*), particularly with regard to the place of resilience at the intersection of these two arenas. The literature has moved forward in its identification of specific overlaps in sustainable development indicators and determinants of adaptive capacity, how adaptation might reduce stress on development processes and their socio-ecological foundation, and how building adaptive capacity might facilitate needed transformative changes. Broadly speaking, work on these topics comes from one of two perspectives. One perspective speaks to adaptation practices that might further sustainable development outcomes, while another perspective draws on deeper understandings of the socio-ecological dynamics of the systems in which we live, and which we may have to transform in the face of climate change impacts. These two literatures are not yet well-integrated, leaving gaps in our knowledge of how best to implement adaptation in a manner that achieves sustainable development.

The literature considering adaptation and development in practice since AR5 suggests that efforts to connect adaptation to sustainable development should address proximate and systemic drivers of vulnerability (Wise et al., 2016) while remaining flexible and reversable to avoid the lock-in of undesirable or mal-adaptive trajectories (Cannon and Müller-Mahn, 2010; Wise et al., 2016). Such goals require critical reflection on processes for decision-making and learning. In the AR5, more inclusive, participatory adaptation processes were presumed to benefit development planning by including a wider set of actors in discussions of future goals (Denton et al., 2014). The post-AR5 literature expands on these critical perspectives to provide context regarding when participation is most effective. For example, (Eriksen et al., 2015) emphasize the need to build participatory adaptation processes to avoid subsuming adaptation goals to development-as-usual while (Kim et al., 2017b) argues that this practice is most effective when it is focused on development efforts and considers how climate change will challenge the goals of those efforts. Adaptation, while presenting an opportunity to foster transformations needed to address the impacts of climate change on human well-being, is also a contested process that is inherently political (*medium agreement, medium evidence*) (Eriksen et al., 2015; Mikulewicz, 2019; Nightingale Böhler, 2019; Eriksen et al., 2021b). How adaptation can challenge development and create a situation where CRD effectively becomes transformative adaptation, adaptation that generates transformation of broader aspects of development, remains unclear (*medium agreement, limited evidence*) (Few et al., 2017; Schipper et al., 2020c).

The critical literature on socio-ecological resilience, which has grown substantially since the last AR *(very high confidence*), speaks to some of these questions. Since AR5, the IPCC and the wider literature on socio-ecological resilience have shifted their use of the term to reflect not only the capacity to cope with a hazardous event or trend or disturbance, but also the ability to adapt, learn, and transform in ways that maintains a socio-ecology's essential function, identity and structure (WGII Chapter 1, Glossary). This change in usage is significant in that it shifts resilience from an emergent property of complex socio-ecological systems to a deeply human product of efforts to manage ecology, economy, and society to specific ends. This definition of resilience recognizes the need to define what is an essential identity, function, and structure for a given system, questions rooted not in ecological dynamics, but in politics, agency, difference, and power that emerge around the management of ecological dynamics (Cote and Nightingale, 2011; Brown, 2013; Cretney, 2014; Forsyth, 2018; Matin et al., 2018; Carr, 2019).

By connecting this framing of socio-ecological dynamics to the literature on the principles for adaptation efforts that meet development goals, new work has begun to identify 1) how adaptation can reduce stress on development processes, 2) how it might facilitate transformative change, and 3) where adaptation interventions might either drive system rigidity and precarity, or otherwise challenge development goals (Castells-Quintana et al., 2018; Carr, 2020). For example, Jordan (2019) draws upon these contemporary framings of resilience to highlight the ways in which coping strategies perpetuate the gendered norms and practices at the heart of women's vulnerability in Bangladesh. Forsyth (2018) draws upon this work to highlight the ways in which the theory of change processes used by development organizations tend to exclude local experiences and sources of risk, and thus foreclose the need for transformative pathways to achieve development goals. Carr (Carr, 2019; 2020) draws upon evidence from sub-Saharan Africa to develop more nuanced understandings of the ways in which different stressors and interventions either facilitate or foreclose transformative pathways, while pointing to the existence of yet poorly-understood thresholds for transformation in systems that can be identified and targeted by interventions.

18.2.5.1.2 Adaptation Gaps

Adaptation gaps are defined as "the difference between actually implemented adaptation and a societally set goal, determined largely by preferences related to tolerated climate change impacts and reflecting resource limitations and competing priorities" (UNEP, 2014; UNEP, 2018a). Adaptation deficit is a similar concept, described as an inadequate or insufficient adaptation to current conditions (see Ch 1). Adaptation gaps or deficits arise from a lack of adequate technological, financial, social, and institutional capacities to adapt effectively to climate change and extreme weather events, which are in turn linked to development *(very high confidence)* (Fankhauser and McDermott, 2014; Milman and Arsano, 2014; Chen et al., 2016; Asfaw et al., 2018) (18.2.2).

Currently, there is no consensus around approaches to assess the effectiveness of adaptation actions across contexts and therefore measure adaptation gaps at a global scale (Singh et al., 2021a). UNEP (2021) suggests that comprehensiveness, inclusiveness, implementability, integration and monitoring and evaluation can be used to assess them (see also Cross-Chapter Box FEASIB). However, limited information is available about future trends in national-level adaptation, and the development of monitoring and evaluation mechanisms. Despite the challenges of measurement associated with adaptation gaps, available evidence from smaller scales across several regions, communities, and businesses suggest that significant adaptation gaps have existed in historical contexts of climate change, while expectations of extreme heat, increasing storm intensity, and rising sea levels will create the context for the emergence of new gaps *(very high confidence*) (Hallegatte et al., 2018; UNEP, 2018a; Dellink et al., 2019; UNEP, 2021). These adaptation gaps create risks to well-being, economic growth, equity, the health of natural systems, and other societal goals. The negative impacts of these gaps can be compounded by adaptation efforts that are considered maladaptive or by development actions that are labelled as adaptation (see Chapter 16).

A higher level of adaptation finance is critical to enhance adaptation planning and implementation and reduce adaptation gaps, particularly in developing countries *(very high confidence*) (UNEP, 2021) (Cross-Chapter Box FINANCE in Chapter 17, 18.4.2.2). However, adaptation finance is not keeping pace with the rising adaptation costs in the context of increasing and accelerating climate change, as "annual adaptation costs in developing countries alone are currently estimated to be in the range of US$70 billion, with the expectation of reaching US$140–300 billion in 2030 and US$280–500 billion in 2050" (UNEP, 2021). Investment in attaining SDGs helps bridge adaptation gaps (Birkmann et al., 2021), but care needs to be taken to avoid maladaptation through mislabeling. Integration of the indigenous and local knowledge systems is anticipated to reduce existing adaptation gaps and secure livelihood transitions.

Analysis of investments by four major climate and development funds (the Global Environment Facility, the Green Climate Fund, the Adaptation Fund and the International Climate Initiative) by UNEP (2021) suggests that support for green and hybrid adaptation solutions has been increasing over the past two decades. These could be effective at reducing climate risks and bridging adaptation gaps while simultaneously bringing important additional benefits for the economy, environment, livelihoods (UNEP, 2021) (see also Cross-Chapter Box NATURAL in Chapter 2).

Lately, the evidence of adaptation activity in the health sector has been increasing (Watts et al., 2019), yet substantial adaptation gaps persist (UNEP, 2018a; UNEP, 2021), including gaps in humanitarian response to climate-related disasters (Watts et al., 2019). It is the under-investment in climate and health research in general and health adaptation in particular that has led to adaptation gaps in the health sector (Ebi et al., 2017).

Costs of implementing efficient adaptation measures and water-related infrastructure in water-deficient regions have received attention at the global and regional level to bridge the 'adaptation gap' (Hallegatte et al., 2018; UNEP, 2018a; Dellink et al., 2019; UNEP, 2021). Livelihood sustainability the drylands, which cover more than 40% of land surface area, are home to roughly 2.5 billion people, and support approximately 50% of the livestock and 45% of the food production, is threatened by a complex and interrelated range of social, economic, and environmental changes that present significant challenges to rural communities, especially women (Abu-Rabia-Queder and Morris, 2018; Gaur and Squires, 2018). Adaptation deficits in arid and semi-arid regions are of high order (see CCP 3). In order to reduce adaptation deficit in arid and semi-arid regions comprehensive and efficient adaptation interventions integrating better water management, use of non-traditional water sources, changes in reservoir operations, soil ecosystem rejuvenation, and enhanced institutional effectiveness are needed (18.5) (Makuvaro et al., 2017; Mohammed and Scholz, 2017; Morote et al., 2019). Communities facing the lack of adequate technological, financial, human, and institutional capacities to adapt effectively to current and future climate change often encounter adaptation deficits. In order to address current adaptation barriers and adaptation deficits, there is a need to promote efficient adaptation measures, coupled with inclusive and adaptive governance involving marginalized groups such as indigenous communities and women.

Although unevenly distributed urban adaptation gaps exist in all world regions (see Chapter 6). Such gaps are higher in the urban centers of the poorer nations. Chapter 6 identified the critical capacity gaps at city and community levels that are responsible for adaptation gaps are: "ability to identify social vulnerability and community strengths, and to plan in integrated ways to protect communities, alongside the ability to access innovative funding arrangements and manage finance and commercial insurance; and locally accountable decision-making with sufficient access to science, technology and local knowledge to support the application of adaptation solutions at scale".

Insufficient financial resources are the main reasons for the coastal adaptation gap particularly in the Global South (see CCP2). Engaging the private sector with a range of financial tools is crucial to address such gaps (see CCP2). An urgent and transformative action to institutionalize locally-relevant integrative adaptation pathways is crucial for closing coastal adaptation gaps. Additional efforts are in place for assessing global adaptation progress (see Cross-Chapter Box PROGRESS in Chapter 17].

18.2.5.1.3 Adaptation implementation

As discussed in Chapter 16, adaptation is a key mechanism for managing climate risks (Chapter 16), and therefore for pursuing CRD. The lower estimates in Table 18.2 are associated with higher levels of adaptation and more conducive development conditions. Furthermore, additional adaptation demand is associated with greater levels of climate change. Adaptation is a broad term referring to many different levels of response and options for natural and human systems, from individuals, specific locations, and specific technologies, to nations, markets, global dynamics, and strategies at the system level. Adaptation also includes endogenous reflexive and exogenous policy responses. Perspectives on limits to adaptation, synergies, trade-offs, and feasibility therefore depend on where the boundaries are drawn and the objective. Overall, there are a broad range of adaptation options relevant to reducing risks posed by climate change to development. However, current understanding of how such options are implemented in practice, their effectiveness across a range of possible climate futures, and their potential limits, is modest.

Past assessments have evaluated individual adaptation options in terms of economic, technological, institutional, socio-cultural, environmental/ecological, and geophysical feasibility (de Coninck et al., 2018). This analysis has been updated for AR6 (Cross-Chapter Box FEASIB). These assessments identify types of barriers that could affect an option's feasibility. Among other things, this work finds that every adaptation option evaluated had at least one feasibility dimension that represented a barrier or obstacle. The barriers also imply that there are trade-offs in these feasibility dimensions to consider. Overall, insights from this work are high-level and difficult to apply to a specific adaptation context. The feasibility and ranking of adaptation opportunities, as well as the list of opportunities themselves, for a given location will vary from location-to-location, with different criteria and weighting of criteria that reflect the relevant social priorities and differences in markets, technology options, and policies for managing risks and trade-offs. Integrated evaluation of criteria and options is needed, that accounts for the relevant geographic context and interactions between options and systems (18.5).

Sustainable development is regarded as generally consistent with climate change adaptation, helping build adaptive capacity by addressing poverty and inequalities and improving inclusion and institutions (Roy et al., 2018). Some sustainable development strategies could facilitate adaptation effectiveness by addressing wider socio-economic barriers, addressing social inequalities, and promoting livelihood security (Roy et al., 2018). With a common goal of reducing risks, sustainable development and adaptation are relatively synergistic. However, trade-offs have been found and important to consider and potentially manage. Synergies have been found between adaptation and poverty reduction, hunger reduction, clean water access, and health; while, trade-offs have also been found, particularly when adaptation strategies prioritize one development objective (e.g., food security or heat-stress risk reduction) or promote high-cost solutions with budget allocation and equity implications (Roy et al., 2018) (18.2.5.3, 18.5). There are also opportunities for managing the trade-offs, in particular distributional effects—by recognizing that there are trade-offs and considering alternatives and complementary strategies to offset the trade-offs (Section 18.2.5.3).

Box 18.3: Climate Resilient Development in Small Islands

Small Islands are particularly vulnerable to climate change and many are already pursuing climate resilient development pathways that enable integrated responses (Allen et al., 2018a; Mycoo, 2018; Hay et al., 2019; Robinson et al., 2021). Countries, such as Belize, have opted for a systems-approach and are working across the SDGs to increase integration (Allen et al., 2018a). This includes rethinking disaster reconstruction mechanisms in the Caribbean and introducing more diversified and sustainable tourism economies that can better withstand external shocks such as disruptions and loss of markets from COVID-19 (Sheller, 2021). In the Seychelles, various government and tourism industry initiatives are focused on the promotion of sustainable tourism ventures that lower emissions, protect and promote biodiversity conservation (e.g. new marine protected areas with mitigation and adaptation benefits), and are climate resilient (Robinson et al., 2021). In 2016 the Seychelles signed the world's first nature-for-debt swap wherein an NGO (The Nature Conservancy) agreed to pay off Seychelles' public debt to the Paris Club (foreign creditors) in return for the Seychelles government establishing marine conservation areas (Silver and Campbell, 2018).

One key area where enhanced climate risk integration is critical is infrastructure-related decisions especially on coastal areas (World Bank, 2017). However, despite increasing awareness of climate risks and experienced impacts, decisions on for example infrastructure locations still reflect cultural preferences. For example, Hay et al. (2019) report that despite recommendations to relocate the redevelopment site of the Parliamentary Complex in Samoa away from the coast, multiple cultural and historical factors influenced the decisions to redevelop at the original site. In the Solomon Islands, however, emerging evidence suggests that adaptation efforts to enhance the resilience of infrastructure are also serving to help urban areas address problems associated with rapid urbanization and provide new opportunities for sustainable development (Robinson et al., 2021).
