SPM.A: Introduction

This Summary for Policymakers (SPM) presents key findings of the Working Group II (WGII) contribution to the Sixth Assessment Report (AR6) of the IPCC[1]. The report builds on the WGII contribution to the Fifth Assessment Report (AR5) of the IPCC, three Special Reports[2], and the Working Group I (WGI) contribution to the AR6 cycle.

This report recognizes the interdependence of climate, ecosystems and biodiversity[3], and human societies (Figure SPM.1) and integrates knowledge more strongly across the natural, ecological, social and economic sciences than earlier IPCC assessments. The assessment of climate change impacts and risks as well as adaptation is set against concurrently unfolding non-climatic global trends e.g., biodiversity loss, overall unsustainable consumption of natural resources, land and ecosystem degradation, rapid urbanisation, human demographic shifts, social and economic inequalities and a pandemic.

The scientific evidence for each key finding is found in the 18 chapters of the underlying report and in the 7 cross-chapter papers as well as the integrated synthesis presented in the Technical Summary (hereafter TS) and referred to in curly brackets {}. Based on scientific understanding, key findings can be formulated as statements of fact or associated with an assessed level of confidence using the IPCC calibrated language[4]. The WGII Global to Regional Atlas (Annex I) facilitates exploration of key synthesis findings across the WGII regions.

---

[1] Decision IPCC/XLVI-3, The assessment covers scientific literature accepted for publication by 1 September 2021.

[2] The three Special Reports are: 'Global Warming of 1.5°C. An IPCC Special Report on the impacts of global warming of 1.5°C above pre-industrial levels and related global greenhouse gas emission pathways, in the context of strengthening the global response to the threat of climate change, sustainable development, and efforts to eradicate poverty (SR1.5)'; 'Climate Change and Land. An IPCC Special Report on climate change, desertification, land degradation, sustainable land management, food security, and greenhouse gas fluxes in terrestrial ecosystems (SRCCL)'; 'IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC)'

[3] Biodiversity: Biodiversity or biological diversity means the variability among living organisms from all sources including, among other things, terrestrial, marine and other aquatic ecosystems, and the ecological complexes of which they are part; this includes diversity within species, between species, and of ecosystems.

[4] Each finding is grounded in an evaluation of underlying evidence and agreement. A level of confidence is expressed using five qualifiers: very low, low, medium, high and very high, and typeset in italics, e.g., *medium confidence*. The following terms have been used to indicate the assessed likelihood of an outcome or a result: virtually certain 99-100% probability, very likely 90-100%, likely 66-100%, as likely as not 33-66%, unlikely 0-33%, very unlikely 0-10%, exceptionally unlikely 0-1%. Assessed likelihood is typeset in italics, e.g., *very likely*. This is consistent with AR5 and the other AR6 Reports.

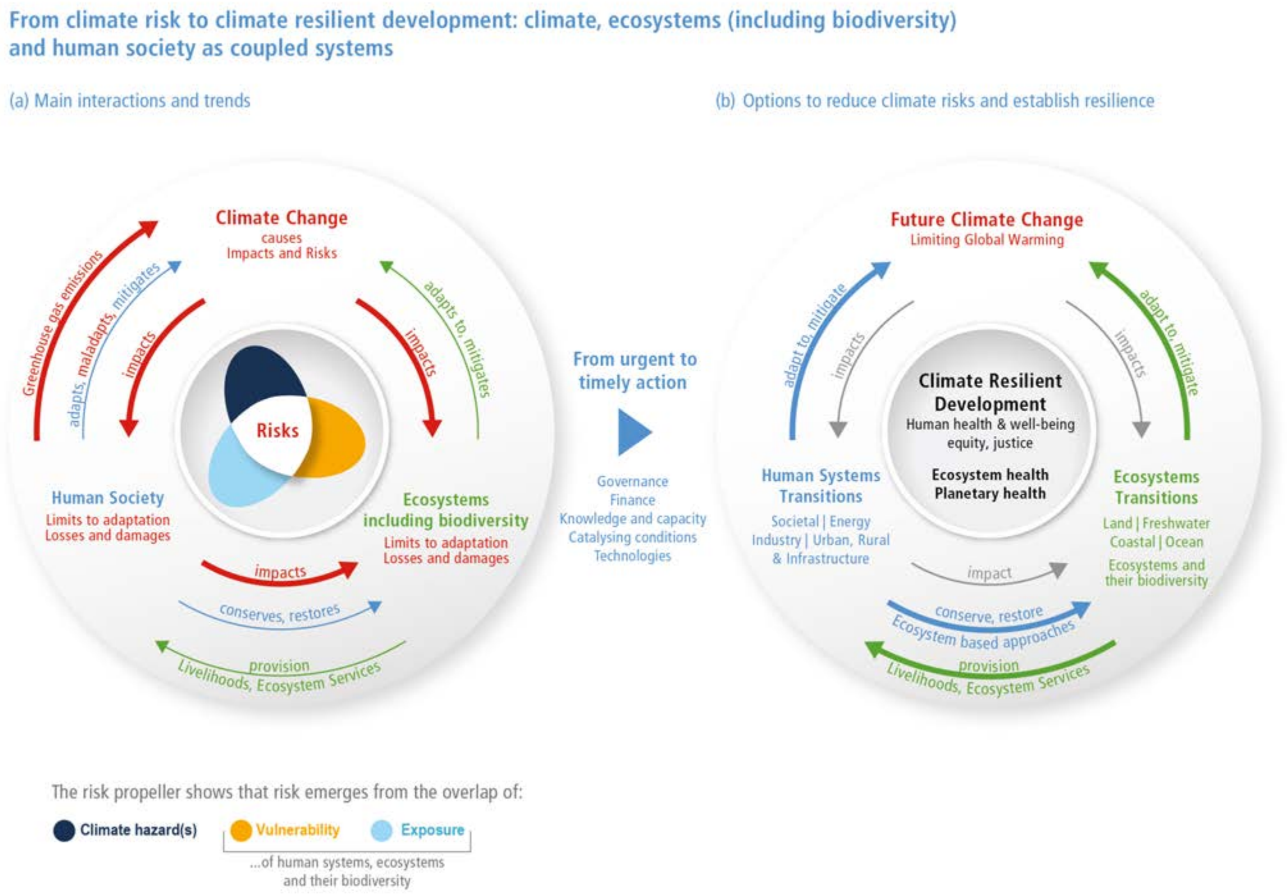

Figure SPM.1: This report has a strong focus on the interactions among the coupled systems climate, ecosystems (including their biodiversity) and human society. These interactions are the basis of emerging risks from climate change, ecosystem degradation and biodiversity loss and, at the same time, offer opportunities for the future. (a) Human society causes climate change. Climate change, through hazards, exposure and vulnerability generates impacts and risks that can surpass limits to adaptation and result in losses and damages. Human society can adapt to, maladapt and mitigate climate change, ecosystems can adapt and mitigate within limits. Ecosystems and their biodiversity provision livelihoods and ecosystem services. Human society impacts ecosystems and can restore and conserve them. (b) Meeting the objectives of climate resilient development thereby supporting human, ecosystem and planetary health, as well as human well-being, requires society and ecosystems to move over (transition) to a more resilient state. The recognition of climate risks can strengthen adaptation and mitigation actions and transitions that reduce risks. Taking action is enabled by governance, finance, knowledge and capacity building, technology and catalysing conditions. Transformation entails system transitions strengthening the resilience of ecosystems and society (Section D). In a) arrow colours represent principle human society interactions (blue), ecosystem (including biodiversity) interactions (green) and the impacts of climate change and human activities, including losses and damages, under continued climate change (red). In b) arrow colours represent human system interactions (blue), ecosystem (including biodiversity) interactions (green) and reduced impacts from climate change and human activities (grey). {1.2, Figure 1.2, Figure TS.1}

The concept of risk is central to all three AR6 Working Groups. A risk framing and the concepts of adaptation, vulnerability, exposure, resilience, equity and justice, and transformation provide alternative, overlapping, complementary, and widely used entry points to the literature assessed in this WGII report.

Across all three AR6 working groups, **risk**[5] provides a framework for understanding the increasingly severe, interconnected and often irreversible impacts of climate change on ecosystems, biodiversity, and human systems; differing impacts across regions, sectors and communities; and how to best reduce adverse

[5] Risk is defined as the potential for adverse consequences for human or ecological systems, recognising the diversity of values and objectives associated with such systems

consequences for current and future generations. In the context of climate change, risk can arise from the dynamic interactions among climate-related **hazards**[6] (see Working Group I), the **exposure**[7] and **vulnerability**[8] of affected human and ecological systems. The risk that can be introduced by human responses to climate change is a new aspect considered in the risk concept. This report identifies 127 key risks[9]. {1.3, 16.5}

The vulnerability of exposed human and natural systems is a component of risk, but also, independently, an important focus in the literature. Approaches to analysing and assessing vulnerability have evolved since previous IPCC assessments. Vulnerability is widely understood to differ within communities and across societies, regions and countries, also changing through time.

Adaptation[10] plays a key role in reducing exposure and vulnerability to climate change. Adaptation in ecological systems includes autonomous adjustments through ecological and evolutionary processes. In human systems, adaptation can be anticipatory or reactive, as well as incremental and/ or transformational. The latter changes the fundamental attributes of a social-ecological system in anticipation of climate change and its impacts. Adaptation is subject to hard and soft limits[11].

Resilience[12] in the literature has a wide range of meanings. Adaptation is often organized around resilience as bouncing back and returning to a previous state after a disturbance. More broadly the term describes not just the ability to maintain essential function, identity and structure, but also the capacity for transformation.

This report recognises the value of diverse forms of **knowledge** such as scientific, as well as Indigenous knowledge and local knowledge in understanding and evaluating climate adaptation processes and actions to reduce risks from human-induced climate change. AR6 highlights adaptation solutions which are effective, **feasible**[13], and conform to principles of **justice**[14]. The term climate justice, while used in different ways in different contexts by different communities, generally includes three principles: *distributive justice* which refers to the allocation of burdens and benefits among individuals, nations and generations; *procedural justice* which refers to who decides and participates in decision-making; and *recognition* which entails basic respect and robust engagement with and fair consideration of diverse cultures and perspectives.

---

[6] Hazard is defined as the potential occurrence of a natural or human-induced physical event or trend that may cause loss of life, injury, or other health impacts, as well as damage and loss to property, infrastructure, livelihoods, service provision, ecosystems and environmental resources. Physical climate conditions that may be associated with hazards are assessed in Working Group I as climatic impact-drivers.

[7] Exposure is defined as the presence of people; livelihoods; species or ecosystems; environmental functions, services and resources; infrastructure; or economic, social or cultural assets in places and settings that could be adversely affected.

[8] Vulnerability in this report is defined as the propensity or predisposition to be adversely affected and encompasses a variety of concepts and elements, including sensitivity or susceptibility to harm and lack of capacity to cope and adapt.

[9] Key risks have potentially severe adverse consequences for humans and social-ecological systems resulting from the interaction of climate related hazards with vulnerabilities of societies and systems exposed.

[10] Adaptation is defined, in human systems, as the process of adjustment to actual or expected climate and its effects in order to moderate harm or take advantage of beneficial opportunities. In natural systems, adaptation is the process of adjustment to actual climate and its effects; human intervention may facilitate this.

[11] Adaptation Limits: The point at which an actor's objectives (or system needs) cannot be secured from intolerable risks through adaptive actions.

- Hard adaptation limit - No adaptive actions are possible to avoid intolerable risks.
- Soft adaptation limit - Options may exist but are currently not available to avoid intolerable risks through adaptive action.

[12] Resilience in this report is defined as the capacity of social, economic and ecosystems to cope with a hazardous event or trend or disturbance, responding or reorganising in ways that maintain their essential function, identity and structure as well as biodiversity in case of ecosystems while also maintaining the capacity for adaptation, learning and transformation. Resilience is a positive attribute when it maintains such a capacity for adaptation, learning, and/or transformation.

[13] Feasibility refers to the potential for an adaptation option to be implemented.

[14] Justice is concerned with setting out the moral or legal principles of fairness and equity in the way people are treated, often based on the ethics and values of society. *Social justice* comprises just or fair relations within society that seek to address the distribution of wealth, access to resources, opportunity and support according to principles of justice and fairness. *Climate justice* comprises justice that links development and human rights to achieve a rights-based approach to addressing climate change.

Effectiveness refers to the extent to which an action reduces vulnerability and climate-related risk, increases resilience, and avoids maladaptation[15].

This report has a particular focus on transformation[16] and system transitions in energy; land, ocean, coastal and freshwater ecosystems; urban, rural and infrastructure; and industry and society. These transitions make possible the adaptation required for high levels of human health and wellbeing, economic and social resilience, ecosystem health[17], and planetary health[18] (Figure SPM.1). These system transitions are also important for achieving the low global warming levels (WGIII) that would avoid many limits to adaptation[11]. The report also assesses economic and non-economic losses and damages[19]. This report labels the process of implementing mitigation and adaptation together in support of sustainable development for all as climate resilient development[20].

[START BOX SPM.1 HERE]

Box SPM.1: AR6 Common Climate Dimensions, Global Warming Levels and Reference Periods

Assessments of climate risks consider possible future climate change, societal development and responses. This report assesses literature including that based on climate model simulations that are part of the fifth and sixth Coupled Model Intercomparison Project phase (CMIP5, CMIP6) of the World Climate Research Programme. Future projections are driven by emissions and/or concentrations from illustrative Representative Concentration Pathways (RCPs)[21] and Shared Socio-economic Pathways (SSPs)[22] scenarios, respectively[23]. Climate impacts literature is based primarily on climate projections assessed in AR5 or earlier, or assumed global warming levels, though some recent impacts literature uses newer projections based on the CMIP6 exercise. Given differences in the impacts literature regarding socioeconomic details and assumptions, WGII chapters contextualize impacts with respect to exposure, vulnerability and adaptation as appropriate for their literature, this includes assessments regarding sustainable development and climate resilient development. There are many emissions and socioeconomic pathways that are consistent with a given global warming outcome. These represent a broad range of possibilities as available in the literature assessed that affect future climate change exposure and vulnerability. Where available, WGII also assesses literature that is based on an integrative SSP-RCP framework where climate projections obtained under the RCP scenarios are analysed against the backdrop of various illustrative SSPs[22]. The WGII assessment combines multiple lines of evidence including impacts modelling driven by climate projections, observations, and process understanding. {1.2, 16.5, 18.2, CCB CLIMATE, WGI SPM.C, WGI Box SPM.1, WGI 1.6, WGI Ch.12, AR5 WGI}

---

[15] Maladaptation refers to actions that may lead to increased risk of adverse climate-related outcomes, including via increased greenhouse gas emissions, increased or shifted vulnerability to climate change, more inequitable outcomes, or diminished welfare, now or in the future. Most often, maladaptation is an unintended consequence.

[16] Transformation refers to a change in the fundamental attributes of natural and human systems.

[17] Ecosystem health: a metaphor used to describe the condition of an ecosystem, by analogy with human health. Note that there is no universally accepted benchmark for a healthy ecosystem. Rather, the apparent health status of an ecosystem is judged on the ecosystem's resilience to change, with details depending upon which metrics (such as species richness and abundance) are employed in judging it and which societal aspirations are driving the assessment.

[18] Planetary health: a concept based on the understanding that human health and human civilisation depend on ecosystem health and the wise stewardship of ecosystems.

[19] In this report, the term 'losses and damages' refers to adverse observed impacts and/or projected risks and can be economic and/or non-economic.

[20] In the WGII report, climate resilient development refers to the process of implementing greenhouse gas mitigation and adaptation measures to support sustainable development for all.

[21] RCP-based scenarios are referred to as RCPy, where 'y' refers to the level of radiative forcing (in watts per square meter, or $W m^{-2}$) resulting from the scenario in the year 2100.

[22] SSP-based scenarios are referred to as SSPx-y, where 'SSPx' refers to the Shared Socio-economic Pathway describing the socio-economic trends underlying the scenarios, and 'y' refers to the level of radiative forcing (in watts per square meter, or $W m^{-2}$) resulting from the scenario in the year 2100.

[23] IPCC is neutral with regard to the assumptions underlying the SSPs, which do not cover all possible scenarios. Alternative scenarios may be considered or developed.

A common set of reference years and time periods are adopted for assessing climate change and its impacts and risks: the reference period 1850–1900 approximates pre-industrial global surface temperature, and three future reference periods cover the near-term (2021–2040), mid-term (2041–2060) and long-term (2081–2100). {CCB CLIMATE}

Common levels of global warming relative to 1850-1900 are used to contextualize and facilitate analysis, synthesis and communication of assessed past, present and future climate change impacts and risks considering multiple lines of evidence. Robust geographical patterns of many variables can be identified at a given level of global warming, common to all scenarios considered and independent of timing when the global warming level is reached. {16.5, CCB CLIMATE, WGI 4.2, WGI CCB11.1, WGI Box SPM.1}

WGI assessed increase in global surface temperature is 1.09 [0.95 to 1.20][24] °C in 2011-2020 above 1850-1900. The estimated increase in global surface temperature since AR5 is principally due to further warming since 2003–2012 (+0.19 [0.16 to 0.22] °C).[25] Considering all five illustrative scenarios assessed by WGI, there is at least a greater than 50% likelihood that global warming will reach or exceed 1.5°C in the near-term, even for the very low greenhouse gas emissions scenario[26]. {WGI CCB 2.3, WGI SPM A1.2, WGI SPM B1.3, WGI Table SPM.1}

[END BOX SPM.1 HERE]

SPM.B: Observed and Projected Impacts and Risks

Since AR5, the knowledge base on observed and projected impacts and risks generated by climate hazards, exposure and vulnerability has increased with impacts attributed to climate change and key risks identified across the report. Impacts and risks are expressed in terms of their damages, harms, economic, and non-economic losses. Risks from observed vulnerabilities and responses to climate change are highlighted. Risks are projected for the near-term (2021-2040), the mid (2041-2060) and long term (2081-2100), at different global warming levels and for pathways that overshoot 1.5°C global warming level for multiple decades[27]. Complex risks result from multiple climate hazards occurring concurrently, and from multiple risks interacting, compounding overall risk and resulting in risks transmitting through interconnected systems and across regions.

Observed Impacts from Climate Change

SPM.B.1 Human-induced climate change, including more frequent and intense extreme events, has caused widespread adverse impacts and related losses and damages to nature and people, beyond natural climate variability. Some development and adaptation efforts have reduced vulnerability. Across sectors and regions the most vulnerable people and systems are observed to be disproportionately affected. The rise in weather

[24] In the WGI report, square brackets [x to y] are used to provide the assessed *very likely* range, or 90% interval.

[25] Since AR5, methodological advances and new datasets have provided a more complete spatial representation of changes in surface temperature, including in the Arctic. These and other improvements have also increased the estimate of global surface temperature change by approximately 0.1°C, but this increase does not represent additional physical warming since AR5.

[26] Global warming of 1.5°C relative to 1850–1900 would be exceeded during the 21st century under the intermediate, high and very high greenhouse gas emissions scenarios considered in this report (SSP2-4.5, SSP3-7.0 and SSP5-8.5, respectively). Under the five illustrative scenarios, in the near term (2021–2040), the 1.5°C global warming level is *very likely* to be exceeded under the very high greenhouse gas emissions scenario (SSP5-8.5), *likely* to be exceeded under the intermediate and high greenhouse gas emissions scenarios (SSP2-4.5 and SSP3-7.0), *more likely than not* to be exceeded under the low greenhouse gas emissions scenario (SSP1-2.6) and *more likely than not* to be reached under the very low greenhouse gas emissions scenario (SSP1-1.9). Furthermore, for the very low greenhouse gas emissions scenario (SSP1-1.9), it is *more likely than not* that global surface temperature would decline back to below 1.5°C toward the end of the 21st century, with a temporary overshoot of no more than 0.1°C above 1.5°C global warming.

[27] Overshoot: In this report, pathways that first exceed a specified global warming level (usually 1.5°C, by more than 0.1°C), and then return to or below that level again before the end of a specified period of time (e.g., before 2100). Sometimes the magnitude and likelihood of the overshoot is also characterized. The overshoot duration can vary from at least one decade up to several decades.

and climate extremes has led to some irreversible impacts as natural and human systems are pushed beyond their ability to adapt. (*high confidence*) (Figure SPM.2) {1.3, 2.3, 2.4, 2.6, 3.3, 3.4, 3.5, 4.2, 4.3, 5.2, 5.12, 6.2, 7.2, 8.2, 9.6, 9.8, 9.10, 9.11, 10.4, 11.3, 12.3, 12.4, 13.10, 14.4, 14.5, 15.3, 16.2, CCP1.2, CCP3.2, CCP4.1, CCP5.2, CCP6.2, CCP7.2, CCP7.3, CCB EXTREMES, CCB ILLNESS, CCB SLR, CCB NATURAL, CCB DISASTER, CCB MIGRATE, Figure TS.5, TS B1

SPM.B.1.1 Widespread, pervasive impacts to ecosystems, people, settlements, and infrastructure have resulted from observed increases in the frequency and intensity of climate and weather extremes, including hot extremes on land and in the ocean, heavy precipitation events, drought and fire weather (*high confidence*). Increasingly since AR5, these observed impacts have been attributed[28] to human-induced climate change particularly through increased frequency and severity of extreme events. These include increased heat-related human mortality (*medium confidence*), warm-water coral bleaching and mortality (*high confidence*), and increased drought related tree mortality (*high confidence*). Observed increases in areas burned by wildfires have been attributed to human-induced climate change in some regions (*medium* to *high confidence*). Adverse impacts from tropical cyclones, with related losses and damages[19], have increased due to sea level rise and the increase in heavy precipitation (*medium confidence*). Impacts in natural and human systems from slow-onset processes[29] such as ocean acidification, sea level rise or regional decreases in precipitation have also been attributed to human induced climate change (*high confidence*). {1.3, 2.3, 2.4, 2.5, 3.2, 3.4, 3.5, 3.6, 4.2, 5.2, 5.4, 5.6, 5.12, 7.2, 9.6, 9.8, 9.7, 9.8, 9.11, 11.3, Box 11.1, Box 11.2, Table 11.9, 12.3, 12.4, 13.3, 13.5, 13.10, 14.2,14.5, 15.7, 15.8, 16.2, Box CCP5.1, CCP1.2, CCP2.2, CCP7.3, CCB EXTREME, CCB ILLNESS, CCB DISASTER, WG1 9, WGI 11.3-11.8, WGI SPM.3, SROCC Ch. 4}

SPM.B.1.2 Climate change has caused substantial damages, and increasingly irreversible losses, in terrestrial, freshwater and coastal and open ocean marine ecosystems (*high confidence*). The extent and magnitude of climate change impacts are larger than estimated in previous assessments (*high confidence*). Widespread deterioration of ecosystem structure and function, resilience and natural adaptive capacity, as well as shifts in seasonal timing have occurred due to climate change (*high confidence*), with adverse socioeconomic consequences (*high confidence*). Approximately half of the species assessed globally have shifted polewards or, on land, also to higher elevations (*very high confidence*). Hundreds of local losses of species have been driven by increases in the magnitude of heat extremes (*high confidence*), as well as mass mortality events on land and in the ocean (*very high confidence*) and loss of kelp forests (*high confidence*). Some losses are already irreversible, such as the first species extinctions driven by climate change (*medium confidence*). Other impacts are approaching irreversibility such as the impacts of hydrological changes resulting from the retreat of glaciers, or the changes in some mountain (*medium confidence*) and Arctic ecosystems driven by permafrost thaw (*high confidence*). (Figure SPM.2a). {2.3, 2.4, 3.4, 3.5, 4.2, 4.3, 4.5, 9.6, 10.4, 11.3, 12.3, 12.8, 13.3, 13.4, 13.10, 14.4, 14.5, 14.6, 15.3, 16.2, CCP1.2; CCP3.2, CCP4.1, CCP5.2, CCP6.1, CCP6.2, CCP7.2, CCP7.3, CCP5.2, Figure CCP5.4, CCB PALEO, CCB EXTREMES, CCB ILLNESS, CCB SLR, CCB NATURAL, CCB MOVING PLATE, Figure TS.5, TS B1, SROCC 2.3}

---

[28] Attribution is defined as the process of evaluating the relative contributions of multiple causal factors to a change or event with an assessment of confidence. {Annex II Glossary, CWGB ATTRIB}

[29] Impacts of climate change are caused by slow onset and extreme events. Slow onset events are described among the climatic-impact drivers of the WGI AR6 and refer to the risks and impacts associated with e.g., increasing temperature means, desertification, decreasing precipitation, loss of biodiversity, land and forest degradation, glacial retreat and related impacts, ocean acidification, sea level rise and salinization (https://interactive-atlas.ipcc.ch).

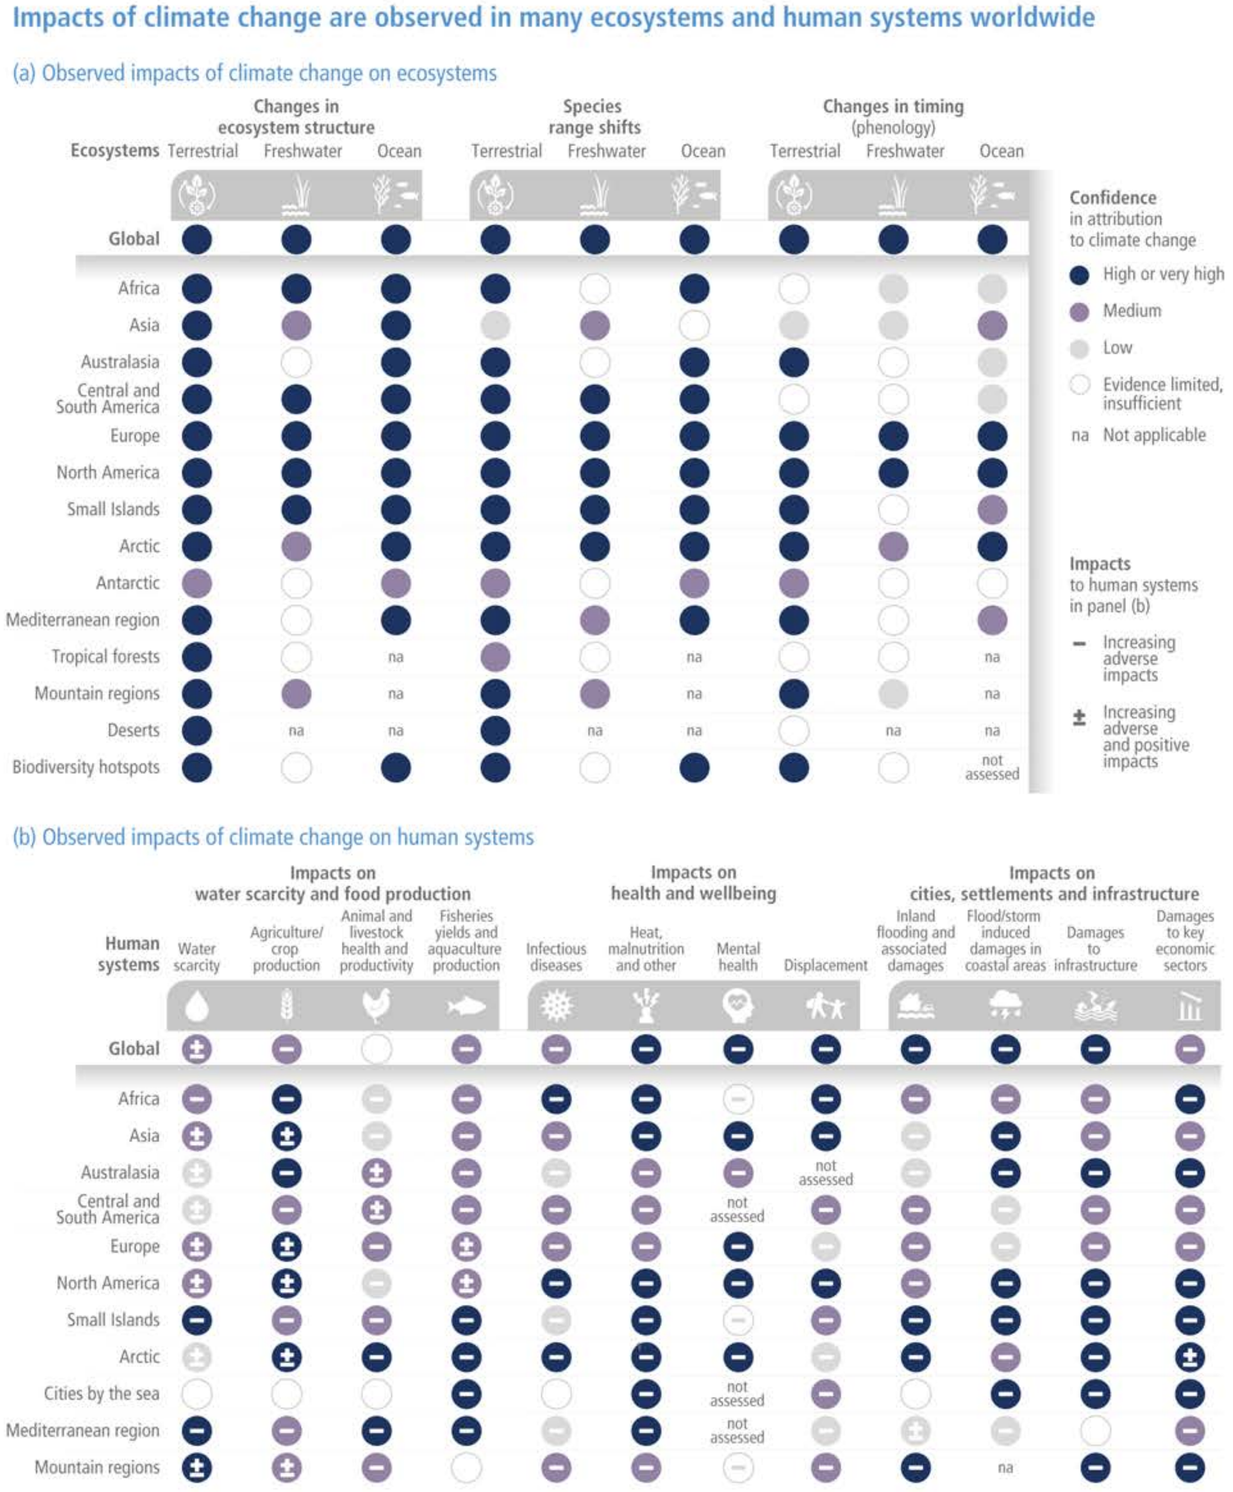

Figure SPM.2: Observed global and regional impacts on ecosystems and human systems attributed to climate change. Confidence levels reflect uncertainty in attribution of the observed impact to climate change. Global assessments focus on large studies, multi-species, meta-analyses and large reviews. For that reason they can be assessed with higher confidence than regional studies, which may often rely on smaller studies that have more limited data. Regional assessments consider evidence on impacts across an entire region and do not focus on any country in particular. (a) Climate change has already altered terrestrial, freshwater and ocean ecosystems at global scale, with multiple impacts evident at regional and local scales where there is sufficient literature to make an assessment. Impacts are evident on ecosystem structure, species geographic ranges and timing of seasonal life cycles (phenology) (for methodology and detailed references to chapters and cross-chapter papers see SMTS.1 and SMTS.1.1). (b) Climate change has already had diverse adverse impacts on human systems, including on water security and food production, health and well-being, and cities, settlements and infrastructure. The + and – symbols indicate the direction of observed impacts, with a – denoting an increasing adverse impact and a ± denoting that, within a region or globally, both adverse and positive impacts have been observed (e.g., adverse impacts in one area or food item may occur with positive impacts in another area or food item). Globally, '–' denotes an overall adverse impact; 'Water scarcity' considers, e.g., water availability in general, groundwater, water quality, demand for water, drought in cities. Impacts on food production were assessed by excluding non-climatic drivers of production increases; Global assessment for agricultural production is based on the impacts on global aggregated production; 'Reduced animal and livestock health and productivity' considers, e.g., heat stress, diseases, productivity, mortality; 'Reduced fisheries yields and aquaculture production' includes marine and freshwater fisheries/production; 'Infectious diseases' include, e.g., water-borne and vector-borne diseases; 'Heat, malnutrition and other' considers, e.g., human heat-related morbidity and mortality, labour productivity, harm from wildfire, nutritional deficiencies; 'Mental health' includes impacts from extreme weather events, cumulative events, and vicarious or anticipatory events; 'Displacement' assessments refer to evidence of displacement attributable to climate and weather extremes; 'Inland flooding and associated damages' considers, e.g., river overflows, heavy rain, glacier outbursts, urban flooding; 'Flood/storm induced damages in coastal areas' include damages due to, e.g., cyclones, sea level rise, storm surges. Damages by key economic sectors are observed impacts related to an attributable mean or extreme climate hazard or directly attributed. Key economic sectors include standard classifications and sectors of importance to regions (for methodology and detailed references to chapters and cross-chapter papers see SMTS.1 and SMTS.1.2).

SPM.B.1.3 Climate change including increases in frequency and intensity of extremes have reduced food and water security, hindering efforts to meet Sustainable Development Goals (*high confidence*). Although overall agricultural productivity has increased, climate change has slowed this growth over the past 50 years globally (*medium confidence*), related negative impacts were mainly in mid- and low latitude regions but positive impacts occurred in some high latitude regions (*high confidence*). Ocean warming and ocean acidification have adversely affected food production from shellfish aquaculture and fisheries in some oceanic regions (*high confidence*). Increasing weather and climate extreme events have exposed millions of people to acute food insecurity[30] and reduced water security, with the largest impacts observed in many locations and/or communities in Africa, Asia, Central and South America, Small Islands and the Arctic (*high confidence*). Jointly, sudden losses of food production and access to food compounded by decreased diet diversity have increased malnutrition in many communities (*high confidence*), especially for Indigenous Peoples, small-scale food producers and low-income households (*high confidence*), with children, elderly people and pregnant women particularly impacted (*high confidence*). Roughly half of the world's population currently experience severe water scarcity for at least some part of the year due to climatic and non-climatic drivers (*medium confidence*). (Figure SPM.2b) {3.5, Box 4.1, 4.3, 4.4, 5.2, 5.4, 5.8, 5.9, 5.12, 7.1, 7.2, 9.8, 10.4, 11.3, 12.3, 13.5, 14.4, 14.5, 15.3, 16.2, CCP5.2, CCP6.2}

SPM.B.1.4 Climate change has adversely affected physical health of people globally (*very high confidence)* and mental health of people in the assessed regions (*very high confidence*). Climate change impacts on health are mediated through natural and human systems, including economic and social conditions and disruptions (*high confidence*). In all regions extreme heat events have resulted in human mortality and morbidity (*very high confidence*). The occurrence of climate-related food-borne and water-borne diseases has increased (*very high confidence*). The incidence of vector-borne diseases has increased from range expansion and/or increased reproduction of disease vectors (*high confidence*). Animal and human diseases, including zoonoses, are emerging in new areas (*high confidence*). Water and food-borne disease risks have increased regionally from climate-sensitive aquatic pathogens, including *Vibrio* spp. (*high confidence*), and from toxic substances from harmful freshwater cyanobacteria (*medium confidence*). Although diarrheal diseases have decreased globally, higher temperatures, increased rain and flooding have increased the occurrence of diarrheal diseases, including cholera (*very high confidence*) and other gastrointestinal infections (*high confidence*). In assessed regions, some mental health challenges are associated with increasing temperatures (*high confidence*), trauma from weather and climate extreme events (*very high confidence*), and loss of livelihoods and culture (*high confidence*). Increased exposure to wildfire smoke, atmospheric dust, and aeroallergens have been associated with climate-sensitive cardiovascular and respiratory distress (*high confidence*). Health services have been disrupted by extreme events such as floods (*high confidence*). {4.3, 5.12, 7.2, Box 7.3, 8.2, 8.3, Figure 8.10,

[30] Acute food insecurity can occur at any time with a severity that threatens lives, livelihoods or both, regardless of the causes, context or duration, as a result of shocks risking determinants of food security and nutrition, and used to assess the need for humanitarian action (IPC Global Partners, 2019).

Box 8.6, 9.10, Figure 9.33, Figure 9.34, 10.4, 11.3, 12.3, 13.7, 14.4, 14.5, Figure 14.8, 15.3, 16.2, Table CCP5.1, CCP5.2.5, CCP6.2, Figure CCP6.3, Table CCB ILLNESS.1}

SPM.B.1.5 In urban settings, observed climate change has caused impacts on human health, livelihoods and key infrastructure (*high confidence*). Multiple climate and non-climate hazards impact cities, settlements and infrastructure and sometimes coincide, magnifying damage (*high confidence*). Hot extremes including heatwaves have intensified in cities (*high confidence*), where they have also aggravated air pollution events (*medium confidence*) and limited functioning of key infrastructure (*high confidence*). Observed impacts are concentrated amongst the economically and socially marginalized urban residents, e.g., in informal settlements (*high confidence*). Infrastructure, including transportation, water, sanitation and energy systems have been compromised by extreme and slow-onset events, with resulting economic losses, disruptions of services and impacts to wellbeing (*high confidence*). {4.3, 6.2, 7.1, 7.2, 9.9, 10.4, 11.3, 12.3, 13.6, 14.5, 15.3, CCP2.2, CCP4.2, CCP5.2}

SPM.B.1.6 Overall adverse economic impacts attributable to climate change, including slow-onset and extreme weather events, have been increasingly identified (*medium confidence*). Some positive economic effects have been identified in regions that have benefited from lower energy demand as well as comparative advantages in agricultural markets and tourism (*high confidence*). Economic damages from climate change have been detected in climate-exposed sectors, with regional effects to agriculture, forestry, fishery, energy, and tourism (*high confidence*), and through outdoor labour productivity (*high confidence*). Some extreme weather events, such as tropical cyclones, have reduced economic growth in the short-term (*high confidence*). Non-climatic factors including some patterns of settlement, and siting of infrastructure have contributed to the exposure of more assets to extreme climate hazards increasing the magnitude of the losses (*high confidence*). Individual livelihoods have been affected through changes in agricultural productivity, impacts on human health and food security, destruction of homes and infrastructure, and loss of property and income, with adverse effects on gender and social equity (*high confidence*). {3.5, 4.2, 5.12, 6.2, 7.2, 8.2, 9.6, 10.4, 13.10, 14.5, Box 14.6, 16.2, Table 16.5, 18.3, CCP6.2, CCB GENDER, CWGB ECONOMICS}

SPM.B.1.7 Climate change is contributing to humanitarian crises where climate hazards interact with high vulnerability (*high confidence*). Climate and weather extremes are increasingly driving displacement in all regions (*high confidence*), with small island states disproportionately affected (*high confidence*). Flood and drought-related acute food insecurity and malnutrition have increased in Africa (*high confidence*) and Central and South America (*high confidence*). While non-climatic factors are the dominant drivers of existing intrastate violent conflicts, in some assessed regions extreme weather and climate events have had a small, adverse impact on their length, severity or frequency, but the statistical association is weak (*medium confidence*). Through displacement and involuntary migration from extreme weather and climate events, climate change has generated and perpetuated vulnerability (*medium confidence*). {4.2, 4.3, 5.4, 7.2, 9.8, Box 9.9, Box 10.4, 12.3, 12.5, CCB MIGRATE, CCB DISASTER, 16.2}

Vulnerability and Exposure of Ecosystems and People

SPM.B.2 Vulnerability of ecosystems and people to climate change differs substantially among and within regions (*very high confidence*), driven by patterns of intersecting socio-economic development, unsustainable ocean and land use, inequity, marginalization, historical and ongoing patterns of inequity such as colonialism, and governance[31] (*high confidence*). Approximately 3.3 to 3.6 billion people live in contexts that are highly vulnerable to climate change (*high confidence*). A high proportion of species is vulnerable to climate change (*high confidence*). Human and ecosystem vulnerability are interdependent (*high confidence*). Current unsustainable development patterns are increasing exposure of ecosystems and people to climate hazards (*high confidence*). {2.3, 2.4, 3.5, 4.3, 6.2, 8.2, 8.3, 9.4, 9.7, 10.4, 12.3, 14.5, 15.3, CCP5.2, CCP6.2, CCP7.3, CCP7.4, CCB GENDER}

[31] Governance: The structures, processes and actions through which private and public actors interact to address societal goals. This includes formal and informal institutions and the associated norms, rules, laws and procedures for deciding, managing, implementing and monitoring policies and measures at any geographic or political scale, from global to local.

SPM.B.2.1 Since AR5 there is increasing evidence that degradation and destruction of ecosystems by humans increases the vulnerability of people (*high confidence*). Unsustainable land-use and land cover change, unsustainable use of natural resources, deforestation, loss of biodiversity, pollution, and their interactions, adversely affect the capacities of ecosystems, societies, communities and individuals to adapt to climate change (*high confidence*). Loss of ecosystems and their services has cascading and long-term impacts on people globally, especially for Indigenous Peoples and local communities who are directly dependent on ecosystems, to meet basic needs (*high confidence*). {2.3, 2.5, 2.6, 3.5, 3.6, 4.2, 4.3, 4.6, 5.1, 5.4, 5.5, 5.7, 5.8, 7.2, 8.1, 8.2, 8.3, 8.4, 8.5, 9.6, 10.4, 11.3, 12.2, 12.5. 13.8, 14.4, 14.5, 15.3, CCP1.2, CCP1.3, CCP2.2, CCP3, CCP4.3, CCP5.2, CCP6.2, CCP7.2, CCP7.3, CCP7.4, CCB ILLNESS, CCB MOVING PLATE, CCB SLR}

SPM.B.2.2 Non-climatic human-induced factors exacerbate current ecosystem vulnerability to climate change (*very high confidence*). Globally, and even within protected areas, unsustainable use of natural resources, habitat fragmentation, and ecosystem damage by pollutants increase ecosystem vulnerability to climate change (*high confidence*). Globally, less than 15% of the land, 21% of the freshwater and 8% of the ocean are protected areas. In most protected areas, there is insufficient stewardship to contribute to reducing damage from, or increasing resilience to, climate change (*high confidence*). {2.4, 2.5, 2.6, 3.4, 3.6, 4.2, 4.3, 5.8, 9.6, 11.3, 12.3, 13.3, 13.4, 14.5, 15.3, CCP1.2 Figure CCP1.15, CCP2.1, CCP2.2, CCP4.2, CCP5.2, CCP 6.2, CCP7.2, CCP7.3, CCB NATURAL}

SPM.B.2.3 Future vulnerability of ecosystems to climate change will be strongly influenced by the past, present and future development of human society, including from overall unsustainable consumption and production, and increasing demographic pressures, as well as persistent unsustainable use and management of land, ocean, and water (*high confidence*). Projected climate change, combined with non-climatic drivers, will cause loss and degradation of much of the world's forests (*high confidence*), coral reefs and low-lying coastal wetlands (*very high confidence*). While agricultural development contributes to food security, unsustainable agricultural expansion, driven in part by unbalanced diets[32], increases ecosystem and human vulnerability and leads to competition for land and/or water resources (*high confidence*). {2.2, 2.3, 2.4, 2.6, 3.4, 3.5, 3.6, 4.3, 4.5, 5.6, 5.12, 5.13, 7.2, 12.3, 13.3, 13.4, 13.10, 14.5, CCP1.2, CCP2.2, CCP5.2, CCP6.2, CCP7.2, CCP7.3, CCB NATURAL, CCB HEALTH}

SPM.B.2.4 Regions and people with considerable development constraints have high vulnerability to climatic hazards (*high confidence*). Global hotspots of high human vulnerability are found particularly in West-, Central- and East Africa, South Asia, Central and South America, Small Island Developing States and the Arctic (*high confidence*). Vulnerability is higher in locations with poverty, governance challenges and limited access to basic services and resources, violent conflict and high levels of climate-sensitive livelihoods (e.g., smallholder farmers, pastoralists, fishing communities) (*high confidence*). Between 2010-2020, human mortality from floods, droughts and storms was 15 times higher in highly vulnerable regions, compared to regions with very low vulnerability (*high confidence*). Vulnerability at different spatial levels is exacerbated by inequity and marginalization linked to gender, ethnicity, low income or combinations thereof (*high confidence*), especially for many Indigenous Peoples and local communities (*high confidence*). Present development challenges causing high vulnerability are influenced by historical and ongoing patterns of inequity such as colonialism, especially for many Indigenous Peoples and local communities (*high confidence*). {4.2, 5.12, 6.2, 6.4, 7.1, 7.2, Box 7.1, 8.2, 8.3, Box 8.4, Figure 8.6, Box 9.1, 9.4, 9.7, 9.9, 10.3, 10.4, 10.6, 12.3, 12.5, Box 13.2, 14.4, 15.3, 15.6, 16.2, CCP6.2, CCP7.4}

SPM.B.2.5 Future human vulnerability will continue to concentrate where the capacities of local, municipal and national governments, communities and the private sector are least able to provide infrastructures and basic services (*high confidence*). Under the global trend of urbanization, human vulnerability will also concentrate in informal settlements and rapidly growing smaller settlements (*high confidence*). In rural areas vulnerability will be heightened by compounding processes including high emigration, reduced habitability and high reliance on climate-sensitive livelihoods (*high confidence*). Key infrastructure systems including sanitation, water, health, transport, communications and energy will be increasingly vulnerable if design

[32] Balanced diets feature plant-based foods, such as those based on coarse grains, legumes fruits and vegetables, nuts and seeds, and animal-source foods produced in resilient, sustainable and low-greenhouse gas emissions systems, as described in SRCCL.

standards do not account for changing climate conditions (*high confidence*). Vulnerability will also rapidly rise in low-lying Small Island Developing States and atolls in the context of sea level rise and in some mountain regions, already characterised by high vulnerability due to high dependence on climate-sensitive livelihoods, rising population displacement, the accelerating loss of ecosystem services and limited adaptive capacities (*high confidence*). Future exposure to climatic hazards is also increasing globally due to socio-economic development trends including migration, growing inequality and urbanization (*high confidence*). {4.5, 5.5, 6.2, 7.2, 8.3, 9.9, 9.11, 10.3, 10.4, 12.3, 12.5, 13.6, 14.5, 15.3, 15.4, 16.5, CCP2.3, CCP4.3, CCP5.2, CCP5.3, CCP5.4, CCP6.2, CCB MIGRATE}

Risks in the near term (2021-2040)

SPM.B.3 Global warming, reaching 1.5°C in the near-term, would cause unavoidable increases in multiple climate hazards and present multiple risks to ecosystems and humans (*very high confidence*). The level of risk will depend on concurrent near-term trends in vulnerability, exposure, level of socioeconomic development and adaptation (*high confidence*). Near-term actions that limit global warming to close to 1.5°C would substantially reduce projected losses and damages related to climate change in human systems and ecosystems, compared to higher warming levels, but cannot eliminate them all (*very high confidence*). (Figure SPM.3, Box SPM.1) {WGI Table SPM.1, 16.4, 16.5, 16.6, CCP1.2, CCP5.3, CCB SLR, WGI SPM B1.3}

SPM.B.3.1 Near-term warming and increased frequency, severity and duration of extreme events will place many terrestrial, freshwater, coastal and marine ecosystems at high or very high risks of biodiversity loss (*medium to very high confidence*, depending on ecosystem). Near-term risks for biodiversity loss are moderate to high in forest ecosystems (*medium confidence*), kelp and seagrass ecosystems (*high* to *very high confidence*), and high to very high in Arctic sea-ice and terrestrial ecosystems (*high confidence*) and warm-water coral reefs (*very high confidence*). Continued and accelerating sea level rise will encroach on coastal settlements and infrastructure (*high confidence*) and commit low-lying coastal ecosystems to submergence and loss (*medium confidence*). If trends in urbanisation in exposed areas continue, this will exacerbate the impacts, with more challenges where energy, water and other services are constrained (*medium confidence*). The number of people at risk from climate change and associated loss of biodiversity will progressively increase (*medium confidence*). Violent conflict and, separately, migration patterns, in the near-term will be driven by socio-economic conditions and governance more than by climate change (*medium confidence*). (Figure SPM.3) {2.5, 3.4, 4.6, 6.2, 7.3, 8.7, 9.2, 9.9, 11.6, 12.5, 13.6, 13.10, 14.6, 15.3, 16.5, 16.6, CCP1.2, CCP2.1, CCP2.2, CCP5.3, CCP6.2, CCP6.3, CCB SLR, CCB MIGRATE}

SPM.B.3.2 In the near term, climate-associated risks to natural and human systems depend more strongly on changes in their vulnerability and exposure than on differences in climate hazards between emissions scenarios (*high confidence*). Regional differences exist, and risks are highest where species and people exist close to their upper thermal limits, along coastlines, in close association with ice or seasonal rivers (*high confidence*). Risks are also high where multiple non-climate drivers persist or where vulnerability is otherwise elevated (*high confidence*). Many of these risks are unavoidable in the near-term, irrespective of emission scenario (*high confidence*). Several risks can be moderated with adaptation (*high confidence*). (Figure SPM.3, Section C) {2.5, 3.3, 3.4, 4.5, 6.2, 7.1, 7.3, 8.2, 11.6, 12.4, 13.6, 13.7, 13.10, 14.5, 16.4, 16.5, CCP2.2, CCP4.3, CCP5.3, CCB SLR, WGI Table SPM.1}

SPM.B.3.3 Levels of risk for all Reasons for Concern (RFC) are assessed to become high to very high at lower global warming levels than in AR5 (*high confidence*). Between 1.2°C and 4.5°C global warming level very high risks emerge in all five RFCs compared to just two RFCs in AR5 (*high confidence*). Two of these transitions from high to very high risk are associated with near-term warming: risks to unique and threatened systems at a median value of 1.5°C [1.2 to 2.0] °C (*high confidence*) and risks associated with extreme weather events at a median value of 2°C [1.8 to 2.5] °C (*medium confidence*). Some key risks contributing to the RFCs are projected to lead to widespread, pervasive, and potentially irreversible impacts at global warming levels of 1.5–2°C if exposure and vulnerability are high and adaptation is low (*medium confidence*). Near-term actions that limit global warming to close to 1.5°C would substantially reduce projected losses and damages related to climate change in human systems and ecosystems, compared to higher warming levels, but cannot eliminate them all (*very high confidence*). (Figure SPM.3b) {16.5, 16.6, CCB SLR}

Mid to Long-term Risks (2041–2100)

SPM.B.4 Beyond 2040 and depending on the level of global warming, climate change will lead to numerous risks to natural and human systems (*high confidence*). For 127 identified key risks, assessed mid- and long-term impacts are up to multiple times higher than currently observed (*high confidence*). The magnitude and rate of climate change and associated risks depend strongly on near-term mitigation and adaptation actions, and projected adverse impacts and related losses and damages escalate with every increment of global warming (*very high confidence*). (Figure SPM.3) {2.5, 3.4, 4.4, 5.2, 6.2, 7.3, 8.4, 9.2, 10.2, 11.6, 12.4, 13.2, 13.3, 13.4, 13.5, 13.6, 13.7, 13.8, 14.6, 15.3, 16.5, 16.6, CCP1.2; CCP2.2, CCP3.3, CCP4.3, CCP5.3, CCP6.3, CCP7.3}

SPM.B.4.1 Biodiversity loss, and degradation, damages to and transformation of ecosystems are already key risks for every region due to past global warming and will continue to escalate with every increment of global warming (*very high confidence*). In terrestrial ecosystems, 3 to 14% of species assessed[33] will *likely* face very high risk of extinction[34] at global warming levels of 1.5°C, increasing up to 3 to 18% at 2°C, 3 to 29% at 3°C, 3 to 39% at 4°C, and 3 to 48% at 5°C. In ocean and coastal ecosystems, risk of biodiversity loss ranges between moderate and very high by 1.5°C global warming level and is moderate to very high by 2°C but with more ecosystems at high and very high risk (*high confidence*), and increases to high to very high across most ocean and coastal ecosystems by 3°C (*medium* to *high confidence*, depending on ecosystem). Very high extinction risk for endemic species in biodiversity hotspots is projected to at least double from 2% between 1.5°C and 2°C global warming levels and to increase at least tenfold if warming rises from 1.5°C to 3°C (*medium confidence*). (Figure SPM.3c, d, f) {2.4, 2.5, 3.4, 3.5,12.3, 12.5, Table 12.6, 13.4, 13.10, 16.4, 16.6, CCP1.2, Figure CCP1.6; Figure CCP1.7, CCP5.3, CCP6.3, CCB PALEO}

SPM.B.4.2 Risks in physical water availability and water-related hazards will continue to increase by the mid- to long-term in all assessed regions, with greater risk at higher global warming levels (*high confidence*). At approximately 2°C global warming, snowmelt water availability for irrigation is projected to decline in some snowmelt dependent river basins by up to 20%, and global glacier mass loss of 18 ± 13% is projected to diminish water availability for agriculture, hydropower, and human settlements in the mid- to long-term, with these changes projected to double with 4°C global warming (*medium confidence*). In small islands, groundwater availability is threatened by climate change (*high confidence*). Changes to streamflow magnitude, timing and associated extremes are projected to adversely impact freshwater ecosystems in many watersheds by the mid- to long-term across all assessed scenarios (*medium confidence*). Projected increases in direct flood damages are higher by 1.4 to 2 times at 2°C and 2.5 to 3.9 times at 3°C compared to 1.5°C global warming without adaptation (*medium confidence*). At global warming of 4°C, approximately 10% of the global land area is projected to face increases in both extreme high and low river flows in the same location, with implications for planning for all water use sectors (*medium confidence*). Challenges for water management will be exacerbated in the near, mid and long term, depending on the magnitude, rate and regional details of future climate change and will be particularly challenging for regions with constrained resources for water management (*high confidence*). {2.3, Box 4.2, 4.4, 4.5, Figure 4.20, 15.3, CCB DISASTER, CCP5.3, SROCC 2.3}

SPM.B.4.3 Climate change will increasingly put pressure on food production and access, especially in vulnerable regions, undermining food security and nutrition (*high confidence*). Increases in frequency, intensity and severity of droughts, floods and heatwaves, and continued sea level rise will increase risks to food security (*high confidence*) in vulnerable regions from moderate to high between 1.5°C and 2°C global warming level, with no or low levels of adaptation (*medium confidence*). At 2°C or higher global warming level in the mid-term, food security risks due to climate change will be more severe, leading to malnutrition and micro-nutrient deficiencies, concentrated in Sub-Saharan Africa, South Asia, Central and South America and Small Islands (*high confidence)*. Global warming will progressively weaken soil health and ecosystem

[33] Numbers of species assessed are in the tens of thousands globally.

[34] The term 'very high risks of extinction' is used here consistently with the IUCN categories and criteria and equates with 'critically endangered'.

services such as pollination, increase pressure from pests and diseases, and reduce marine animal biomass, undermining food productivity in many regions on land and in the ocean (*medium confidence*). At 3ºC or higher global warming level in the long term, areas exposed to climate-related hazards will expand substantially compared with 2ºC or lower global warming level (*high confidence*), exacerbating regional disparity in food security risks (*high confidence*). (Figure SPM.3) {1.1, 3.3, CCB SLR, 4.5, 5.2, 5.4, 5.5, 5.8, 5.9, 5.12, CCB MOVING PLATE, 7.3, 8.3, 9.11,13.5,15.3, 16.5, 16.6}

SPM.B.4.4 Climate change and related extreme events will significantly increase ill health and premature deaths from the near- to long-term (*high confidence*). Globally, population exposure to heatwaves will continue to increase with additional warming, with strong geographical differences in heat-related mortality without additional adaptation (*very high confidence*). Climate-sensitive food-borne, water-borne, and vector-borne disease risks are projected to increase under all levels of warming without additional adaptation (*high confidence*). In particular, dengue risk will increase with longer seasons and a wider geographic distribution in Asia, Europe, Central and South America and sub-Saharan Africa, potentially putting additional billions of people at risk by the end of the century (*high confidence*). Mental health challenges, including anxiety and stress, are expected to increase under further global warming in all assessed regions, particularly for children, adolescents, elderly, and those with underlying health conditions (*very high confidence*). {4.5, 5.12, Box 5.10, 7.3, Fig 7.9, 8.4, 9.10, Fig 9.32, Fig 9.35, 10.4, Fig 10.11, 11.3, 12.3, Fig 12.5, Fig 12.6, 13.7, Fig 13.23, Fig 13.24, 14.5, 15.3, CCP6.2}

SPM.B.4.5 Climate change risks to cities, settlements and key infrastructure will rise rapidly in the mid- and long-term with further global warming, especially in places already exposed to high temperatures, along coastlines, or with high vulnerabilities (*high confidence*). Globally, population change in low-lying cities and settlements will lead to approximately a billion people projected to be at risk from coastal-specific climate hazards in the mid-term under all scenarios, including in Small Islands (*high confidence*). The population potentially exposed to a 100-year coastal flood is projected to increase by about 20% if global mean sea level rises by 0.15 m relative to 2020 levels; this exposed population doubles at a 0.75 m rise in mean sea level and triples at 1.4 m without population change and additional adaptation (*medium confidence*). Sea level rise poses an existential threat for some Small Islands and some low-lying coasts (*medium confidence*). By 2100 the value of global assets within the future 1-in-100 year coastal floodplains is projected to be between US$7.9 and US$12.7 trillion (2011 value) under RCP4.5, rising to between US$8.8 and US$14.2 trillion under RCP8.5 (*medium confidence*). Costs for maintenance and reconstruction of urban infrastructure, including building, transportation, and energy will increase with global warming level (*medium confidence*), the associated functional disruptions are projected to be substantial particularly for cities, settlements and infrastructure located on permafrost in cold regions and on coasts (*high confidence*). {6.2, 9.9, 10.4, 13.6, 13.10, 15.3, 16.5, CCP2.1, CCP2.2, CCP5.3, CCP6.2, CCB SLR, SROCC 2.3, SROCC CCB9}

SPM.B.4.6 Projected estimates of global aggregate net economic damages generally increase non-linearly with global warming levels (*high confidence*).[35] The wide range of global estimates, and the lack of comparability between methodologies, does not allow for identification of a robust range of estimates (*high confidence*). The existence of higher estimates than assessed in AR5 indicates that global aggregate economic impacts could be higher than previous estimates (*low confidence*).[36] Significant regional variation in aggregate economic damages from climate change is projected (*high confidence*) with estimated economic damages per capita for developing countries often higher as a fraction of income (*high confidence*). Economic damages, including both those represented and those not represented in economic markets, are projected to be lower at 1.5°C than at 3°C or higher global warming levels (*high confidence*). {4.4, 9.11, 11.5, 13.10, Box 14.6, 16.5, CWGB ECONOMICS}

SPM.B.4.7 In the mid- to long-term, displacement will increase with intensification of heavy precipitation and associated flooding, tropical cyclones, drought and, increasingly, sea level rise (*high confidence*). At progressive levels of warming, involuntary migration from regions with high exposure and low adaptive

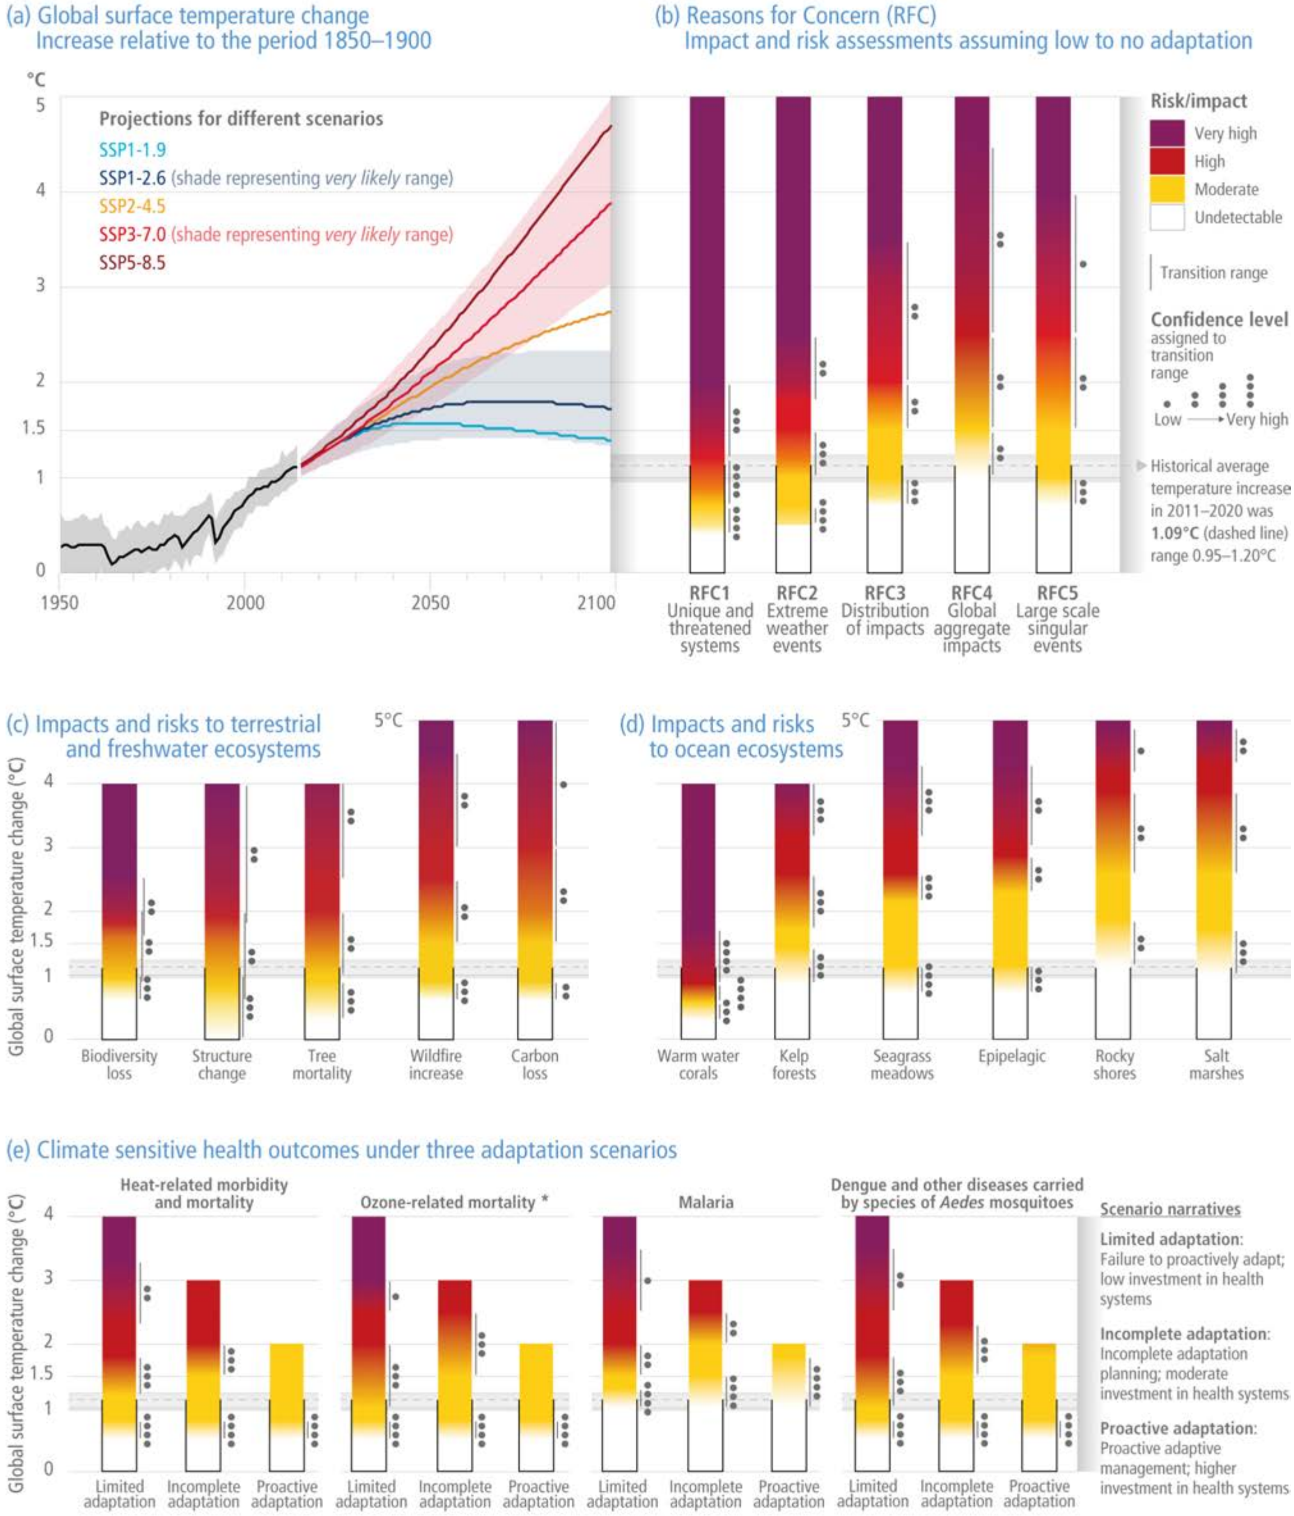
---

[35] The assessment found estimated rates of increase in projected global economic damages that were both greater than linear and less than linear as global warming level increases. There is evidence that some regions could benefit from low levels of warming (*high confidence*). {CWGB ECONOMICS}

[36] *Low confidence* assigned due to the assessed lack of comparability and robustness of global aggregate economic damage estimates. {CWGB ECONOMICS}

capacity would occur (*medium confidence*). Compared to other socioeconomic factors the influence of climate on conflict is assessed as relatively weak (*high confidence*). Along long-term socioeconomic pathways that reduce non-climatic drivers, risk of violent conflict would decline (*medium confidence*). At higher global warming levels, impacts of weather and climate extremes, particularly drought, by increasing vulnerability will increasingly affect violent intrastate conflict (*medium confidence*). {7.3, 16.5, CCB MIGRATE, TSB7.4}

Global and regional risks for increasing levels of global warming



* Mortality projections include demographic trends but do not include future efforts to improve air quality that reduce ozone concentrations.

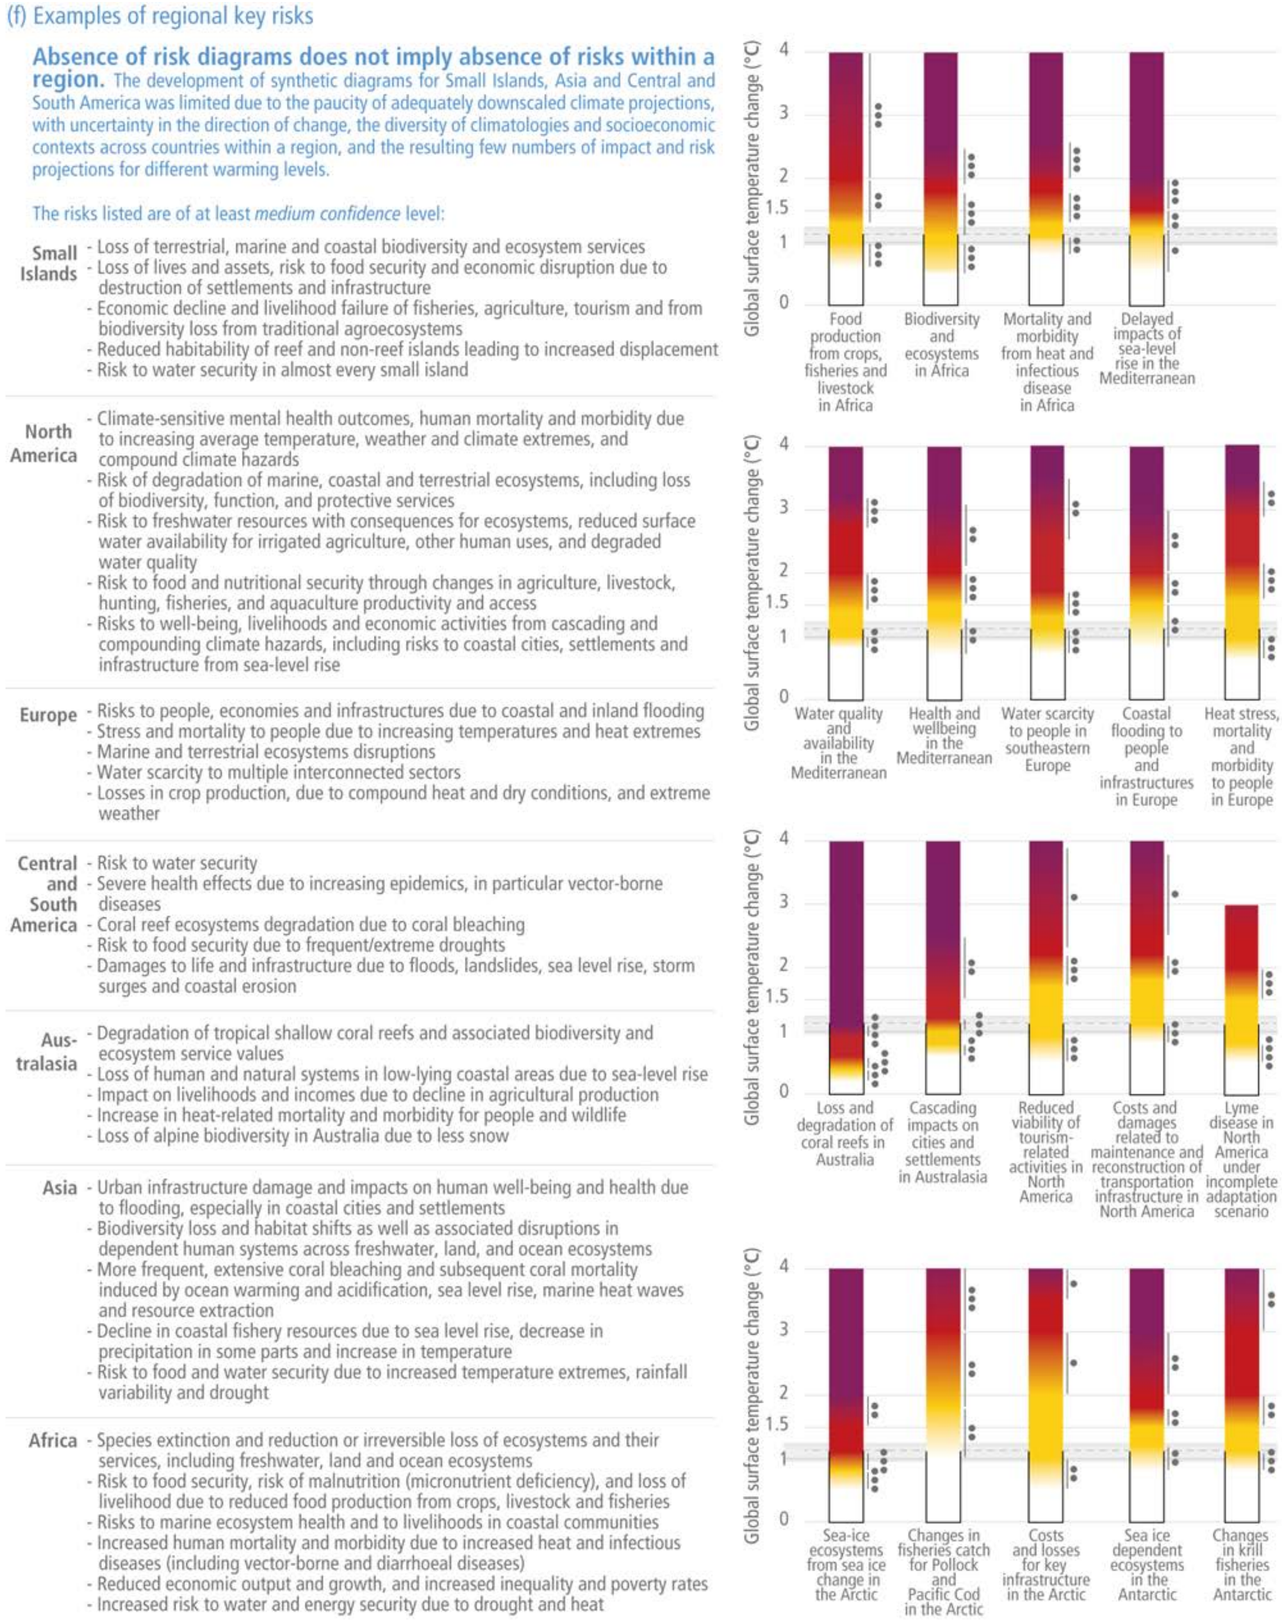


Figure SPM.3: Synthetic diagrams of global and sectoral assessments and examples of regional key risks. Diagrams show the change in the levels of impacts and risks assessed for global warming of 0-5°C global surface temperature change relative to pre-industrial period (1850-1900) over the range. (a) Global surface temperature changes in °C relative to 1850–1900. These changes were obtained by combining CMIP6 model simulations with observational constraints based on past simulated warming, as well as an updated assessment of equilibrium climate sensitivity (Box SPM.1). Changes relative to 1850–1900 based on 20-year averaging periods are calculated by adding 0.85°C (the observed global surface temperature increase from 1850–1900 to 1995–2014) to simulated changes relative to 1995–2014. *Very likely* ranges are shown for SSP1-2.6 and SSP3-

7.0 (WGI Figure SPM.8). Assessments were carried out at the global scale for (b), (c), (d) and (e). (b) The Reasons for Concern (RFC) framework communicates scientific understanding about accrual of risk for five broad categories. Diagrams are shown for each RFC, assuming low to no adaptation (i.e., adaptation is fragmented, localized and comprises incremental adjustments to existing practices). However, the transition to a very high risk level has an emphasis on irreversibility and adaptation limits. Undetectable risk level (white) indicates no associated impacts are detectable and attributable to climate change; moderate risk (yellow) indicates associated impacts are both detectable and attributable to climate change with at least *medium confidence*, also accounting for the other specific criteria for key risks; high risk (red) indicates severe and widespread impacts that are judged to be high on one or more criteria for assessing key risks; and very high risk level (purple) indicates very high risk of severe impacts and the presence of significant irreversibility or the persistence of climate-related hazards, combined with limited ability to adapt due to the nature of the hazard or impacts/risks. The horizontal line denotes the present global warming of 1.09°C which is used to separate the observed, past impacts below the line from the future projected risks above it. RFC1: Unique and threatened systems: ecological and human systems that have restricted geographic ranges constrained by climate-related conditions and have high endemism or other distinctive properties. Examples include coral reefs, the Arctic and its Indigenous Peoples, mountain glaciers and biodiversity hotspots. RFC2: Extreme weather events: risks/impacts to human health, livelihoods, assets and ecosystems from extreme weather events such as heatwaves, heavy rain, drought and associated wildfires, and coastal flooding. RFC3: Distribution of impacts: risks/impacts that disproportionately affect particular groups due to uneven distribution of physical climate change hazards, exposure or vulnerability. RFC4: Global aggregate impacts: impacts to socio-ecological systems that can be aggregated globally into a single metric, such as monetary damages, lives affected, species lost or ecosystem degradation at a global scale. RFC5: Large-scale singular events: relatively large, abrupt and sometimes irreversible changes in systems caused by global warming, such as ice sheet disintegration or thermohaline circulation slowing. Assessment methods are described in SM16.6 and are identical to AR5, but are enhanced by a structured approach to improve robustness and facilitate comparison between AR5 and AR6. Risks for (c) terrestrial and freshwater ecosystems and (d) ocean ecosystems. For c) and d), diagrams shown for each risk assume low to no adaptation. The transition to a very high risk level has an emphasis on irreversibility and adaptation limits. (e) Climate-sensitive human health outcomes under three scenarios of adaptation effectiveness. The assessed projections were based on a range of scenarios, including SRES, CMIP5, and ISIMIP, and, in some cases, demographic trends. The diagrams are truncated at the nearest whole ºC within the range of temperature change in 2100 under three SSP scenarios in panel (a). (f) Examples of regional key risks. Risks identified are of at least *medium confidence* level. Key risks are identified based on the magnitude of adverse consequences (pervasiveness of the consequences, degree of change, irreversibility of consequences, potential for impact thresholds or tipping points, potential for cascading effects beyond system boundaries); likelihood of adverse consequences; temporal characteristics of the risk; and ability to respond to the risk, e.g., by adaptation. The full set of 127 assessed global and regional key risks is given in SM16.7. Diagrams are provided for some risks. The development of synthetic diagrams for Small Islands, Asia and Central and South America were limited by the availability of adequately downscaled climate projections, with uncertainty in the direction of change, the diversity of climatologies and socio-economic contexts across countries within a region, and the resulting low number of impact and risk projections for different warming levels. Absence of risks diagrams does not imply absence of risks within a region. (Box SPM.1) {16.5, 16.6, Figure 16.15, SM16.3, SM16.4, SM16.5, SM16.6 (methodologies), SM16.7, Figure 2.11, Figure SM3.1, Figure 7.9, Figure 9.6, Figure 11.6, Figure 13.28, Figure CCP6.5, Figure CCP4.8, Figure CCP4.10, Figure TS.4, WGI Figure SPM.8, WGI SPM A.1.2, Box SPM.1, WGI Ch. 2}

Complex, Compound and Cascading Risks

SPM.B.5 Climate change impacts and risks are becoming increasingly complex and more difficult to manage. Multiple climate hazards will occur simultaneously, and multiple climatic and non-climatic risks will interact, resulting in compounding overall risk and risks cascading across sectors and regions. Some responses to climate change result in new impacts and risks. (*high confidence*) {1.3, 2.4, Box 2.2, Box 9.5, 11.5, 13.5, 14.6, Box 15.1, CCP1.2, CCP2.2, CCB DISASTER, CCB INTERREG, CCB SRM, CCB COVID}

SPM.B.5.1 Concurrent and repeated climate hazards occur in all regions, increasing impacts and risks to health, ecosystems, infrastructure, livelihoods and food (*high confidence*). Multiple risks interact, generating new sources of vulnerability to climate hazards, and compounding overall risk (*high confidence*). Increasing concurrence of heat and drought events are causing crop production losses and tree mortality (*high confidence*). Above 1.5°C global warming increasing concurrent climate extremes will increase risk of simultaneous crop losses of maize in major food-producing regions, with this risk increasing further with higher global warming levels (*medium confidence*). Future sea level rise combined with storm surge and heavy rainfall will increase compound flood risks (*high confidence*). Risks to health and food production will be made more severe from the interaction of sudden food production losses from heat and drought, exacerbated by heat-induced labour productivity losses (*high confidence*). These interacting impacts will increase food prices, reduce household incomes, and lead to health risks of malnutrition and climate-related mortality with no or low levels of adaptation, especially in tropical regions (*high confidence*). Risks to food safety from climate change will further compound the risks to health by increasing food contamination of crops from mycotoxins and contamination of seafood from harmful algal blooms, mycotoxins, and chemical contaminants (*high confidence*). {5.2, 5.4, 5.8, 5.9, 5.11, 5.12, 7.2, 7.3, 9.8, 9.11, 10.4, 11.3, 11.5, 12.3, 13.5, 14.5, 15.3, Box 15.1, 16.6, CCP1.2, CCP6.2, Figure TS10C, WG1 SPM A.3.1, A.3.2 and C.2.7}

SPM.B.5.2 Adverse impacts from climate hazards and resulting risks are cascading across sectors and regions (*high confidence*), propagating impacts along coasts and urban centres (*medium confidence*) and in mountain regions (*high confidence*). These hazards and cascading risks also trigger tipping points in sensitive ecosystems and in significantly and rapidly changing social-ecological systems impacted by ice melt, permafrost thaw and changing hydrology in polar regions (*high confidence*). Wildfires, in many regions, have affected ecosystems and species, people and their built assets, economic activity, and health (*medium to high confidence*)**.** In cities and settlements, climate impacts to key infrastructure are leading to losses and damages across water and food systems, and affect economic activity, with impacts extending beyond the area directly impacted by the climate hazard (*high confidence*). In Amazonia, and in some mountain regions, cascading impacts from climatic (e.g., heat) and non-climatic stressors (e.g., land use change) will result in irreversible and severe losses of ecosystem services and biodiversity at 2°C global warming level and beyond (*medium confidence*). Unavoidable sea level rise will bring cascading and compounding impacts resulting in losses of coastal ecosystems and ecosystem services, groundwater salinisation, flooding and damages to coastal infrastructure that cascade into risks to livelihoods, settlements, health, well-being, food and water security, and cultural values in the near to long-term (*high confidence*). (Figure SPM.3) {2.5, 3.4, 3.5, Box 7.3, Box 8.7, Box 9.4, Box 11.1, 11.5, 12.3, 13.9, 14.6, 15.3, 16.5, 16.6, CCP1.2, CCP2.2, CCP5.2, CCP5.3, CCP6.2, CCP6.3, Box CCP6.1, Box CCP6.2, CCB EXTREMES, Figure TS.10, WGI SPM Figure SPM.8d}

SPM.B.5.3 Weather and climate extremes are causing economic and societal impacts across national boundaries through supply-chains, markets, and natural resource flows, with increasing transboundary risks projected across the water, energy and food sectors (*high confidence*). Supply chains that rely on specialized commodities and key infrastructure can be disrupted by weather and climate extreme events. Climate change causes the redistribution of marine fish stocks, increasing risk of transboundary management conflicts among fisheries users, and negatively affecting equitable distribution of food provisioning services as fish stocks shift from lower to higher latitude regions, thereby increasing the need for climate-informed transboundary management and cooperation (*high confidence*). Precipitation and water availability changes increases the risk of planned infrastructure projects, such as hydropower in some regions, having reduced productivity for food and energy sectors including across countries that share river basins (*medium confidence*). {Figure TS.10e-f, 3.4, 3.5, 4.5, 5.8, 5.13, 6.2, 9.4, Box 9.5,14.5, Box 14.5, Box 14.6, CCP5.3, CCB EXTREMES, CCB MOVING PLATE, CCB INTERREG, CCB DISASTER}

SPM B.5.4 Risks arise from some responses that are intended to reduce the risks of climate change, including risks from maladaptation and adverse side effects of some emission reduction and carbon dioxide removal measures (*high confidence*). Deployment of afforestation of naturally unforested land, or poorly implemented bioenergy, with or without carbon capture and storage, can compound climate-related risks to biodiversity, water and food security, and livelihoods, especially if implemented at large scales, especially in regions with insecure land tenure (*high confidence*). {Box 2.2, 4.1, 4.7, 5.13, Table 5.18, Box 9.3, Box 13.2, CCB NATURAL, CWGB BIOECONOMY}

SPM B.5.5 Solar radiation modification approaches, if they were to be implemented, introduce a widespread range of new risks to people and ecosystems, which are not well understood (*high confidence*). Solar radiation modification approaches have potential to offset warming and ameliorate some climate hazards, but substantial residual climate change or overcompensating change would occur at regional scales and seasonal timescales (*high confidence*). Large uncertainties and knowledge gaps are associated with the potential of solar radiation modification approaches to reduce climate change risks. Solar radiation modification would not stop atmospheric CO_2 concentrations from increasing or reduce resulting ocean acidification under continued anthropogenic emissions (*high confidence*). {XWGB SRM}

Impacts of Temporary Overshoot

SPM.B.6 If global warming transiently exceeds 1.5°C in the coming decades or later (overshoot)[37], then many human and natural systems will face additional severe risks, compared to remaining below 1.5°C (*high confidence*). Depending on the magnitude and duration of overshoot, some impacts will cause release of additional greenhouse gases (*medium confidence*) and some will be irreversible, even if global warming is reduced (*high confidence*). (Figure SPM.3) {2.5, 3.4, 12.3, 16.6, CCB SLR, CCB DEEP, Box SPM.1}

SPM.B.6.1 While model-based assessments of the impacts of overshoot pathways are limited, observations and current understanding of processes permit assessment of impacts from overshoot. Additional warming, e.g., above 1.5°C during an overshoot period this century, will result in irreversible impacts on certain ecosystems with low resilience, such as polar, mountain, and coastal ecosystems, impacted by ice-sheet, glacier melt, or by accelerating and higher committed sea level rise (*high confidence*).[38] Risks to human systems will increase, including those to infrastructure, low-lying coastal settlements, some ecosystem-based adaptation measures, and associated livelihoods (*high confidence*), cultural and spiritual values (*medium confidence*). Projected impacts are less severe with shorter duration and lower levels of overshoot (*medium confidence*). {2.5, 3.4, 12.3, 13.2, 16.5, 16.6, CCP 1.2, CCP5.3, CCP6.1, CCP6.2, CCP2.2, CCB SLR, Box TS4, SROCC 2.3, SROCC 5.4, WG1 SPM B5 and C3}

SPM.B.6.2 Risk of severe impacts increase with every additional increment of global warming during overshoot (*high confidence*). In high-carbon ecosystems (currently storing 3,000 to 4,000 GtC)[39] such impacts are already observed and are projected to increase with every additional increment of global warming, such as increased wildfires, mass mortality of trees, drying of peatlands, and thawing of permafrost, weakening natural land carbon sinks and increasing releases of greenhouse gases (*medium confidence*). The resulting contribution to a potential amplification of global warming indicates that a return to a given global warming level or below would be more challenging (*medium confidence*). {2.4, 2.5, CCP4.2, WG1 SPM B.4.3, SROCC 5.4}

SPM.C: Adaptation Measures and Enabling Conditions

Adaptation, in response to current climate change, is reducing climate risks and vulnerability mostly via adjustment of existing systems. Many adaptation options exist and are used to help manage projected climate change impacts, but their implementation depends upon the capacity and effectiveness of governance and decision-making processes. These and other enabling conditions can also support Climate Resilient Development (Section D).

Current Adaptation and its Benefits

---

[37] In this report, overshoot pathways exceed 1.5°C global warming and then return to that level, or below, after several decades.

[38] Despite limited evidence specifically on the impacts of a temporary overshoot of 1.5°C, a much broader evidence base from process understanding and the impacts of higher global warming levels allows a high confidence statement on the irreversibility of some impacts that would be incurred following such an overshoot.

[39] At the global scale, terrestrial ecosystems currently remove more carbon from the atmosphere (-3.4 ± 0.9 Gt yr^{-1}) than they emit ($+1.6 \pm 0.7$ Gt yr^{-1}), a net sink of -1.9 ± 1.1 Gt yr^{-1}. However, recent climate change has shifted some systems in some regions from being net carbon sinks to net carbon sources.

SPM.C.1 Progress in adaptation planning and implementation has been observed across all sectors and regions, generating multiple benefits (*very high confidence*). However, adaptation progress is unevenly distributed with observed adaptation gaps[40] (*high confidence*). Many initiatives prioritize immediate and near-term climate risk reduction which reduces the opportunity for transformational adaptation (*high confidence*). {2.6, 5.14, 7.4, 10.4, 12.5, 13.11, 14.7, 16.3, 17.3, CCP5.2, CCP5.4}

SPM.C.1.1 Adaptation planning and implementation have continued to increase across all regions (*very high confidence*). Growing public and political awareness of climate impacts and risks has resulted in at least 170 countries and many cities including adaptation in their climate policies and planning processes (*high confidence*). Decision support tools and climate services are increasingly being used (*very high confidence*). Pilot projects and local experiments are being implemented in different sectors (*high confidence*). Adaptation can generate multiple additional benefits such as improving agricultural productivity, innovation, health and well-being, food security, livelihood, and biodiversity conservation as well as reduction of risks and damages (*very high confidence*). {1.4, CCB ADAPT, 2.6, CCB NATURE, 3.5, 3.6, 4.7, 4.8, 5.4, 5.6, 5.10, 6.4.2, 7.4, 8.5, 9.3, 9.6, 10.4, 12.5, 13.11, 15.5, 16.3, 17.2, 17.3, 17.5 CCP5.4}

SPM.C.1.2 Despite progress, adaptation gaps exist between current levels of adaptation and levels needed to respond to impacts and reduce climate risks (*high confidence*). Most observed adaptation is fragmented, small in scale, incremental, sector-specific, designed to respond to current impacts or near-term risks, and focused more on planning rather than implementation (*high confidence*). Observed adaptation is unequally distributed across regions *(high confidence)*, and gaps are partially driven by widening disparities between the estimated costs of adaptation and documented finance allocated to adaptation (*high confidence*)*.* The largest adaptation gaps exist among lower income population groups (*high confidence*). At current rates of adaptation planning and implementation the adaptation gap will continue to grow (*high confidence*). As adaptation options often have long implementation times, long-term planning and accelerated implementation, particularly in the next decade, is important to close adaptation gaps, recognising that constraints remain for some regions (*high confidence*). {1.1, 1.4, 5.6, 6.3, Figure 6.4, 7.4, 8.3, 10.4, 11.3, 11.7, 15.2, Box 13.1, 13.11, 15.5, Box16.1, Figure 16.4, Figure 16.5, 16.3, 16.5, 17.4, 18.2, CCP2.4, CCP5.4, CCB FINANCE, CCB SLR}

---

[40] Adaptation gaps are defined as the difference between actually implemented adaptation and a societally set goal, determined largely by preferences related to tolerated climate change impacts and reflecting resource limitations and competing priorities.

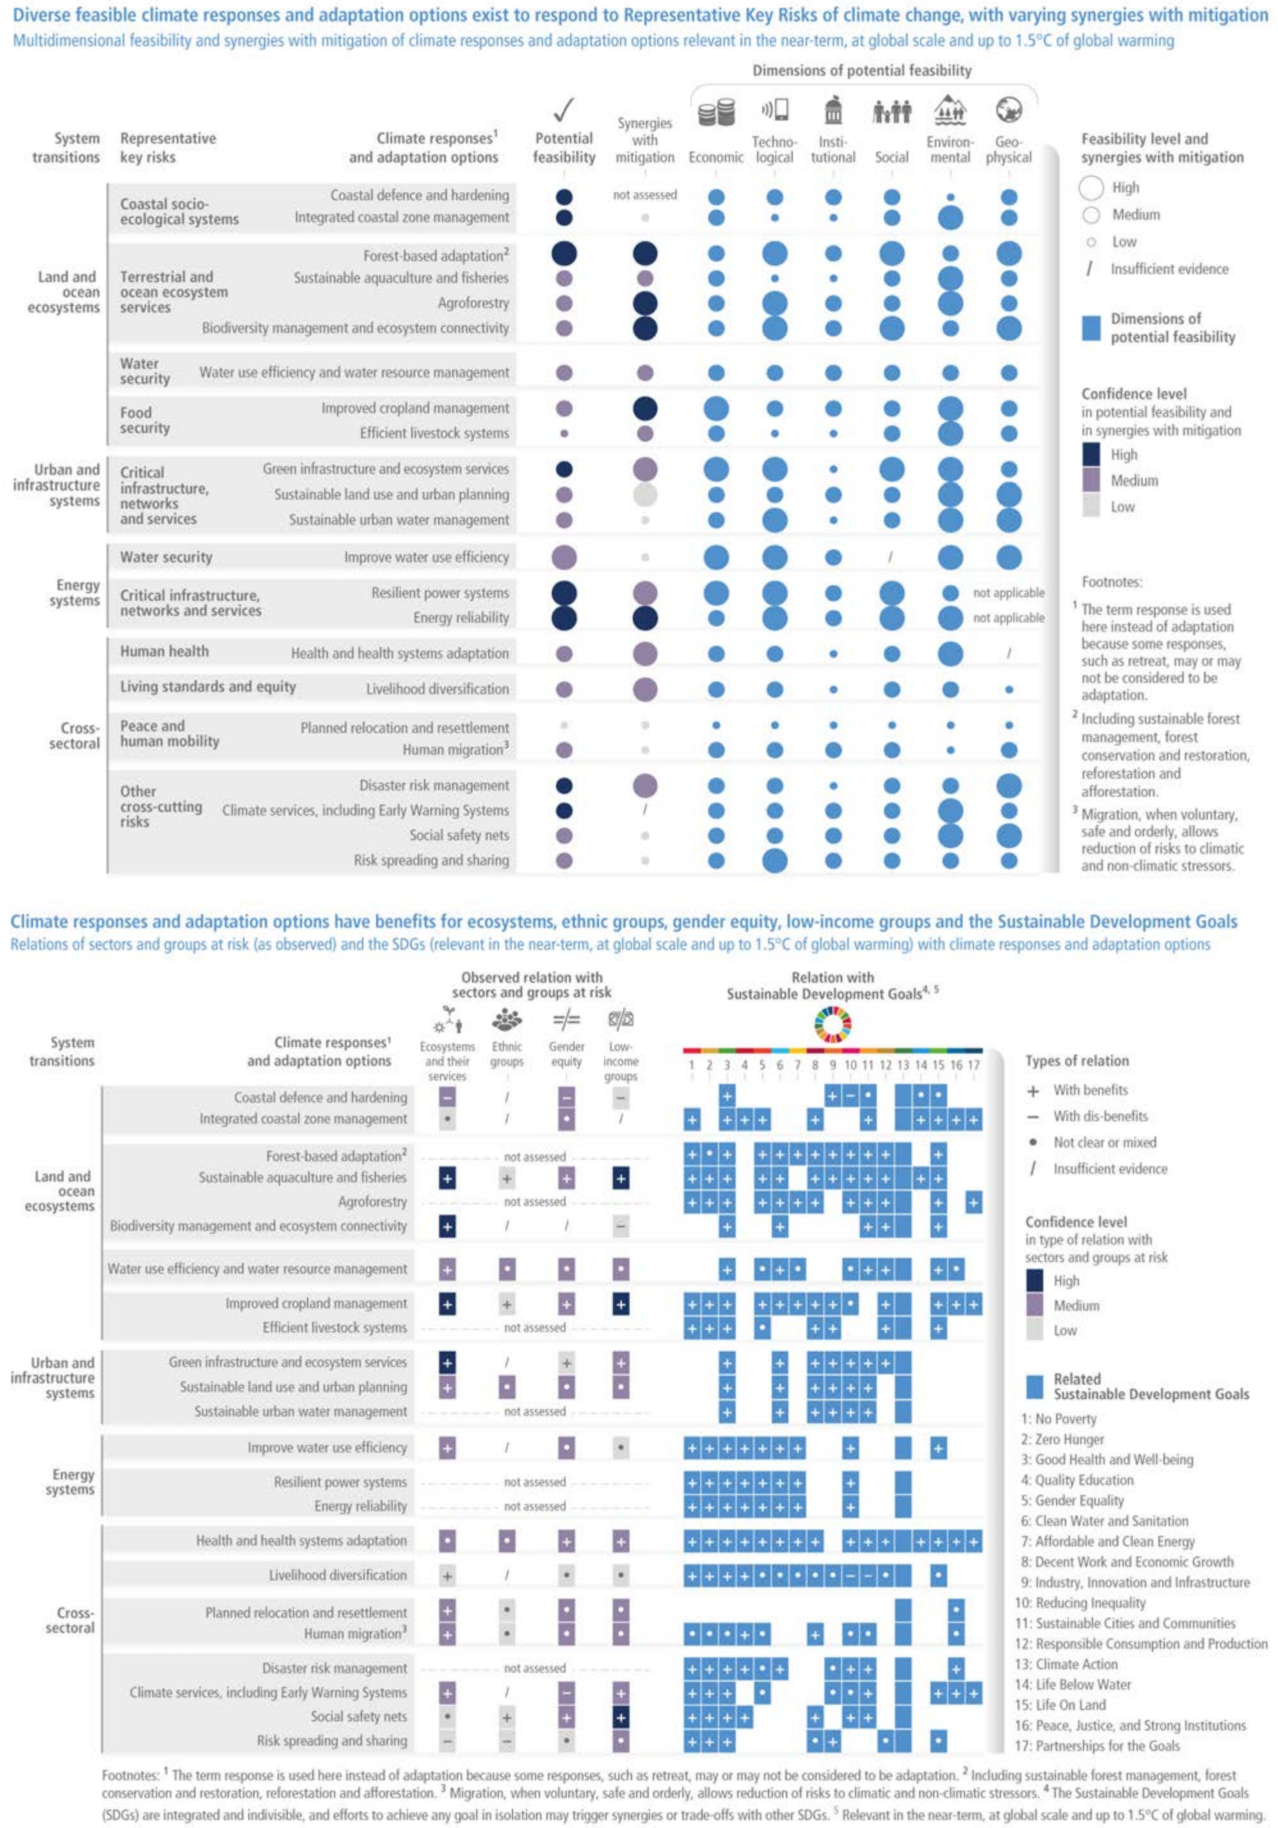

Figure SPM.4: (a) Climate responses and adaptation options, organized by System Transitions and Representative Key Risks (RKRs), are assessed for their multidimensional feasibility at global scale, in the near term and up to 1.5°C global warming. As literature above 1.5°C is limited, feasibility at higher levels of warming may change, which is currently not possible to assess robustly. Climate responses and adaptation options at global scale are drawn from a set of options assessed in AR6 that have robust evidence across the feasibility dimensions. This figure shows the six feasibility dimensions (economic, technological, institutional, social, environmental and geophysical) that are used to calculate the potential feasibility of climate responses and adaptation options, along with their synergies with mitigation. For potential feasibility and feasibility dimensions, the figure shows high, medium, or low feasibility. Synergies with mitigation are identified as high, medium, and low. Insufficient evidence is denoted by a dash. {CCB FEASIB., Table SMCCB FEASIB.1.1; SR1.5 4.SM.4.3}

Figure SPM.4: (b) Climate responses and adaptation options, organized by System Transitions and Representative Key Risks, are assessed at global scale for their likely ability to reduce risks for ecosystems and social groups at risk, as well as their relation with the 17 Sustainable Development Goals (SDGs). Climate responses and adaptation options are assessed for observed benefits (+) to ecosystems and their services, ethnic groups, gender equity, and low-income groups, or observed dis-benefits (-) for these systems and groups. Where there is highly diverging evidence of benefits/ dis-benefits across the scientific literature, e.g., based on differences between regions, it is shown as not clear or mixed (•). Insufficient evidence is shown by a dash. The relation with the SDGs is assessed as having benefits (+), dis-benefits (-) or not clear or mixed (•) based on the impacts of the climate response and adaptation option on each SDG. Areas not coloured indicate there is no evidence of a relation or no interaction with the respective SDG. The climate responses and adaptation options are drawn from two assessments. For comparability of climate responses and adaptation options see Table SM17.5. {17.2, 17.5; CCB FEASIB}

Future Adaptation Options and their Feasibility

SPM.C.2 There are feasible[41] and effective[42] adaptation options which can reduce risks to people and nature. The feasibility of implementing adaptation options in the near-term differs across sectors and regions (*very high confidence*). The effectiveness of adaptation to reduce climate risk is documented for specific contexts, sectors and regions (*high confidence*) and will decrease with increasing warming (*high confidence*). Integrated, multi-sectoral solutions that address social inequities, differentiate responses based on climate risk and cut across systems, increase the feasibility and effectiveness of adaptation in multiple sectors (*high confidence*). (Figure SPM.4) {Figure TS.6e, 1.4, 3.6, 4.7, 5.12, 6.3, 7.4, 11.3, 11.7, 13.2, 15.5, 17.6, CCB FEASIB, CCP2.3}

Land, Ocean and Ecosystems Transition

SPM.C.2.1 Adaptation to water-related risks and impacts make up the majority of all documented adaptation (*high confidence*). For inland flooding, combinations of non-structural measures like early warning systems and structural measures like levees have reduced loss of lives (*medium confidence*). Enhancing natural water retention such as by restoring wetlands and rivers, land use planning such as no build zones or upstream forest management, can further reduce flood risk (*medium confidence*). On-farm water management, water storage, soil moisture conservation and irrigation are some of the most common adaptation responses and provide economic, institutional or ecological benefits and reduce vulnerability (*high confidence*). Irrigation is effective in reducing drought risk and climate impacts in many regions and has several livelihood benefits, but needs appropriate management to avoid potential adverse outcomes, which can include accelerated depletion of groundwater and other water sources and increased soil salinization (*medium confidence*). Large scale irrigation can also alter local to regional temperature and precipitation patterns (*high confidence*), including both alleviating and exacerbating temperature extremes (*medium confidence*). The effectiveness of most water-related adaptation options to reduce projected risks declines with increasing warming (*high confidence*). {4.1,

[41] In this report, feasibility refers to the potential for a mitigation or adaptation option to be implemented. Factors influencing feasibility are context-dependent, temporally dynamic, and may vary between different groups and actors. Feasibility depends on geophysical, environmental-ecological, technological, economic, socio-cultural and institutional factors that enable or constrain the implementation of an option. The feasibility of options may change when different options are combined and increase when enabling conditions are strengthened.

[42] Effectiveness refers to the extent to which an adaptation option is anticipated or observed to reduce climate-related risk.

4.6, 4.7, Box 4.3, Box 4.6, Box 4.7, Figure 4.28, Figure 4.29, Table 4.9, 9.3, 9.7, 11.3, 12.5, 13.1, 13.2, 16.3, CCP5.4, Figure 4.22}

SPM.C.2.2 Effective adaptation options, together with supportive public policies enhance food availability and stability and reduce climate risk for food systems while increasing their sustainability (*medium confidence*). Effective options include cultivar improvements, agroforestry, community-based adaptation, farm and landscape diversification, and urban agriculture (*high confidence*). Institutional feasibility, adaptation limits of crops and cost effectiveness also influence the effectiveness of the adaptation options (*limited evidence*, *medium agreement*). Agroecological principles and practices, ecosystem-based management in fisheries and aquaculture, and other approaches that work with natural processes support food security, nutrition, health and well-being, livelihoods and biodiversity, sustainability and ecosystem services (*high confidence*). These services include pest control, pollination, buffering of temperature extremes, and carbon sequestration and storage (*high confidence*). Trade-offs and barriers associated with such approaches include costs of establishment, access to inputs and viable markets, new knowledge and management (*high confidence*) and their potential effectiveness varies by socio-economic context, ecosystem zone, species combinations and institutional support (*medium confidence*). Integrated, multi-sectoral solutions that address social inequities and differentiate responses based on climate risk and local situation will enhance food security and nutrition (*high confidence*). Adaptation strategies which reduce food loss and waste or support balanced diets[33] (as described in the IPCC Special Report on Climate Change and Land) contribute to nutrition, health, biodiversity and other environmental benefits (*high confidence*). {3.2, 4.7, 4.6, Box 4.3, 5.4, 5.5, 5.6, 5.8, 5.9, 5.10, 5.11, 5.12, 5.13, 5.14, 7.4, Box 5.10, Box 5.13, 6.3, 10.4, 12.5, 13.5, 13.10, 14.5, CWGB BIOECONOMY, CCB MOVING PLATE, CCB NATURAL, CCB FEASIB, CCP5.4, CCB HEALTH}

SPM.C.2.3 Adaptation for natural forests[43] includes conservation, protection and restoration measures. In managed forests[44], adaptation options include sustainable forest management, diversifying and adjusting tree species compositions to build resilience, and managing increased risks from pests and diseases and wildfires. Restoring natural forests and drained peatlands and improving sustainability of managed forests, generally enhances the resilience of carbon stocks and sinks. Cooperation, and inclusive decision making, with local communities and Indigenous Peoples, as well as recognition of inherent rights of Indigenous Peoples, is integral to successful forest adaptation in many areas. (*high confidence*) {2.6, Box 2.2, CCB NATURAL, CCB FEASIB, CCB INDIG, 5.6, 5.13, 11.4, 12.5, 13.5, Box 14.1, Box 14.2, Table 5.23, Box CCP7.1, CCP7.5}.

SPM.C.2.4 Conservation, protection and restoration of terrestrial, freshwater, coastal and ocean ecosystems, together with targeted management to adapt to unavoidable impacts of climate change, reduces the vulnerability of biodiversity to climate change (*high confidence*). The resilience of species, biological communities and ecosystem processes increases with size of natural area, by restoration of degraded areas and by reducing non-climatic stressors (*high confidence*). To be effective, conservation and restoration actions will increasingly need to be responsive, as appropriate, to ongoing changes at various scales, and plan for future changes in ecosystem structure, community composition and species' distributions, especially as 1.5°C global warming is approached and even more so if it is exceeded (*high confidence*). Adaptation options, where circumstances allow, include facilitating the movement of species to new ecologically appropriate locations, particularly through increasing connectivity between conserved or protected areas, targeted intensive management for vulnerable species and protecting refugial areas where species can survive locally (*medium confidence*). {2.3, Figure 2.1, 2,6, Table 2.6, 2.6, 3.6, Box 3.4, 4.6, Box 11.2, 12.3, 12.5, 3.3, 13.4, 14.7, Box 4.6, CCP5.4, CCB FEASIB}

SPM.C.2.5 Effective Ecosystem-based Adaptation[44] reduces a range of climate change risks to people, biodiversity and ecosystem services with multiple co-benefits (*high confidence*). Ecosystem-based Adaptation

---

[43] In this report, the term natural forests describes those which are subject to little or no direct human intervention, whereas the term managed forests describes those where planting or other management activities take place, including those managed for commodity production.

[44] Ecosystem based Adaptation (EbA) is recognised internationally under the Convention on Biological Diversity (CBD14/5). A related concept is Nature-based Solutions (NbS), which includes a broader range of approaches with safeguards, including those that contribute to adaptation and mitigation. The term 'Nature-based Solutions' is widely but not universally used in the scientific literature. The term is the subject of ongoing debate, with concerns that it may lead to the misunderstanding that NbS on its own can provide a global solution to climate change.

is vulnerable to climate change impacts, with effectiveness declining with increasing global warming (*high confidence*). Urban greening using trees and other vegetation can provide local cooling (*very high confidence*). Natural river systems, wetlands and upstream forest ecosystems reduce flood risk by storing water and slowing water flow, in most circumstances (*high confidence*). Coastal wetlands protect against coastal erosion and flooding associated with storms and sea level rise where sufficient space and adequate habitats are available until rates of sea level rise exceeds natural adaptive capacity to build sediment (*very high confidence*). {2.4, 2.5, 2.6, Table 2.7, 3.4, 3.5, 3.6, Figure 3.26, 4.6, Box 4.6, Box 4.7, 5.5, 5.14, Box 5.11, 6.3, 6.4, Figure 6.6, 7.4, 8.5, 8.6, 9.6, 9.8, 9.9, 10.2, 11.3, 12.5, 13.3, 13.4, 13.5, 14.5, Box 14.7, 16.3, 18.3, CCB HEALTH, CCB NATURAL, CCB MOVING PLATE, CCB FEASIB.3, CWGB BIOECONOMY, CCP5.4}

Urban, Rural and Infrastructure Transition

SPM.C.2.6 Considering climate change impacts and risks in the design and planning of urban and rural settlements and infrastructure is critical for resilience and enhancing human well-being (*high confidence*). The urgent provision of basic services, infrastructure, livelihood diversification and employment, strengthening of local and regional food systems and community-based adaptation enhance lives and livelihoods, particularly of low-income and marginalised groups (*high confidence*). Inclusive, integrated and long-term planning at local, municipal, sub-national and national scales, together with effective regulation and monitoring systems and financial and technological resources and capabilities foster urban and rural system transition (*high confidence*). Effective partnerships between governments, civil society, and private sector organizations, across scales provide infrastructure and services in ways that enhance the adaptive capacity of vulnerable people (*medium to high confidence*). {5.12, 5.13, 5.14, Box 6.3, 6.3, 6.4, Box 6.6, Table 6.6, 7.4, 12.5, 13.6, 14.5, Box14.4, Box17.4, CCB FEASIB, CCP2.3, CCP2.4, CCP5.4}

SPM.C.2.7 An increasing number of adaptation responses exist for urban systems, but their feasibility and effectiveness is constrained by institutional, financial, and technological access and capacity, and depends on coordinated and contextually appropriate responses across physical, natural and social infrastructure (*high confidence*). Globally, more financing is directed at physical infrastructure than natural and social infrastructure (*medium confidence*) and there is *limited evidence* of investment in the informal settlements hosting the most vulnerable urban residents (*medium* to *high confidence*). Ecosystem-based adaptation (e.g., urban agriculture and forestry, river restoration) has increasingly been applied in urban areas (*high confidence).* Combined ecosystem-based and structural adaptation responses are being developed, and there is growing evidence of their potential to reduce adaptation costs and contribute to flood control, sanitation, water resources management, landslide prevention and coastal protection (*medium confidence*). {3.6, Box 4.6, 5.12, 6.3, 6.4, Table 6.8, 7.4, 9.7, 9.9, 10.4, Table 10.3, 11.3, 11.7, Box 11.6, 12.5, 13.2, 13.3, 13.6, 14.5, 15.5, 17.2, Box 17.4, CCB FEASIB, CCP2.3, CCP 3.2, CCP5.4, CCB SLR, SROCC ES}

SPM C.2.8: Sea level rise poses a distinctive and severe adaptation challenge as it implies dealing with slow onset changes and increased frequency and magnitude of extreme sea level events which will escalate in the coming decades (*high confidence*). Such adaptation challenges would occur much earlier under high rates of sea level rise, in particular if low-likelihood, high impact outcomes associated with collapsing ice sheets occur (*high confidence*). Responses to ongoing sea level rise and land subsidence in low-lying coastal cities and settlements and small islands include protection, accommodation, advance and planned relocation (*high confidence*)[45]. These responses are more effective if combined and/or sequenced, planned well ahead, aligned with sociocultural values and development priorities, and underpinned by inclusive community engagement processes (*high confidence*). {CCB SLR, CCP2.3, 6.2, 10.4, 11.7, Box 11.6, 13.2.2, 14.5.9.2, 15.5, SROCC ES: C3.2, WGI SPM B5, C3}

SPM.C.2.9 Approximately 3.4 billion people globally live in rural areas around the world, and many are highly vulnerable to climate change. Integrating climate adaptation into social protection programs, including cash transfers and public works programmes, is highly feasible and increases resilience to climate change, especially when supported by basic services and infrastructure. Social safety nets are increasingly being reconfigured to build adaptive capacities of the most vulnerable in rural and also urban communities. Social

[45] The term 'response' is used here instead of adaptation because some responses, such as retreat, may or may not be considered to be adaptation.

safety nets that support climate change adaptation have strong co-benefits with development goals such as education, poverty alleviation, gender inclusion and food security. (*high confidence*) {5.14, 9.4, 9.10, 9.11, 12.5, 14.5, CCB GENDER, CCB FEASIB, CCP5.4}

Energy System Transition

SPM.C.2.10 Within energy system transitions, the most feasible adaptation options support infrastructure resilience, reliable power systems and efficient water use for existing and new energy generation systems (*very high confidence*). Energy generation diversification, including with renewable energy resources and generation that can be decentralised depending on context (e.g., wind, solar, small scale hydroelectric) and demand side management (e.g., storage, and energy efficiency improvements) can reduce vulnerabilities to climate change, especially in rural populations (*high confidence*). Adaptations for hydropower and thermo-electric power generation are effective in most regions up to 1.5°C to 2°C, with decreasing effectiveness at higher levels of warming (*medium confidence*). Climate responsive energy markets, updated design standards on energy assets according to current and projected climate change, smart-grid technologies, robust transmission systems and improved capacity to respond to supply deficits have high feasibility in the medium- to long-term, with mitigation co-benefits (*very high confidence*). {4.6, 4.7, Figure 4.28, Figure 4.29, 10.4, Table 11.8, Figure 13.19, Figure 13.16, 13.6, 18.3, CCB FEASIB, CWGB BIOECONOMY, CCP5.2, CCP5.4}

Cross-cutting Options

SPM.C.2.11 Strengthening the climate resiliency of health systems will protect and promote human health and wellbeing (*high confidence*). There are multiple opportunities for targeted investments and finance to protect against exposure to climate hazards, particularly for those at highest risk. Heat Health Action Plans that include early warning and response systems are effective adaptation options for extreme heat (*high confidence*). Effective adaptation options for water-borne and food-borne diseases include improving access to potable water, reducing exposure of water and sanitation systems to flooding and extreme weather events, and improved early warning systems (*very high confidence*). For vector-borne diseases, effective adaptation options include surveillance, early warning systems, and vaccine development (*very high confidence*). Effective adaptation options for reducing mental health risks under climate change include improving surveillance, access to mental health care, and monitoring of psychosocial impacts from extreme weather events (*high confidence*). Health and well-being would benefit from integrated adaptation approaches that mainstream health into food, livelihoods, social protection, infrastructure, water and sanitation policies requiring collaboration and coordination at all scales of governance (*very high confidence*). {5.12, 6.3, 7.4, 9.10, Box 9.7, 11.3, 12.5, 13.7, 14.5, CCB FEASIB, CCB ILLNESS, CCB COVID}.

SPM.C.2.12 Increasing adaptive capacities minimises the negative impacts of climate-related displacement and involuntary migration for migrants and sending and receiving areas (*high confidence*). This improves the degree of choice under which migration decisions are made, ensuring safe and orderly movements of people within and between countries (*high confidence*). Some development reduces underlying vulnerabilities associated with conflict, and adaptation contributes by reducing the impacts of climate change on climate sensitive drivers of conflict (*high confidence*). Risks to peace are reduced, for example, by supporting people in climate-sensitive economic activities (*medium confidence*) and advancing women's empowerment (*high confidence*). {7.4, 12.5, CCB MIGRATE, Box 9.8, Box 10.2, CCB FEASIB}

SPM.C.2.13 There are a range of adaptation options, such as disaster risk management, early warning systems, climate services and risk spreading and sharing that have broad applicability across sectors and provide greater benefits to other adaptation options when combined (*high confidence*). For example, climate services that are inclusive of different users and providers can improve agricultural practices, inform better water use and efficiency, and enable resilient infrastructure planning (*high confidence*). {2.6, 3.6, 4.7, 5.4, 5.5, 5.6, 5.8, 5.9, 5.12, 5.14, 9.4, 9.8, 10.4, 12.5, 13.11, CCB MOVING PLATE, CCB FEASIB, CCP5.4}

Limits to Adaptation

SPM.C.3 Soft limits to some human adaptation have been reached, but can be overcome by addressing a range of constraints, primarily financial, governance, institutional and policy constraints (*high confidence*). Hard limits to adaptation have been reached in some ecosystems (*high confidence*). With increasing global warming, losses and damages will increase and additional human and natural systems will reach adaptation limits (*high confidence*). {Figure TS.7, 1.4, 2.4, 2.5, 2.6, CCB SLR, 3.4, 3.6, 4.7, Figure 4.30, 5.5, Table 8.6, Box 10.7, 11.7, Table 11.16, 12.5 13.2, 13.5, 13.6, 13.10, 13.11, Figure 13.21, 14.5, 15.6, 16.4, Figure 16.8, Table 16.3, Table 16.4, CCP1.2, CCP1.3, CCP2.3, CCP3.3, CCP5.2, CCP5.4, CCP6.3, CCP7.3}

SPM.C.3.1 Soft limits to some human adaptation have been reached, but can be overcome by addressing a range of constraints, which primarily consist of financial, governance, institutional and policy constraints (*high confidence*). For example, individuals and households in low lying coastal areas in Australasia and Small Islands and smallholder farmers in Central and South America, Africa, Europe and Asia have reached soft limits (*medium confidence*). Inequity and poverty also constrain adaptation, leading to soft limits and resulting in disproportionate exposure and impacts for most vulnerable groups (*high confidence*). Lack of climate literacy[46] at all levels and limited availability of information and data pose further constraints to adaptation planning and implementation (*medium confidence*). {1.4, 4.7, 5.4, Table 8.6, 8.4, 9.1, 9.4, 9.5, 9.8, 11.7, 12.5 13.5, 15.3, 15.5, 15.6, 16.4, Figure 16.8, 16.4, Box 16.1, CCP5.2, CCP5.4, CCP6.3}

SPM.C.3.2 Financial constraints are important determinants of soft limits to adaptation across sectors and all regions (*high confidence*). Although global tracked climate finance has shown an upward trend since AR5, current global financial flows for adaptation, including from public and private finance sources, are insufficient for and constrain implementation of adaptation options especially in developing countries (*high confidence*). The overwhelming majority of global tracked climate finance was targeted to mitigation while a small proportion was targeted to adaptation (*very high confidence*). Adaptation finance has come predominantly from public sources (*very high confidence*). Adverse climate impacts can reduce the availability of financial resources by incurring losses and damages and through impeding national economic growth, thereby further increasing financial constraints for adaptation, particularly for developing and least developed countries (*medium confidence*). {1.4, 2.6, 3.6, 4.7, Figure 4.30, 5.14, 7.4, Table 8.6, 8.4, 9.4, 9.9, 9.11, 10.5, 12.5, 13.3, 13.11, Box 14.4, 15.6, 16.2, 16.4, Figure 16.8, Table 16.4, 17.4, 18.1, CCB FINANCE, CCP2.4, CCP5.4, CCP6.3, Figure TS 7}

SPM.C.3.3 Many natural systems are near the hard limits of their natural adaptation capacity and additional systems will reach limits with increasing global warming (*high confidence*). Ecosystems already reaching or surpassing hard adaptation limits include some warm water coral reefs, some coastal wetlands, some rainforests, and some polar and mountain ecosystems (*high confidence*). Above 1.5°C global warming level, some ecosystem-based adaptation measures will lose their effectiveness in providing benefits to people as these ecosystems will reach hard adaptation limits (*high confidence*). {1.4, 2.4, 2.6, 3.4, 3.6, CCB SLR, 9.6, Box11.2, 13.4, 14.5, 15.5, 16.4, 16.6, 17.2, CCP1.2, CCP5.2, CCP6.3, CCP7.3, Figure SPM.4}

SPM.3.4 In human systems, some coastal settlements face soft adaptation limits due to technical and financial difficulties of implementing coastal protection (*high confidence*). Above 1.5°C global warming level, limited freshwater resources pose potential hard limits for Small Islands and for regions dependent on glacier and snow-melt (*medium confidence*). By 2°C global warming level, soft limits are projected for multiple staple crops in many growing areas, particularly in tropical regions (*high confidence*). By 3°C global warming level, soft limits are projected for some water management measures for many regions, with hard limits projected for parts of Europe (*medium confidence*). Transitioning from incremental to transformational adaptation can help overcome soft adaptation limits (*high confidence*). {1.4, 4.7, 5.4, 5.8, 7.2, 7.3, 8.4, Table 8.6, 9.8, 10.4, 12.5, 13.2, 13.6, 16.4, 17.2, CCB SLR, CCP1.3. Box CCP1.1, CCP2.3, CCP3.3, CCP4.4, CCP5.3}

SPM.C.3.5 Adaptation does not prevent all losses and damages, even with effective adaptation and before reaching soft and hard limits. Losses and damages are unequally distributed across systems, regions and sectors and are not comprehensively addressed by current financial, governance and institutional arrangements, particularly in vulnerable developing countries. With increasing global warming, losses and damages increase and become increasingly difficult to avoid, while strongly concentrated among the poorest vulnerable

[46] Climate literacy encompasses being aware of climate change, its anthropogenic causes and implications.

populations. (*high confidence*) {1.4, 2.6, 3.4, 3.6, 6.3, Figure 6.4, 8.4, 13.7, 13.2, 13.10, 17.2, CCB LOSS, CCB SLR, CCP2.3, CCP4.4, CWGB ECONOMIC}

Avoiding Maladaptation

SPM.C.4 There is increased evidence of maladaptation[15] across many sectors and regions since the AR5. Maladaptive responses to climate change can create lock-ins of vulnerability, exposure and risks that are difficult and expensive to change and exacerbate existing inequalities. Maladaptation can be avoided by flexible, multi-sectoral, inclusive and long-term planning and implementation of adaptation actions with benefits to many sectors and systems. (*high confidence*) {1.3, 1.4, 2.6., Box 2.2, 3.2, 3.6, Box 4.3, Box 4.5, 4.6, 4.7, Figure 4.29, 5.6, 5.13, 8.2, 8.3, 8.4, 8.6, 9.6, 9.7, 9.8, 9.9, 9.10, 9.11, Box 9.5, Box 9.8, Box 9.9, Box 11.6, 13.11, 13.3, 13.4, 13.5, 14.5, 15.5, 15.6, 16.3, 17.3, 17.4, 17.6, 17.2, 17.5, CCP5.4, CCB NATURAL, CCB SLR, CCB DEEP, CWGB BIOECONOMY, CCP2.3, CCP2.3}

SPM.C.4.1 Actions that focus on sectors and risks in isolation and on short-term gains often lead to maladaptation if long-term impacts of the adaptation option and long-term adaptation commitment are not taken into account (*high confidence*). The implementation of these maladaptive actions can result in infrastructure and institutions that are inflexible and/or expensive to change (*high confidence*). For example, seawalls effectively reduce impacts to people and assets in the short-term but can also result in lock-ins and increase exposure to climate risks in the long-term unless they are integrated into a long-term adaptive plan (*high confidence*). Adaptation integrated with development reduces lock-ins and creates opportunities (e.g., infrastructure upgrading) (*medium confidence*). {1.4, 3.4, 3.6, 10.4, 11.7, Box 11.6, 13.2, 17.2, 17.5, 17.6, CCP 2.3, CCB SLR, CCB DEEP}

SPM.C.4.2 Biodiversity and ecosystem resilience to climate change are decreased by maladaptive actions, which also constrain ecosystem services. Examples of these maladaptive actions for ecosystems include fire suppression in naturally fire-adapted ecosystems or hard defences against flooding. These actions reduce space for natural processes and represent a severe form of maladaptation for the ecosystems they degrade, replace or fragment, thereby reducing their resilience to climate change and the ability to provide ecosystem services for adaptation. Considering biodiversity and autonomous adaptation in long-term planning processes reduces the risk of maladaptation. (*high confidence*) {2.4, 2.6, Table 2.7, 3.4, 3.6, 4.7, 5.6, 5.13, Table 5.21, 5.13, Box 13.2, 17.2, 17.5, Table 5.23, Box 11.2, 13.2, CCP5.4}

SPM.C.4.3 Maladaptation especially affects marginalised and vulnerable groups adversely (e.g., Indigenous Peoples, ethnic minorities, low-income households, informal settlements), reinforcing and entrenching existing inequities. Adaptation planning and implementation that do not consider adverse outcomes for different groups can lead to maladaptation, increasing exposure to risks, marginalising people from certain socio-economic or livelihood groups, and exacerbating inequity. Inclusive planning initiatives informed by cultural values, Indigenous knowledge, local knowledge, and scientific knowledge can help prevent maladaptation. (*high confidence*) (Figure SPM.4) {2.6, 3.6, 4.3, 4.6, 4.8, 5.12, 5.13, 5.14, 6.1, Box 7.1, 8.4, 11.4, 12.5, Box 13.2, 14.4, Box 14.1, 17.2, 17.5, 18.2, 17.2., CCP2.4}

SPM.C.4.4 To minimize maladaptation, multi-sectoral, multi-actor and inclusive planning with flexible pathways encourages low-regret[47] and timely actions that keep options open, ensure benefits in multiple sectors and systems and indicate the available solution space for adapting to long-term climate change (*very high confidence*). Maladaptation is also minimized by planning that accounts for the time it takes to adapt (*high confidence*), the uncertainty about the rate and magnitude of climate risk (*medium confidence*) and a wide range of potentially adverse consequences of adaptation actions (*high confidence*). {1.4, 3.6, 5.12, 5.13, 5.14, 11.6, 11.7, 17.3, 17.6, CCP2.3, CCP2.4, CCB SLR, CCB DEEP; CCP5.4}

---

[47] From AR5, an option *that would generate net social and/or economic benefits under current climate change and a range of future climate change scenarios*, and represent one example of robust strategies.

Enabling Conditions

SPM.C.5 Enabling conditions are key for implementing, accelerating and sustaining adaptation in human systems and ecosystems. These include political commitment and follow-through, institutional frameworks, policies and instruments with clear goals and priorities, enhanced knowledge on impacts and solutions, mobilization of and access to adequate financial resources, monitoring and evaluation, and inclusive governance processes. (*high confidence*) {1.4, 2.6, 3.6, 4.8, 6.4, 7.4, 8.5, 9.4, 10.5, 11.4, 11.7, 12.5, 13.11, 14.7, 15.6, 17.4, 18.4, CCB INDIG, CCB FINANCE, CCP2.4, CCP5.4}

SPM.C.5.1 Political commitment and follow-through across all levels of government accelerate the implementation of adaptation actions (*high confidence*). Implementing actions can require large upfront investments of human, financial and technological resources (*high confidence*), whilst some benefits could only become visible in the next decade or beyond (*medium confidence*). Accelerating commitment and follow-through is promoted by rising public awareness, building business cases for adaptation, accountability and transparency mechanisms, monitoring and evaluation of adaptation progress, social movements, and climate-related litigation in some regions (*medium confidence*). {3.6, 4.8, 5.8, 6.4, 8.5, 9.4, 11.7, 12.5, 13.11, 17.4, 17.5, 18.4, CCB COVID, CCP2.4}

SPM.C.5.2 Institutional frameworks, policies and instruments that set clear adaptation goals and define responsibilities and commitments and that are coordinated amongst actors and governance levels, strengthen and sustain adaptation actions (*very high confidence*). Sustained adaptation actions are strengthened by mainstreaming adaptation into institutional budget and policy planning cycles, statutory planning, monitoring and evaluation frameworks and into recovery efforts from disaster events (*high confidence*). Instruments that incorporate adaptation such as policy and legal frameworks, behavioural incentives, and economic instruments that address market failures, such as climate risk disclosure, inclusive and deliberative processes strengthen adaptation actions by public and private actors (*medium confidence*). {1.4, 3.6, 4.8, 5.14, 6.3, 6.4, 7.4, 9.4, 10.4, 11.7, Box 11.6, Table 11.17, 13.10, 13.11, 14.7, 15.6, 17.3, 17.4, 17.5, 17.6, 18.4, CCB DEEP, CCP2.4, CCP5.4, CCP6.3}

SPM.C.5.3 Enhancing knowledge on risks, impacts, and their consequences, and available adaptation options promotes societal and policy responses (*high confidence*). A wide range of top-down, bottom-up and co-produced processes and sources can deepen climate knowledge and sharing, including capacity building at all scales, educational and information programmes, using the arts, participatory modelling and climate services, Indigenous knowledge and local knowledge and citizen science (*high confidence*). These measures can facilitate awareness, heighten risk perception and influence behaviours (*high confidence*). {1.3, 3.6, 4.8, 5.9, 5.14, 6.4, Table 6.8, 7.4, 9.4, 10.5, 11.1, 11.7, 12.5, 13.9, 13.11, 14.3, 15.6, 15.6, 17.4, 18.4, CCB INDIG, CCP2.4.1}.

SPMC.5.4 With adaptation finance needs estimated to be higher than those presented in AR5, enhanced mobilization of and access to financial resources are essential for implementation of adaptation and to reduce adaptation gaps (*high confidence*). Building capacity and removing some barriers to accessing finance is fundamental to accelerate adaptation, especially for vulnerable groups, regions and sectors (*high confidence*). Public and private finance instruments include inter alia grants, guarantee, equity, concessional debt, market debt, and internal budget allocation as well as savings in households and insurance. Public finance is an important enabler of adaptation (*high confidence*). Public mechanisms and finance can leverage private sector finance for adaptation by addressing real and perceived regulatory, cost and market barriers, for example via public-private partnerships (*high confidence*). Financial and technological resources enable effective and ongoing implementation of adaptation, especially when supported by institutions with a strong understanding of adaptation needs and capacity (*high confidence*). {4.8, 5.14, 6.4, Table 6.10, 7.4, 9.4, Table 11.17, 12.5, 13.11, 15.6, 17.4, 18.4, BOX 18.9, CCP5.4, CCB FINANCE}.

SPM.C.5.5 Monitoring and evaluation (M&E) of adaptation are critical for tracking progress and enabling effective adaptation (*high confidence*). M&E implementation is currently limited (*high confidence*) but has increased since AR5 at local and national levels. Although most of the monitoring of adaptation is focused towards planning and implementation, the monitoring of outcomes is critical for tracking the effectiveness and progress of adaptation *(high confidence)*. M&E facilitates learning on successful and effective adaptation measures, and signals when and where additional action may be needed. M&E systems are most effective when supported by capacities and resources and embedded in enabling governance systems (*high confidence*). {1.4, 2.6, 6.4, 7.4, 11.7, 11.8, 13.2, 13.11, 17.5, 18.4, CCB PROGRESS, CCB NATURAL, CCB ILLNESS, CCB DEEP, CCP2.4}.

SPM.C.5.6 Inclusive governance that prioritises equity and justice in adaptation planning and implementation leads to more effective and sustainable adaptation outcomes (*high confidence*). Vulnerabilities and climate risks are often reduced through carefully designed and implemented laws, policies, processes, and interventions that address context specific inequities such as based on gender, ethnicity, disability, age, location and income (*high confidence*). These approaches, which include multi-stakeholder co-learning platforms, transboundary collaborations, community-based adaptation and participatory scenario planning, focus on capacity-building, and meaningful participation of the most vulnerable and marginalised groups, and their access to key resources to adapt (*high confidence*). {1.4, 2.6, 3.6, 4.8, 5.4, 5.8, 5.9, 5.13, 6.4, 7.4, 8.5, 11.8, 12.5, 13.11, 14.7, 15.5, 15.7, 17.3, 17.5, 18.4, CCB HEALTH, CCB GENDER, CCB INDIG, CCP2.4, CCP5.4, CCP6.4}

SPM.D: Climate Resilient Development

Climate Resilient Development integrates adaptation measures and their enabling conditions (Section C) with mitigation to advance sustainable development for all. Climate resilient development involves questions of equity and system transitions in land, ocean and ecosystems; urban and infrastructure; energy; industry; and society and includes adaptations for human, ecosystem and planetary health. Pursuing climate resilient development focuses on both where people and ecosystems are co-located as well as the protection and maintenance of ecosystem function at the planetary scale. Pathways for advancing climate resilient development are development trajectories that successfully integrate mitigation and adaptation actions to advance sustainable development. Climate resilient development pathways may be temporarily coincident with any RCP and SSP scenario used throughout AR6, but do not follow any particular scenario in all places and over all time.

Conditions for Climate Resilient Development

SPM.D.1 Evidence of observed impacts, projected risks, levels and trends in vulnerability, and adaptation limits, demonstrate that worldwide climate resilient development action is more urgent than previously assessed in AR5. Comprehensive, effective, and innovative responses can harness synergies and reduce trade-offs between adaptation and mitigation to advance sustainable development. (*very high confidence*) {2.6, 3.4, 3.6, 4.2, 4.6, 7.2, 7.4, 8.3, 8.4, 9.3, 10.6, 13.3, 13.8, 13.10, 14.7, 17.2, 18.3, Figure 18.1, Table 18.5, Box 18.1}

SPM.D.1.1 There is a rapidly narrowing window of opportunity to enable climate resilient development. Multiple climate resilient development pathways are still possible by which communities, the private sector, governments, nations and the world can pursue climate resilient development – each involving and resulting from different societal choices influenced by different contexts and opportunities and constraints on system transitions. Climate resilient development pathways are progressively constrained by every increment of warming, in particular beyond 1.5°C, social and economic inequalities, the balance between adaptation and mitigation varying by national, regional and local circumstances and geographies, according to capabilities including resources, vulnerability, culture and values, past development choices leading to past emissions and future warming scenarios, bounding the climate resilient development pathways remaining, and the ways in which development trajectories are shaped by equity, and social and climate justice. (*very high confidence*) {2.6, 4.7, 4.8, 5.14, 6.4, 7.4, 8.3, 9.4, 9.3, 9.4, 9.5, 10.6, 11.8, 12.5, 13.10, 14.7, 15.3, 18.5, CCP2.3, CCP3.4, CCP4.4, CCP5.3, CCP5.4, Table CCP5.2, CCP6.3, CCP7.5, Figure TS14.d}

SPM.D.1.2 Opportunities for climate resilient development are not equitably distributed around the world (*very high confidence*). Climate impacts and risks exacerbate vulnerability and social and economic inequities and consequently increase persistent and acute development challenges, especially in developing regions and sub-regions, and in particularly exposed sites, including coasts, small islands, deserts, mountains and polar regions. This in turn undermines efforts to achieve sustainable development, particularly for vulnerable and marginalized communities (*very high confidence*). {2.5, 4.4, 4.7, 6.3, 9.4, Box 6.4, Figure 6.5, Table 18.5, CWGB URBAN, CCB HEALTH, CCP2.2, CCP3.2, CCP3.3, CCP5.4, CCP6.2}

SPM.D.1.3 Embedding effective and equitable adaptation and mitigation in development planning can reduce vulnerability, conserve and restore ecosystems, and enable climate resilient development. This is especially challenging in localities with persistent development gaps and limited resources (*high confidence*). Dynamic trade-offs and competing priorities exist between mitigation, adaptation, and development. Integrated and inclusive system-oriented solutions based on equity and social and climate justice reduce risks and enable climate resilient development (*high confidence*). {1.4, 2.6, 3.6, 4.7, 4.8, Box 4.5, Box 4.8, 5.13, 7.4, 8.5, 9.4, 10.6, Box 9.3, Box 2.2, 12.5, 12.6, 13.3, 13.4, 13.10, 13.11, 14.7, 18.4, CCB HEALTH, SRCCL, CCB DEEP, CCP2, CCP5.4}

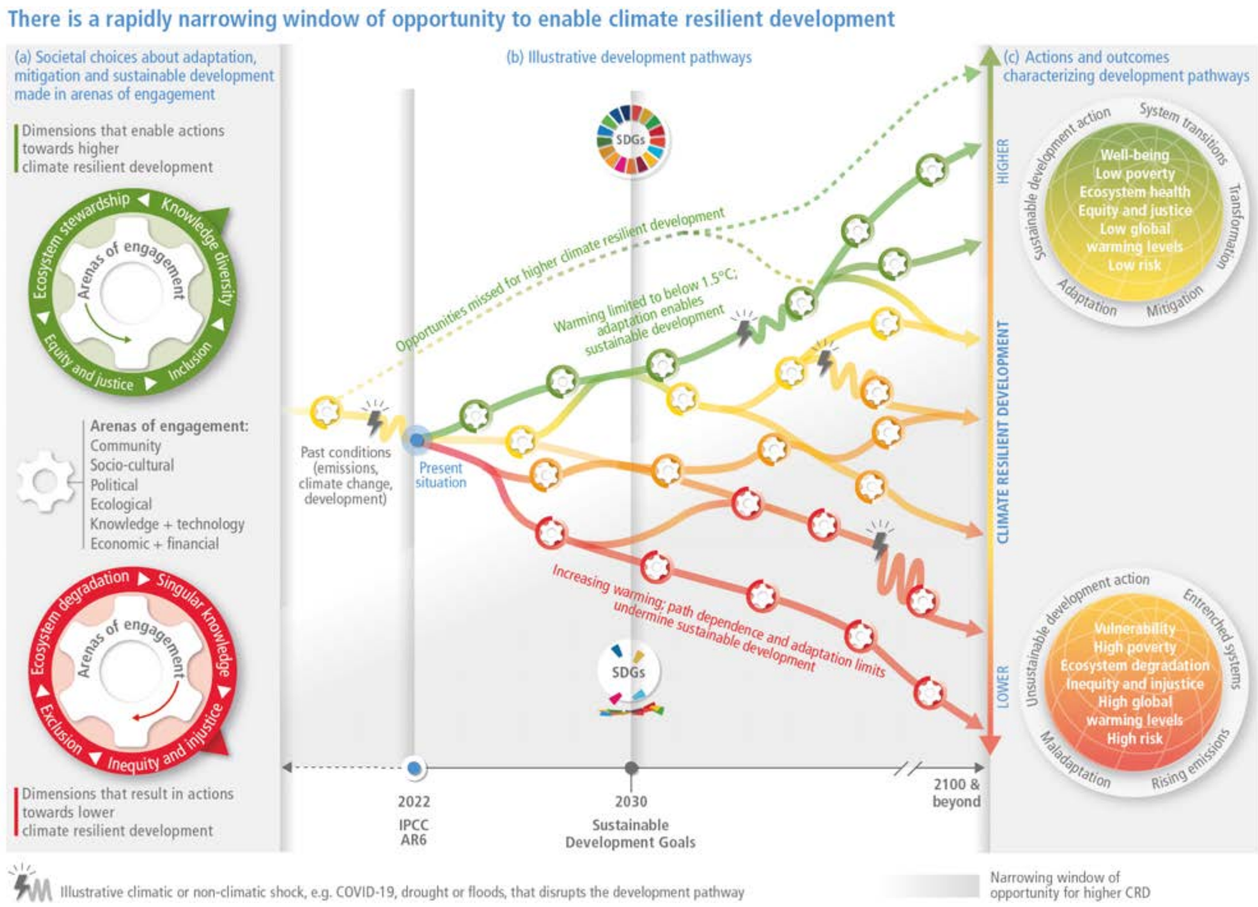

Figure SPM.5: Climate resilient development (CRD) is the process of implementing greenhouse gas mitigation and adaptation measures to support sustainable development. This figure builds on Figure SPM.9 in AR5 WGII (depicting climate resilient pathways) by describing how CRD pathways are the result of cumulative societal choices and actions within multiple arenas. Panel (a): Societal choices towards higher CRD (green cog) or lower CRD (red cog) result from interacting decisions and actions by diverse government, private sector and civil society actors, in the context of climate risks, adaptation limits and development gaps. These actors engage with adaptation, mitigation and development actions in political, economic and financial, ecological, socio-cultural, knowledge and technology, and community arenas from local to international levels. Opportunities for climate resilient development are not equitably distributed around the world. Panel (b): Cumulatively, societal choices, which are made continuously, shift global development pathways towards higher (green) or lower (red) climate resilient development. Past conditions (past emissions, climate change and development) have already eliminated some development pathways towards higher CRD (dashed green line). Panel (c): Higher CRD is characterised by outcomes that advance sustainable development for all. Climate resilient development is progressively harder to achieve with global warming levels beyond 1.5°C. Inadequate progress towards the Sustainable Development Goals (SDGs) by 2030 reduces climate resilient development prospects. There is a narrowing window of opportunity to shift pathways towards more climate resilient development futures as reflected by the adaptation limits and increasing climate risks, considering the remaining carbon budgets. (Figure SPM.2, Figure SPM.3) {2.6, 3.6, 7.2, 7.3, 7.4, 8.3, 8.4, 8.5, 16.4, 16.5, 17.3, 17.4, 17.5, 18.1, 18.2, 18.3, 18.4, Figure 18.1, Figure 18.2, Figure 18.3, Box 18.1, CCB COVID, CCB GENDER, CCB HEALTH, CCB INDIG, CCB SLR, AR6 WGI Table SPM.1 and Table SPM.2, SR1.5 Figure SPM.1, Figure TS.14b}

Enabling Climate Resilient Development

SPM.D.2 Climate resilient development is enabled when governments, civil society and the private sector make inclusive development choices that prioritise risk reduction, equity and justice, and when decision-making processes, finance and actions are integrated across governance levels, sectors and timeframes (*very high confidence*). Climate resilient development is facilitated by international cooperation and by governments at all levels working with communities, civil society, educational bodies, scientific and other institutions, media, investors and businesses; and by developing partnerships with traditionally marginalised groups, including women, youth, Indigenous Peoples, local communities and ethnic minorities (*high confidence*). These partnerships are most effective when supported by enabling political leadership, institutions, resources, including finance, as well as climate services, information and decision support tools (*high confidence*). (Figure SPM.5) {1.3, 1.4, 1.5, 2.7, 3.6, 4.8, 5.14, 6.4, 7.4, 8.5, 8.6, 9.4, 10.6, 11.8, 12.5, 13.11, 14.7, 15.6, 15.7, 17.4, 17.6, 18.4, 18.5, CCP2.4, CCP3.4, CCP4.4, CCP5.4, CCP6.4, CCP7.6, CCB HEALTH, CCB GENDER, CCB INDIG, CCB DEEP, CCB NATURAL, CCB SLR}

SPM.D.2.1 Climate resilient development is advanced when actors work in equitable, just and enabling ways to reconcile divergent interests, values and worldviews, toward equitable and just outcomes (*high confidence*). These practices build on diverse knowledges about climate risk and chosen development pathways account for local, regional and global climate impacts, risks, barriers and opportunities (*high confidence*). Structural vulnerabilities to climate change can be reduced through carefully designed and implemented legal, policy, and process interventions from the local to global that address inequities based on gender, ethnicity, disability, age, location and income (*very high confidence*). This includes rights-based approaches that focus on capacity-building, meaningful participation of the most vulnerable groups, and their access to key resources, including financing, to reduce risk and adapt (*high confidence).* Evidence shows that climate resilient development processes link scientific, Indigenous, local, practitioner and other forms of knowledge, and are more effective and sustainable because they are locally appropriate and lead to more legitimate, relevant and effective actions (*high confidence*). Pathways towards climate resilient development overcome jurisdictional and organizational barriers, and are founded on societal choices that accelerate and deepen key system transitions (*very high confidence*). Planning processes and decision analysis tools can help identify 'low regrets' options[47] that enable mitigation and adaptation in the face of change, complexity, deep uncertainty and divergent views (*medium confidence*). {1.3, 1.4, 1.5, 2.7, 3.6, 4.8, 5.14, 6.4, 7.4, 8.5, 8.6, 9.4, 10.6, 11.8, 12.5, 13.11, 14.7, 15.6, 15.7, 17.2-17.6, 18.2-18.4, CCP2.3-2.4, CCP3.4, CCP4.4, CCP5.4, CCP6.4, CCP7.6, Box 8.7, Box 9.2, CCB HEALTH, CCB INDIG, CCB DEEP, CCB NATURAL, CCB SLR}

SPM.D.2.2 Inclusive governance contributes to more effective and enduring adaptation outcomes and enables climate resilient development (*high confidence*). Inclusive processes strengthen the ability of governments and other stakeholders to jointly consider factors such as the rate and magnitude of change and uncertainties, associated impacts, and timescales of different climate resilient development pathways given past development choices leading to past emissions and scenarios of future global warming (*high confidence*). Associated societal choices are made continuously through interactions in arenas of engagement from local to international levels. The quality and outcome of these interactions helps determine whether development pathways shift towards or away from climate resilient development (*medium confidence*). (Figure SPM.5) {2.7, 3.6, 4.8, 5.14, 6.4, 7.4, 8.5, 8.6, 9.4, 10.6, 11.8, 12.5, 13.11, 14.7, 15.6, 15.7, 17.2-17.6, 18.2, 18.4, CCP2.3-2.4, CCP3.4, CCP4.4, CCP5.4, CCP6.4, CCP7.6, CCB HEALTH, CCB GENDER, CCB INDIG}

SPM.D.2.3 Governance for climate resilient development is most effective when supported by formal and informal institutions and practices that are well-aligned across scales, sectors, policy domains and timeframes. Governance efforts that advance climate resilient development account for the dynamic, uncertain and context-specific nature of climate-related risk, and its interconnections with non-climate risks. Institutions[48] that enable climate resilient development are flexible and responsive to emergent risks and facilitate sustained and timely action. Governance for climate resilient development is enabled by adequate and appropriate human and technological resources, information, capacities and finance. (*high confidence*) {2.7, 3.6, 4.8, 5.14, 6.3, 6.4, 7.4, 8.5, 8.6, 9.4, 10.6, 11.8, 12.5, 13.11, 14.7, 15.6, 15.7, 17.2-17.6, 18.2, 18.4, CCP2.3-2.4, CCP3.4, CCP4.4, CCP5.4, CCP6.4, CCP7.6, CCB HEALTH, CCB GENDER, CCB INDIG, CCB DEEP, CCB NATURAL, CCB SLR}

Climate Resilient Development for Natural and Human Systems

SPM.D.3 Interactions between changing urban form, exposure and vulnerability can create climate change-induced risks and losses for cities and settlements. However, the global trend of urbanisation also offers a critical opportunity in the near-term, to advance climate resilient development (*high confidence*). Integrated, inclusive planning and investment in everyday decision-making about urban infrastructure, including social, ecological and grey/physical infrastructures, can significantly increase the adaptive capacity of urban and rural settlements. Equitable outcomes contributes to multiple benefits for health and well-being and ecosystem services, including for Indigenous Peoples, marginalised and vulnerable communities (*high confidence*). Climate resilient development in urban areas also supports adaptive capacity in more rural places through maintaining peri-urban supply chains of goods and services and financial flows (*medium confidence*). Coastal cities and settlements play an especially important role in advancing climate resilient development (*high confidence*). {6.2, 6.3, 18.3, Table 6.6, Box 9.8, CCP6.2, CCP2.1. CCP2.2, CWGB URBAN}

SPM.D.3.1 Taking integrated action for climate resilience to avoid climate risk requires urgent decision making for the new built environment and retrofitting existing urban design, infrastructure and land use. Based on socioeconomic circumstances, adaptation and sustainable development actions will provide multiple benefits including for health and well-being, particularly when supported by national governments, non-governmental organisations and international agencies that work across sectors in partnerships with local communities. Equitable partnerships between local and municipal governments, the private sector, Indigenous Peoples, local communities, and civil society can, including through international cooperation, advance climate resilient development by addressing structural inequalities, insufficient financial resources, cross-city risks and the integration of Indigenous knowledge and Local knowledge. (*high confidence*) {6.2, 6.3, 6.4, 7.4, 8.5, 9.4, 10.5. 12.5, 17.4, 18.2, Table 6.6, Table 17.8, Box 18.1, CCP2.4, CCB GENDER, CCB INDIG, CCB FINANCE, CWGB URBAN}

SPM.D.3.2 Rapid global urbanisation offers opportunities for climate resilient development in diverse contexts from rural and informal settlements to large metropolitan areas (*high confidence*). Dominant models of energy intensive and market-led urbanisation, insufficient and misaligned finance and a predominant focus on grey infrastructure in the absence of integration with ecological and social approaches, risks missing opportunities for adaptation and locking in maladaptation (*high confidence*). Poor land use planning and siloed approaches to health, ecological and social planning also exacerbates, vulnerability in already marginalised

[48] Institutions: Rules, norms and conventions that guide, constrain or enable human behaviours and practices. Institutions can be formally established, for instance through laws and regulations, or informally established, for instance by traditions or customs. Institutions may spur, hinder, strengthen, weaken or distort the emergence, adoption and implementation of climate action and climate governance.

communities (*medium confidence*). Urban climate resilient development is observed to be more effective if it is responsive to regional and local land use development and adaptation gaps, and addresses the underlying drivers of vulnerability (*high confidence*). The greatest gains in well-being can be achieved by prioritizing finance to reduce climate risk for low-income and marginalized residents including people living in informal settlements (*high confidence*). {5.14, 6.1, 6.2, 6.3, 6.4, 6.5, 7.4, 8.5, 8.6, 9.8, 9.9, 10.4, 18.2, Table 17.8, Table 6.6, Figure 6.5, CCB HEALTH, CCP2.2, CCP5.4, CWGB URBAN}

SPM.D.3.3 Urban systems are critical, interconnected sites for enabling climate resilient development, especially at the coast. Coastal cities and settlements play a key role in moving toward higher climate resilient development given firstly, almost 11% of the global population – 896 million people – lived within the Low Elevation Coastal Zone[49] in 2020, potentially increasing to beyond 1 billion people by 2050, and these people, and associated development and coastal ecosystems, face escalating climate compounded risks, including sea level rise. Secondly, these coastal cities and settlements make key contributions to climate resilient development through their vital role in national economies and inland communities, global trade supply chains, cultural exchange, and centres of innovation. (*high confidence*) {6.2, Box 15.2, CCP2.1, CCP2.2, Table CCP2.4, CCB SLR}

SPM.D.4 Safeguarding biodiversity and ecosystems is fundamental to climate resilient development, in light of the threats climate change poses to them and their roles in adaptation and mitigation (*very high confidence*). Recent analyses, drawing on a range of lines of evidence, suggest that maintaining the resilience of biodiversity and ecosystem services at a global scale depends on effective and equitable conservation of approximately 30% to 50% of Earth's land, freshwater and ocean areas, including currently near-natural ecosystems (*high confidence*). {2.4, 2.5, 2.6, 3.4, Box 3.4, 3.5, 3.6, 12.5, 13.3, 13.4, 13.5, 13.10, CCB NATURAL, CCB INDIG}

SPM.D.4.1 Building the resilience of biodiversity and supporting ecosystem integrity[50] can maintain benefits for people, including livelihoods, human health and well-being and the provision of food, fibre and water, as well as contributing to disaster risk reduction and climate change adaptation and mitigation.{2.2, 2.5, 2.6, Table 2.6, Table 2.7, 3.5, 3.6, 5.8, 5.13, 5.14, 12.5, Box 5.11 CCP5.4, CCB NATURAL, CCB ILLNESS, CCB COVID, CCB GENDER, CCB INDIG, CCB MIGRATE}

SPM.D.4.2 Protecting and restoring ecosystems is essential for maintaining and enhancing the resilience of the biosphere (*very high confidence*). Degradation and loss of ecosystems is also a cause of greenhouse gas emissions and is at increasing risk of being exacerbated by climate change impacts, including droughts and wildfire *(high confidence)*. Climate resilient development avoids adaptation and mitigation measures that damage ecosystems (*high confidence*). Documented examples of adverse impacts of land-based measures intended as mitigation, when poorly implemented, include afforestation of grasslands, savannas and peatlands, and risks from bioenergy crops at large scale to water supply, food security and biodiversity (*high confidence*). {2.4, 2.5, Box 2.2, 3.4, 3.5, Box 3.4, Box 9.3, CCP7.3, CCB NATURAL, CWGB BIOECONOMY}

SPM.D.4.3 Biodiversity and ecosystem services have limited capacity to adapt to increasing global warming levels, which will make climate resilient development progressively harder to achieve beyond 1.5°C warming (*very high confidence*). Consequences of current and future global warming for climate resilient development include reduced effectiveness of EbA and approaches to climate change mitigation based on ecosystems and amplifying feedbacks to the climate system (*high confidence*). {2.4, 2.5, 2.6, 3.4, 3.5, 3.6, 12.5, 13.2, 13.3, 13.10, 14.5, 14.5, 15.3, 17.3, 17.6, Box 14.3, Box 3.4, Table 5.2, CCP5.3, CCP5.4, Figure TS.14d, CCB EXTREMES, CCB ILLNESS, CCB NATURAL, CCB SLR, SR1.5, SRCCL, SROCC}

---

[49] LECZ, coastal areas below 10 m of elevation above sea level that are hydrologically connected to the sea

[50] Ecosystem integrity refers to the ability of ecosystems to maintain key ecological processes, recover from disturbance, and adapt to new conditions.

Achieving Climate Resilient Development

SPM.D.5 It is unequivocal that climate change has already disrupted human and natural systems. Past and current development trends (past emissions, development and climate change) have not advanced global climate resilient development (*very high confidence*). Societal choices and actions implemented in the next decade determine the extent to which medium- and long-term pathways will deliver higher or lower climate resilient development (*high confidence*). Importantly climate resilient development prospects are increasingly limited if current greenhouse gas emissions do not rapidly decline, especially if 1.5°C global warming is exceeded in the near term (*high confidence*). These prospects are constrained by past development, emissions and climate change, and enabled by inclusive governance, adequate and appropriate human and technological resources, information, capacities and finance (*high confidence*). {1.2, 1.4, 1.5, 2.6, 2.7, 3.6, 4.7, 4.8, 5.14, 6.4, 7.4, 8.3, 8.5, 8.6, 9.3, 9.4, 9.5, 10.6, 11.8, 12.5, 13.10, 13.11, 14.7, 15.3, 15.6, 15.7, 16.2, 16.4, 16.5, 16.6, 17.2-17.6, 18.2-18.5, CCP2.3-2.4, CCP3.4, CCP4.4, Table CCP5.2, CCP5.3, CCP5.4, CCP6.3, CCP6.4, CCP7.5, CCP7.6, Figure TS.14d, CCB DEEP, CCB HEALTH, CCB INDIG, CCB DEEP, CCB NATURAL, CCB SLR}

SPM.D.5.1 Climate resilient development is already challenging at current global warming levels (*high confidence*). The prospects for climate resilient development will be further limited if global warming levels exceeds 1.5°C (*high confidence*) and not be possible in some regions and sub-regions if the global warming level exceeds 2°C (*medium confidence*). Climate resilient development is most constrained in regions/subregions in which climate impacts and risks are already advanced, including low-lying coastal cities and settlements, small islands, deserts, mountains and polar regions (*high confidence*). Regions and subregions with high levels of poverty, water, food and energy insecurity, vulnerable urban environments, degraded ecosystems and rural environments, and/or few enabling conditions, face many non-climate challenges that inhibit climate resilient development which are further exacerbated by climate change (*high confidence*). {1.2, 9.3, 9.4, 9.5, 10.6, 11.8, 12.5, 13.10, 14.7, 15.3, CCP2.3, CCP3.4, CCP4.4, Box 6.6. CCP5.3, Table CCP5.2, CCP6.3, CCP7.5, Figure TS.14d}

SPM.D.5.2 Inclusive governance, investment aligned with climate resilient development, access to appropriate technology and rapidly scaled-up finance, and capacity building of governments at all levels, the private sector and civil society enable climate resilient development. Experience shows that climate resilient development processes are timely, anticipatory, integrative, flexible and action focused. Common goals and social learning build adaptive capacity for climate resilient development. When implementing adaptation and mitigation together, and taking trade-offs into account, multiple benefits and synergies for human well-being as well as ecosystem and planetary health can be realised. Prospects for climate resilient development are increased by inclusive processes involving local knowledge and Indigenous Knowledge as well as processes that coordinate across risks and institutions. Climate resilient development is enabled by increased international cooperation including mobilising and enhancing access to finance, particularly for vulnerable regions, sectors and groups. (*high confidence*) (Figure SPM.5) {2.7, 3.6, 4.8, 5.14, 6.4, 7.4, 8.5, 8.6, 9.4, 10.6, 11.8, 12.5, 13.11, 14.7, 15.6, 15.7, 17.2-17.6, 18.2-18.5, CCP2.3-2.4, CCP3.4, CCP4.4, CCP5.4, CCP6.4, CCP7.6, CCB HEALTH, CCB INDIG, CCB DEEP, CCB NATURAL, CCB SLR}

SPM.D.5.3 The cumulative scientific evidence is unequivocal: Climate change is a threat to human well-being and planetary health. Any further delay in concerted anticipatory global action on adaptation and mitigation will miss a brief and rapidly closing window of opportunity to secure a liveable and sustainable future for all. (*very high confidence*) {1.2, 1.4, 1.5, 16.2, 16.4, 16.5, 16.6, 17.4, 17.5, 17.6, 18.3, 18.4, 18.5, CWGB URBAN, CCB DEEP, Table SM16.24, WGI SPM, SROCC SPM, SRCCL SPM}

Chapter 1: Point of Departure and Key Concepts

Executive Summary

The IPCC Working Group II contribution to the Sixth Assessment Report addresses the challenges of climate action in the context of sustainable development with a particular focus on climate change impacts, adaptation and vulnerability. This chapter frames the point of departure and key concepts building on the IPCC's Fifth Assessment Report (WGII AR5), the Special Report on Global Warming of 1.5°C, the Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC) and the Special Report on Climate Change and Land (SRCCL); as well as the WGI contributions to the Sixth Assessment Report and compliments the contribution of the WGIII Sixth Assessment Report which will be published after this report.

Since IPCC AR5, human influence on the Earth's climate has become unequivocal, increasingly apparent, and widespread, reflected in both the growing scientific literature and in the perception and experiences of people worldwide (*high confidence*). Current changes in the climate system and those expected in the future will increasingly have significant and deleterious impacts on human and natural systems. The impacts of climate change and extreme weather events have adversely affected, or caused the loss of ecosystems including terrestrial, freshwater, ocean and coastal ecosystems, including tropical coral reefs; reduced food security; contributed to migration and displacement; damaged livelihoods, health and security of people; and increased inequality. Climate change impacts are concurrent and interact with other significant societal changes that have become more salient since AR5, including a growing and urbanising global population; significant inequality and demands for social justice; rapid technological change; continuing poverty, land and water degradation, biodiversity loss; food insecurity; and a global pandemic. {1.1.1, 1.3, Cross-Working Group Box ATTRIB in Chapter 1}

Since AR5, climate action has grown in salience worldwide across all levels of government as well as among non-governmental organisations, small and large enterprises and citizens (*high confidence*). At the international level the Paris Agreement and the Sustainable Development Goals (SDGs), along with other targets and frameworks such as the Sendai Framework for Disaster Risk Reduction, the Convention on Biological Diversity (CBD) Aichi targets, the Addis Ababa Action Agenda for finance and the New Urban Agenda, provide overarching goals and policy context. These agreements also provide policy goals used by this IPCC Report to assess climate action across all levels of society. {1.1.2, 1.4.1, 1.4.3}

IPCC's assessments have grown and changed substantially over the last three decades. Compared to earlier IPCC assessments, this report emphasizes a common risk-solution framing across all three working groups. This report focuses on solutions for risk reduction and adaptation, provides more integration across the natural and social sciences, applies a more comprehensive risk framework; assesses adaptation directly in the context of sectoral or regional risks; engages with different forms of knowledge, including Indigenous knowledge and local knowledge; and includes an increasing focus on social justice. {1.1.4, 1.4.2, Cross-Chapter Box ADAPT in Chapter 1}

Adaptation plays a key role in reducing risks and vulnerability from climate change. Implementing adaptation and mitigation actions together with SDGs helps to exploit synergies, reduce trade-offs and makes all three more effective. From a risk perspective, limiting atmospheric greenhouse gas concentrations reduces climate-related hazards while adaptation and sustainable development reduce exposure and vulnerability to those hazards. Adaptation facilitates development, which is increasingly hindered by impacts and risks from climate change. Development facilitates adaptation by expanding the resources and capacity to reduce climate risks and vulnerability. {1.1.3, 1.5.1, 1.5.3}

The concepts of risk and risk management have become increasingly central to climate change literature, research, practice and decision making (*medium confidence*). Risk, defined as the potential for adverse consequences for human and ecological systems, recognising the diversity of values and objectives associated with such systems, provides a framework for understanding the increasingly severe, interconnected and often irreversible impacts of climate change; how these impacts differentially affect different regions, sectors and populations; how to allocate resources best to manage the resulting risks and how to evaluate the responses that reduce residual risks for current and future generations, economies and ecosystems. {1.2.1, 1.3.1, 1.4.2}

The concepts of adaptation, vulnerability, resilience and risk provide overlapping, alternative entry points for the climate change challenge (*high confidence*). Vulnerability is a component of risk, but also an important focus independently, improving understanding of the differential impacts of climate change on people of different gender, race, wealth, social status and other attributes. Vulnerability also provides an important link between climate adaptation and disaster risk reduction. Resilience, which can refer to either a process or outcome, encompasses not just the concept of maintaining essential function, identity and structure, but also maintaining a capacity for transformation. Such transformations bring forth questions of justice, power and politics. {1.2.1, 1.4.1}

Risks from climate change differ through space and time and cascade across and within regions and systems. The total risk in any location may thus differ from the sum of individual risks if these interactions, as well as risks from responses themselves, are not considered (*high confidence*). The risks of climate change responses include the possibility of mitigation or adaptation responses not achieving their intended objectives or having trade-offs or adverse side effects for other societal objectives. Another core area of complexity in climate risk is the behaviour of systems, which includes multiple stressors unfolding together, cascading or compounding interactions within and across sectors and regions and non-linear responses and the potential for surprises, all of which is crucial for effective decision-making and decision-support methods. The key risks assessed in this report become important in interaction with the cultures, values, ethics, identities, experiences and knowledge systems of affected communities and societies. {1.3.1}

Increasingly, impacts are detected and attributed to the changing climate. Improved understanding of deep history (palaeoclimate and biotic responses) suggests that past climate changes have already caused substantial ecological, evolutionary and socio-economic impacts (*high confidence*). Many recent impacts are not detected, due to a shortage of monitoring and robust attribution analysis (*high confidence*). Detection and attribution assessments inform the risk assessment by demonstrating the sensitivity of a system to climate change, and they can inform the loss and damage estimates including those involved in potential climate litigation cases. Robust detection and attribution methods now exist, they play a significant role in increasing awareness and willingness to act among decision makers and the general population. {1.3.2.1, Cross-Working Group Box ATTRIB in Chapter 1, Cross-Chapter Box PALEO in Chapter 1}

Narratives play an important role in communicating climate risks and motivating solutions. A narrative describes a chronological chain of events, often with a premise and conclusions. In the AR6, as in previous IPCC assessments, climate change scenarios and related narratives (also called storylines) are central in the analysis, synthesis and communication of climate change impacts and of adaptation and mitigation responses. AR6 employs narratives to describe the assumptions, evolution and driving forces for the Representative Concentration Pathways (RCPs) and Shared Socioeconomic Pathways (SSPs) and links these to Global Warming Levels (GWLs) as a complement to RCPs and SSPs for framing impacts (Ch1 Cross-Chapter Box CLIMATE). Narratives can also be enablers of transformation by communicating societal goals and the actions needed to achieve them {1.2.2, 1.3.3, 1.5.2}

AR6 highlights adaptation solutions and the extent to which they are successful and adequate at reducing climate risk, increasing resilience and pursuing other climate-related societal goals. For adaptation, a solution is defined as an option which is effective, feasible and conforms to principles of justice. Effectiveness refers to the extent to which an action is anticipated or is observed to reduce climate-related risk. Feasibility refers to the extent to which a measure is considered possible and desirable in a particular context. A successful action is one observed to be effective, feasible and just. Adequacy refers to a set of solutions that together are sufficient to avoid dangerous, intolerable, or severe climate risks. {1.4}

Indigenous knowledge and local knowledge (IK and LK) can provide important understanding for acting effectively on climate risk and can help diversify knowledge that may enrich adaptation policy and practice (*high confidence*). Indigenous Peoples have been faced with adaptation challenges for centuries and have developed strategies for resilience in changing environments that can enrich and strengthen current and future adaptation efforts. Valuing IK and LK is also important for recognition, a key component of climate justice. {1.3.2.3}

AR6 highlights three principles of climate justice: distributive justice, procedural justice and recognition. Distributive justice refers to the allocation of burdens and benefits among individuals, nations and generations; procedural justice refers to who decides and participates in decision-making; and recognition entails basic respect and robust engagement with and fair consideration of diverse cultures and perspectives. This report considers all three principles in the assessment of adaptation options and evaluates the extent to which better outcomes are obtained by choosing just ones. Since potential trade-offs exist among the principles, adaptation assessments will in general involve normative judgements as well as science-based evidence. {1.4.1.1}

Concepts of justice and measures of well-being are increasingly used to evaluate the extent to which climate change adaptation is equitable and effective (*medium confidence*). AR6 employs evaluation frameworks based on both single and multi-criteria to assess adaptation effectiveness and consistency with principles of justice. Single criteria frameworks aggregate many attributes into a one number or ranking, often quantified using benefit-cost analysis or measures of social welfare. Existing decision processes often favour such single criteria, which also correlate well with many measures of social progress and sustainable development. Multi-criteria frameworks simultaneously report several different biophysical and socio-economic attributes, which provides more information on potential trade-offs and synergies and can engage with emerging concepts of well-being. {1.4.1.1, 1.4.1.2}
The concepts of enablers, catalysts and the solution space help AR6 assess ways to speed the implementation of and expand the range of adaptation solutions. Many potential solutions exist, which have not yet been implemented despite the gap between current and adequate levels of adaption. Enablers enhance the feasibility of adaptation options and include governance, finance and knowledge**.** Catalysts accelerate and motivate the adaptation decision-making process. The concept of solution space -- defined as the space within which opportunities and constraints determine why, how, when and who adapts to climate risks – helps this report assess how human choices and exogenous changes can expand and contract the set of effective, feasible and just solutions. {1.4.2}

Effective governance, adaptation finance and nature-based solutions are important enablers for expanding the solutions space and reducing adaptation gaps (*high confidence*). Actors at many scales and in many sectors are adapting already and can take additional and more significant adaptation action. These include individuals and households, communities, governments at all levels, private sector businesses, non-governmental organisations and religious groups and social movements. Many forms of adaptation (depending on the type of climatic risk and societal context) are likely to be more effective, cost-efficient, and potentially also more equitable when organized collectively. Stronger governance and adaptation finance capabilities are usually associated with more ambitious adaptation plans and more effective implementation of such plans. {1.4.2, 1.4.2}

Monitoring and Evaluation (M&E) of adaptation refers to a broad range of activities necessary for tracking adaptation progress over time, improving adaptation effectiveness and successful iterative risk management. Monitoring usually refers to continuous information gathering whereas evaluation denotes more comprehensive assessments of effectiveness and equity, often resulting in recommendations for decision makers. In some literatures M&E refers solely to efforts undertaken after implementation. In other literatures, M&E refers both to efforts conducted before and after implementation. Since AR5, a growing literature provides initial inventories of adaptation plans and implementation worldwide, but information on effectiveness remains scare (*high confidence*). {1.4.3, Cross-Chapter Box ADAPT in Chapter 1}

The concept of limits to adaptation is dynamic in terms of the temporal, spatial and contextual dimensions of climate change risks, impacts and response. Socioeconomic, technological, governance and institutional systems or policies can be changed or transformed in responses to the different dimensions of adaptation limits to climate change and extreme events. Adaptation limits can be soft or hard. Soft adaptation limits occur when options may exist but are currently not available to avoid intolerable risks through adaptive actions and hard adaptation limits occur when no adaptive actions are possible to avoid intolerable risks. The level of greenhouse gas reduction, adaptation and risk management measures are the key factors determining if and when adaptation limits are reached. When a limit (soft) is reached, then intolerable risks and impacts may occur and additional adaptations (incremental or transformational) would be required. Transformational adaptation can allow a system to extend beyond its soft limits and prevent soft limits to become hard limits. The loss and damage associated with the future climate change impacts, beyond the limits to adaptation, is an area of increasing focus, although yet to be fully developed in terms of methods of assessing including non-economic values and identifying means to avoid and reduce both economic (loss of asset, infrastructure, land etc.) and non-economic (loss of societal beliefs and values, cultural heritage, biodiversity and ecosystem services) losses and damages. {1.4.4.1, 1.4.4.2}

Key concepts in this report provide a framework for assessing the urgency of climate change adaptation. Adaptation is urgent to the extent that soft adaptation limits are currently being approached or exceeded and that achieving levels of adaptation adequate to address these soft limits requires action at a speed and scale faster than that represented by current trends (*high confidence*). In addition, adaptation is urgent to the extent that any needed expansion of the future solution space requires near-term strengthening and expansion of enablers such as governance, finance and information. Finally, adaptation is urgent to the extent that current maladaptation and socio-economic trends, such as rapid urbanisation and continued inequalities, lock in patterns of vulnerability and exposure that increase future risk (*high confidence*). {1.1.3, 1.4.4, 1.5.1}

AR6 highlights the role of transformation in meeting the Paris Agreement, the SDG and other policy goals. Transformation, and the related term transition, are pluralistic concepts, embracing the idea of major, fundamental changes in society or natural systems as opposed to changes that are minor, marginal, or incremental. AR6 has a particular focus on transformational adaptation, which changes the fundamental attributes of a socio-economic system in anticipation of climate change and its impacts. AR6 describes transitions in five systems: energy, land and ecosystem, urban and infrastructure, industrial and societal. In the past, transformations of such scale have been associated not only with technological and economic changes, but with shifts in most aspects of society. {1.2.1.3, 1.4.4, 1.5.1}

Future transformation could be deliberate, envisioned and intended by at least some societal actors, who seek to expand the solution space, overcome soft limits to adaptation, reduce residual risk to tolerable levels and achieve societal goals. If such a transformation is not pursued or is not successful and risk remains above intolerable levels a forced transformation may occur less consistent with societal goals. The literature describes incremental and transformational change as linked processes. The transformational adaptation literature suggests shifts from incremental to transformational processes are made possible by knowledge and skills, as well adjustments to vision, agendas and coalitions achieved through monitoring and learning. The socio-ecological and sustainability transitions literature suggests that actors seeking deliberate transformation may take incremental steps that aim to induce societal tipping point behaviour in the near or longer-term. Alternative pathways for pursuing deliberate transformations range from a focus on modernisation of sectors such as energy, agriculture and use of natural resources to proposals for degrowth that aim for intentional decreases in both GDP and coupled GHG emissions. {1.2.1.3, 1.4.4, 1.5.1}

Transformation is understood as a collective action challenge among actors with both common and differing values interacting with a mix of competition and cooperation. Significant innovations often begin in niches or protected spaces, sometimes introduced by new entrants or outsiders. The drivers of transformation are multi-dimensional, involving social, cultural, economic, environmental, technical and political processes the combination of which create the potential for abrupt and systemic change, the stability of entrenched and interlocked power structures and the importance of individual beliefs and behaviours. Decision frameworks that consider multiple objectives and multiple scenarios can avoid privileging some views over others and help multiple actors to identify resilient and equitable solutions to complex, deeply uncertain challenges. Nonetheless, common goals and narratives are both enablers of transformation and help align the activities of multiple, loosely co-ordinated actors. {1.5.2}.

This report employs the climate resilient development concept to inform co-ordinated implementation of adaptation and mitigation solutions to support sustainable development for all. As a transformation that emerges from the choices of many different actors, climate resilient development follows no single or preferred pathway and no single best combination of adaptation, mitigation and sustainable development strategies. All pathways involve complex trade-offs and synergies among different actions. The climate resilient development concept helps assess the extent to which solutions currently exist to meet societal goals or the extent to which an expanded solution space is required. The concept also helps assess the role of various actors, including governments, citizens, civil society, knowledge institutions, media, investors and businesses as well as assessing the need for arenas of engagement in which they can interact. {1.2.3, 1.5.2, 1.5.3}

1.1 The Current Urgent Moment

1.1.1 A Changing Climate in a Changing World

Numerous additional significant climate-related changes have unfolded worldwide since publication of the IPCC Fifth Assessment Report (AR5) in 2014 (IPCC, 2014a). Consistent with projections, multiple, concurrent, changes in the physical climate system have grown more salient, including increasing global temperatures, loss of ice volume, rising sea levels and changes in global precipitation patterns (WGI AR6 Chapter 1). The changes in the physical climate system, most notably more intensive extreme events, have adversely affected natural and human systems around the world, contributing to a loss and degradation of ecosystems including tropical coral reefs; reduced water and food security; increased damage to infrastructure; additional mortality and morbidity; human migration and displacement; damaged livelihoods; increased mental health issues; and increased inequality. Since AR5, a growing literature attributes change in particular climate variables to observed damages to specific, localized human and natural systems in many regions of the world, as shown in Figure 1.1 (Chapter 1 BOX ATTRIBUTE).

Concurrently, since AR5, a growing share of people around the world perceive a changing climate, regard these changes as significant, and consider climate action as a matter of high urgency (Wilson and Orlove, 2019; Section 17.4.5). A survey, representing over half the world's population, found that almost two-thirds of people across 50 countries view climate change as an emergency (Flynn et al., 2021), compared to just over half across 23 countries in 2013 (Fagan, 2019). The highest level of support for climate action is among small-island developing states (74%), followed by high income countries (72%), middle income countries (62%), and, then, least developed countries (58%) (Flynn et al., 2021). Notably after mid-2018, global media showed a large increase number of mentions of "global warming", "climate change" and similar terms (Thackeray et al., 2020). The business communities' now consistently includes climate change, including "climate action failure" as a major risk (World Economic Forum, 2021). In late 2019, protests calling for strengthened climate action reached an unprecedented level of over 6000 events in 185 countries, with a reported estimate of 7.6 million participants, largely led by the "Fridays for Future" youth movement (Chase-Dunn and Almeida, 2020).

Since AR5, governments, businesses and civil society have increasingly responded with planning and actions aimed at reducing current and future risks from climate change (Section 1.1.2; Chapter 16 and 17). Concern with climate change has increasingly motivated actions by governments, the private sector, and civil society (Hale et al., 2021; Section 18.4.3). As described in this report, however, current climate policies and actions alone are not sufficient to meet stated policy goals (Section 1.1.3) *(high confidence*).

This report addresses the challenges of climate action in the context of sustainable development. Climate action takes place in a world already undergoing some of the most rapid and significant societal and environmental change in decades (IPCC, 2018c, Box 1.1), including: species and ecosystems lost due to land- and sea-use change and pollution (IPBES, 2019a); a growing and urbanising world population (Gerten et al., 2019; van Vliet et al., 2017); technology reshaping the workplace through automation (Schwab, 2017) and information dissemination through social media (Mavrodieva et al., 2019; Pearce et al., 2019), and increasing inequalities due to gender, poverty, age, race and ethnicity (Cross-Chapter Box GENDER in Chapter 18). Economic inequality grows within nations even as it has narrowed among them (UN Department of Economic and Social Affairs, 2020). International polycentric governance and nonstate actors play an important role (Beck and Mahony, 2018; Sections 1.4.2 and 17.1.2.1). In 2020 and 2021, a global pandemic dramatically affected the lives of most of the world's population, likely accelerating many of the changes already underway (Cross-Chapter Box COVID in Chapter 7).

The point of departure for this AR6 Working Group II report thus lies in rapid and significant changes in our climate and our world, growing attentiveness to those changes, a gap between current climate action and that needed to address policy goals, and a growing literature that improves understanding and informs potential responses. This chapter defines key concepts and the connections among them useful for comprehending and evaluating these changes, the risks they generate, and options for incremental and transformative solutions that could reduce climate-related risks, impacts and vulnerability.

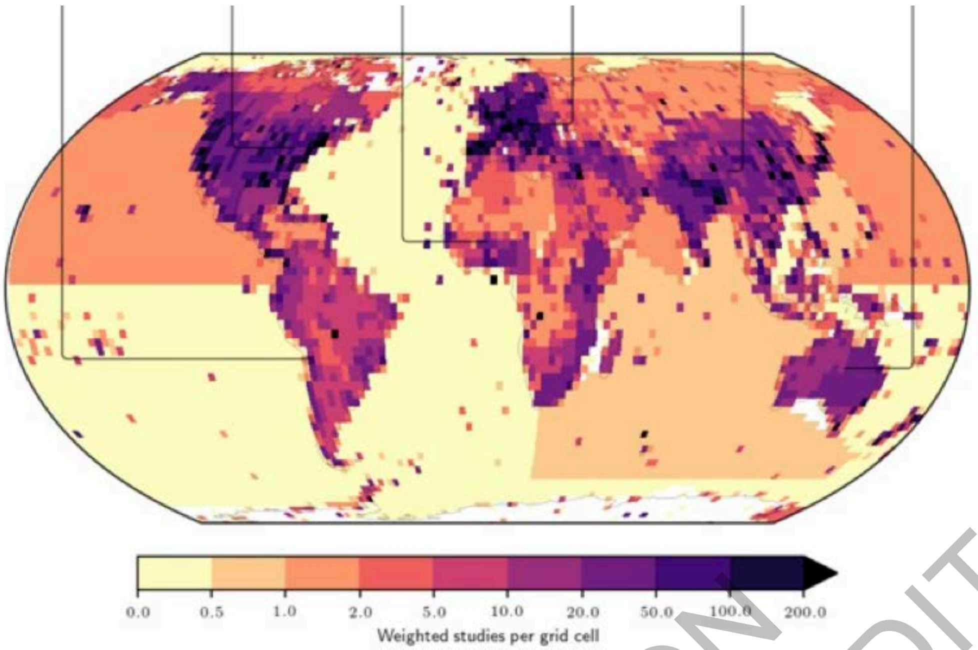

Figure 1.1: Evidence of climate change impacts in many regions of the world. Global density map shows climate impact evidence, derived by machine-learning from 77,785 studies. Bar charts show the number of studies per continent and impact category. Bars are coloured by the climate variable predicted to drive impacts. Colour intensity indicates the percentage of cells a study refers to where a trend in the climate variable can be attributed (partially attributable: >0% of grid cells, mostly attributable: >50% of grid cells) From Callaghan et al. (2021)

1.1.2 Policy Context

Since AR5, climate action has grown at all levels of governance as well as among non-governmental organisations, small and large enterprises, and citizens. Two international agreements – the United Nations Framework Convention on Climate Change (UNFCCC) Paris Agreement and the 2030 Agenda for Sustainable Development – jointly provide overarching goals for climate action. The 2015 Paris Agreement frames direct local, national, and private sector actions aligned with long-term goals addressing mitigation, adaptation, and finance. For mitigation, the agreement calls for "holding the increase in global average temperature to well below 2°C above pre-industrial levels", "pursuing efforts to limit the temperature increase to 1.5°C," and "reaching net-zero greenhouse gas emissions in the second half of this century" (UNFCCC, 2016). For adaptation, the agreement calls for "increasing the ability to adapt to the adverse impacts of climate change and foster climate resilience" (UNFCCC, 2016, Article 2) as well as a dedicated "global goal on adaptation" (Lesnikowski et al., 2017; Persson, 2019b). For finance, the agreement seeks to make "financial flows consistent with a pathway towards low greenhouse gas emissions and climate-resilient development."

The 2030 Agenda for Sustainable Development, adopted in 2015 by UN member states, sets out 17 Sustainable Development Goals (SDGs), frames policies for achieving a more sustainable future and aligns efforts globally to prioritizing ending extreme poverty, protecting the planet, and promoting more peaceful, prosperous, and inclusive societies. SDG 13 ("Climate Action") provides benchmarks to align the Paris Agreement's call to "strengthen the global response to the threat of climate change, in the context of sustainable development and efforts to eradicate poverty." Since AR5, several new international conventions have identified climate change adaptation and risk reduction as important global priorities for sustainable development, including the Sendai Framework for Disaster Risk Reduction (SFDRR) (Tozier de la Poterie and Baudoin, 2015; UNISDR, 2015), the finance-oriented Addis Ababa Action Agenda (UN, 2015), and the New Urban Agenda (UN, 2017). For example, the SFDRR recognizes some disasters as "exacerbated by climate change and increasing in frequency and intensity, significantly [impeding] progress towards sustainable development" (UNISDR, 2015). The Convention on Biological Diversity (CBD) is one of the key international legal instruments for sustainable development for "the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources" (CBD, 2011). The CBD and its Aichi targets recognizes that biodiversity is affected by climate change, with negative consequences for human well-being, but biodiversity, through the ecosystem services, contributes to both climate-change mitigation and adaptation (CBD, 2010). There is concern that many of the proposed post-2020 Biodiversity-targets of the Convention on Biological Diversity (CBD) may not be met due to climate change impacts (Arneth et al., 2020; post-2020 biodiversity targets from Chapter 2).

At the national level, over 2,315 laws and policies that address climate change now exist in 196 countries and a number of territories as of May 2021 (Grantham Research Institute on Climate Change and the Environment and Sabin Center for Climate Change Law, 2021). Sub-national and non-state actors, including city and state governments and firms and investors, have also increasingly launched climate actions (Hale et al., 2021). Climate change litigation is gaining salience for both governments and corporations as the number of cases filed around the world grew from 834 between 1986 and 2014 to 1,006 since 2015 and growing (Setzer and Higham, 2021).

[START BOX 1.1 HERE]

Box 1.1: Summary of IPCC AR5 and Special Report findings

The IPCC WGII AR6 builds upon key findings of the IPCC AR5, three subsequent special reports, and the simultaneous assessment of the IPCC WGI and WGIII AR6. The findings and assessment approaches adopted across these reports have implications for the point of departure in the WGII AR6, including the strong recognition of the urgency for climate action, the enhanced focus on risk, and the aim to connect the search for near-term climate solutions with longer-term transitions. Headline conclusions of the IPCC AR5 include the following, directly quoted (IPCC, 2014a):

- Human influence on the climate system is clear.
- Recent climate changes have had widespread impacts on human and natural systems.
- Continued emission of greenhouse gases will cause further warming and long-lasting changes in all components of the climate system, increasing the likelihood of severe, pervasive and irreversible impacts for people and ecosystems.
- Adaptation and mitigation are complementary strategies for reducing and managing the risks of climate change.
- Substantial emissions reductions over the next few decades can reduce climate risks in the 21st century and beyond, increase prospects for effective adaptation, reduce the costs and challenges of mitigation in the longer term and contribute to climate-resilient pathways for sustainable development.
- Effective implementation depends on policies and cooperation at all scales and can be enhanced through integrated responses that link adaptation and mitigation with other societal objectives.

Compared to previous IPCC assessments of impacts, adaptation and vulnerability, the IPCC WGII AR5 assessment highlighted new data and more formal approaches for attributing observed climate changes and impacts (Cramer et al., 2014; IPCC, 2014c), a more formal approach to risk in WGII (IPCC, 2014c; Jones et al., 2014), and an expanded assessment of adaptation (Chambwera et al., 2014; IPCC, 2014c; Klein et al., 2014a; Mimura et al., 2014; Noble et al., 2014).

At the time of the IPCC AR5, very few scientific studies relevant to the impacts of global warming of 1.5°C above pre-industrial levels were available. In 2018, the IPCC concluded a Special Report on the impacts of global warming of 1.5°C levels and related global greenhouse gas emission pathways, following an invitation expressed in the Decision text of the Paris Agreement (UNFCCC, 2015a). The report assessed available literature on global warming of 1.5°C and on comparison between global warming of 1.5°C and 2°C above preindustrial levels. It also addressed possible pathways for achieving the ambitious goals of the Paris Agreement. Key findings from this report include the following, directly quoted (IPCC, 2018d):

- Global warming is *likely* to reach 1.5°C between 2030 and 2052 if it continues to increase at the current rate.
- Climate-related risks for natural and human systems are higher for global warming of 1.5°C than at present, but lower than at 2°C. Most adaptation needs will be lower for global warming of 1.5°C compared to 2°C.

- In model pathways with no or limited overshoot of 1.5°C, global net anthropogenic CO_2 emissions decline by about 45% from 2010 levels by 2030 (40–60% interquartile range), reaching net zero around 2050 (2045-2055 interquartile range).
- Pathways reflecting current nationally stated mitigation ambitions as submitted under the Paris Agreement would not limit global warming to 1.5°C, even if supplemented by very challenging increases in the scale and ambition of emissions reductions after 2030.

In 2019, a Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC) was published, motivated by the observation that many of the world's most exposed people to risks caused by climate change live in the mountains or near the coast. Key findings include the following, directly quoted (IPCC, 2019c):

- Over the last decades, global warming has led to widespread shrinking of the cryosphere and unabated ocean warming with an uptake of more than 90% of the excess heat in the climate system. Marine heatwaves have doubled in frequency since 1982 and the oceans acidify (*virtually certain*). Global mean sea level is rising, with acceleration in recent decades. Increases in tropical cyclone winds and rainfall exacerbate extreme sea level events and coastal hazards.
- All these trends have impacted ecosystems, food security, water resources, water quality, livelihoods, health and well-being, infrastructure, transportation, tourism and recreation, as well as the culture of human societies, particularly for Indigenous peoples.
- The Greenland and Antarctic Ice Sheets are projected to lose mass at an increasing rate throughout the 21st century and beyond. Projected ecosystem responses include losses of species habitat and diversity, and degradation of ecosystem functions. Warm-water corals are at high risk already and are projected to transition to very high risk even if global warming is limited to 1.5°C.
- Increased mean and extreme sea level, alongside ocean warming and acidification, are projected to exacerbate risks for human communities in low-lying coastal areas. People with the highest exposure and vulnerability are often those with lowest capacity to respond.
- Services provided by ocean and cryosphere-related ecosystems can be supported by protection, restoration, precautionary ecosystem-based management of renewable resource use, and the reduction of pollution and other stressors.
- Coastal communities face challenging choices in crafting context-specific and integrated responses to sea level rise that balance costs, benefits and trade-offs of available options and that can be adjusted over time.

Also in 2019, IPCC published a Special Report on Climate Change and Land, addressing greenhouse gas (GHG) fluxes in land-based ecosystems, land use and sustainable land management in relation to climate change adaptation and mitigation, desertification, land degradation and food security. Key findings include the following, directly quoted (IPCC, 2019c):

- Human use directly affects more than 70% of the global, ice-free land surface. Land also plays an important role in the climate system. Climate change has adversely impacted food security and terrestrial ecosystems as well as contributed to desertification and land degradation in many regions. Changes in land conditions, either from land-use or climate change, affect global and regional climate.
- Pathways with higher demand for food, feed, and water, more resource-intensive consumption and production, and more limited technological improvements in agriculture yields result in higher risks from water scarcity in drylands, land degradation, and food insecurity. Most of the response options assessed contribute positively to sustainable development and other societal goals. Sustainable land management, including sustainable forest management, can prevent and reduce land degradation, maintain land productivity, and sometimes reverse the adverse impacts of climate change on land degradation. It can also contribute to mitigation and adaptation.
- Response options throughout the food system, from production to consumption, including food loss and waste, can be deployed and scaled up to advance adaptation and mitigation. All assessed modelled pathways that limit warming to 1.5°C or well below 2°C require land-based mitigation and land-use change.

- The effectiveness of decision-making and governance is enhanced by the involvement of local stakeholders (particularly those most vulnerable to climate change including Indigenous peoples and local communities, women, and the poor and marginalised) in policies for land-based climate change adaptation and mitigation.
- Near-term action to address climate change adaptation and mitigation, desertification, land degradation and food security can bring social, ecological, economic and development co-benefits.

In 2021, IPCC Working Group 1 published its Sixth Assessment Report on The Physical Science Basis. Key findings from the report include the following, directly quoted from its SPM quoted (IPCC, 2019c):
:

- The scale of recent changes across the climate system as a whole and the present state of many aspects of the climate system are unprecedented over many centuries to many thousands of years.
- Global surface temperature will continue to increase until at least the mid-century under all emissions scenarios considered. Global warming of 1.5°C and 2°C will be exceeded during the 21st century unless deep reductions in carbon dioxide and other greenhouse gas emissions occur in the coming decades.
- Many changes due to past and future greenhouse gas emissions are irreversible for centuries to millennia, especially changes in the ocean, ice sheets and global sea level.
- With further global warming, every region is projected to increasingly experience concurrent and multiple changes in climatic impact-drivers. Changes in several climatic impact-drivers would be more widespread at 2°C compared to 1.5°C global warming and even more widespread and/or pronounced for higher warming levels. Low-likelihood outcomes, such as ice sheet collapse, abrupt ocean circulation changes, some compound extreme events and warming substantially larger than the assessed very likely range of future warming cannot be ruled out and are part of risk assessment.
- From a physical science perspective, limiting human-induced global warming to a specific level requires limiting cumulative CO2 emissions, reaching at least net zero CO2 emissions, along with strong reductions in other greenhouse gas emissions. Strong, rapid and sustained reductions in Chapter 4 emissions would also limit the warming effect resulting from declining aerosol pollution and would improve air quality.

Other assessment processes also inform the IPCC AR6. For example, a recent joint workshop between IPBES and IPCC, the first of its kind, made key observations relevant to the work of IPCC AR6 WG2 (Pörtner et al., 2021). In this broad context, the workshop explored diverse facets of the interaction between climate and biodiversity, from current trends to the role and implementation of nature-based solutions and the sustainable development of human society. Key highlighting synopsis of the workshop include the following, directly quoted from the workshop report:

- Limiting global warming to ensure a habitable climate and protecting biodiversity are mutually supporting goals, and their achievement is essential for sustainably and equitably providing benefits to people.
- Several land- and ocean-based actions to protect, sustainably manage and restore ecosystems have co-benefits for climate mitigation, climate adaptation and biodiversity objectives.
- Measures narrowly focused on climate mitigation and adaptation can have direct and indirect negative impacts on nature and nature's contributions to people.
- Measures narrowly focusing on protection and restoration of biodiversity have generally important knock-on benefits for climate change mitigation, but those benefits may be sub-optimal compared to measures that account for both biodiversity and climate.
- Treating climate, biodiversity and human society as coupled systems is key to successful outcomes from policy interventions.
- Transformative change in governance of socio-ecological systems can help create climate and biodiversity resilient development pathways.

[END BOX 1.1 HERE]

1.1.3 Adaptation Efforts and Gaps

Adaptation to climate change plays a key role in reducing climate-related risks along with mitigation and sustainable development. From a risk perspective (Section 1.2), emission reductions and carbon removal can both reduce the greenhouse gas forcing and thus climate-related hazards while adaptation and sustainable development reduce exposure and vulnerability to those hazards.

Important synergies and trade-offs exist among adaptation and mitigation actions (Section 1.5, Chapter 18). Limiting atmospheric concentrations of greenhouse gases reduces the extent of adaptation needed to keep risk within tolerable levels (Section 1.3; Chapter 16). From a global perspective, understanding of adaptation and its limits can inform judgements about the best balance among levels of mitigation and adaptation .Such judgements underlie the mitigation goals of the Paris Agreement. From a more local perspective, there exist a wide range of mitigation scenarios (Cross-Chapter Box CLIMATE in Chapter 1), including those which meet or miss the Paris Agreement goals, and overshoot scenarios in which global mean temperature exceed targets for several decades before dropping to desired levels. Such scenarios inform assessments of the level of adaptation that may be required (Section 1.4, Chapter 17).

Adaptation and sustainable development are also interlinked (Section 18.1). Adaptation facilitates development, which is hindered by impacts and risks from climate change. Development facilitates adaptation by expanding the resources and capacity available to manage climate risks. Viewed from a climate justice perspective, some argue that a more just society is more capable of successful adaptation while others argue that only adaptation that results in a more just society can be judged successful (Section 1.4.1, Chapter 18).

Two concepts – adaptation gaps and limits to adaptation – help frame this report's assessment of the extent to which current adaptation efforts are adequate to meet societal goals. **Adaptation gaps** are defined as "the difference between actually implemented adaptation and a societally set goal, determined largely by preferences related to tolerated climate change impacts and reflecting resource limitations and competing priorities" (UNEP et al., 2021). Limits to adaptation describe the extent to which no plausible level of adaptation can meet societal goals (Section 1.4.4). Within the limits, adaptation gaps can be closed by increased and more successful adaptation actions. Beyond the limits, only mitigation can close adaptation gaps.

Numerous climate-related impacts already cause severe damages in many places and are projected to increase in the future (Chapter 16). Adaptation can reduce these risks, often significantly, but limits to adaptation have already been reached or are being approached in some sectors and regions (Sections 16.3.1, 16.4). While natural systems worldwide are changing in response to climate change, many are not adapting sufficiently quickly to retain their resilience in the face of current and projected future climate change (Section 16.4). For human systems, numerous lines of evidence suggest that in many regions and sectors current infrastructure, settlement patterns, policies, practices, and institutions remain inadequate for current changes in climate conditions (Section 16.2). Inadequate or insufficient adaptation to current conditions is called an adaptation deficit.

In response, adaptation efforts have increased significantly since AR5 (Sections 16.3, 17.2, 17.5.2, Chapter 1 Cross-Chapter Box ADAPT in Chapter 1). Assessing the adequacy and effectiveness of these efforts as called for in Article 7 of the Paris Agreement remains challenging (Section 1.3.2.2), because much adaptation is not recorded in the literature and because assessment depends on judgements of effectiveness (Section 1.4.1.2), judgements about societal goals including climate justice (Section 1.4.1.1), and expectations about future greenhouse gas concentration pathways and other socio-economic conditions (16.5, Cross-Chapter Box DEEP in Chapter 17).

Knowledge about adaptation has significantly expanded since AR5 (Cross-Chapter Box ADAPT in Chapter 1). While understanding regarding the extent of adaptation gaps remains limited, the available evidence suggests significant adaptation gaps exist (*high confidence*). Many current adaptation efforts constitute adaptation planning, rather than implementation (Section 16.3). Most current implementation efforts represent incremental as opposed to transformational adaptation despite the proximity to adaptation limits (Sections 17.2 and 17.5.2). Some current adaptation efforts are considered maladaptive because they increase some climate-related risks even if they reduce others (Sections 1.4.2.4 and 17.5; Chapter 16). Gaps exist in key enablers of adaptation, such as finance (Cross-Chapter Box FINANCE in Chapter 17). Given the long-time scales involved with many adaptation actions and the potential to significantly reduce longer-term costs with near-term actions, closing many adaptation gaps requires actions over the next few years by governments, business, civil society and individuals at a scale and speed significantly faster than that represented by current trends.

1.1.4 What is New in the History of Interdisciplinary Climate Change Assessment

Interdisciplinary climate change assessment, which has played a prominent role in science–society interactions on the climate issue since 1988, has advanced in important ways since AR5 (Mach and Field, 2017; Mitchell et al., 2006; Oppenheimer et al., 2019). Building on a substantially expanded scientific and technical literature (Burkett et al., 2014; Minx et al., 2017), this AR6 report emphasizes at least three broad themes.

First, this AR6 assessment has an increased focus on risk- and solutions-frameworks. The risk framing can move beyond the limits of single best estimates or most-likely outcomes and include high-consequence outcomes for which probabilities are low or in some cases unknown (Jones et al., 2014; Mach and Field, 2017). In this report, the risk framing for the first time spans all three working groups, includes risks from the responses to climate change, considers dynamic and cascading consequences (Section 1.3.1.1), describes with more geographic detail risks to people and ecosystems, and assesses such risks over a range of scenarios (Chapter 16). The focus on solutions encompasses the interconnections among climate responses, sustainable development, and transformation—and the implications for governance across scales within the public and private sectors (Section 17.5.2, Chapter 18). The assessment therefore includes climate-related decision-making and risk management, climate-resilient development pathways, implementation and evaluation of adaptation, and also limits to adaptation and loss and damage (Cross-Chapter Box LOSS in Chapter 17, Section 1.4.4). Specific focal areas reflect contexts increasingly important for the implementation of responses, such as cities (Chapter 6).

Second, emphases on social justice and different forms of expertise have emerged (Section 1.4.1.1, 17.5.2). As climate change impacts and implemented responses increasingly occur, there is heightened awareness of the ways that climate responses interact with issues of justice and social progress. In this report, there is expanded attention to inequity in climate vulnerability and responses, the role of power and participation in processes of implementation, unequal and differential impacts, and climate justice. The historic focus on scientific literature has also been increasingly accompanied by attention to and incorporation of Indigenous knowledge, local knowledge, and associated scholars (Section 1.3.2.3, Chapter 12).

Third, AR6 has a more extensive focus on the role of transformation in meeting societal goals (Section 1.5).

To support these three themes, this report assesses a literature with an increasing diversity of topics and geographical areas covered. The diversity is encompassed through sectoral and regional chapters (Chapters 2-15) as well as cross-chapter papers and boxes. The literature also increasingly evaluates the lived experiences of climate change—the physical changes underway, the impacts for people and ecosystems, the perceptions of the risks, and adaptation and mitigation responses planned and implemented. In particular, scientific capabilities to attribute individual extreme weather and climate events to greenhouse gas emissions have gone from hypothetical to standard and routine over the last three decades, and societal perceptions of these events and their impacts for people and ecosystems are now being studied as well (Figure 1.1; Cross-Working Group Box: ATTRIBUTION in Chapter 1; see synthesis in Chapter 16).

Finally, climate change assessment has become increasingly integrative across multiple disciplines within the natural and social sciences. This report's chapters combine experts across working groups and disciplines, such as natural and social sciences, engineering, humanities, law, and business administration. In this assessment cycle, the special reports (Allen et al., 2018; IPCC, 2019a; IPCC, 2019b) all emphasize such integration, and the chapter teams in the present report integrate disciplinary perspectives and also science-policy interactions inherent in climate change impacts, adaptation and vulnerability. There has been increasing real-time assessment of the assessment process itself, including interpersonal dynamics and how they shape key findings (Oppenheimer et al., 2019). Additionally, best practices are being adopted from applied decision and policy analysis, decision support, and co-production, in order to increase assessment relevance and usability for decision-making (Hall et al., 2019; Mach et al., 2019). Methods of integration in this report include systematic review, meta-analysis, multi-criteria integration, and expert elicitation (see synthesis in Chapter 16). The emphasis on knowledge for action has also included the role of public communication, stories, and narratives within assessment and associated outreach (Section 1.2.2).

1.2 Different Entry Points for Understanding Climate Change Impacts, Adaptation, and Vulnerability

This section introduces key concepts used in this report and the connections between them that present different entry points for understanding climate change impacts, adaptation, and vulnerability.

1.2.1 Overlapping, Complementary Entry Points

Many actors from different research and practice communities engage with understanding and responding to climate risk. Not surprisingly, there thus exist alternative, overlapping, and complementary entry points to the discussion widely used throughout the literature and this report.

The concepts of risk and risk management have in recent years been central to climate change research and practice related to impacts, adaptation, and vulnerability. The concepts provide a framework for understanding climate change and its increasingly severe, interconnected, and irreversible impacts. They support the implementation of solutions that reduce adverse consequences, pursue opportunities, and enable beneficial outcomes for people, economies, and nature (IPCC, 2014c; IPCC, 2018d). All three AR6 Working Groups now apply a common risk framework (IPCC, 2020).

Additional concepts—adaptation, vulnerability, exposure, resilience, and transformation —also provide important framings for the climate change challenge.

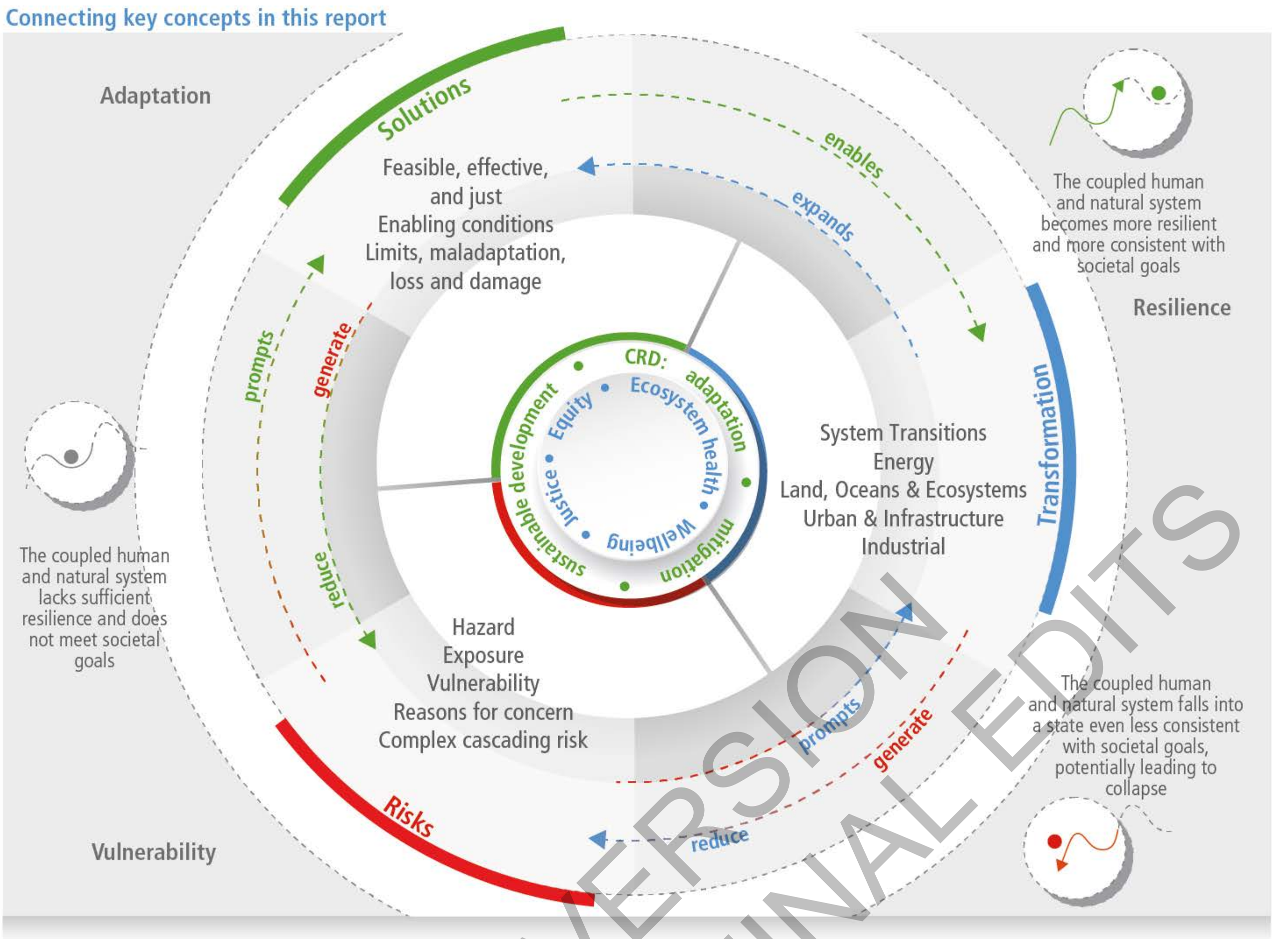

Figure 1.2: Connecting Key Concepts in this Report The current coupled human and natural system is insufficiently resilient and does not meet societal goals of equity, well-being, and ecosystem health. Meeting the objectives of the Paris Agreement, Sustainable Development Goals, and other policy statements requires the system to move to a new and more resilient state. Key concepts used in this report help illuminate our current situation and potential solutions. These key concepts are usefully organized around the concepts of risk, solutions, and transformation. Risk can prompt solutions and transformation. Both solutions and transformation seek to reduce some risks but may also generate others. Solutions can enable transformation, and transformation can expand the set of feasible solutions.

Figure 1.2 displays the connections among many of the key concepts used in this report. This chapter, the Summary for Policymakers, Technical Summary, and sectoral and regional chapters are organized around the concepts of risks (Section 1.3), solutions (Section 1.4), and transformation (Section 1.5).

Key concepts that contribute to an understanding of risk include its components hazards, exposure, and vulnerability (Section 1.2.1.1); the recognition that risks may be complex and cascading (Section 1.3.1.2); and the reasons for concern framework used to summarize the most policy-relevant risks (Section 1.3.1.1). Key concepts that contribute to an understanding of solutions include the enablers of governance, finance, and knowledge (Section 1.4.2); learning processes supported by monitoring and evaluation (Section 1.4.3); and nature-based solutions (Section 1.4.2). Transformation is supported by systems transitions in energy, land, infrastructure, industry, and society (Section 1.5.1), which if successful can contribute to climate resilient development (Section 1.5).

The centre of Figure 1.2 shows societal goals of equity, effectiveness, well-being, and climate justice as articulated by the Paris Agreement, Sustainable Development Goals, and other policies and plans (Section 1.4.1). The ring around these goals shows the limits to adaptation (Section 1.4.4), potential for maladaptation (Sections 1.4.2. 17.5.2), and loss and damage (Section 1.4.4.2) that present barriers to reaching these goals.

The concept of vulnerability can provide a unique window into the effects of climate change on different communities, individuals, and ecosystems, in particular as human systems are affected by race, gender, wealth inequalities, and other attributes (Section 1.2.1.2). The concept of adaptation can provide a unique window into the process of adjustment to climate change by human and natural systems (Section 1.2.1.3). Resilience (Section 1.3.1.4) is a broad concept, encompassing both outcomes and processes, an ability to main essential function, and an ability to transform.

The ball and cup diagrams (Holling, 1973) in Figure 1.2 indicate that the current coupled human and natural system is not resilient, nor does it meet societal goals of equity, well-being, and ecosystem health. Some types of transformation may prove inevitable (Section 1.5.1), either a deliberate transformation that results in a more resilient state consistent with societal goals or a forced transformation to a system state inconsistent with the goals.

1.2.1.1 Risk Framing

Risk in this report is defined as the potential for adverse consequences for human or ecological systems, recognising the diversity of values and objectives associated with such systems. In the context of climate change impacts, risks result from dynamic interactions between climate-related hazards with the exposure and vulnerability of the affected human or ecological system. In the context of climate change responses, risks result from the potential for such responses not achieving the intended objective(s), or from potential trade-offs or negative side-effects (see Annex II: Glossary). **Risk management** is defined as plans, actions, strategies or policies to reduce the likelihood and/or magnitude of adverse potential consequences, based on assessed or perceived risks (see Annex II: Glossary).

A risk framing is increasingly used to assess climate change impacts on human and natural systems (Connelly et al., 2018; IPCC, 2012; Mach and Field, 2017; O'Neill et al., 2017; see also WGII AR6 Sections 1.2.4.1, 16.1, and 17.3 and Cross-Chapter Box CLIMATE; Oppenheimer et al., 2014). A risk framing reflects key dimensions of the climate challenge. These features include the changing likelihoods of many different outcomes (including adverse consequences and beneficial opportunities), uncertainties that will persist, and different and contested values, priorities, and goals (Jones and Preston, 2011; Mach et al., 2016). The IPCC AR6 and associated Special Reports apply a broad definition of risk (WGI AR6 Cross-Chapter Box 1.3. WGI AR6 uses the Climatic Impact Driver (CID) terminology, rather than hazard, to neutrally assess changing climatic conditions that are relevant to human and natural systems, leaving the determination of positive/negative consequences and resulting impacts and risks for WGII assessment (WGI AR6 Section 12.3). In most cases throughout this WGII report, the term "risk" refers to the risks of climate change impacts. The full assessment, however, incorporates all relevant risks from climate change impacts and responses.

The broad definition of risk involves quantitative and integrative understandings of risk (Mach and Field, 2017; Oppenheimer et al., 2014; see also Section 17.3). Risk is sometimes defined as the probability of a consequence, multiplied by the magnitude of that consequence, acknowledging both the diversity of possible consequences and the relevance of values. Yet it also applies in circumstances where probabilities cannot be fully quantified (e.g., Adger et al., 2013). For example, in some cases the probability and magnitude of consequences may be more uncertain, dependent on complex dimensions of the climate (e.g., a cyclone, high tide, and heatwave co-occurring) or the vulnerability of different communities (e.g., the ways in which social networks and community cohesion support most-vulnerable individuals during disasters) (Ford et al., 2018). The determinants of risk vary dynamically through space and time (Jurgilevich et al., 2017; Viner et al., 2020). They interact, compound, and cascade (Adger et al., 2018; Dawson, 2015; see also Section 16.1.2).

A risk framing supports connections with solutions (Adger et al., 2018; Jones and Preston, 2011; Mach et al., 2016). First, a risk framing connects the present with the future. (Papathoma-Kohle et al., 2016). For instance, whether wildfire or drought, recent experiences have demonstrated limits to current response capacities, relevant to future preparedness (e.g., evacuation of large communities on tight time frames or water management simultaneously responsive to intensifying drought and flooding). Second, a risk framing emphasizes that uncertainties and complex interactions are integral to decision-making (Dawson, 2015; Jones et al., 2014). The uncertainties include high-impact, low-probability outcomes and deep uncertainties for which core processes are not understood and meaningful probabilities cannot be applied (Adler et al., 2016see also Section 17.2.1 and Cross-Chapter Box DEEP in Chapter 17; Chapter 7 in SRCCL, IPCC, 2019a; Cross-Chapter Box 5 in SROCC, IPCC, 2019b). In these circumstances, risk assessment can occur through tools used for risk management across contexts, such as insurance, business, social protection, security, and policy planning, and decision-making can be iterative and support dynamic adaptive pathways through time (Aven, 2016; Jones and Preston, 2011; Watkiss et al., 2015; see also Section 17.3.2)

Iterative risk management (Vervoort and Gupta, 2018) emphasizes that anticipating and responding to climate change does not consist of a single set of judgments at a single point in time, but rather an "ongoing cycle of assessment, action, reassessment, learning, and response" (USGCRP, 2018). It is consistent with most approaches applied for implementing adaptation (Jones et al., 2014; Jones and Preston, 2011). For instance, the Paris Agreement is organized as a polycentric process (see Section 1.4) of iterative risk management in which national governments pledge to take specific actions, those actions are monitored and assessed, and nations asked to update their pledges in light of that assessment.

1.2.1.2 Vulnerability

Vulnerability is a component of risk, but also an important focus independently. Vulnerability in this report is defined as the propensity or predisposition to be adversely affected and encompasses a variety of concepts and elements including sensitivity or susceptibility to harm and lack of capacity to cope and adapt (see Annex II: Glossary). Over the past several decades, approaches to analysing and assessing vulnerability have evolved. An early emphasis on top-down, biophysical evaluation of vulnerability included -and often started with - exposure to climate hazards in assessing vulnerability. From this starting point, attention to bottom-up, social and contextual determinants of vulnerability, which often differ, has emerged, although this approach is incompletely applied or integrated across contexts (Bergstrand et al., 2015; Rufat et al., 2015; Spielman et al., 2020; Taberna et al., 2020). Vulnerability is now widely understood to differ within communities and across societies, also changing through time (Jurgilevich et al., 2017; Kienberger et al., 2013; see also Chapter 16). In the WGII AR6, assessment of the vulnerability of people and ecosystems encompasses the differing approaches that exist within the literature, both critiquing and harmonizing them based on available evidence. In this context, **exposure** is defined as the presence of people; livelihoods; species or ecosystems; environmental functions, services, and resources; infrastructure; or economic, social, or cultural assets in places and settings that could be adversely affected (Annex II: Glossary). Potentially affected places and settings can be defined geographically, as well as more dynamically, for example through transmission or interconnections through markets or flows of people.

Vulnerability is also a link between the climate risk and disaster risk communities, recognizing complementarities and differences between these communities. **Disaster risk management** is the set of processes that improve understanding of disaster risk, foster disaster risk reduction and transfer, and promote continuous improvement in disaster preparedness, response, and recovery practices, increasing human security, well-being, and sustainable development (see Annex II: Glossary). Climate risk and disaster risk are increasingly addressed together, bridging the climate change adaptation and disaster risk reduction communities (e.g., IPCC, 2012; UNDRR, 2019, especially Chapter 13 in that report). Building from the scientific literature and adaptation and risk reduction practice, the IPCC Special Report on Extremes resulted in several major IPCC advances that continue to the present report, including emphasis on risk and climate-related extremes (e.g., Burton et al., 2012; Lavell et al., 2012) and re-conceptualisation of vulnerability to encompass both social and biophysical orientations (i.e., bridging contextual/bottom-up and climate-driven/top-down approaches) (Cardona et al., 2012; Polsky et al., 2007). Linking disaster risk reduction and climate change adaptation can also be an important basis for discussion in climate negotiations regarding the allocation of funds needed for tackling climate change, especially in developing countries and small island developing states (Begum et al., 2014). The integration of disaster risk management and climate change adaptation in the IPCC AR6 is seen for example in the assessment of key risks within and across sectors and regions, along with global-scale reasons for concern, which is attuned to extreme events and disasters (Oppenheimer et al., 2014; see also Chapter 16). Additionally, the assessment of adaptation has prioritized these interconnections (e.g., Mimura et al., 2014), as have literature and practice especially in the context of sustainable development (e.g., Schipper et al., 2016).

1.2.1.3 Adaptation

Adaptation in this report is defined, in human systems, as the process of adjustment to actual or expected climate and its effects, in order to moderate harm or exploit beneficial opportunities. In natural systems, adaptation is the process of adjustment to actual climate and its effects; human intervention may facilitate adjustment to expected climate and its effects (see Annex II: Glossary). Adaptation planning in human systems generally entails a process of iterative risk management. Different types of adaptation have been distinguished, including anticipatory versus reactive, autonomous versus planned, and incremental versus transformational adaptation (IPCC WGII glossaries for the TAR, AR4, AR5, and AR6; Chapters 16–18). Adaptation is often seen as having five general stages: 1) awareness, 2) assessment, 3) planning, 4) implementation, and 5) monitoring and evaluation (Jones et al., 2014; Mimura et al., 2014; Moser and Boykoff, 2013; Noble et al., 2014; see also Section 17.4). Government, non-government, and private-sector actors have adopted a wide variety of specific approaches to adaptation that, to varying degrees, address these five general stages. Adaptation in natural systems includes “autonomous” adjustments through ecological and evolutionary processes. It also involves the use of nature through ecosystem-based adaptation. The role of species, biodiversity, and ecosystems in such adaptation options can range from the rehabilitation or restoration of ecosystems (e.g., wetlands or mangroves) to hybrid combinations of “green and grey” infrastructure (e.g., horizontal levees) (Chapters 2-3; IPBES, 2018).

The IPCC assessment of adaptation has evolved through time. The WGII AR4 included one chapter dedicated to adaptation, the WGII AR5 expanded to four, and the WGII AR6 mainstreams adaptation comprehensively throughout the report. Adaptation science is rapidly evolving, including evaluation of adaptation effectiveness, feasibility, implementation, and maladaptation, although major knowledge gaps persist in modeling and analysis (CCB ADAPT; Chapter 16; Section 1.4; Holman et al., 2019). The WGII AR6 emphasizes assessment of observed adaptation-related responses to climate change, governance and decision-making in adaptation, and the role of adaptation in reducing key risks and global-scale reasons for concern, as well as limits to such adaptation (e.g., Chapters 16 and 17). The assessment approach includes adaptation needs, options, planning, and implementation across sectors and regions, as well as adaptation opportunities, constraints, and also limits (Capela Lourenço et al., 2019; Eisenack et al., 2014; Herrmann and Guenther, 2017; Klein et al., 2014b; Lehmann et al., 2015; Moser et al., 2019b; Oberlack, 2017; Oberlack and Eisenack, 2014; Roggero, 2015; Russel et al., 2020; Sieber et al., 2018; Thaler et al., 2019; see also Chapters 16 and 17).

Since AR5, more adaptation has progressed (IPCC, 2014a; Lesnikowski et al., 2016; see also Sections 16.2.5 and 17.2) and the focus of activity has expanded to include social, institutional, and governance dimensions beyond engineered and technical options and to decision processes beyond technocratic, linear framings (IPCC, 2014a; see also Chapter 17). Adaptation includes increasing attention to implementation, monitoring and evaluation, and learning through time, not just planning processes (Section 17.3 and 17.5.1). On the one hand, an important advance has been recognition of generalized capacities, such as resources and knowledge, necessary for the feasibility of effective adaptation. Adaptation thereby strongly overlaps with risk management and with the building of resilience and sustainable development (Chapters 17–18).

1.2.1.4 Resilience, Including Connections with Development Pathways and Transformation

Resilience in this report is defined as the capacity of social, economic and environmental systems to cope with a hazardous event or trend or disturbance, responding or reorganising in ways that maintain their essential function, identity and structure while also maintaining the capacity for adaptation, learning and transformation (see Annex II: Glossary). Resilience is an entry point commonly used, although under a wide spectrum of meanings (Aldunce et al., 2015; Fisichelli et al., 2016; Flood and Schechtman, 2014; Meerow et al., 2016; Moser et al., 2019a; Reghezza-Zitt et al., 2012; Tanner et al., 2015). Resilience as a system trait overlaps with concepts of vulnerability, adaptive capacity, and thereby risk, and resilience as a strategy overlaps with risk management, adaptation, and also transformation (Moser et al., 2019a; Woodruff et al., 2018). Implemented adaptation is often organized around resilience as bouncing back and returning to a previous state after a disturbance (Fisichelli et al., 2016).

In much of the literature, resilience encompasses not just maintaining essential function, identity, and structure, but also maintaining a capacity for adaptation, learning, and transformation. Since the earliest framings of resilience around stability and persistence, ecology and allied fields have come to recognize that while systems are often persistent in the face of disturbance, disturbance also creates opportunity for transformation and the emergence of new pathways (Section 1.5.2) (Allen and Holling, 2010; Doppelt, 2017; Folke, 2006; Folke et al., 2010; Gelcich et al., 2010; Stockholm Resilience Center, 2015). Across this literature, disturbance is framed as outside the system in question, for which the timeframes and spatial scales of disturbances, impacts, and responses are central to outcomes (Béné et al., 2011; Brown, 2014; Hamborg et al., 2020). Endogenous processes of transformation are presented as emergent, characterized by thresholds, and as a result very difficult to anticipate (Hughes et al., 2013; Scheffer et al., 2001; Scheffer et al., 2015; Scheffer et al., 2012; Suding and Hobbs, 2009; Walker and Meyers, 2004). In the last 5 years (2016-2020), the concept of resilience has gained prominence as a core theme in the climate change adaptation literature (Nalau and Verrall, 2021).

Often, development and adaptation communities of practice default to persistence and stability in their use of resilience (Cote and Nightingale, 2012; MacKinnon and Derickson, 2013). Such a framing aligns resilience with a long-standing but increasingly questioned belief that sustainable development can be achieved through incremental adjustments in behaviour and advances in technology that allow for the persistence of existing socio-economic and socio-ecological arrangements (Banerjee, 2003; Klauer, 1999; Redclift, 2005; UN Inter-agency Task Force on Financing for Development 2019; Chap 18; Section 1.5). However, the literature increasingly suggests that the achievement of sustainable development will require transformative change in socio-ecological systems at scales ranging from the community to the globe. The concept of climate resilient development, initially introduced in AR5 and now a key focus in this report (see Chapter 18), engages with such transformations and the associated questions of justice, power, and politics as shaped by internal, endogenous social factors and their interactions with other drivers of change (Carr, 2019; Eriksen et al., 2015; Nightingale, 2015b; Nightingale et al., 2019; see also Chapter 18).

1.2.2 Narratives, Storylines, Scenarios and Pathways

The concepts of narratives, storylines, scenarios, and pathways play an important role in this report. While distinct concepts, they are inter-related and sometimes confused.
A **narrative** is a story with a chronological order or, when cast in the form of an argument, with premises and conclusions (Adger et al., 2001; Roe, 1991). Narratives enable people to envision what various potential futures may mean for environments and livelihoods and in this way facilitate the development of scenarios for the future (Miller et al., 2015). Narratives can also play a key role in enabling collective action (Section 1.5) by helping disparate groups co-create a common vision of a desirable future and achieve a common understanding of actions needed to move towards that future (Linnér and Wibeck, 2019; Muiderman et al., 2020).

A narrative contains a storyline in addition to a set of actors (Elliott, 2005). A **storyline** is a series of events including their causal connections within a narrative. The IPCC and climate change literature more broadly often use the terms storylines and narratives interchangeably (O'Neill et al., 2017; see also WGI AR6 Cross-Chapter Box 6 in Chapter 1 and Sections 1.4.4 and 10.5.3). A **scenario storyline** refers to a narrative description of a scenario including its main characteristics, relationships between driving forces and how these factors evolve (AR6 WG1 Section 1.4.4.2). Storylines are used to assess risks related to low-likelihood, but high-impact events (Sutton, 2018). In this use of the terms, narratives and storylines do not include specific actors. There is also a critical literature on the use of narratives and storylines based on projected scenarios, which points out the conservative character of these concepts whose performative effect tends to preserve the status quo and the current socio-economic relationships. (Chollet and Felli, 2015; Demortain, 2019; Lövbrand et al., 2015; Malm and Hornborg, 2014; Theys J. and Cornu, 2019).

Standard research communication may fail to engage policymakers, media and the public at large (WGI AR6 Section 1.2.4). Rather, policies and decision-making tend to be based on narratives and storylines (Roe, 1994; Roe, 2017). Although mathematical models and narratives are often presumed to be antithetical, in practice they may be complementary and work together (Morgan and Wise, 2017). Communicating research insights through storylines and narratives may have a better chance of transmitting key messages. AR6 employs these communication tools in many places, for instance storylines for constructing and communicating regional climate information or climate services (WGI AR6 Chapter 10, Chapter 12) or "Low-Likelihood High Warming Storylines" (Chapter 4). To better communicate deep uncertainty in sea level rise projections, WGI uses storylines to describe the physical events that would have to unfold to generate its high-end estimates (Cross-Chapter Box DEEP in Chapter 17).

Scenarios are defined in IPCC reports as plausible descriptions of how the future may develop, based on a coherent and internally consistent set of assumptions about key driving forces (e.g., rate of technological change, prices) and relationships (Annex II: Glossary). Scenarios are neither predictions nor forecasts but rather 'foresights', which imply envisioning challenging futures (Vervoort and Gupta, 2018). Scenarios are used to provide a view of the potential consequences and implications of developments and actions in a 'what-if' mode of exploring the future (AR6 WGIII Section 1.5.1; AR6 WGI Section 1.6.1). They may be presented as numerical or mental models. Climate change scenarios are generated by climate modellers to highlight possible alternative greenhouse gas emission pathways and are used to develop and integrate projections of emissions and their climate change impacts and for analysing and contrasting climate policy choices. Cross-Chapter Box CLIMATE in Chapter 1 describes scenarios used in this report.

Pathways are one element of a larger scenario (O'Neill et al., 2017), focusing on just one element of a larger system of drivers, emissions or concentrations. Scenarios provide one means to represent deep uncertainty when there is disagreement or uncertainty about conceptual models (IPCC, 2019b; Cross-Chapter Box DEEP in Chapter 17). In addition, scenarios provide several important functions in decision support. A lack of strong association with probabilities enables scenarios to promote buy-in from parties to a decision who hold different expectations about the future, helping them to expand the range of futures and options they consider. The process of generating scenarios can serve as the focus of participatory stakeholder exercises and processes, and scenarios can also be used to support risk management by stress testing alternative policies and identifying robust and adaptive policies under conditions of deep uncertainty (Cross-Chapter Box DEEP in Chapter 17).

[START CROSS-CHAPTER BOX CLIMATE HERE]

Cross-Chapter Box CLIMATE: Climate Reference Periods, Global Warming Levels, and Common Climate Dimensions

Authors: Steven Rose (USA), Richard Betts (United Kingdom), Philippus Wester (Nepal/Netherlands), Aris Koutroulis (Greece)

This Cross-Chapter Box sets out common climate dimensions to contextualize and facilitate AR6 WGII analyses, presentation, synthesis, and communication of assessed, observed and projected climate change impacts across WGII Chapters and Cross-Chapter Papers. "Common climate dimensions" are defined as common Global Warming Levels (GWLs), time periods, and levels of other variables as needed by WGII authors for consistent communications. The set of climate variable ranges given below were derived from the AR6 WGI report and supporting resources and help contextualize and inform the projection of potential future climate impacts and key risks. The information enables the mapping of climate variable levels to climate projections and vice versa, with ranges of results provided to characterize the physical uncertainties relevant to assessing climate impacts risk.

AR6 WGI Reference Periods, Climate Projections and Global Warming Levels

AR6 WGI adopts a common set of reference years and time periods to assess observed and projected climate change, namely the pre-industrial (PI) period, the current 'modern' period and future reference time periods. The IPCC Glossary defines the pre-industrial period as "the multi-century period prior to the onset of large-scale industrial activity around 1750. The reference period 1850-1900 is used to approximate pre-industrial global mean surface temperature (GMST)". The 'modern' period is defined as 1995 to 2014 in AR6, while three future reference periods are used for presenting climate change projections, namely near-term (2021-2040), mid-term (2041-2060) and long-term (2081-2100), in both the AR6 WGI and WGII reports. Importantly, the historical rate of warming assessed by WGI in AR6 is different to that assessed in AR5 and SR1.5, due to methodological updates (see WGI Cross-Chapter Box 2.3 in Chapter 2 for details). This means that the 'modern' period is assessed as slightly warmer compared to 1850-1900 than it would have been with AR5-era methods. This also has implications for the projected timing of reaching policy-relevant levels of global warming, which need to be understood.

To explore and investigate climate futures, climate change projections are developed using sets of different input projections. These inputs consist of sets of projections of greenhouse gas emissions, aerosols or aerosol precursor emissions, land use change, and concentrations designed to facilitate evaluation of a large climate space and enable climate modelling experiments. For AR5 (and the CMIP5 climate model experiments), the input projections were referred to as Representative Concentration Pathways (RCPs). For AR6 (and the CMIP6 climate model experiments), new sets of inputs are used and referred to as SSP scenarios, where SSP refers to socioeconomic assumptions called the Shared Socio-Economic Pathways (SSPs).

The RCPs are a set of four trajectories that span a large radiative forcing range, defined as increased energy input at surface level in Watts per square meter, ranging from 2.6 W m^{-2} (RCP2.6) to 8.5 W m^{-2} (RCP8.5) by the end of the 21st century, with RCP4.5 and RCP6.0 as intermediate scenarios, and RCP2.6 a peak and decline scenario reaching 3 W m^{-2} before 2100. A range of emissions scenarios compatible with each specific RCP was also assessed in AR5 (Ciais et al., 2013).

A core set of five SSP scenarios, namely SSP1–1.9, SSP1–2.6, SSP2–4.5, SSP3–7.0, and SSP5–8.5, was selected in the AR6 WGI report with the objective to fill certain gaps identified in the RCPs (see AR6 WG1 Cross-Chapter Box 1.4 in Chapter 1). The first number in the label is the particular set of socioeconomic assumptions driving the emissions and other climate forcing inputs taken up by climate models and the second number is the radiative forcing level reached in 2100. WG1 Cross-Chapter Box 1.4 in Chapter 1 provides a comparison of this core set of SSP scenarios with scenarios used in previous reports, with SSP1–1.9 a low overshoot scenario consistent with limiting global average warming to 1.5°C, and SSP1-2.6 a scenario consistent with limiting warming to 2°C.

Also of importance to the impact literature and the WGII report are SSP-RCP combinations, that is, studies that employ climate outcomes based on RCPs and socio-economic assumptions based on SSPs. SSPs can be paired with a range of different RCPs because SSPs can be combined with mitigation policy assumptions to produce a range of emissions pathways. In addition to the SSPs, there are many other emissions pathways and societies consistent with any global mean temperature outcome. These represent uncertainty and broad ranges of possibilities that affect climate change exposure and vulnerability (Rose and and M. Scott, 2020; Rose and Scott, 2018). Furthermore, there are large uncertainties in translating emissions scenarios into concentration pathways due to uncertainties in climate-carbon cycle feedbacks (Booth et al., 2017; Jones et al., 2013).

The plausibility of emissions levels as high as the emissions scenario conventionally associated with the RCP8.5 and SSP5–8.5 concentration pathways has been called into question since AR5, as has the emissions pathway feasibility of the low scenarios (Hausfather and Peters, 2020; Rose and and M. Scott, 2020). However, these views are contested (Schwalm et al., 2020, for RCP8.5), and it is important to realise that emissions scenarios and concentration pathways are not the same thing, and higher concentration pathways such as RCP8.5 could arise from lower emissions scenarios if carbon cycle feedbacks are stronger than assumed in the integrated assessment models (IAMs) used to create the standard scenarios (Booth et al., 2017). In the majority of full-complexity Earth System Models, these feedbacks are stronger than in the IAMs (Jones et al., 2013), so the RCP8.5 concentration pathway cannot be ruled out purely through consideration of the economic aspects of emissions scenarios. Nonetheless, the likelihood of a climate outcome, and the overall distribution of climate outcomes, are a function of the emissions scenario's likelihood. Note that the original RCPs were created explicitly to facilitate a broad range of climate modelling experiments, with the expectation that other issues, such as socioeconomic uncertainty, could be subsequently explored (Moss et al., 2010).

An important feature of the AR6 cycle is a stronger emphasis on the use of future Global Warming Levels (GWLs) to support consistency and comparability across the three IPCC Working Groups' contributions to the AR6 and improve communication. The common range of GWLs relative to the 1850 to 1900 period, termed the "Tier 1" range by WGI, are 1.5, 2.0, 3.0, and 4.0°C. The use of GWLs assists in the comparison of climate states across climate change scenarios (projections) and in assessing the broader literature as well as for cross-chapter and cross-working group comparisons. They facilitate the integration of climate projections, impacts, adaptation challenges and mitigation challenges within and across the three WGs as there is a close connection between the level of global warming and climate change impacts. Of particular interest is the timing of when the "Tier 1" global warming levels are reached, relative to the period 1850–1900, under the five SSP x–y scenarios, as well as RCP scenarios . For climate change impacts and adaptation responses, linking GWLs to RCP and SSP climate projections using a climate information translation resource is of great relevance for the WGII contribution to AR6.

AR6 WGII Common Climate Dimensions

WGII's common climate dimensions include (1) a common range of GWLs from WGI, (2) common ranges for other climate variables, (3) information for translating climate variable levels to climate projections and vice versa. See Table Cross-Chapter Box CLIMATE.1 for global warming level ranges by time periods for RCP and SSP climate projections, and Table Cross-Chapter Box CLIMATE.2 for information regarding the timing for when GWLs are reached in climate projections. The common GWL range is based on WGI's "Tier 1" dimensions of integration range: 1.5, 2, 3, and 4°C. The first table illustrates the greater levels of projected global warming with higher emissions pathways, as well as the increasing uncertainty in the climate response over time for a given pathway. The second table illustrates significant uncertainty in the timing for passing GWL thresholds which can narrow for a given GWL the higher the emissions pathway. Finally, given the importance of geographic heterogeneity in projected changes in future climate, Table Cross-Chapter Box CLIMATE.3a and 3b are provided with ranges for select climate variables (temperature, precipitation, ocean) by global warming level and continent (or ocean biome). The ranges illustrate spatial heterogeneity in potential physical changes in levels and uncertainty that are relevant to assessing climate impacts risk. There is significantly more spatial heterogeneity than represented in the table that is relevant to local decision makers (see, for instance, WGI AR6 Interactive Atlas).

The common climate dimensions can be used as a dimension of integration for impacts studies in WGII, for example by providing a common framework for comparison of projected impacts for different studies (Figure Cross-Chapter Box CLIMATE.1). Moreover, GWL bands are needed in WGII to map the diverse temperature levels found across WGII's literature. The GWL's also facilitate integration with WGIII's global emissions projections categorisation by global mean temperature (WGIII Chapter 3).

Table Cross-Chapter Box CLIMATE.1: GWL ranges by time periods for CMIP5 (RCP) and CMIP6 (SSP) climate projections (20-yr averages). Temperature anomalies relative to 1850-1900. Full ranges for CMIP raw results (across all models and ensemble runs) and WGI AR6 assessed very likely (5-95%) ranges. *Sources: Hauser et al. (2019); WGI AR6 SPM,* Table *SPM.1*

Figure Cross-Chapter Box CLIMATE.1: Illustration of the use of Global Warming Levels (GWLs) as a dimension of integration for impact studies: projected changes in river flows in major basins at 4°C global warming from four different multi-model ensembles. Results are shown for projected flow changes direct from Earth System Models (ESMs) in CMIP5 and CMIP6, for the JULES (Joint UK Land Environment Simulator) land surface model driven by meteorological outputs of the HadGEM3 and EC-Earth model in the HELIX (High-End cLimate Impacts and eXtremes) ensemble (Betts et al., 2018; Koutroulis et al., 2019), and 9 hydrological models driven by a subset of 5 CMIP5 ESMs in the Inter-Sectoral Impacts Model Intercomparison Project (ISIMIP; Warszawski et al., 2014). Dots show results from individual models, blue for increased flows and red for decreased flows, black circles show the median for each ensemble, and black bars show the 95% confidence range in the median. See Chapter 4 Figure 4.11 for further details.

To contextualize reported impacts by warming level for the influence of other determinants of risk where appropriate and feasible (e.g., level of exposure/vulnerability, level of adaptation, time period), common time periods for the past and future are available to align with WGI's historical and projected time windows. Given differences in available literature, WGII chapters and CCPs contextualize impacts with respect to exposure, vulnerability and adaptation as they see fit and appropriate for their literature.

Common ranges for other "climate" variables, such as min/max temperature and regional climates, are available based on WGI projections, with feasible combinations with GWLs taken into consideration using the WGI Interactive Atlas. Climate information translation may have been necessary within chapters for mapping the WGII literature and assessments to the common climate dimensions. WGII's climate impacts literature is based primarily on climate projections circa AR5 and earlier or assumed temperature levels, though some recent impacts literature uses newer climate projections based on the CMIP6 exercise. Thus, it was important to be able to map climate variable levels to climate projections of different vintages and vice versa and adjust variables, when possible, to a common reference year. Note that WGII Chapters and CCPs only provide climate impact information for the common climate dimensions that their literature supports and only provide information for dimensions where there is sufficient evidence.

Interpretation of the update in projected time of reaching 1.5°C global warming from SR1.5 to AR6

In an assessment using multiple lines of evidence including models, observational constraints and improved understanding of climate sensitivity, WG1 project a central estimate of the 20-year average warming crossing the 1.5°C GWL in the early 2030s in all scenarios assessed except SSP5-8.5 (Lee et al., 2021). This is about ten years earlier than the midpoint of the likely range (2030–2052) assessed in the SR1.5, which assumed continuation of the observed warming rate reported at that time. However, this does not imply that the projected impacts of 1.5°C will be reached ten years earlier, because roughly half of the ten-year difference is a result of updating the diagnosed historical rate of warming due to methodological advances, new datasets and other improvements (Gulev et al., 2021). The other half of the ten-year difference arises because, for central estimates of climate sensitivity, most scenarios show stronger warming over the near term than was assessed as 'current' in SR1.5 (*medium confidence*).

The revised historical warming rate does not necessarily contribute to a change in timing of estimated impacts. It depends on how impacts are calculated relative to climate. Because the revised historical warming results in a redefinition of the 1.5°C GWL relative to the modern time period (1995-2014) rather than a different level of overall change (Figure Cross-Chapter Box CLIMATE.2), impacts assessed relative to the modern time period are unaffected. There are, in effect 'old' and 'new' definitions of the 1.5°C GWL with different levels of impacts, and the impacts assessed for the 'old' 1.5°C GWL now apply to a different level of global warming. However, the timing of impacts assessed relative to pre-industrial (e.g., aggregate economic impact estimates), are affected and we are closer to impact levels associated with 1.5°C and 2°C.

To illustrate with a worked example: in SR1.5, the historical warming between 1850-1900 and the modern period of 2006-2015 was assessed as 0.87°C, implying that the 1.5°C GWL would be accompanied by impacts associated with 0.63°C warming from the modern period. However, AR6 WG1 (Gulev et al., 2021) revised the assessment of warming between 1850-1900 and 2006-2015 to 0.94°C, implying that the 1.5°C GWL would be accompanied by a slightly lower level of impacts associated with only 0.56°C warming from the modern period. So, while the redefined 1.5°C GWL would be reached earlier, it would also be accompanied by a lower level of impacts (Figure Cross-Chapter Box CLIMATE.2). The impacts associated with the 'old' 1.5°C GWL would now be seen at 1.57°C global warming relative to 1850-1900, reached at the time of the 'old' 1.5°C GWL, if the same future level of warming were to be used as in SR1.5.

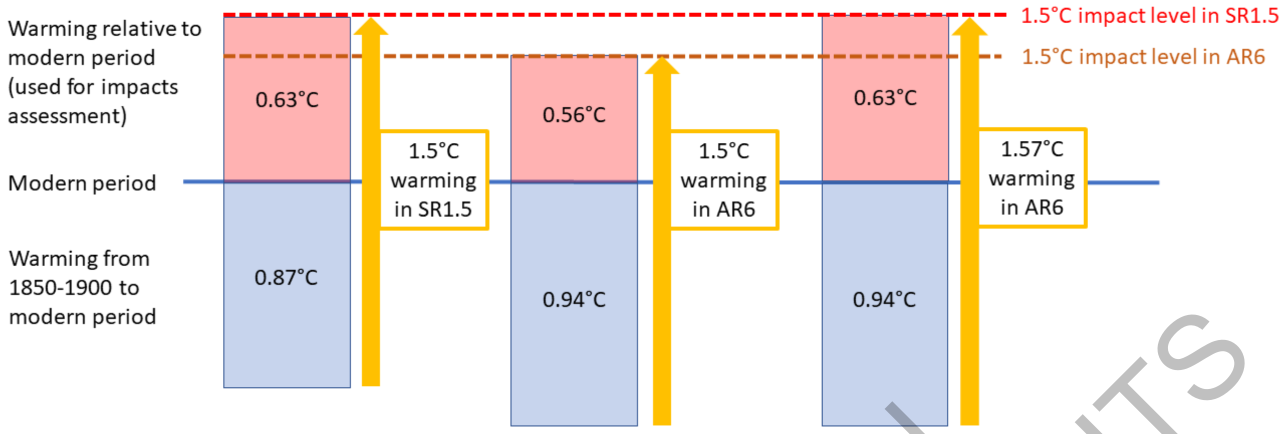

Figure Cross-Chapter Box CLIMATE.2: Definitions of the 1.5°C Global Warming Level (GWL) in SR1.5 and AR6 WG1. GWLs are defined relative to 1850-1900 but impacts at the GWL are typically assessed in association with warming relative to a modern period 1995-2014, which in SR1.5 was 2006-2015. Revised assessment of the historical warming between 1850-1900 and the modern period (0.87°C in SR1.5 to 0.94°C in AR6) has the effect of slightly reducing the warming between the modern period and the 1.5°C GWL (0.63°C in SR1.5 to 0.56°C in AR6), and the impacts at the GWL previously defined as 1.5°C in SR1.5 now occur at 1.57°C global warming with the AR6 definition. Warming values are central estimates. Heights of the bars are not to scale.

However, in addition to this redefinition of the historical warming rate, the assessed future warming in AR6 is also slightly faster than the continuation of reported recent warming used in SR1.5. This means that both the 'old' and 'new' 1.5°C GWLs are projected to be reached earlier than they would have been using the SR1.5 method. This and the revised historical warming diagnosis contribute approximately equally to the assessment of 1.5°C global warming being reached about ten years earlier than projected in SR1.5.

Central estimates of impacts associated with a specifically defined 1.5°C GWL could therefore be considered to be projected to be reached approximately 5 years earlier than implied by SR1.5. However, uncertainties in regional climate responses at a given GWL are large (Table Cross-Chapter Box CLIMATE.3a) and natural climate variability occurs in parallel with ongoing warming, so the potential for impacts higher than central estimates could be a more urgent consideration for risk assessments and adaptation planning than the earlier projected timing of reaching 1.5°C (*high confidence*). It should also be noted that individual years may exceed 1.5°C above 1850-1900 sooner, but this is not the same as exceedance of the 1.5°C GWL which refers to the 20-year mean.

[END CROSS-CHAPTER BOX CLIMATE HERE]

1.3 Understanding and Evaluating Climate Risks

Understanding of climate change has advanced in important ways that shape the AR6 assessment. This section describes advances in the understanding of the complex nature of climate change risks, the deep integration of social sciences, and increased utilization of Indigenous knowledge and local knowledge. These multifaceted dimensions of understanding climate change and evaluating risks are introduced here.

1.3.1 Nature of Climate Risk

Since AR5, understanding of the nature of climate risk has advanced substantially. The AR6 assesses the serious, complex, and cascading climate risks unfolding across sectors and regions. These risks are shaped by many societal factors including cultural norms and social practice, socioeconomic development, underlying physical and social vulnerability, and societal responses themselves (Section 1.2.1.1). Throughout, there is increased attention to the important role of different forms of knowledge, especially Indigenous knowledge and local knowledge, in the understanding and the management of the changing climate.

1.3.1.1 The Nature of Climate Risk as Assessed in this Report

Greater understanding of climate-related risks is emerging; however, there are important shortcomings for the information in some regions and sectors and for developing versus developed countries. These risks assume significance in interaction with the cultures, values, ethics, identities, experiences, and knowledge systems of affected communities and societies, as well as their governance, finances, capabilities, and resources. The key risk assessment in the IPCC AR5 informed the long-term temperature goal in the 2015 Paris Agreement—limiting the increase in global mean temperature to well below 2°C and pursuing efforts towards limiting warming to 1.5°C (Oppenheimer et al., 2014; Pachauri et al., 2014). The IPCC Special Report on Global Warming of 1.5°C, responding to an invitation by UNFCCC, used new scientific information to provide a specific risk assessment associated with the ambitious warming levels targeted by the Paris Agreement (Hoegh-Guldberg et al., 2019), and the Special Reports on Oceans and Land further advanced the methods of transparent risk assessment (Zommers et al., 2020). The current assessment expands significantly from the previous reports, aiming to inform and advance understanding of the following core themes: (1) the ways changes in vulnerability and exposure modulate risks of climate change impacts and risk complexity in addition to warming; (2) the knowledge basis relevant to continued refinement of temperature goals; (3) the effectiveness of adaptation solutions; (4) the management of risks at higher levels of warming, should ambitious climate change mitigation be unsuccessful, including limits to adaptation; and (5) the benefits of climate change mitigation and emissions reductions (Section 16.1).

This report evaluates key risks—potentially severe risks—meriting society's full attention globally and regionally across sectors, in order to inform judgments about dangerous anthropogenic interference with the climate system (Mach et al., 2016; Oppenheimer et al., 2014; see also Sections 16.1.2 and 16.4; WGI AR6 Section 1.2.4.1). As described detail in Chapter 16, evaluation of key risks is based on expert judgment applied to all relevant lines of evidence, with attention to the role of societal values in determining the importance of a risk. Specific criteria considered relate to the magnitude of adverse consequences, including the potential for irreversibility, thresholds, or cascading effects; the likelihood of adverse consequences; the timing of the risk; and the ability to respond to the risk (Section 16.5.1).

The key risk assessment conveys increasing urgency given the growing visibility of climate change impacts in the current world (Sections 1.1 and 16.1). Representative key risks emerging across sectors and regions include risks to coastal socio-ecological systems and terrestrial and ocean ecosystems, risks associated with critical infrastructure, networks, and services; risks to living standards and human health; risks to food and water security; and risks to peace and migration (Section 16.5). Compared to the AR5, the emphasis on human dimensions of key climate-related risks has continued and increased, for instance the potentially severe impacts for cultural heritage (IPCC, 2014c; Pachauri et al., 2014; see also Section 16.4). These human dimensions are essential for understanding vulnerability, impacts, and risks central to ensuring human well-being, human security, sustainable development, and poverty reduction in a changing climate.

To encompass the nature of climate risk, IPCC assessment since the Third Assessment Report has used five overarching domains, named "reasons for concern", to assess increasing risk for societies and ecosystems under climate change (IPCC, 2014b; O'Neill et al., 2017; see also Section 16.5; WGI AR6 Section 1.2.4.1). The reasons-for-concern approach has enabled evidence to combine with expert judgment, in order to provide a holistic assessment across multiple lines of evidence (O'Neill et al., 2017). The approach also respects the uncertainties inherent to climate risk and highlights the ways in which values are relevant in connecting scientific knowledge to societal decision-making and risk management. The different reasons for concern underscore that there is no single metric that can reflect all dimensions of climate-related risk and the diversity of consequences for lives and livelihoods, health and well-being, economic and sociocultural assets, infrastructure, and ecosystems (Mach and Field, 2017; see also Section 1.4.1.2).

The AR6 Reasons for Concern framework enables integration across key risks and representative key risks, including how risks vary with the magnitude of global warming, socioeconomic development pathways, and levels of adaptation (Section 16.6). Risk levels are determined through a formal elicitation approach for both representative key risks and reasons for concern, following the authors' assessment of the literature. The reasons for concern consider *unique and threatened systems* (RFC1), such as coral reefs or Arctic Sea ice systems that have especially high vulnerability and low capacity to adapt. They also include the role of *extreme weather events* (RFC2), such as heat waves, heavy rain, drought, coastal flooding, or wildfires. The reasons for concern address both the *distributional* and the *aggregate impacts* of climate change (RFC3, RFC4), including the unfairness factor for populations that have contributed little in terms of historic emissions but that are disproportionately vulnerable to the impacts of a changing climate. The final reason for concern relates to *large-scale singular events*, nonlinearities, and tipping points (RFC5), including ice sheet collapse and ecosystem regime shifts.

1.3.1.2 The Complexities of Climate Risk

The AR6 assessment incorporates the inherently complex nature of climate risk, vulnerability, exposure, and impacts, which includes feedbacks, cascades, non-linear behaviour, and the potential for surprise (Figure 1.3, 1.4). Many different overlapping and complementary terms and methods are used to evaluate and understand complex climate risk relevant to this report, such as aggregated, compounding, or cascading risks, all of which are considered here as relevant to complex climate risk (Pescaroli and Alexander, 2018; Simpson, In review).

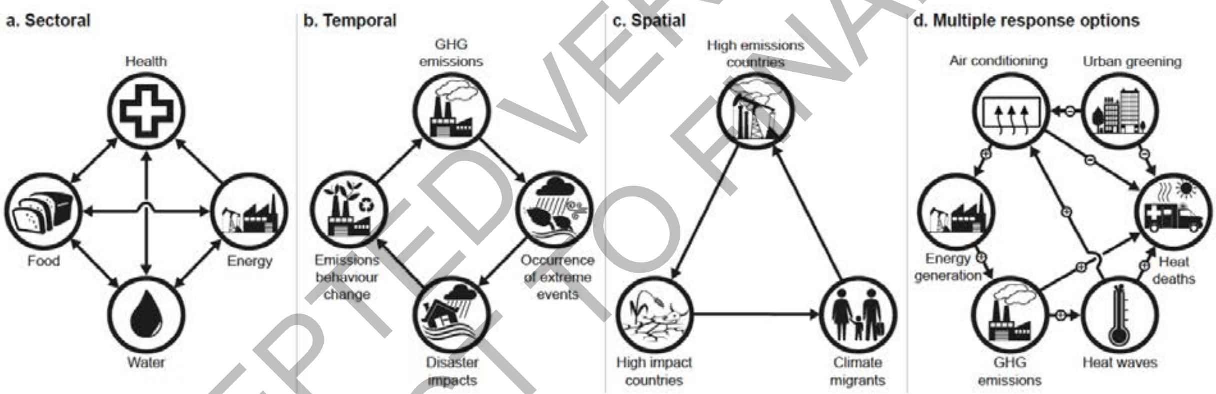

Figure 1.3: Different interactions can decrease or increase climate-related risks. Key examples include interactions (a) among sectors, (b) through time, (c) across regions, or (d) between impacts and responses. The specific interactions indicated within each panel of this figure are illustrative, not comprehensive or indicative of relative importance. Source: (Simpson, In review)

The dynamic nature of risk and its determinants is one important dimension of complexity. The risk of climate change impacts can be usefully understood as resulting from dynamic interactions among climate-related hazards, the exposure and vulnerability of affected human and ecological systems, and also responses (see AR6 Glossary; Section 1.2.1; WGI AR6 Cross-Chapter Box 2 in Chapter 1; Oppenheimer et al., 2014). The determinants of risk all can vary and change through space and time in response to socioeconomic development and decision-making (Figures 1.4 and 1.5, Section 16.1). Hazards are affected by current and future changes in climate, including altered climate variability and shifts in frequency and intensity of extreme events (WGI AR6 Chapter 12). Such hazards can be sudden, e.g., a heat wave or heavy rain event, or slower onset, e.g., land loss, degradation, and erosion linked to multiple climate hazards compounding. The severity of climate change impacts will depend strongly on vulnerability, which is also dynamic and includes the sensitivity and adaptive capacity of affected human and ecological systems (Ford et al., 2018; Jurgilevich et al., 2017; McDowell et al., 2016; Viner et al., 2020). As a result, risks vary at fine scale across communities and societies and also among people within societies, for example dependent on intersecting inequalities and context-specific factors such as culture, gender, religion, ability and disability, or ethnicity (Carr and Thompson, 2014; Jones and Boyd, 2011; Kuruppu, 2009; also Section 16.1.4). The dynamic social distribution of impacts is the subject of increasing attention within climate assessment and responses), including the role of adaptation, iterative risk management, and climate-resilient sustainable development (Section 16.1).

Another core area of complexity in climate risk is the behaviour of complex systems, which includes multiple stressors unfolding together, cascading or compounding interactions, and non-linear responses and the potential for surprises (Clarke et al., 2018; Kopp et al., 2017; Yokohata et al., 2019). Risks and responses, including their determinants, can all interact dynamically in shaping the complexity of climate risk (Figure 1.4). The combined effects of multiple stressors or compound hazards and risks are unlikely to be assessed through simple addition of the independent effects and instead require system approaches to understanding risk. While some components may cancel out each other, others may non-linearly increase risk. Non-linearities can result from abrupt climate changes, tipping points or thresholds in responses, alternative stable states, low-probability/high-consequence outcomes, or events that cannot be predicted based on current understanding (WGI AR6 Section 1.4.4.3).

The nature of climate risk also involves risks from responses themselves (Figure 1.4). The risks of climate change responses include the possibility of responses not achieving their intended objectives or having trade-offs or adverse side effects for other societal objectives (Annex II: Glossary; Section 16.1). In particular, human responses may create novel hazards and unexpected side effects and entail opportunity costs and path dependencies (Boonstra, 2016). Such feedback loops can unfold at local and global scales, including large-scale interactions among climate, ecological, and human systems with human behaviour and decision-making affecting such interactions. Response risks can originate from uncertainty in implementation, maladaptation, action effectiveness, technology development or adoption, or transitions in systems (see Sections 1.4 and 1.5). Typical risks may be related to regulation, litigation, competition, socio-politics, or reputation. Interactions across responses can importantly involve co-benefits for other objectives, such as for human health and well-being which may be improved from both reduced air pollution (e.g., WGI Chapter 6, WGIII) and enhanced adaptation to climate change. The nature of risk also entails residual impacts that will occur even with ambitious societal responses, given limits to adaptation at sectoral and regional levels (Section 1.4, Sections 16.1 and 16.4). In some cases, the losses will be irreversible.

Due to these complexities, the challenge of assessing risks of climate change is not well bounded, will be framed differently by individuals and groups, involves large and deep uncertainties, and will have unclear solutions and pathways to solutions (Renn, 2008; Rittel and Webber, 1973; see also Sections 1.5.2 and 17.2.1). Challenges also include the degree to which time is running out, there is no central authority, those seeking the solutions are also causing the problem, and the present is favoured over the future (Sun and Yang, 2016; see also Section 17.2.1). Both the needs for and the limits to adaptation responses fundamentally depend on progress achieved in reducing greenhouse gas emissions and limiting the magnitude of climate change that occurs, interlinked with socioeconomic development trajectories and the many social and political factors shaping climate risks and responses.

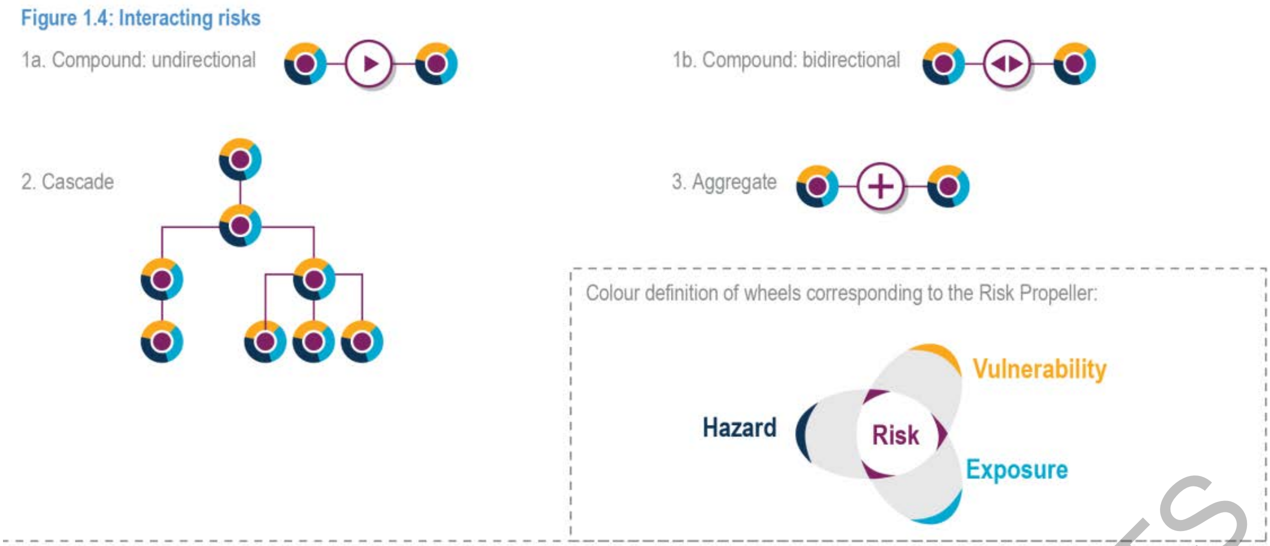

Figure 1.4: Increasingly complex climate-related risks. Risk results from interactions among the determinants of risk—hazard, vulnerability, and exposure, shaped by responses—which can interact in complex ways. Different risks and responses can compound (e.g., often linked to compounding hazards; 1a and 1b), cascade (e.g., with one event triggering another; 2), and aggregate (e.g., with independent determinants of risks co-occurring; 3). This complex nature of risk is central in the AR6 assessment. Figure adapted from Simpson et al., 2021.

a)

Figure 1.5: Risk in IPCC assessment through time. (a) An explicit risk framing emerged in the IPCC SREX and WGII AR5. (b) In the current assessment, the role of responses in modulating the determinants of risk is a new emphasis (the "wings" of the hazard, vulnerability, and exposure "propellers" represents the ways in which responses modulate each of these risk determinants). (c) As the risk assessment spans working groups, the differential role of risk determinants for risk related to impacts, adaptation, and vulnerability versus risk related to mitigation becomes an increasingly important feature of climate risk assessment as well as management.

1.3.2 Assessing, Evaluating, and Understanding Climate Impacts and Risks

Multiple, diverse sources of information underlie our understanding of climate risks and response, including climate change science, diverse social sciences, and Indigenous knowledge and local knowledge.

1.3.2.1 Detection and Attribution of Climate Change and Its Impacts

Anthropogenic climate change is unequivocal and ongoing. The detection of specific changes in the climate and their diverse impacts on people and nature is advancing, with robust attribution of climate change to greenhouse gas emissions as well as to other contributing factors (e.g., socio-economic development, land-use change). In the AR6, advances include increasing ability to link individual extreme weather and climate events to emissions of greenhouse gases, increasing identification of impacts for societies and economies, and strong linkages in the attribution methods across working groups (Cross-Working Group Box: ATTRIBUTION in Chapter 1).

[START CROSS-WORKING GROUP BOX: ATTRIBUTION HERE]

Cross-Working Group Box: ATTRIBUTION: Attribution in the IPCC Sixth Assessment Report

Authors: Pandora Hope (Australia), Wolfgang Cramer (France/Germany), Maarten van Aalst (Netherlands), Greg Flato (Canada), Katja Frieler (Germany), Nathan Gillett (Canada/United Kingdom), Christian Huggel (Switzerland), Jan Minx (Germany), Friederike Otto (United Kingdom /Germany), Camille Parmesan (France/ United Kingdom /USA), Joeri Rogelj (United Kingdom /Belgium), Maisa Rojas (Chile), Sonia I. Seneviratne (Switzerland), Aimee Slangen (Netherlands), Daithi Stone (New Zealand), Laurent Terray (France), Robert Vautard (France), Xuebin Zhang (Canada)

Introduction

Changes in the climate system are becoming increasingly apparent, as are the climate-related impacts on natural and human systems. Attribution is the process of evaluating the contribution of one or more causal factors to such observed changes or events. Typical questions addressed by the IPCC are for example: 'To what degree is an observed change in global temperature induced by anthropogenic greenhouse gas and aerosol concentration changes or influenced by natural variability?' or 'What is the contribution of climate change to observed changes in crop yields that are also influenced by changes in agricultural management?' Changes in the occurrence and intensity of extreme events can also be attributed, addressing questions such as: 'Have human greenhouse gas emissions increased the likelihood or intensity of an observed heat wave?'

This Cross-Working Group Box briefly describes why attribution studies are important. It also describes some new developments in the methods used and provides recommendations for interpretation.

Attribution studies serve to evaluate and communicate linkages associated with climate change, for example: between the human-induced increase in greenhouse gas concentrations and the observed increase in air temperature or extreme weather events (WGI Chapters 3, 10 and 11); or between observed changes in climate and changing species distributions and food production (e.g., Verschuur et al., 2021; WGII Chapter 2 and others; summarised in Chapter 16) or between climate change mitigation policies and atmospheric greenhouse gas concentrations (WGI Chapter 5; WGIII Chapter 14). As such, they support numerous statements made by the IPCC (IPCC, 2013; IPCC, 2014c; WGI Section 1.3; Appendix 1A) (IPCC, 2013b, 2014b; WGI Chapter 1, Section 1.3, Appendix 1A).

Attribution assessments can also serve to monitor mitigation and assess the efficacy of applied climate protection policies (e.g., Banerjee et al., 2020; Nauels et al., 2019; WGI Section 4.6.3)), inform and constrain projections (Gillett et al., 2021; Ribes et al., 2021; WGI Section 4.2.3) or inform the loss and damages estimates and potential climate litigation cases by estimating the costs of climate change (Frame et al., 2020; Huggel et al., 2015; Marjanac et al., 2017). These findings can thus inform mitigation decisions as well as risk management and adaptation planning (e.g., Climate & Development Knowledge Network, 2017).

Steps towards an attribution assessment

The unambiguous framing of what is being attributed to what is a crucial first step for an assessment (Easterling et al., 2016; Hansen et al., 2016; Stone et al., 2021), followed by the identification of the possible and plausible drivers of change and the development of a hypothesis or theory for the linkage (see Figure ATTRIBUTION.1). The next step is to clearly define the indicators of the observed change or event and note the quality of the observations. There has been significant progress in the compilation of fragmented and distributed observational data, broadening and deepening the data basis for attribution research (Cohen et al., 2018; Poloczanska et al., 2013; Ray et al., 2015; WGI Section 1.5). The quality of the observational record of drivers should also be considered (e.g., volcanic eruptions: WGI Chapter 2, Section 2.2.2). Impacted systems also change in the absence of climate change; this baseline and its associated modifiers such as agricultural developments or population growth need to be considered, alongside the exposure and vulnerability of people depending on these systems.

There are many attribution approaches, and several methods are detailed below. In physical and biological systems, attribution often builds on the understanding of the mechanisms behind the observed changes and numerical models are used, while in human systems other methods of evidence-building are employed. Confidence in the attribution can be increased if more than one approach is used and the model is evaluated as fit-for-purpose (Hegerl et al., 2010; Otto et al., 2020a; Philip et al., 2020; Vautard et al., 2019; WGI Section 1.5). Finally, appropriate communication of the attribution assessment and the accompanying confidence in the result (e.g., Lewis et al., 2019).

Attribution methods

Attribution of changes in atmospheric greenhouse gas concentrations to anthropogenic activity

AR6 WGI Chapter 5 presents multiple lines of evidence that unequivocally establish the dominant role of human activities in the growth of atmospheric CO_2, including through analysing changes in atmospheric carbon isotope ratios and the atmospheric O_2-N_2 ratio (WGI Section 5.2.1.1). Decomposition approaches can be used to attribute emissions underlying those changes to various drivers such as population, energy efficiency, consumption or carbon intensity (Hoekstra and van den Bergh, 2003; Raupach et al., 2007; Rosa and Dietz, 2012). Combined with attribution of their climate outcomes, the attribution of the sources of greenhouse gas emissions can inform the attribution of anthropogenic climate change to specific countries or actors (Matthews, 2016; Nauels et al., 2019; Otto et al., 2017; Skeie et al., 2017), and in turn inform discussions on fairness and burden sharing (WGIII Chapter 14).

Attribution of observed climate change to anthropogenic forcing

Changes in large-scale climate variables (e.g., global mean temperature) have been reliably attributed to anthropogenic and natural forcings (e.g., Bindoff and et al., 2014; Hegerl et al., 2010; WGI Section 1.3.4). The most established method is to identify the 'fingerprint' of the expected space-time response to a particular climate forcing agent such as the concentration of anthropogenically induced greenhouse gases or aerosols, or natural variation of solar radiation. This technique disentangles the contribution of individual forcing agents to an observed change (e.g., Gillett et al., 2021). New statistical approaches have been applied to better account for internal climate variability and the uncertainties in models and observations (e.g., Naveau et al., 2018; Santer et al., 2019; WGI Section 3.2). There are many other approaches, for example, global mean sea-level change has been attributed to anthropogenic climate forcing by attributing the individual contributions from, for example, glacier melt or thermal expansion, while also examining which aspects of the observed change are inconsistent with internal variability (WGI Section 3.5.2 and WGI Section 9.6.1.4).

Specific regional conditions and responses may simplify or complicate attribution on those scales. For example, some human forcings, such as regional land use change or aerosols, may enhance or reduce regional signals of change (Boé et al., 2020; Lejeune et al., 2018; Thiery et al., 2020; Undorf et al., 2018; see also WGI Sections 10.4.2, 11.1.6, and 11.2.2). In general, regional climate variations are larger than the global mean climate, adding additional uncertainty to attribution (e.g., in regional sea-level change, WGI Section 9.6.1). These statistical limitations may be reduced by 'process-based attribution', focusing on the physical processes known to influence the response to external forcing and internal variability (WGI Section 10.4.2).

Attribution of weather and climate events to anthropogenic forcing

New methods have emerged since AR5 to attribute the change in likelihood or characteristics of weather or climate events or classes of events to underlying drivers (Jézéquel et al., 2018; National Academies of Sciences, 2016; Stott et al., 2016; Wang et al., 2020; Wehner et al., 2019; WGI Sections 10.4.1 and 11.2.2). Typically, historical changes, simulated under observed forcings, are compared to a counterfactual climate simulated in the absence of anthropogenic forcing. Another approach examines facets of the weather and thermodynamic status of an event through process-based attribution (Grose et al., 2020; Hauser et al., 2016; Shepherd et al., 2018; WGI Section 10.4.1 and Chapter 11). Events where attributable human influences have been found include hot and cold temperature extremes (including some with wide-spread impacts), heavy precipitation, and certain types of droughts and tropical cyclones (e.g., Herring et al., 2021; Vogel et al., 2019; WGI Section 11.9). Event attribution techniques have sometimes been extended to 'end-to-end' assessments from climate forcing to the impacts of events on natural or human systems (Otto et al., 2017; examples in WGII Table 16.1, SI of WGII Chapter 16, Section 16.2).

Attribution of observed changes in natural or human systems to climate-related drivers

The attribution of observed changes to climate-related drivers across a diverse set of sectors, regions and systems is part of each chapter in the WGII contribution to the AR6 and is synthesised in WGII Chapter 16 (Section 16.2). The number of attribution studies on climate change impacts has grown substantially since AR5, generally leading to higher confidence levels in attributing the causes of specific impacts. New studies include the attribution of changes in socio-economic indicators such as economic damages due to river floods (e.g., Sauer et al., 2021; Schaller et al., 2016), the occurrence of heat related human mortality (e.g., Sera et al., 2020; Vicedo-Cabrera et al., 2018), or economic inequality (e.g., Diffenbaugh and Burke, 2019).

Impact attribution covers a diverse set of qualitative and quantitative approaches, building on experimental approaches, observations from remote sensing, long-term in situ observations, and monitoring efforts, teamed with local knowledge, process understanding and empirical or dynamical modelling (WGII Section 16.2; Cramer et al., 2014; Stone et al., 2013). The attribution of a change in a natural or human system (e.g., wild species, natural ecosystems, crop yields, economic development, infrastructure or human health) to changes in climate-related systems (i.e., climate, and ocean acidification, permafrost thawing or sea-level rise) requires accounting for other potential drivers of change, such as technological and economic changes in agriculture affecting crop production (Butler et al., 2018; Hochman et al., 2017), changes in human population patterns and vulnerability affecting flood or wildfire induced damages (Huggel et al., 2015; Sauer et al., 2021), or habitat loss driving declines in wild species (IPBES, 2019b). These drivers are accounted for by estimating a baseline condition that would exist in the absence of climate change. The baseline might be stationary and be approximated by observations from the past, or it may change over time and be simulated by statistical or process-based impact models (Cramer et al., 2014; WGII Section 16.2). Assessment of multiple independent lines of evidence, taken together, can provide rigorous attribution when more quantitative approaches are not available (Parmesan et al., 2013). These include palaeodata, physiological and ecological experiments, natural 'experiments' from very long-term datasets indicating consistent responses to the same climate trend/event, and 'fingerprints' in species' responses that are uniquely expected from climate change (e.g. poleward range boundaries expanding and equatorial range boundaries contracting in a coherent pattern world-wide, Parmesan and Yohe, 2003). Meta-analyses of species/ecosystem responses, when conducted with wide geographic coverage, also provide a globally coherent signal of climate change at an appropriate scale for attribution to anthropogenic climate change (Parmesan et al., 2013; Parmesan and Yohe, 2003).

Impact attribution does not always involve attribution to anthropogenic climate forcing. However, a growing number of studies include this aspect (e.g., Diffenbaugh and Burke, 2019 for the attribution of economic inequality between countries; Frame et al., 2020 for the attribution of damages induced by Hurricane Harvey; or Schaller et al., 2016for flood damages).

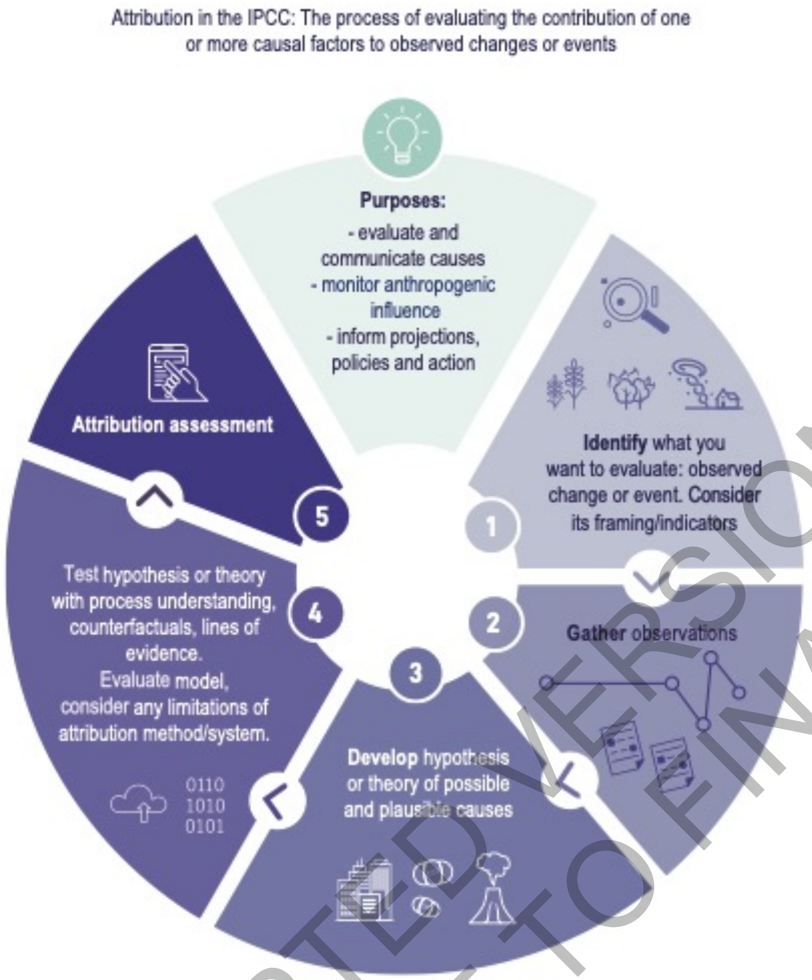

Figure Cross-Working Group Box: ATTRIBUTION.1: Schematic of the steps to develop an attribution assessment, and the purposes of such assessments. Methods and systems used to test the attribution hypothesis or theory include model-based fingerprinting, other model-based methods, evidence-based fingerprinting, process-based approaches, empirical or decomposition methods and the use of multiple lines of evidence. Many of the methods are based on the comparison of the observed state of a system to a hypothetical counterfactual world that does not include the driver of interest to help estimate the causes of the observed response.

[END CROSS-WORKING GROUP BOX: ATTRIBUTION HERE]

Impacts occurring today can be put into context through understanding of long-term changes on Earth, introduced in the Cross-Chapter Box PALEO (see below). Climate has always varied and changed in the past, and this change often caused substantial ecological, evolutionary and socio-economic impacts. Adaptation of ecosystems and societies occurred through responses as diverse as migration to mass extinction. Humankind is at the verge of leaving the Holocene climatic envelope, in which all human achievement since the advent of agriculture has occurred. In some systems, the changes and losses will be irreversible.

[START CROSS-CHAPTER BOX PALEO HERE]

Cross-Chapter Box PALEO: Vulnerability and Adaptation to Past Climate Changes

Authors: Wolfgang Kiessling (Germany, Chapter 3, Cross-Chapter Paper 1), Timothy A. Kohler (USA, Chapter 14), Wolfgang Cramer (France, Chapter 1, Cross-Chapter Paper 4), Gusti Anshari (Indonesia, Chapter 2), Jo Skeie Hermansen (Norway, CA Chapter 1), Darrell S. Kaufman (USA, WG 1, Chapter 2), Guy Midgley (South Africa, Chapter 16), Nussaïbah Raja (Mauritius, CA Chapter 3), Daniela N. Schmidt (UK/Germany, Chapter 13), Nils Chr. Stenseth (Norway, Chapter 1), Sukumar Raman (India, Chapter 1)

Understanding how Earth's biota have responded to past climate dynamics is essential to understanding current and future climate-related risks, as well as the adaptive capacity and vulnerabilities of ecosystems and the human livelihoods depending on them. Here we assess climate impacts on long geological time scales (Figure PALEO.1), as well as for the last 70 kyr of *Homo sapiens*' existence (Figure PALEO.2). Climate responses of natural and human systems are intertwined through the physiological limits of wild animals, livestock, plants and humans, subject to a slow evolutionary dynamic (Pörtner, 2021; Sections 2.6.1 and 3.3).

Climate has always changed, often with severe effects on nature, including species loss

Observations provided by the historical, archaeological, and paleontological records, together with paleoclimatic data, demonstrate that climatic variability has high potential to affect biodiversity and human society (*high confidence*). The evolution of the Earth's biota has been punctuated by global biodiversity crises often triggered by rapid warming (*high confidence*) (Benton, 2018; Figure PALEO.1; Bond and Grasby, 2017; Foster et al., 2018). These so-called hyperthermal events were marked by rapid warming of >1°C, which coincided with global disturbances of the carbon and water cycles, and by reduced oxygen and pH in seawater (Clapham and Renne, 2019; Foster et al., 2018). Magnitudes of global temperature shifts in hyperthermal events were sometimes greater than those predicted for the current century but extended over longer periods of time. Rates inferred from paleo records that are coarsely resolved are inevitably lower than those from direct observations during recent decades, and caution must be exercised when describing the rate of recent temperature changes as unprecedented (Kemp et al., 2015). Mass extinctions, each with greater than 70% marine species extinctions, occurred when the magnitude of temperature change exceeded 5.2°C (Song et al., 2021), albeit species extinctions occurred at lower magnitudes of warming (*medium confidence*).

Adaptation options to rapid climate change are limited

Responses of biota to rapid climate change have included range shifts (*very high confidence*), phenotypic plasticity (*high confidence*), evolutionary adaptation (*medium confidence*), and species extinctions, including mass extinctions (*very high confidence*). While knowledge about the relative roles of these processes in promoting survival during times of climate change is still limited (Nogués-Bravo et al., 2018), they have influenced the evolutionary trajectories of species and entire ecosystems (*high confidence*), and also the course of human history (*medium confidence*). The combined ecological and evolutionary responses to ancient rapid warming events ranged from extinction of 81% of marine animal species and 70% of terrestrial tetrapod species on land at the end of the Permian period (~ 252 million years ago, Ma) (Smith and Botha, 2005; Stanley, 2016) to low rates of species extinctions but biome- and range-shifts on land and in the ocean at the Palaeocene-Eocene Thermal Maximum (PETM, ~ 56 Ma) (Figure PALEO.1; Fraser and Lyons, 2020; Huurdeman et al., 2021; Ivany et al., 2018). Temperature and deoxygenation were key drivers of past biotic responses in the oceans (Gibbs et al., 2016; Section 3.3; Penn et al., 2018) (*high confidence*), whereas on land the interplay between temperature and precipitation is less well established in ancient hyperthermals (Frank et al., 2021) (*medium confidence*). Climate-driven extinction risk increased by up to 40% when a short-term climate change added to a long-term trend in the same direction, for example when a long-term warming trend was followed by rapid warming (Mathes et al., 2021).

Organismic traits associated with extinctions during ancient climate changes help identify present-day vulnerabilities and conservation priorities (Barnosky et al., 2017; Calosi et al., 2019; Reddin et al., 2020; Chapters 2 and 3; Cross-Chapter Paper 1). Marine invertebrates and fishes are at greater extinction risk in response to warming than terrestrial ones because of reduced availability of thermal refugia in the sea (Pinsky et al., 2019) (*high confidence*). Terrestrial plants showed reduced extinction during past rapid warming compared to animals (*high confidence*), although they readily adjusted their ranges and reorganized vegetation types (Heimhofer et al., 2018; Huurdeman et al., 2021; Lindström, 2016; Slater et al., 2019; Yu et al., 2015).

Population range shifts including migrations are common adaptations to climate changes across multiple time scales and ecological systems in the past and in response to current warming (*high confidence*). Poleward expansions and retractions (Fordham et al., 2020; Reddin et al., 2018; Williams et al., 2018) as well as migration upslope and downslope in response to warming and cooling were common adaptations (Iglesias et al., 2018; Ortega-Rosas et al., 2008). During warming periods, diversity loss was common near the equator (*medium confidence*)(Kiessling et al., 2012; Kröger, 2017; Yasuhara et al., 2020) while diversity gains and forest expansion occurred in high latitudes (Brovkin et al., 2021). Comparison of contemporary shells and skeletons with historical collections in museums (Barnes et al., 2011) and the analysis of skeletons of long-lived organisms (Cantin et al., 2010) indicate significant climate-induced change in organismic growth rates today (*high agreement, medium confidence*).

Humankind has responded to regional climate variability within a narrow Holocene climatic envelope

Early human evolution (beginning ~2.1 Ma) occurred in a highly variable climate characterized by glacial-interglacial cycles. This variability may have favoured key hominin adaptations such as bipedality, increased brain size, complex sociality, and more diverse tools (Potts, 1998; Potts et al., 2020) (*medium confidence*), but extinctions of five species of *Homo* have also been attributed partly to climate change (Raia et al., 2020) (*low confidence*). The "out-of-Africa" dispersal of anatomically modern humans may have been driven by climate variability (Tierney et al., 2017; Timmermann and Friedrich, 2016) (*medium confidence, low agreement*). Most late Pleistocene megafaunal extinctions are attributed to direct and indirect human impacts (Sandom et al., 2014), although some were likely accelerated by climate change (Carotenuto et al., 2018; Saltré et al., 2019; Wan and Zhang, 2017; Westaway et al., 2017) (*low confidence*).

The emergence of agriculture (~10.2 ka) in SW Asia was associated with stable (within ± 1°C global mean annual on multi-century time scale; *WGI Chapter 2*) warm and moist conditions (Palmisano et al., 2021; Richerson et al., 2001; Rohling et al., 2019). Variability in resource availability and agricultural production, entrained by climatic variability, is implicated in the disruption and decline of numerous past human societies (*medium confidence*) (Cookson et al., 2019; d'Alpoim Guedes and Bocinsky, 2018; Jones, 2019; Park et al., 2019). These crises are partially caused by regional climate anomalies including Holocene "Rapid Climate Change Events" (Rohling et al., 2019) not visible in the globally averaged conditions shown in Fig. Palaeo.2. Such anomalies affected human population size (Clark et al., 2019; Kuil et al., 2019; Riris and Arroyo-Kalin, 2019), health (Campbell and Ludlow, 2020), social stability/conflict (Büntgen et al., 2011; Kohler et al., 2014), and triggered migrations (Chiotis, 2018; D'Andrea et al., 2011; Pei et al., 2018; Schwindt et al., 2016) or retarded them (Betti et al., 2020; FAQ 14.2). Populations have also been impacted by sea-level change in coastal areas (Turney and Brown, 2007; Cross-Chapter Box SLR in Chapter 3).

Evidence for widespread droughts ~4.2 ka lasting for several centuries in some regions has been tentatively linked to declines of the Akkadian Empire (Carolin et al., 2019; Weiss, 2017), the Indus Valley (Giosan et al., 2018; Sengupta et al., 2020) and the Egyptian Old Kingdom and Yangtze River Valley (Ran and Chen, 2019). Deteriorating climates often exacerbate accumulating weaknesses in social systems to which population growth and urban expansion contribute (Knapp and Manning, 2016; Lawrence et al., 2021; Scheffer et al., 2021). The rather narrow climatic niche favoured by human societies over the last six thousand years is poised to move on the Earth's surface at speeds unprecedented in this time span (IPCC, 2021), with consequences for human well-being and migration that could be profound under high-emission scenarios (Xu et al., 2020). This will overturn the long-lasting stability of interactions between humans and domesticated plants and animals as well as challenge the habitability for humans in several world regions (Horton et al., 2021) (*medium confidence*).

Climate change destroys unique natural archives and important cultural heritage sites

Climate change not only impacts past ecosystems and societies but also the remains they have left. The progressive loss of archaeological and historical sites and natural archives of paleo environmental data WGI Chapter 2 constitutes often-overlooked impacts of climate change (Anderson et al., 2017; Climate Change

Cultural Heritage Working Group International, 2019; Cross-Chapter Box SLR in Chapter 3; Hollesen et al., 2018). These archives include peat bogs and coastal archives lost to sea-level rise, droughts and fires, degradation through permafrost thaw, and dissolution. The ancient cultural diversity documented by such sites is an important resource for future adaptation (Burke et al., 2021; Rockman and Hritz, 2020). Since many of these sites constitute anchors for indigenous knowledge, their loss is not just data lost to science; it also interrupts intergenerational transmission of knowledge (Green et al., 2009).

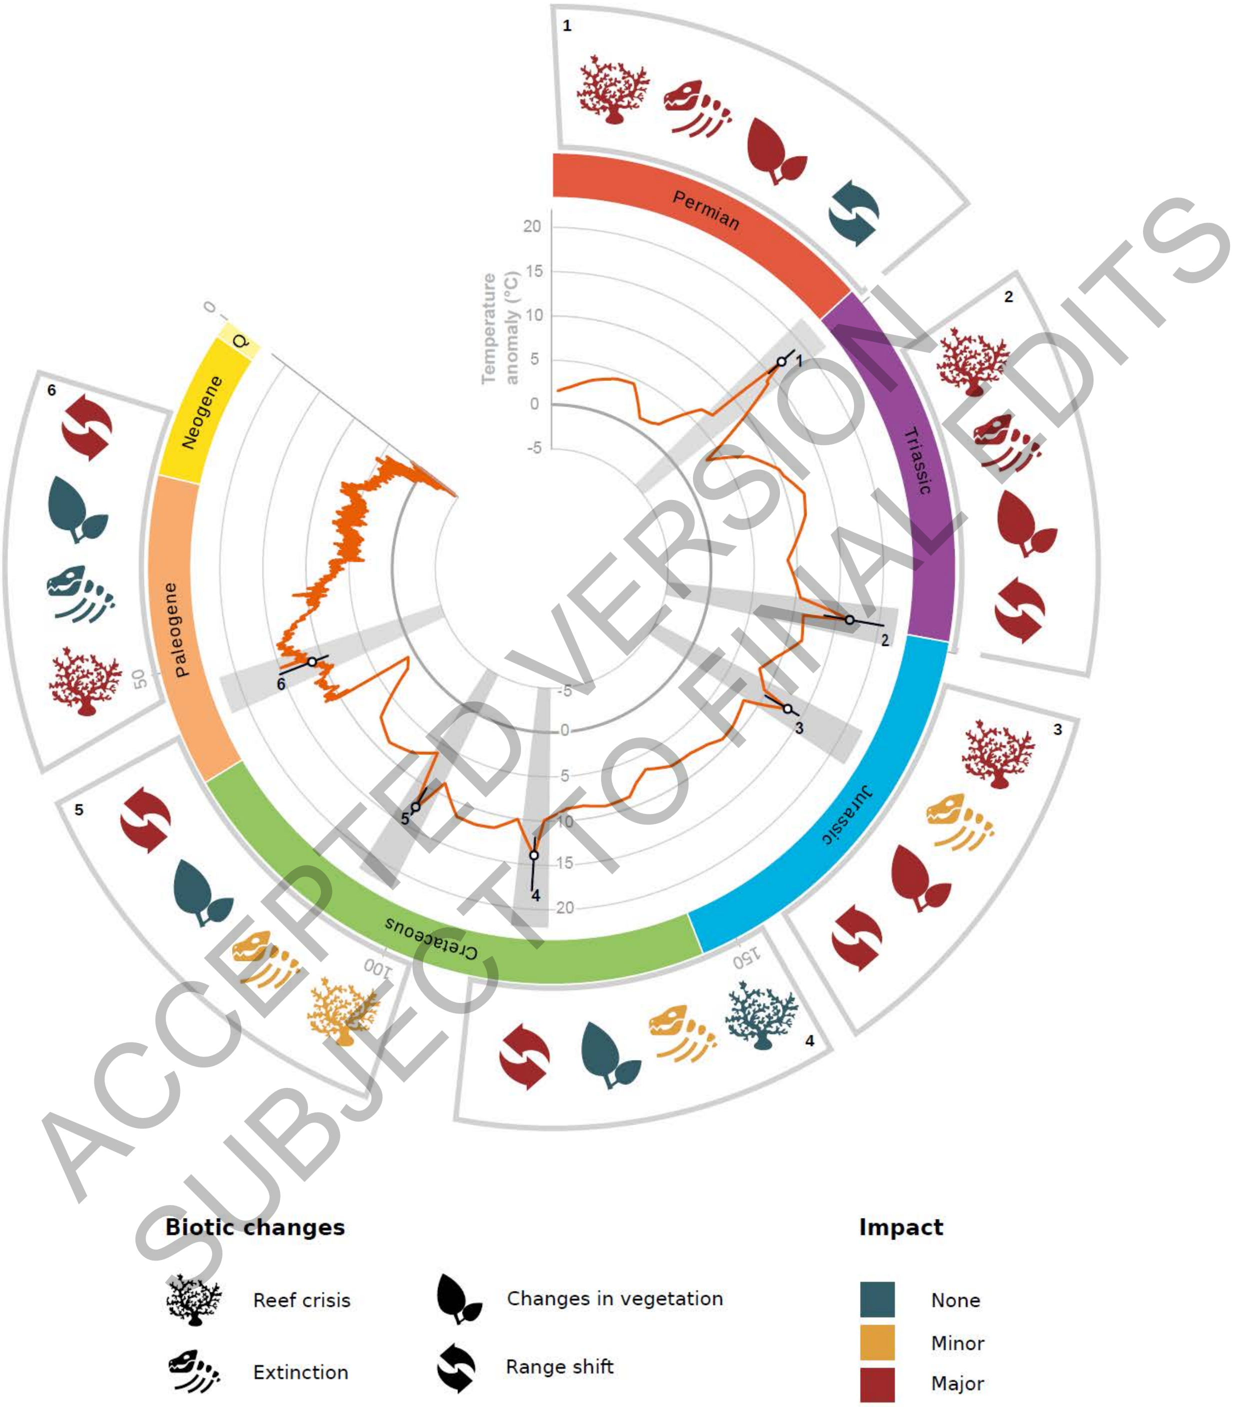

Figure Cross-Chapter Box PALEO.1: Biological responses to six well-known ancient rapid warming events (hyperthermals) over the last 300 million years. Temperature anomalies (mean temperature difference to pre-industrial (1850–1900), solid orange curve) derived from climate modelling (300–66 Ma) (Haywood et al., 2019) and deep-sea proxy data (66–0.1 Ma) (Hansen et al., 2013). Temperature peaks underneath the grey bars indicate well-known hyperthermals with temperature anomalies derived from temperature-sensitive proxy data (Foster et al., 2018). Error bars indicate uncertainties in peak warming events (ranges in the literature). Insets show observed impacts to the biosphere. Q = Quaternary.

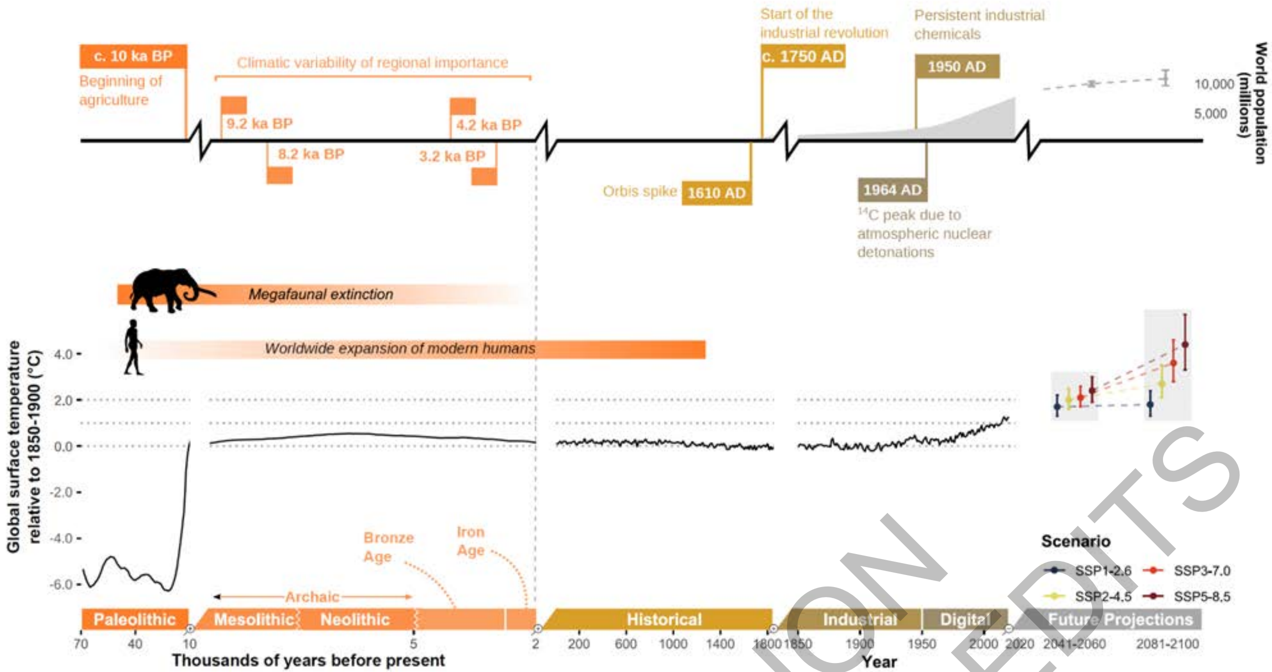

Figure Cross-Chapter Box PALEO 2: Humankind is embarking on a trajectory beyond the global temperatures experienced since at least the advent of agriculture. Global surface temperature change for the last 70,000 years [relative to 1850-1900; data from AR6-WGI-Ch2] alongside projections (with 5-95% range; AR6-WGI-Ch4) and major events in human societies. Global climatic parameters do not always capture regional variability of importance to specific societies. The "Orbis Spike" represents a pronounced dip in atmospheric CO_2 from the Law Dome ice core (Antarctica) (MacFarling Meure et al., 2006) marking the globalization in biota and trade of the Columbian Exchange and population declines and afforestation in the Americas. This, and the 1964 ^{14}C peak, have been suggested as possible markers for the onset of the Anthropocene (Lewis and Maslin, 2015). Population trends from United Nations (2019).

[END CROSS-CHAPTER BOX PALEO HERE]

1.3.2.2 Perceiving Climate Risk and Human Response

Since AR5, social science literature on how individuals and societies perceive and respond to climate risk has dramatically advanced (Jones et al., 2014; Neaves and Royer, 2017; Renn, 2008; Taylor et al., 2014; Van Valkengoed and Steg, 2019). The literature is increasingly integrating and advancing long-standing scholarship on environmental and social governance, human dimensions of environmental change, risk perception and communication, and enabling conditions for effective policy making. These emergent literatures on climate risk, human action, and solution reflect into three broad areas of analysis: 1) root drivers (i.e., role of cultural norms and social practice, social structures and economic development status that shape physical and social vulnerability; 2) context specific barriers and enablers (i.e., governance structures, institutional structure and function, risk perceptions, access to financing and knowledge availability and needs) and 3) the solution-proximate decision space (i.e., climate urgency and catalysing conditions, risk communication strategies, monitoring and evaluation strategies) (see Jorgenson et al., 2019; Solecki et al., 2017).

These three areas are deeply embedded in the social sciences and reflect fundamental questions of how and why humans and their institutions act and respond (Chapter 17). In the past two decades, these basic issues have been applied to research of climate change, dynamic risk, and adaptation. Underlying this analysis, particularly of root drivers and barriers and enablers are assertions regarding the foundational properties of individual and collective behaviour (i.e., self-interest, optimisation, rationality, bounded rationality), how they are structured, and how these properties can be revealed. This literature draws on several academic disciplines including anthropology, economics, geography, political science, psychology, sociology, and urban studies. Climate change social science research is often interdisciplinary or transdisciplinary and hence utilizes a variety of methods to derive new knowledge (Orlove et al., 2020).

In contrast to previous assessments, AR6 is increasingly focused on the needs for and challenges of assessing the societal response to climate change. The accurate tabulation of adaptation, a key question for examining the solution space is difficult (Chapter 16, Cross-Chapter Box ADAPT in Chapter 1), since many forms of adaptation activity are under-represented in the peer-reviewed and grey literature. Moreover, the related question of assessing the effectiveness of adaptation, that is, the extent to which it reduces risk, is also difficult. Estimating risk reduction often involves counterfactuals, for instance, quantifying the damage a flood would have caused had a community not adapted prior to a storm or projecting the damage averted by today's adaptation in some future storm (see Cross-Chapter Box PROGRESS in Chapter 17). Many socio-economic drivers affect risk, so attribution for any observed or projected changes must be allocated among those due to adaptation and those due to economic development, cultural changes, and other types of policies and trends. For instance, many measures of sustainable development overlap with those for adaptive capacity and both can reduce climate risk while also yielding benefits irrespective of future climate regimes (UNEP, 2018). There also exist many different goals for adaptation both among and within different jurisdictions, so that adaptation efforts deemed effective by some individuals may not be deemed effective by others (Dilling et al., 2019).

1.3.2.3 Indigenous Knowledge and Local Knowledge

While scientific knowledge is vital, Indigenous knowledge (IK) and local knowledge (LK) are also necessary for understanding and acting effectively on climate risk (IPCC, 2014a; SROCC Chapter 1,IPCC, 2019b; see also Section 2.4). **Indigenous knowledge** refers to the understandings, skills and philosophies developed by societies with long histories of interaction with their natural surroundings (IPCC, 2019a). **Local knowledge** is defined as the understandings and skills developed by individuals and populations, specific to the places where they live (IPCC, 2019a). These definitions relate to the debates on the world's cultural diversity (UNESCO, 2018a), which are increasingly connected to climate change debates (UNESCO, 2018b). However, there is agreement that, in the same way that there is not a unique definition of Indigenous Peoples because it depends on self-determination, there is not a single definition of neither Indigenous knowledge nor local knowledge. Therefore, contextualisation is highly needed. IK and LK will shape perceptions of climate risk which are vital to managing climate risk in day-to-day activities to longer term actions.

Such experience-based and practical knowledge is obtained over generations through observing and working directly within various environments. Knowledge may be place-based and rooted in local cultures, especially when it reflects the beliefs of long-settled communities who have strong ties to their natural environments (Orlove et al., 2010). Other times, knowledge may be embedded in institutions or oral traditions that mobilise them across contexts, for example, as migrant populations bring their knowledge across different regions, and have global relevance. Scientific insights often confirm findings from both IK and LK (Ignatowski and Rosales, 2013), but IK and LK also provide specific, alternative ways to understand environmental change including tacit and embodied aspects of knowledge (Mellegård and Boonstra, 2020), that may be crucial to foster local action and which are not easily captured in scientific knowledge (including cultural indicators, scales and interconnectedness between ecosystems). Multiple knowledge systems (i.e. IK, LK, disciplinary knowledge, technical expertise) may coevolve in iterative and interactive processes whereby they influence each other, but at the same time, they may have specific characteristics so that they cannot be reduced to each other, or subsumed under it and they all have relevance to understand the interactions between society and climate (Bremer et al., 2019).

Moreover, IK and LK may be particularly relevant to ensure that climate action not only does not cause further harm, but also addresses historical injustices committed against Indigenous Peoples and other marginalised social groups, recognising them as active agents of their own change (Nursey-Bray et al., 2019). There are between 370 and 500 in at least 90 countries belonging to about 5,000 different ethnic groups that are classified as 'Indigenous' (Sangha et al., 2019). While there is no single, universal definition of Indigenous Peoples, self-determination is a core criteria within both the ILO Convention on Indigenous and Tribal Peoples (1989) and the UN Declaration on the Rights of Indigenous Peoples distinct social and cultural groups that retain collective ancestral ties to the lands they inhabited or to the lands from which they have been displaced. Indigenous peoples attribute cultural and spiritual values to land, environmental features and landscapes (ILO, 2013; ILO, 2019). Indigenous Peoples suffer disproportionally. For example they are three times more likely to live in extreme poverty than non-Indigenous Peoples; they are also more likely to suffer discrimination and violence (UN, 2020). At the same time, Indigenous Peoples have long led climate change and environmental protection agendas.

Indigenous Peoples have been faced with adaptation challenges for centuries and have developed coping strategies in changing environments (Coates, 2004). Along with other local groups, they hold relevant knowledge about the environment and environmental change, the impact of those changes on ecosystems and livelihoods, and possible effective adaptive responses (see Cross-Chapter Box INDIG in Chapter 18). Therefore, the participation of Indigenous Peoples in climate change decisions and the inclusion of Indigenous knowledge in the IPCC assessment process should be of high priority (following recommendations in UN, 2020 and UNESCO, 2018b). Furthermore, the participation of scientifically trained climate specialists with indigenous backgrounds is valuable to the work of IPCC because the assessment must reflect a diverse range of views and expertise (for examples of IK please see Cross-Chapter Box INDIG in Chapter 18). Including IK & LK in the IPCC assessment process is supported by Article 31 in the UN Declaration on the Rights of Indigenous Peoples (2007) which calls for the use of IK and LK to be protected and validated by Indigenous Peoples themselves and include them as active participants in the assessment (Klenk et al., 2017). Paying special attention to the mechanism whereby some forms of knowledge have been excluded in previous reports- such as the use of technical knowledge or acronyms, or the deployment of discipline-specific validation mechanism- is a first step towards developing an inclusive assessment that reflects a wide range of voices.

The AR4 was the first IPCC report to explicitly discuss the value of IK and LK in adaptation and mitigation processes. AR5 recognized the importance of creating synergies across disciplines in the production of knowledge, acknowledging the importance of 'non-scientific sources such as Indigenous knowledge, which may not follow discipline conventions but nevertheless reflects the outcomes of learning across generations (Burkett et al., 2014) and explains the importance of including local and Indigenous knowledge and diverse stakeholder interests, values, and in local decision-making processes (Jones et al., 2014). Such processes should not only be done in partnership with IK and LK knowledge holders but, when possible, led by them (Inuit Tapiriit Kanatami, 2018). Recent IPCC reports have included distinct sections dedicated to IK and LK (e.g., SROCC, IPCC, 2019b). The IPCC Special Report on Climate Change and Land (SRCCL) includes a section on "Local and Indigenous knowledge for addressing land degradation" (2019a) and the IPCC Special Report on Ocean and Cryosphere (SROCC) describes local knowledge as 'what non-Indigenous communities, both rural and urban, use on a daily and lifelong basis,' a type of knowledge which is recognized as 'multi-generational, embedded in community practices and cultures, and adaptive to changing conditions' (2019b). The IPCC Special Report on Global Warming of 1.5°C emphasized the high vulnerability of Indigenous Peoples to climate change, and stated that disadvantaged and vulnerable populations including Indigenous Peoples and certain local communities are at disproportionately higher risk of suffering adverse consequences with global warming of 1.5°C and beyond (IPCC, 2018b). The report also assessed evidence in relation to the importance of including IK and LK in adaptation options, explaining their role in early warning systems and arguing that they are part of a range of approaches to catalyse wide-scale values and consistent with adapting to and limiting global warming to 1.5°C (IPCC, 2018b).

Since AR5, several academic publications have directly addressed the challenges of including IK and LK in climate research (David-Chavez and Gavin, 2018; Ford et al., 2016; Yeh, 2016) and demonstrated its value in building resilience to extreme events related to climate change (Janif et al., 2016; Olazabal et al., 2021). For instance, IK and LK has proved useful in land management methods that reduce wildfire risk (Cook et al., 2012)(Mistry et al., 2016; Nepstad et al., 2006; Welch et al., 2013). Since Indigenous knowledge is traditionally communicated through storytelling and oral history, there is a practical challenge integrating it in a assessment that prioritises scientific knowledge, and a need for increased critical engagement towards a co-production of knowledge (Ford et al., 2016). Scholars now recognize the ontological and epistemological differences in approaches, understandings and effects of climate change (Yeh, 2016). One common strategy has been assessing Indigenous observations of climate change alongside scientific data (Klein et al., 2014a) as a means to bridge the gap between scientific inquiry and Indigenous knowledge systems (Fernández-Llamazares et al., 2017). The Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) and the Convention on Biological Diversity (CBD) have helped illustrate how to bridge multiple knowledge systems, particularly those conceived from different ontologies. Rather than viewing Indigenous knowledge as a single source of knowledge to be compared with scientific data, recent scholarship suggests assessments such as the IPCC directly involve Indigenous researchers (Yumagulova et al., 2019) to ensure ethical and equitable engagement with Indigenous knowledge. Such partnership with and leadership of Indigenous Peoples on climate research is also consistent with the UN Declaration on the Rights of Indigenous Peoples (e.g., Bawaka Country et al., 2015; Inuit Tapiriit Kanatami, 2018; Cross-Chapter Box INDIG in Chapter 18).

1.3.3 Regional Assessment

As climate change is a multiscale phenomenon from the local to the global, the assessment of climate risks and climate change impacts is strongly spatial, with a focus on regional climate change. The term "regions" is used in different ways throughout the AR6 assessment as the use of the term varies across disciplines and context.

First, there are chapters dedicated to regional assessment in AR6 WGII (Chapters 9-14 and Cross-Chapter Papers 4 and 6), and within the content of these and other chapters of AR6, the term region is often used to describe continental and sub-continental regions, oceanic regions, hemispheres, or more specific localities within these geographic areas. Building on the continental domains defined in AR5 WGII and to ensure consistency with WGI Chapter 12 and the WGI Atlas, AR6 WGII uses a Continental Set of Regions, namely Africa, Asia, Australasia, Europe, North America, Central & South America, Small Islands, Polar Regions, and the Ocean.

Second, the term regions is used to categorize areas around the globe with common topographical characteristics or biological characteristics. For example, Chapter 2 introduces regions in its discussion of biomes, as in arid, grassland, savanna, tundra, tropical, temperate, and boreal forested regions. Chapter 3 adds reference to an area's orientation with bodies of water, using terms such as deltaic, coastal, intercoastal, freshwater, and salty. In addition, Cross-Chapter Paper 2 uses a coastal region typology based on physical geomorphology considering elevation, coastal type, and topography (see Cross-Chapter Paper 2, pg. 5; Barragán and de Andrés, 2015; Haasnoot et al., 2019a; Kay and and Adler, 2017).

Third, Cross-Chapter Papers are dedicated to *typological regions*, defined in the Annex II: Glossary as regions that share one or more specific features (known as 'typologies'), such as geographic location (e.g., *coastal*), physical processes (e.g., *monsoons*), and biological (e.g., coral reefs, tropical forests, deserts), geological (e.g., mountains) or *anthropogenic* (e.g., megacities) formation, and for which it is useful to consider the common climate features. Typological regions are generally discontinuous (such as monsoon areas, mountains, deserts, and megacities) and are specifically used to integrate across similar climatological, geological and human domains.

Understanding climate risks across regions also requires attention to the capabilities of developing countries and scientists across country contexts in conducting climate assessments. Substantial unevenness of available climate observations, risks assessments, and scientific literature across regions and country capacities substantially challenges a globally comprehensive assessment (Connelly et al., 2018).

1.3.4 Evaluating and Characterising the Degree of Certainty in Assessment Findings

Since 1990, IPCC assessments have included designated terms and other approaches for communicating the expert judgments made by authors (Mastrandrea and Mach, 2011). The goal of such methods has been consistent treatment of uncertainties in assessing and communicating the current state of knowledge. Because terms such as "probable" or "likely" hold very different meanings to different people, a standardized approach is essential for enabling consistent interpretation (WGI AR6 Section 1.2.3.1). Since its 2001 assessment, IPCC authors have applied common guidance on expert judgment across the working groups (IPCC, 2005; Moss and Schneider, 2000). The AR5, iteratively building from past IPCC guidance, was the first report to apply a single framework consistently across the working groups and their diverse topics and associated disciplines (Figure 1.3; Mastrandrea et al., 2010; Mastrandrea and Mach, 2011). The outcome was increased comparability of assessment conclusions across the full spectrum of the physical science basis of climate change and resulting impacts, risks, and responses (Mach et al., 2017).

This framework for expert judgment is again being applied in the AR6 and associated special reports in the assessment cycle (Mastrandrea et al., 2010; see also WGI AR6 Box 1.1). Under the framework, the assessment of scientific understanding and uncertainties begins with evaluation of **evidence** and **agreement**—especially the type, amount, quality, and consistency of evidence and the degree of agreement (steps 1–3 in Figure 1.6). Evidence assessed can reflect observations, experimental results, process-based understanding, statistical analyses, or model outputs. Evidence is most robust when it consists multiple lines of consistent, independent, and high-quality evidence. The degree of agreement considers the extent of established, competing, or speculative explanations for a given topic or phenomenon across the scientific community. Together, this evaluation of evidence and agreement forms a traceable account for each key finding in the assessment. Subsequently, the framework proceeds to evaluation of levels of **confidence**, which integrate evidence and agreement (steps 3–5 in Figure 1.6). Confidence reflects qualitative judgments of the validity of findings. It thereby facilitates, more readily, comparisons across assessment conclusions. Increasing evidence and agreement corresponds to increasing confidence (step 4 in Figure 1.6).

If uncertainties can be quantified, the framework involves a further option of characterising assessment findings with **likelihood** terms or more precise presentations of probability (steps 5–6 in Figure 1.6). The relevant probabilities can pertain to single events or broader outcomes. Probabilistic judgments can be based on statistical or modeling analyses, elicitation of expert views, or other quantitative analyses. Where appropriate, authors can present probability more precisely with complete probability distributions or percentile ranges, also considering tails of distributions important for risk management. Usually, likelihood assignments are underpinned by high or very high confidence in the findings.

Confidence is often most applicable in characterising key findings in WGII assessment (Mach et al., 2017). This tendency results from the diverse lines of evidence across disciplines relevant to climate change impacts, adaptation, and vulnerability. By contrast, likelihood is more common in WGI assessment.

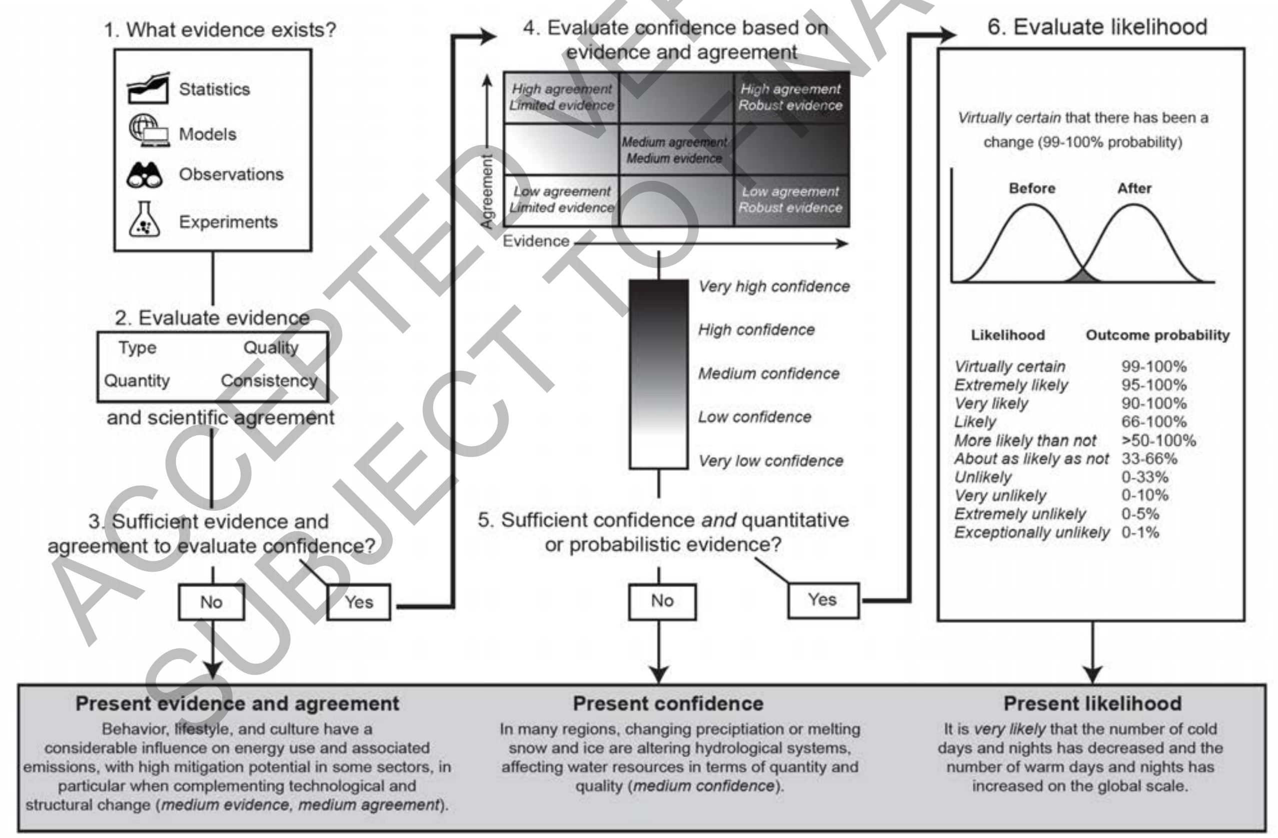

Figure 1.6: The IPCC AR5 and AR6 framework for applying expert judgment in the evaluation and characterisation of assessment findings. This illustration depicts the process assessment authors apply in evaluating and communicating the current state of knowledge. Guidance for the application of this framework is described in full detail in Mastrandrea et al., 2010. In addition to scientific knowledge, Indigenous knowledge and local knowledge are central to understanding and acting effectively on climate risk (Section 1.3.2.3). The diagram in this figure is reproduced from Mach et al. (2017)

The guidance to authors additionally identifies other practices and approaches relevant in applying expert judgment and developing assessment findings (Mach and Field, 2017; Mastrandrea et al., 2010; Mastrandrea and Mach, 2011). First, authors are encouraged to carefully consider appropriate generalisation within assessment findings, emphasising insights that are integrative, nuance, and rigorous (IAC, 2010; Mastrandrea et al., 2010; NEAA, 2010). Second, authors are instructed to attend to potential biases, including in group dynamics, such as tendencies towards overconfidence and anchoring or Type I (false positive) error aversion (Anderegg et al., 2014; Brysse et al., 2013; Mastrandrea et al., 2010; Morgan, 2014). Third, particular attention is drawn to the importance of evaluating and communicating ranges of potential outcomes to inform decision-making and risk management (Mastrandrea et al., 2010). In some cases, deep uncertainties related to parameters or processes that are unknown or disagreed upon strongly benefit from dedicated methods of assessment and decision support (see Cross-Chapter Box DEEP in Chapter 17). Fourth, the guidance explores the different ways that framings of conclusions can shape their interpretation by readers. Finally, the guidance underscores the importance of reflecting upon all sources of uncertainty, which can include deep, difficult-to-quantify, and easy-to-underestimate uncertainties arising from incomplete understanding of relevant processes or competing conceptualisations across the literature (Mastrandrea et al., 2010). A detailed review of literature assessing IPCC uncertainty characterization methods is provided in WGI AR6 1.2.3.1.

1.4 Societal Responses to Climate Change Risks

AR6 highlights the concept of **solutions**, defined as *effective*, *feasible,* and *just* means of reducing climate risk, increasing resilience, and pursuing other climate-related societal goals. This section introduces key concepts used in this report to assess the goals associated with adaptation, its process and governance, its implementation, monitoring and evaluation, and its limits.

The term solutions has various synonyms used across this and previous IPCC reports, including options, measures, actions, and responses. All denote policies, technologies, processes, investments, or other activities undertaken in reaction to or with the intent to address some aspect of climate change (Chapter 17). The term solutions has drawbacks, suggesting a finality, that is, the problem is solved. Solving climate change in this sense is not likely for the foreseeable future. In addition, the word solutions sometimes denotes a narrow set of responses, such as “technical solution,” as opposed to more wide-ranging actions as might be involved in a transition to resilience. Nonetheless, AR6 highlights the term solutions because, compared to these other terms, when acted upon or incorporated in policy, it denotes effectiveness and some degree of progress at achieving desired goals.

Assessing successful adaptation is, however, difficult (Cross-Chapter Box ADAPT in Chapter 1). WGIII Section 1.6 summarizes four broad analytic frameworks -- aggregate efficiency; ethics and equity; transition dynamics; and psychology and politics -- relevant to mitigation and concludes that failure to integrate understanding across them has been a fundamental reason for inadequate progress to date in reducing greenhouse gas emissions. While the four analytic frameworks used in WGIII also all contribute to the understanding of adaptation, an integrated view remains elusive because adaptation differs strongly from mitigation. In particular, the goals of adaptation are harder to define and measure than those for mitigation. The feasibility, effectiveness, and success of many adaptation actions depend more strongly on context. A different, often more diffuse set of actors are involved, and it is often hard to distinguish what activities count as adaptation.

Given these challenges, this report provides an assessment of adaptation solutions based on the attributes **justice**, **feasibility**, and **effectiveness**, as shown in Figure 1.7.

A solution is just when its outcomes, the process of implementing the action, and the process of choosing the action respects principles of distributive, procedural, and recognitional **justice** (Section 1.4.1.1). Any assessment of justice depends on an understanding of potential outcomes of alternative options (Chapter 16) as well as processes of decision-making (Chapter 17). Consideration of justice necessarily introduces normative elements into any assessment of what constitutes a solution.

A solution is **effective** to the extent it reduces climate risk. Effectiveness can refer to whether an adaptation-related action reduces risk (Section 1.4.1.2, Chapter 16) or the extent to which an action achieves its intended outcomes within a stated time frame (Chapter 17). Effectiveness can also include measures of economic efficiency, assessment of net benefits over costs, and the extent to which an action enhances broader and multi-dimensional measures of societal well-being (Section 1.4.1.2). Assessments of effectiveness will often involve uncertainty, which may affect judgements about the comparative effectiveness and justice of alternative options (Chapters 16 and 17, Cross-Chapter Box DEEP in Chapter 17). Assessment of effectiveness also involves consideration of maladaptation (Section 1.4.2.4) in which an action, often inadvertently, increases risk or vulnerability for some or all affected individuals or communities.

A solution is **feasible** to the extent it is consider possible and desirable, taking into consideration barriers, enablers, synergies, and trade-offs (Section 1.4.2). AR6 assesses the feasibility of a wide range of adaptation options (Cross-Chapter Box FEASIB in Chapter 18), building on the approach of the SR1.5 report, which uses five dimensions of feasibility: geophysical, environmental-ecological, technological, economic, socio-cultural, institutional. In addition, feasibility can also refer to a specific set of actions, so that feasibility in any particular situation may depend on specific conditions of governance capacity, financial capacity, public opinion, interest group pressure, and the distribution of political and economic power (Chapter 17). For instance, a particular jurisdiction may find either of two options feasible when implemented alone but might lack the capacity to implement them both at the same time. Feasibility can be a context-dependent and time-varying attribute. Many solutions, for instance those that seek to unlock financing or build public support for certain actions, aim at increasing the feasibility of future adaptation responses (Sections 1.4.2 and 1.5).

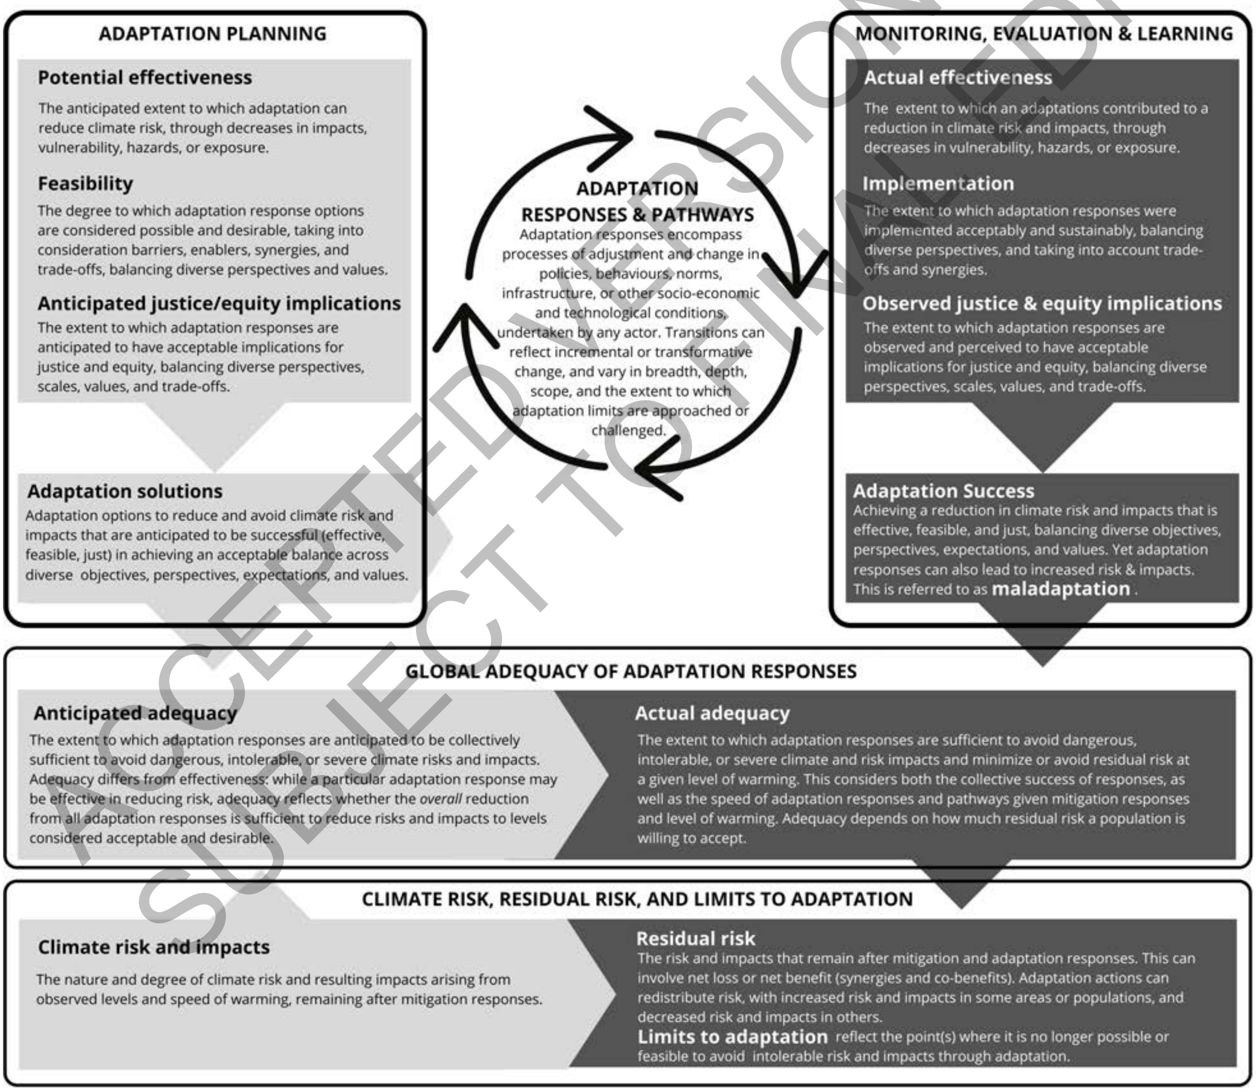

Figure 1.7: **Assessing adaptation solutions and success**. A solution is defined as an adaptation option which is effective, feasible, and conforms to principles of justice. These attributes can be assessed ex ante during adaptation planning. During implementation, the overall success of a response can be judged via monitoring and evaluation of these attributes. Adaptation unfolds as an iterative learning process of assessment, implementation, monitoring, adjustment, and learning. A set of responses is adequate to the extent that they sufficiently reduce climate risk to levels considered tolerable. Adaptation may not fully avoid residual risks, but the more adequate the response, the less

residual risk. Remains. Adaptation also has limits beyond which it is no longer possible to avoid intolerable risks and impacts.

1.4.1 What is Equitable, Just and Effective Adaptation?

Articulating the goals of adaptation is an important initial step in the decision-making process (Jones et al 2014). Adaptation often involves trade-offs among various options of adaptation, mitigation and sustainable development as well as judgements based on science, engineering, and economics and questions of distribution and democratic participation (Jafry et al., 2018). Articulating the goals of adaptation at the international, national, and local levels thus requires engaging with the concepts of equity, justice, and effectiveness (*high confidence*).

1.4.1.1 Equitable Adaptation Informed by Concepts of Justice

Assessing climate action involves ethical considerations that the literature often describes as climate justice. The term 'climate justice,' however, has been used in different ways in different contexts and by different communities. Grassroot organisations and activists often focus on unequal global power relations, wealth, and interests within communities, within nations, and along the North-South divide, as well as the historical responsibility for climate change (Chatterton et al., 2013). Some national governments also view climate justice as the right of developing countries to industrialize. Balancing these issues, international climate change negotiations have primarily focused on current capacities and responsibilities for addressing climate change as reflected in the UNFCCC principle of 'common but differentiated responsibilities' (Fisher, 2015).

Since principles of justice are substantive normative commitments that have been debated for centuries, it would be unrealistic to expect a universal consensus. Nevertheless, there is broad agreement about the core issues. Just normative principles are ones that result in fair and equitable allocation of goods, vulnerabilities and risks (Caney, 2014; Jafry et al., 2018; Schlosberg, 2009; Schlosberg, 2013)

It is common to distinguish between distributive justice, procedural justice and recognition (Forsyth, 2018; Fraser, 1999; Olazabal et al., 2021; Reckien et al., 2017; Schlosberg, 2003; Schlosberg, 2009). The first refers to the distribution of burdens and benefits; the second to who decides and participates in decision-making; while recognition entails basic respect and robust engagement with and fair consideration of diverse values, cultures, perspectives, and worldviews. Recognition is closely to distributive and procedural justice (Hourdequin, 2016). Without recognition, actors may not benefit from the two other aspects of justice (*medium confidence*). Recognition thus represents both a normative principle as well as an underlying cause of unjust distribution and lack of democratic participation (Svarstad and Benjaminsen, 2020). However, recognition is still under-represented in climate justice compared to general scholarship and debate on justice principles (Benjaminsen et al., 2021; Chu and Michael, 2018).

Three principles of distributive justice are especially relevant to adaptation: *fairness between individuals*, *fairness between states*, and *fairness between generations* (Fleurbaey et al., 2014*)*. Fairness between individuals means that the distribution of goods, vulnerabilities, and risks of climate change should not fall on individuals for arbitrary reasons. It would be arbitrary if, say, a family were disproportionately affected by climate-induced drought by chance alone. Similarly, an adaptation action that protects some and creates risks for others is unfair if the final distribution of burdens and benefits is arbitrary.

The second consideration of distributive justice is *international justice*, or fairness between states. An important idea in international climate negotiations has been *common but differentiated responsibilities* and respective capabilities (CBDR**)** **(**stated in Principle 7 in the Rio Declaration (1992)as well as by the Kyoto Protocol (1997). The principle reflects the underlying idea that *all* countries must address climate change, but the form of climate action depends on the situation the country finds itself in. Developed countries may find themselves in a position where they can decarbonize more rapidly and ensure financial flows, while the responsibilities of LDCs and SIDS may primarily come in the form of adaptation actions. This means that uneven distribution of wealth and power between (and within) countries is a key driver of climate injustice.

The third consideration of distributive justice relevant to climate adaptation is fairness between generations and the obligation to ensure that future generations are guaranteed at least a minimally decent life (Jonas, 1985; Llavador et al., 2010). For example, youth climate activists and political philosophers have argued that today's children, as well as generations yet unborn, will be exposed to far greater risks than most living adults so that policymakers should work to avoid shifting all burdens of adaptation to future generations.

Procedural justice addresses the fairness of the processes by which decisions are made and the legitimacy of those making the decisions (Gutmann and Thompson, 2009; Kitcher, 2011). Criteria include transparency, the application of neutral principles among parties, respect for participants' rights, and inclusive participation in decision-making, which often takes the form of participatory processes. Article 6 of the Framework Convention creates a binding commitment on parties to promote public participation in addressing climate change. Increased participation by civil society in climate policy discussion, including new forums such as the Local Communities and Indigenous People's Platform of the UNFCCC work toward this goal (UNFCCC, 2021). Genuine, not merely formal, participation requires communities be well-acquainted with the climate change risks they face and are given a full voice in the process of adaptation planning. Many local communities, especially those most vulnerable to climate change, remain excluded, which is inconsistent with principles of procedural justice. In addition to a normative principle, models of decision making also suggest that diverse, representative decision makers can be expected to make better decisions than more limited groups (Hong and Page, 2004; Landemore, 2013; Singer, 2019).

In AR5 WGIII discussions of justice and ethical concepts were combined with discussions of economic principles while the adaptation chapters did not explicitly discuss climate justice. This report moves beyond AR5 by connecting the assessment of policy choices to normative principles and showing how better outcomes are obtained by choosing just ones.

1.4.1.2 Equitable and Effective Adaptation Informed by Concepts and Measures of Well-Being

Planning and assessment of effective and just adaptation require appropriate measures of both criteria. This report uses both single and multi-criteria measures.

Local and regional decision makers employ benefit-cost analysis to efficiently allocate scarce resources among alternative adaptation efforts and among adaptation and other societal needs. Decision makers at national and global levels can employ measures of social welfare to consider trade-offs and synergies among adaptation, mitigation, and development. Such measures can avoid wasteful allocation of resources and help avoid maladaptation. Such measures also prove useful because well-established approaches exist to evaluate such quantities, and because income is highly correlated with a wide range of indicators of social progress and climate change adaptation capacity (Dasgupta et al., 2018).

Aggregate, monetized economic measures are, however, insufficient to address fully issues of climate justice or to reflect that wide range of worldviews and values that different people bring to questions of climate action and development (Chambwera et al., 2014). While recent work has enriched the consideration of distributive justice in aggregate social welfare functions (Adler, 2012), multi-objective approaches that separately report several biophysical and socio-economic attributes can prove valuable (17.3.3). Many adaptation measures, in particular those that encompass transformational social changes (Section 1.5), involve complicated trade-offs among multi-dimensional benefits and costs (Adger, 2016). Different people commonly value such trade-offs differently, particularly in heterogeneous societies. Multi-objective measures can thus enhance transparency, fairness, legitimacy, and participation by highlighting the different outcomes that different people and communities might find important, making the specific trade-offs more transparent and explicit, and avoiding privileging any particular view on the appropriate trade-offs (Lempert et al., 2018; Siders, 2019b; Siders and Keenan, 2020).

The SDGs and Key Representative Risks (Chapter 16) exemplify such multi-criteria measures. In addition, many communities increasingly measure policy outcomes using multi-objective measures, often organized around the concept of well-being and designed to allocate resources and implement policies to advance social progress (City of Santa Monica, 2018; Lee et al., 2015). Similarly, the Human Development Index (HDI), which derives from the capabilities approach, combines income (as Gross National Income-GNI and Parity Purchasing Power-PPP) with an education and a health indicator and integrates human and socio-economic factors (Herrero et al., 2012; Leal Filho et al., 2018; Nagy et al., 2018; UNDP, 2018; USEPA, 2016). The inequality-adjusted HDI value, or IHDI, can be interpreted as the level of human development when inequality is accounted for (UNDP, 2018).

The multi-criteria concept of well-being has been increasingly employed as a structured framework for measuring social progress in many areas of public policy (Lamb and Steinberger, 2017) including climate and health (Chapter 7) and, to a lesser extent in other areas of the climate change adaptation literature (Singh et al., 2021). Wellbeing reflects the ability of a person to pursue and realize the goals that they value (Sen, 1985). The disaster risk management community employs well-being to evaluate mental health impacts in terms of peoples' abilities to cope with trauma and loss because of natural disasters (Berry et al., 2010; MacDonald et al., 2015; Willox et al., 2015). The term appears in the literature with concepts such as human security (Adger, 2010; Koren and Butler, 2006; Pasgaard et al., 2017), subjective wellbeing or happiness (Fanning and O'Neill, 2019; Rehdanz et al., 2015; Sekulova and van den Bergh, 2013), welfare (Gough, 2015), and living standards or quality of life (Degorska and Degorski, 2018; Rao and Min, 2018).

Recent work has used quantified measures of well-being and multi-objective decision support tools) to balance among equity and efficiency objectives in disaster risk management (Markhvida et al., 2020; Section 1.5.2; Chapter 17). Rather than focus on the economic value of lost assets, the well-being measure evaluates disaster impacts and recovery policies by considering the fraction of consumption lost at the household level for different income cohorts. Not surprisingly, poor households account for twice as much of the disaster losses when evaluated by effects on well-being rather than by asset losses. The most effective policy responses also differ when using well-being and asset loss-based measures. Ciullo et. al. (2020) compare flood control strategies using multi-objective decision criteria that include both benefit-cost and distributional components, show how the favoured strategy can depend on whether one seeks equitable risk or equitable risk reduction, and propose tools that can help embed both ethical and efficiency considerations in adaptation decisions. Widespread use of such approaches could strengthen consideration of climate justice along with efficiency in the evaluation of climate risks and adaptation. (Dryzek et al., 2013; Section 1.5.2).

1.4.2 Enabling and Governing Adaptation

Adaptation actions taken by individuals, social groups, and organisations in response to climate and environmental stimuli depend, in part, on the options they have (see Chapters 16 and 17). Actions previously taken can reduce the scale of responses needed subsequently, increase the options available, reduce barriers to additional action, and increase capacity to respond. Successful adaptation sufficient to meet Paris and SDG Goals needs to involve actors at many scales and in many sectors, including individuals and households, communities, governments at all levels, private sector businesses, non-governmental organisations, religious groups and social movements. This report highlights the increased range of societal actors engaged in adaptation and the need for multi-level and polycentric governance. The section describes key concepts related to the process of adaptation and assessment of how human choices and exogenous changes can expand and contract the set of available solutions.

1.4.2.1 Adaptation Process and Expanding the Solution Space

Adaptation actions include those taken with the explicit intention of reducing climate risk, as well as actions taken without reference to climate change, e.g., building community resilience irrespective of any particular hazard. Adaptation actions can include those aimed at reducing a specific risk, or actions aimed at systemic changes and also include adjustments to current practices, or transformational changes. In addition, the success of adaptation in one place or jurisdiction can depend on activities in other places or jurisdictions.

Adaptation actions span a vast range of activities. Successful adaptation generally requires a portfolio of actions, often implemented by multiple actors in different sectors, often in different places and over time (Section 17.2.2). Useful taxonomies include categorizing such actions around Representative Key Risks (RKRs) (Figure 17.3), and by human systems and scenarios of adaptation extent for four components of adaptation (depth, scope, speed, and limits) (Table 16.2). As shown in Chapter 17, for instance, ecosystem-based adaptation, hardening buildings and physical barriers, and changes to zoning and planned retreat can reduce risks to coastal socio-ecological systems. Restoration and protection of forests, enhancing ecosystem connectivity through corridors, and ecosystem-based adaptation can reduce risks to terrestrial and ocean ecosystems. Increased use of grey, green, and blue infrastructure, and upgrading design standards, city plans, and more redundancy in power systems and other networks can reduce risks associated with critical infrastructure. Insurance and diversified or changed livelihoods can reduce risks to living standards and equity. Improved health care systems, disaster management and early warning can reduce risks to human health. Better management of land, soil and fisheries; and changing diets and reducing food waste can reduce risks to food security. Improved water efficiency, and policies to reduce demand can reduce risks to water security.

Previous IPCC reports have described in detail adaptation for individual actors as an iterative risk management process of scoping (identifying risks, vulnerabilities, objectives, and decision-making criteria), analysis (identifying options, assessing risks, evaluating trade-offs), and implementation (implementing chosen options, monitoring, and reviewing and learning) (Jones et. al. 2014). This AR6 report expands the focus to consider adaptation processes with multiple actors and a richer temporal dimension in which actions taken at one time can expand or contract the set of feasible, effective, and just options available at another time, thereby increasing or decreasing the ability of adaptation to reduce risks (Section 17.1). This AR6 report also expands the focus to include decision processes the implement both adaptation and mitigation (Chapter 18) as well as a heightened attention to Monitoring and Evaluation (M&E), which is a key prerequisite for successful iterative risk management and achieving effective and just adaptation outcomes at local to global levels (Section 1.4.3, 17.5.2). The challenges of implications for adaptation, mitigation and sustainable development outcomes result from decision-making process at different levels (Bertram et al., 2016, Von Stechow et al., 2015). To overcome these challenges often require significant learning and innovative ways of linking science, practice and policy at all scales (Shaw and Kristjanson, 2014).

Two concepts – enabling conditions and catalysing conditions – help frame this report's assessment of factors that over time can help expand the set of available solutions (Section 17.4). Enabling conditions enhance the feasibility of adaptation and mitigation options (cross-AR6 glossary). Enablers include finance, technological innovation, strengthening policy instruments, institutional capacity, multi-level governance, and changes in human behaviour and lifestyles. Chapter 17 (see also WGIII Figure 1.4) identifies three broad categories of enabling conditions: (Section 17.4): governance; finance and knowledge. Catalysing conditions motivate and accelerate the adaptation decision-making process, leading to more frequent and more substantial adaptation (Chapter 17). While enablers make adaptation more feasible and effective, catalysing conditions provide an impetus for action. These later conditions include a sense of urgency (Section 17.4.5.1); system shocks, such as those from natural disasters; policy entrepreneurs; and social movements.

The concept of the **solution space** provides a framework for assessing how the options available for adaptation for any particular community are not constant over time and can depend on the past, current and future choices of many actors. The solution space is defined as the space within which opportunities and constraints determine why, how, when and who adapts to climate risks (Haasnoot et al., 2020). The concept aims to capture the dynamic inter-temporal, spatial and jurisdictional interconnections among adaptation actions. A larger solution space indicates people and organisations with more options for adapting to and reducing their risk from climate change. Both human choices and exogenous changes in human and natural systems affect the future solution space. For instance, changes such as the magnitude and rate of climate change may shrink the space. Economic growth can generate more resources that expand the solution space as can implemented adaptation actions such as pilot projects, awareness raising, and changes in laws and regulations.

AR5 used the concept of solution space in its SPM Figure 8. Several AR6 chapters, in particular 13, 14, and 18, use the concept to address challenges salient in AR6. In any assessment of solutions, what is feasible, effective, and just depends not only on the potential solution itself but the particular biophysical and societal context in which it might occur (Section 17.5; Gorddard et al., 2016; Wise et al., 2014). Solutions can also be space and time dependent because the biophysical and societal context can change over space and time (Section 18.1.4). In addition, the large gap that exists between current climate action and that needed to meet policy goals suggests that decision-makers may not only seek to implement available solutions but seek to actively expand the set of solutions (Chapters 17, 18). Finally, as used in this report the concept of solution does not fully engage with questions of "by whom?" and "for whom?" In many cases solutions would necessarily be implemented by multiple, independent actors interacting with varying degrees of cooperation and competition (Sections 1.4.2, 1.5.2).

[START BOX 1.2 HERE]

Box 1.2: Financing as an Example of Enabler

According to the UNFCCC, adaptation finance includes public, private and alternative sources of finance for supporting adaptation actions, whereby adaptation and resilience are often used interchangeably in this context. Adaptation finance constitutes a crucial enabling condition and shaper of the solution space, depending on other enabling conditions such as proper planning, implementation and governance which are also the triggers for investments and finance to flow and to ensure that positive adaptation outcomes. Details of adaptation finance can be found in Chapter 17 (Cross-Chapter Box FINANCE in Chapter 17, Section 17.4). The adaptation and resilience options offer multiple benefits including avoiding risks and losses, economic growth, wellbeing as well as social and environmental benefits (Agrawal and Lemos, 2015; Bayleyegn et al., 2018; Global Commission on Adaptation, 2019). Hence, the rate of return on adaptation is large, for example, there is a huge potential of net benefits i.e. $7.1 trillion while investing $1.8 trillion globally in climate resilience and adaptation options such as early warning systems, climate-resilient infrastructure, improved dryland agriculture crop production, global mangrove protection, and resilience of water resources (Global Commission on Adaptation, 2019). These net benefits resulted primarily from reducing future losses and risk, increasing productivity and innovation, and social and environmental benefits. Despite strong uncertainty associated with benefit-cost estimates, and concerns on focusing efficiency (monetary) ignore important issues of non-economic values, effectiveness of risk reduction and climate justice (procedural/distributional).

The current public and private financial flows to adaptation are much smaller than needed (Cross-Chapter Box FINANCE in Chapter 17). Only a small portion of overall adaptation finance needs is likely to be covered by public sector finance. Private sector investment thus needs to play a crucial role. Hence, tracking adaptation finance flows is important for enabling effective planning and prioritisation of investments, assessing whether needs are being met, and ensuring accountability towards funding commitments, such as the 100 billion USD promised to developing countries per year by 2020 under the Paris Agreement (Donner et al., 2016). Since AR5, significant progress has been made in tracking adaptation finance flows through UNFCCC channels, multilateral development banks and bilateral finance (Cross-Chapter Box FINANCE in Chapter 17), but large information gaps on adaptation finance via national public finance, commercial lenders, investors, asset managers and insurers, company finance, and individuals and households remain. That these financial flows do not occur suggests misaligned incentives and other governance challenges that could be addressed as part of a response to climate change (Chapter 17). Across regions and sectors, financial constraints have identified most significant which leading to limits to adaptation (Chapter 16).

[START BOX 1.3 HERE]

Box 1.3: Nature-Based Solutions

Nature-based solutions (NbS) (Section 2.6 and Cross-Chapter Box NATURAL in Chapter 2) provides an example of how innovative ideas can expand the climate solution space (IPCC, 2018b; Seddon et al., 2019). A commonly-used definition of Nature-based solutions (NbS) is that of IUCN (The World Conservation Union) which defines it as "actions to protect, sustainably manage, and restore natural or modified ecosystems, that address societal challenges effectively and adaptively, simultaneously providing human well-being and biodiversity benefits" (Cohen-Shacham et al., 2016); in the context of IPCC, it focuses on NbS which deliver climate change adaptation and / or mitigation benefits. NbS generally benefits biodiversity and supports its role in both climate mitigation and adaptation. While the carbon sequestering mitigation role of increasing forest and tree cover has dominated much of the earlier discussions, the role of

NbS in promoting adaptation of natural ecosystems and human societies to climate change is being increasingly emphasized. The details of different categories of ecosystem services in the ocean or on land including biodiversity, food provision, other provisioning services e.g., medicinal and commercial products, regulating and cultural services have been described in Chapters 2 and 3.

Forest restoration would certainly contribute substantially towards climate-proofing and achievement of several Sustainable Development Goals as well as the Paris Agreement. There is increasing evidence that diverse, native tree species plantations are more likely to be resilient to climate change in contrast to fast-growing monocultures, (Hulvey et al., 2013) often of exotic species. At the same time, other natural ecosystems such as savannas, grasslands, peatlands, wetlands and mangroves have considerable value in acting as carbon sinks as well as providing other ecosystem services such as hydrological regulation, coastal protection, maintaining biodiversity and contributing to human livelihoods especially pastoralists and fishermen (Conant et al., 2017; Leifeld and Menichetti, 2018; Seddon et al., 2019; Veldman et al., 2015). Coastal and marine ecosystems including wetlands and mangroves have featured prominently in studies of NbS in climate adaptation and mitigation potential for "blue carbon" sequestration (Inoue, 2019; Sections 3.6.2.1; 6.3.3; Cross-Chapter Paper 2.3.2.3). Agroecological practices such as agroforestry, intercropping, rotational grazing, organic manuring, and integrating livestock production with cropping etc can also consider as NbS which contribute to both climate mitigation and adaptation (Altieri and Nicholls, 2017; Bezner Kerr et al., 2019; Leakey, 2020; Webb et al., 2017; Box 5.10).

There are concerns about large-scale conversion of non-forest land into forest plantations for the sole purpose of increasing carbon sinks through bioenergy with carbon capture and storage (BECCS) (Hanssen et al., 2020; Heck et al., 2018; Cross-Chapter Box in Chapter 2), which may actually result in negative carbon sink (Jackson et al., 2002; Mureva et al., 2018) and significant loss of overall biodiversity (Abreu et al., 2017). Such large-scale afforestation may also lead to the dispossession of previous users, such as smallholders and pastoralists. Hence, when NBS includes forest plantations or other large-scale conversion of land-use, there is a risk that it results in maladaptation and malmitigation including climate injustice (Cousins, 2021; Seddon et al., 2019).

Much of the conceptual framework for NbS has come from initiatives to bring environmental, social and economic dimensions to the same level of importance particularly in the context of a highly urbanized society (Faivre et al., 2017; Nesshöver et al., 2017; Section 6.3.3). Emphasis has been given on urban storm water management (Section 2.6.5.2) and heat mitigation using measures such as sustainable drainage systems, urban forests, parks and green roof-tops apart from coastal defences using NbS (Section 13.6.2.3) This has triggered much debate on how distinct the concept of NbS is in relation to other similar concepts such as ecosystem-based adaptation (EbA) approaches (Section 9.11.4.2), and call for an assessment framework for proving the "effectiveness and efficiency" of NbS in providing superior ecosystem and societal benefits (Calliari et al., 2019). Instead, EbA can be treated as a subset of NbS (Chapter 2). However, the time frame of ecosystem-based adaptation is also an important consideration; thus, grassland and forest restoration would operate at different time scales, while mangrove restoration can promote adaptation only at local to national scales, depending on the extent and nature of coastlines (Taillardat et al., 2018). Given the complex nature of plant and animal species adapting to climate change through dispersal and migration to more suitable habitat, this also means that landscape-scale approaches, as opposed to purely protected areas, are needed to promote adaptation, conserve and sustainably use biodiversity, and sustain livelihoods (Sukumar et al., 2016; Vos et al., 2008).

[END BOX 1.3 HERE]

1.4.2.2 Governing Adaptation

Governance and governing refer to the structures, processes, and actions through which private and public actors interact to address societal goals. This includes formal and informal institutions and the associated norms, rules, laws and procedures for deciding, managing, implementing and monitoring policies and measures at any geographic or political scale, from global to local. Governance systems and the specific societal institutions through which they are organized are crucial to the feasibility and success of climate change adaptation, both in terms of its effectiveness in reducing climate risk and vulnerability as well as equity (including climate justice), and with respect to incremental as well as transformational adaptation. This is why AR6 WGII pays even more attention than previous assessments to governance as an important enabling condition, and to the wide range of new actors beyond governments involved in planning, implementing, and monitoring and evaluating adaptation action. The assessments in subsequent chapters of AR6 WGII show that successful and equitable collective adaptation efforts at different levels and scales, and based on key principles of iterative risk management, require strong, usually multi-level governance systems. Multi-level governance refers to the dispersion of governance across multiple levels of jurisdiction and decision-making, including, global, regional, national and local, as well as trans-regional and trans-national levels (see also WG III Chapter 1). The concept emphasises that modern governance generally consists of, and is more flexible, when there are linkages of governance processes across different scales and levels. Multi-level governance is widely regarded as crucial particularly for transformational adaptation, defined as "adapting to climate change resulting in significant changes in structure or function that go beyond adjusting existing practices including approaches that enable new ways of decision-making on adaptation" (IPCC SR1.5, see also Section 1.5). The assessment in subsequent chapters also shows that public governance arrangements and institutions support the majority of adaptation for addressing the most important climate risks, though the importance of the private sector and community organizations in adaptation is increasing. It also shows that polycentric governance tends to benefit adaptation.

The empirical literature on adaptation governance has advanced strongly since AR5. It shows that stronger general governance capabilities are usually associated with more ambitious adaptation plans and more effective implementation of such plans (Chen et al., 2016; Keskitalo and Preston, 2019b: 24; ND-GAIN, 2019; Oberlack, 2017; Oberlack and Eisenack, 2018; UNEP, 2014; UNEP, 2018; UNEP et al., 2021; Woodruff and Regan, 2019). Governance capabilities are, to a significant degree, but not exclusively, a function of available financial resources and technology, but also a function of social capital and societal institutions, including well-functioning local, regional, and national governments and collaboration among these governmental actors and non-governmental stakeholders, including civil society and the private sector. The literature also points to governance conditions that are likely to enable transformational adaptation (Maor et al., 2017; see also Sections 1.4.4 and 1.5, Chapter 17).

Existing comparative data for adaptive capacity worldwide is at a rather coarse level of temporal and spatial resolution. It can, nonetheless, provide a very general picture of rates of change in adaptive capacity at the national scale, and differences between countries. Further empirical research is needed to identify the most important predictors of variation across countries and time, though the available data suggests that differing national income and education levels play a major role in accounting for differences in adaptive capacity (Andrijevic et al., 2020). Spatially more resolved (subnational) data is needed because a large body of case study research suggests that there is strong variation also within countries, particularly the large ones (e.g. India, China, Brazil, United States) (Chapter 16, see also Nalau and Verrall, 2021 and Cross-Chapter Box ADAPT). Moreover, higher degrees of adaptive capacity do not mean that adaptation action will follow automatically, nor that it will succeed in terms of equity and effectiveness in reducing vulnerability to climate change and enhancing well-being. How differences across and within countries in climate risk exposure translate into adaptation action, contingent on differences in adaptive capacity, can to some extent be inferred from case studies, but remains to be studied at a larger, comparable and generalizable scale.

Governance capacity constitutes an important enabling condition not only because it facilitates the (efficient) organization and implementation of adaptation action, but also because it contributes to learning. The latter is central to the process of adaptation as information regarding current and future climate conditions continues to evolve, as does understanding of appropriate response options and the actors involved. In addition, norms, values and practices may change in response to changing conditions (Jones et al., 2014). Much learning by individuals, communities and organisations is unplanned (National Research Council, 2009) as is much current adaptation (Berrang-Ford, 2020), which can reduce near-term costs and administrative complexity, but may prove maladaptive (Section 1.4.2.4). Iterative risk management (Section 1.2.1.1) and related concepts such as risk governance (Renn, 2008) describe a planned learning process of ongoing assessment, action and reassessment. Iterative risk management can be as simple as scheduling future updates of assessments and plans, as with the five-year updates of the global stocktake after 2023 called for in the Paris Agreement or encompass more elaborate learning processes, such as dynamic adaptive pathways (Haasnoot et al., 2019b; Cross-Chapter Box DEEP in Chapter 17) which include specific near-term actions, specific trends to monitor and specific contingency actions to take depending on the future conditions observed. While often more effective at meeting goals, such planned learning processes may pose implementation and governance challenges (Metzger et al., 2021)

Mainstreaming adaptation into existing governance structures and associated organisations and their investments, policies and practices can contribute to expanding the solution space and support efforts at transformative adaptation. For instance, urban planning can support adaptation by mainstreaming adaptation into city plans, such as land-use planning, procuring resilient infrastructure and transportation, supporting health and social services, promoting community-based adaptation, and protecting and integrating biodiversity and ecosystem services into city planning (Section 17.4.3). Mainstreaming adaptation also shows many shortcomings, such as, diminish the visibility of dedicated, stand-alone adaptation approaches (Persson et al., 2016), unequal distribution of adaptation efforts; dilute responsibilities for implementation (Nalau et al., 2016; Reckien et al., 2019); exhibit disconnects between planning, investment and implementation and limited policy coherence (Bizikova et al., 2015; England et al., 2018; Friend et al., 2014; Koch, 2018); and fail to adequately balance overlapping and/or competing policy objectives (Vij et al., 2018).

Finally, governing adaptation in ways that maximize the solution space and facilitate learning can help avoid maladaptation. Maladaptation refers to potentially adverse effects of certain forms of adaptation action, such as increased GHG emissions, or increased vulnerability to climate change and diminished welfare of certain parts of a population now or in the future (Anguelovski et al., 2016; Benzie et al., 2018; IPCC, 2018b; Keskitalo and Pettersson, 2016; Munia et al., 2018; Nadin and Roberts, 2018; Prabhakar et al., 2018; Veldkamp et al., 2017; Zimmermann et al., 2018). Maladaptation is an example of response risk, which is increasingly highlighted in both AR6 WGII and WGIII (Section 1.3.1.2, see also IPCC Risk Guidance). One example is that adaptation action may set paths that limit the choices of future generations to adapt. This last characteristic refers to the lock-in effects of improperly designed and costly infrastructures that affect the ability of future generations to amend.

Maladaptation can result from many potential barriers, including administrative, human, financial and technical resource constraints (Hassanali, 2017; Pardoe et al., 2018; Singh et al., 2018); lack of transparency and/or capacity in governance (Friend et al., 2014); unreliable information on climate impacts and the lack of key policy guidelines (Pilato et al., 2018); entrenched institutional, legal and technical obstacles (Gao, 2018) and low literacy, including environmental and scientific literacy (Wright et al., 2014); and exclusion of vulnerable groups (Forsyth, 2018); governance fragmentation (that is, a fragmentation of laws, regulations, and policy requirements); and limited cross-sectoral collaboration, meaning that there is limited coordination and that top-down planning approaches are not connected to local dynamics (Archer et al., 2014; Pardoe et al., 2018). This report draws attention to maladaptation challenges recognising that not all adaptation-related responses reduce risks (Chapter 16). Besides, maladaptation is the opposite of successful adaptation which is associated with reduction of climate risks and vulnerabilities for humans and ecosystems, increased well-being, and co-benefits with other sustainable development objectives. (Chapter 17)

1.4.3 Monitoring and Evaluation of Adaptation

Monitoring and evaluation (M&E) encompasses a broad range of activities serving multiple purposes, including tracking progress of adaptation efforts over time, understanding equity and effectiveness of adaptation options and outcomes, and informing ongoing adaptation processes (Section 17.5.2.1). While monitoring and evaluation are often referred to jointly as "M&E," monitoring usually refers to continuous information gathering whereas evaluation denotes more comprehensive assessments of effectiveness and equity, often resulting in recommendations for decision makers (Sections 17.5.1.1 and 17.5.1.7). In some literatures M&E refers solely to efforts undertaken after implementation. In other literatures, M&E refers both to efforts conducted before and after implementation. As shown in Figure 1.8, M&E is essential to the process of iterative risk management, both in terms of adaptation assessment prior to implementation and M&E of implemented adaptation measures. AR6 highlights that M&E after implementation is much less common than adaptation assessment prior to implementation (Section 17.5.2.1; Berrang-Ford, 2020).

Tracking adaptation planning and policies: Since AR5, interest in M&E for tracking progress in adaptation has grown substantially at the local, national and global level. I The Paris Agreement calls for a Global Stocktake every five years starting in 2023 (Cross-Chapter Box PROGRESS in Chapter 17). It also encourages states to monitor and evaluate their adaptation plans, policies, programmes and actions and provides guidance on communicating information about adaptation to the international community (UNFCCC, 2015b, Article 7.9d; UNFCCC, 2018a, Decision 9/CMA.1; UNFCCC, 2018b, Decision 18/CMA.1).

Since AR5, a large number of case studies on individual local to national level adaptation measures have been published (see Chambwera et al., 2014; Keskitalo and Preston, 2019b), as well as comparative studies across countries over multiple years (Biesbroek et al., 2018; Biesbroek and Delaney, 2020; Lesnikowski et al., 2016). The existing literature now allows for at least preliminary conclusions about where and why we observe adaptation efforts, as described in the sectoral, regional and synthesis chapters of this report.

While case studies provide context-specific insights, global inventories are essential for tracking global progress on adaptation (UNEP, 2018; UNEP et al., 2021; Cross-Chapter Box PROGRESS). Until recently, the dominant approach surveyed National Communications to the UNFCCC to measure the amount of adaptation planning activity worldwide (Gagnon-Lebrun and Agrawala, 2007; Lesnikowski et al., 2016). More recent assessments have focused also on the quality of local and national adaptation planning to better characterize its potential merits, shortcomings and effects (UNEP et al., 2021; Woodruff and Regan, 2019) and have compiled inventories of adaptation projects (Leiter, 2021) and local adaptation policies (Lesnikowski et al., 2019b; Olazabal et al., 2019; Reckien et al., 2018; see also Section 6.4.6). Chapters 16 and 17 of this report offer an initial synthesis, but efforts to compile a comprehensive global, empirical inventory of climate change adaptation remain in an early phase (e.g., Berrang-Ford et al., 2011; Fankhauser, 2017; Ford et al., 2015; GEF, 2014; Leiter, 2021; Lesnikowski et al., 2016; Tompkins et al., 2010; Tompkins et al., 2018).

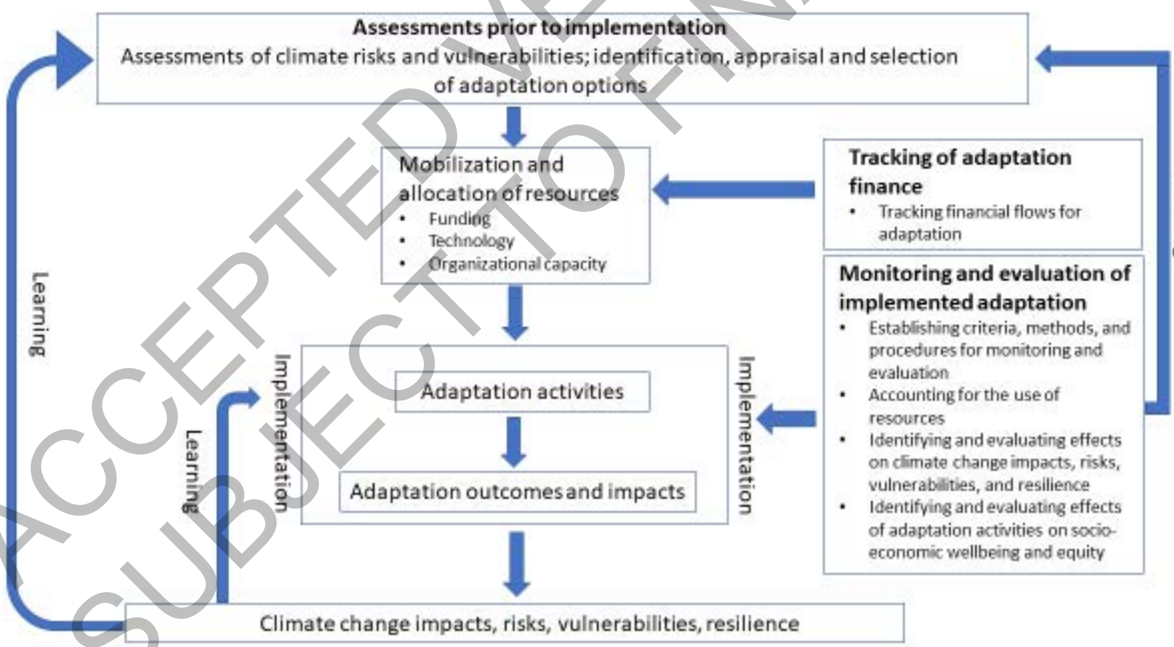

Figure 1.8: Adaptation assessment prior to implementation and M&E during and after implementation. Both systematic assessment of adaptation needs and options and M&E of implemented adaptation are key to iterative climate risk management, and to achieving effective and equitable adaptation. Most assessments to date have referred to aspects prior to implementation. There is much less systematic evidence on adaptation action, and even less evidence on adaptation outcomes and impacts and their implications for climate change impacts, risks, vulnerabilities and resilience. Figure 17.9 in Chapter 17 provides more detail on M&E.

Improving effectiveness: Information regarding the effectiveness of adaptation remains scarce (UNEP et al., 2021), which hinders efforts to improve adaptation practice. A recent comprehensive review found that only 2.3% of the close to 1,700 articles identified by the Global Adaptation Mapping Initiative as documenting implemented adaptation provide evidence of risk reduction (Chapter 16; Berrang-Ford, 2020). However, there exists limited but emerging evidence of the use of M&E by different actors to assess adaptation progress (Section 17.5.1).

Existing case studies use varying criteria for assessing effectiveness, complicating comparisons. Judgements regarding successful adaptation are contingent on the chosen scale and perspective (success for whom?) (Adger et al., 2005; Dilling et al., 2019) and on the level of risk, i.e., increasing climate risks may cause previously successful adaptation to become insufficient. Rather than a binary outcome (successful or unsuccessful), adaptation can be viewed on a continuum from successful adaptation to maladaptation (Section17.5.2). Assessments of adaptation success need to account for distributional effects and differential vulnerability, as well as consider connections across different scales and complex interactions with other change processes (Section 17.5.1). Recent literature has begun to identify how adaptation can better achieve its intended objectives (Eriksen et al., 2021). For instance, inclusive M&E can legitimize and validate M&E and foster commitment and learning.

Informing ongoing adaptation: Iterative risk management involves an ongoing cycle of assessment, action, learning and response in which M&E plays a central, enabling role (Section 1.2.1.1). Assessing the risk reduction provided by adaptation, both planned and implemented, often requires projections of anticipated future climate, socio-economic conditions, and the effectiveness and implications for justice of each option (Section 17.4.4). Understanding the potential for maladaptation may also require such assessments (Section 1.4.2). Processes, such as adaptive pathways, that involve anticipating future responses (Box 11.4; Box 11.6; Sections 11.7; 17.3) entail monitoring to detect early warning of approaching thresholds or changes in the solution space (e.g. more rapid than expected sea level rise or new social acceptance of managed retreat) that suggest the need or opportunity to adjust or expand current adaptation efforts (Haasnoot et al., 2021).

[START CROSS-CHAPTER BOX ADAPT HERE]

Cross-Chapter Box ADAPT: Adaptation Science

Authors: Johanna Nalau (Australia/Finland), Lauren Rickards (Australia), Tabea Lissner (Germany), Katharine J. Mach (USA), Lisa Schipper (Sweden/United Kingdom), Chandni Singh (India), William Solecki (USA), Adelle Thomas (Bahamas) and Edmond Totin (Benin)

High-level statements:

- Adaptation knowledge consists of a diverse set of sources including academic research, applied analysis and practice and experience with projects and policy on the ground.
- Adaptation science encompasses both research 'on adaptation', documenting and analysing experiences of adaptation, and 'for adaptation', aiming to advance the planning and implementation of adaptation.
- The nature of adaptation research is diversifying and examines different approaches from local case studies to more global, transboundary, comparative and interactive perspectives, although critical conceptual and empirical gaps remain in defining effectiveness in adaptation and measuring adaptation progress.

This cross-chapter box complements the reviews of specific adaptation knowledge, content and progress described throughout WG2 by providing a higher-level analysis of the shifting characteristics of and trends in **adaptation research** and its evolution over time.

The characteristics and diversity of adaptation knowledge

The knowledge base on adaptation has matured significantly since AR5. Whereas adaptation research was primarily academic during the 1990s and 2000s, it now includes a proliferation of on-the-ground experience of how to adapt to climate change, increasingly documented in reports and papers. Furthermore, academic research on adaptation has diversified significantly. Understanding the characteristics and diversity of this knowledge base is key for it to effectively inform decision making and action on adaptation.

Academic work on adaptation now spans an increasing number of disciplines and countries and is published across diverse academic outlets and disciplines, with 28.5% annual average increase in adaptation specific publications (Nalau and Verrall, 2021). This expands the range of considerations and perspectives within adaptation research and increases the challenge of identifying and synthesising all relevant research on adaptation in reviews or assessments (Berrang-Ford et al., 2015; Sietsma et al., 2021; Singh et al., 2020; Webber, 2016). Also, large bodies of research and knowledge exist that support climate adaptation ideas, theoretical development, and practical implementation, but are not explicitly framed as climate change adaptation (Biesbroek et al., 2018; Dupuis and Biesbroek, 2013; Keskitalo and Preston, 2019a). Therefore, debates still emerge about what actually counts as "adaptation" (Dupuis and Biesbroek, 2013), and what knowledge is being assessed and measured for this purpose.

IPCC assessment reports combine two complementary approaches to adaptation research: that which is 'on' or 'about' adaptation and that which is 'for adaptation'. Both are needed because research 'on adaptation' helpfully investigates the phenomenon and processes of adaptation (e.g., via analyses of others' adaptation practices and efforts) while research 'for adaptation' generates knowledge that can enable the planning and implementation of adaptation (e.g., action research as part of an adaptive capacity building process) (Swart et al., 2014).

One of the contributions of research 'on adaptation' is to track and debate the broader trends, core characteristics and overall assumptions embedded in adaptation knowledge. This reflexive turn about the foundational assumptions is itself one emerging trend in adaptation research (e.g., Atteridge and Remling, 2017; Juhola, 2016; Nalau et al., 2015; Preston et al., 2013). This signals the influence of more social science in adaptation research and increased awareness of the practical value of being transparent and critically reflective about the content, topics, frames and approaches that researchers use (Lacey et al., 2015; Nalau et al., 2021; Singh et al., 2021). For example, different conceptions of adaptation contribute to different definitions of "adaptation success", different ideas about what "effective" adaptation practice looks like and, thus, different conclusions about what is and is not working well (Berrang-Ford et al., 2019; Dilling et al., 2019; Eriksen et al., 2021; Magnan et al., 2020; Owen, 2020; Singh et al., 2021; Section 17.5.1.1). This diversity adds richness and options, but also poses challenges in constructing a conventional evidence base for decision- and policy making. Adaptation researchers are increasingly expected to offer clear and confident advice on adaptation success, yet are also increasingly aware of how context-specific and contested success is (see also Lacey et al., 2015 on ethics).

Grey literature on adaptation is also proliferating, typically authored by organisations funding and implementing adaptation. This literature often documents a range of adaptation strategies (Sections 9.8.3; 10.4.6.4; 14.4.3.3; 17.2.1.) and lived experiences of adaptation efforts, including helping give voice to marginalised groups, and highlighting the importance of Indigenous knowledge and local knowledge (Nunn et al., 2016; Section 4.7.5.4; Box 9.2; 15.6.4; Cross-Chapter Box INDIG in Chapter 18; Petzold et al., 2020). However, most of the lessons learned through implementation of adaptation projects and programmes are still not captured in academic or even grey literature and thus remains less systematically analysed. Crucially, the large gaps in documentation of adaptation knowledge mean that a lack of published evidence about a given issue does not necessarily reflect its absence in real life – a qualification about adaptation research that readers of AR6 need to appreciate.

The evolution of adaptation research trends

In the 1990s, climate change adaptation was constrained as a specific topic of inquiry by the dominant focus on mitigation of greenhouse gas emissions and the related assumption that successful mitigation would render unnecessary the need for adaptation beyond what human and natural systems could inherently manage (Pielke, 1998; Schipper, 2006; Schipper and Burton, 2009). Several key developments in the 1990s included the IPCC 2nd report (1996) and the establishment of several key journals including Climatic Change (1978), Mitigation and Adaptation Strategies to Global Change (1996), and the Global Environmental Change journal that strengthened more dedicated focus on climate change related research.
Many foundational papers on key concepts central to adaptation were published in 1990s and early 2000s onwards (Adger et al., 2005; Burton, 1992; Fankhauser et al., 1999; Klein, 2003; Parry and Carter, 1998; Pittock and Jones, 2000; Smit, 1993; Smit et al., 1999; Smithers and Smit, 1997) while adaptation began to gain more prominence in IPCC's 3rd assessment (2001) and 4th assessment (2007). For example, the Canada

Climate Program report (Smit, 1993) report set out many of the principles of adaptation, and was highly influential charting these concepts also in IPCC's 3rd Assessment Report (Schipper and Burton, 2009). These papers and IPCC reports remain key foundations of climate adaptation science literature (Nalau and Verrall, 2021).

Helping to differentiate adaptation from mitigation during this period was a focus on theoretical principles and a framing of adaptation as local and context-specific, in contrast to mitigation's global character (Nalau et al., 2015; Westoby et al., 2020), leading to locally oriented adaptation research and practice, including the rise of community-based adaptation (Kirkby et al., 2017). Since AR5, however, adaptation has extended beyond the local, recognising the 'borderless' character of many climate change risks and vulnerabilities (Benzie and Persson, 2019) and framing adaptation and global adaptation governance as a global public good (Persson, 2019a). Encompassing this expanded scale is challenging for adaptation research compared to treating adaptation as a local issue, which fits more easily with social research methods. Adaptation now works across scales (Biesbroek et al., 2013; Dzebo and Stripple, 2015; Keskitalo and Preston, 2019a) and attends simultaneously to both the opportunities and risks arising from climate change (Juhola, 2016; Keskitalo and Preston, 2019a). This suggests that empirical adaptation research should incorporate multi-scalar research designs and methods.

A strong focus has been and remains on case studies of adaptation practice, but adaptation science literature reviews have become common. Recent systematic reviews cover topics such as adaptation effectiveness (Owen, 2020), public participation and engagement (Hügel and Davies, 2020), role of local knowledge (Klenk et al., 2017), adaptive capacity (Mortreux and Barnett, 2017; Mortreux et al., 2020; Siders, 2019a), evolution of adaptation science (Nalau and Verrall, 2021), empirical adaptation research in the Global South (Vincent and Cundill, 2021), how cities are adapting (Reckien et al., 2018), how decisions can be made (Siders and Pierce, 2021), Indigenous knowledge (Petzold et al., 2020) and small island developing states (Robinson, 2020). Review papers have developed common methodologies for how to undertake robust reviews in adaptation research (Berrang-Ford et al., 2015; Biesbroek et al., 2018; Lesnikowski et al., 2019a; Singh et al., 2020), and noted an existing imbalance as the majority of the literature still originates from the Global North compared to Global South (Nalau and Verrall, 2021; Robinson, 2020; Sietsma et al., 2021).

At the same time, adaptation research is also challenged by increasing attention to transformational adaptation (TA), which refers to fundamental changes going beyond existing practices, including new approaches to adaptation decision-making (Section 1.5). Whereas AR5 noted TA as an area of future research (Klein et al., 2014b), it has continued to grow in profile since then. Rather than a future or fringe consideration - e.g., an extreme action necessitated by the limits of incremental adaptation - transformational adaptation is increasingly an option that decision-makers are considering today. This increasing attention on TA is driven by a growing recognition of climate risks and impacts as well as the need for urgent, systemic action as laid out in the IPCC's recent special reports (IPCC, 2018d). Yet what incremental and transformational adaptation look like, how they relate in practice, and how to appropriately choose incremental or transformational options, is uncertain and increasingly debated (Few et al., 2017; Magnan et al., 2020; Termeer et al., 2016; Vermeulen et al., 2018; Wilson et al., 2020; Section 17.2.2.3). One of the main challenges is now to generate empirical evidence and policy relevant insights on transformational adaptation (e.g., Jakku et al., 2016). Transformative approaches are especially being discussed in the context of COVID-19 (Schipper et al., 2020; Cross-Chapter Box COVID in Chapter 7).

Increasingly reflective adaptation research

Another characteristic of recent adaptation research is a stronger focus on ethics, justice and power (Byskov et al., 2021; Coggins et al., 2021; Eriksen et al., 2021; Singh et al., 2021). Researchers and practitioners are increasingly impatient to address the root causes of vulnerability and use inclusive climate adaptation processes to generate effective adaptation responses for marginalised and misrecognized groups (Eriksen et al., 2015; Gillard et al., 2016; Scoones et al., 2015; Tschakert et al., 2013; Wisner, 2016). Increasingly ambitious, normative adaptation research often challenges technological solutions that simply reinforce the existing *status quo* (Nightingale et al., 2019, p. 2) and calls for "socially-just pathways for change". Here work on adaptation overlaps with mitigation, transitions and other large-scale social change, encouraging the move towards more systemic, integrated approaches that discern between options according to multiple criteria (Goldman et al., 2018).

Fundamental questions about equity and justice in adaptation include gender and intersectionality (see Cross-Chapter Box GENDER in Chapter 18, Section 1.4.1.1 Chapter 18;) and broader critiques of who participates in processes of adaptation planning and implementation, who receives investments, who and what benefits from them, who makes key decisions regarding adjustments through time (Boeckmann and Zeeb, 2016; Byskov et al., 2021; Eriksen et al., 2021; Nightingale et al., 2019; Pelling and Garschagen, 2019; Taylor et al., 2014), and how climate justice intersects with other justice agendas. Attention is also turning to relations and tensions between different adaptation approaches, scales, constraints, limits, losses, enablers and outcomes (Barnett et al., 2015; Crichton and Esteban, 2017; Deshpande et al., 2018; Gharbaoui and Blocher, 2017; McNamara and Jackson, 2019; Mechler and Schinko, 2016; Pelling et al., 2015). Evident here is an ongoing, serious knowledge gap around the long-term repercussions of adaptation interventions. There is growing awareness of the need to address the potential for maladaptation (Sections 1.4.2.4; 5.13.3; 15.5.1, 17.5.2, Chapter 4 on Water). Concerns about maladaptation have led to renewed calls to open the “black box” of decision making to examine the influence of power relationships, politics and institutional culture(Biesbroek et al., 2013; Eriksen et al., 2015; Goldman et al., 2018), including the power-adaptation linkage itself (Woroniecki et al., 2019), external factors outside the decision-making process (Eisenack et al., 2014) and the influence of leadership on adaptation processes and outcomes (Meijerink et al., 2014; Vignola et al., 2017).

All of these developments indicate that adaptation research is not only more reflexive about some of its central assumptions, methodologies and tools (Biesbroek et al., 2013; Conway and Mustelin, 2014; Eriksen et al., 2015; Lubell and Niles, 2019; Nalau et al., 2015; Nightingale, 2015a; Porter et al., 2015; Singh et al., 2021; Woroniecki et al., 2019), but also cognisant of the need to critically consider its underpinning goals, purpose and impact in the world.

[END CROSS CHAPTER BOX ADAPT HERE]

1.4.4 Limits to Adaptation

The effectiveness of adaptation efforts also depends on the constraints and limits that human and natural systems face when confronted with increasingly higher levels of climate risks. The concept of adaptation limits strongly affects any appropriate balance among adaptation and mitigation actions in the sense that less mitigation makes adaptation harder or even infeasible. **Adaptation limits** refer to the point at which an actor’s objectives (or system needs) cannot be secured from intolerable risks through adaptive actions (WGII AR6 Glossary). Adaptation limits can be soft or hard. **Soft adaptation limits** occur when options may exist but are currently not available to avoid intolerable risks through adaptive actions and **hard adaptation limits** occur when no adaptive actions are possible to avoid intolerable risks. Intolerable risks are those which fundamentally threaten a private or social norm — threatening, for instance, public safety, continuity of traditions, a legal standard or a social contract -- despite adaptive action having been taken (Dow et. al. 2013). Intolerable risks threaten core social objectives associated with health, welfare, security, or sustainability (WGII AR5 Chapter 16). Through the lens of resilience, hard limits represent the range of change or disturbance beyond which a system cannot maintain its essential function, identity, and structure. Soft limits represent the range of change or disturbance of a system which can be sustained over time by innovation or policy changes. The level of greenhouse gas reduction, adaptation and risk management measures are the key factors determining if and when adaptation limits are reached.

1.4.4.1 Limits to Adaptation and Relation to Transformation

A species ability to adapt may be significantly impacted by the dynamics of interactions between the ecosystems and species, so that a species may reach its limit to adapt even in a gradually changing environment, leading to sudden changes in range fragmentation (Radchuk et al., 2019). As human interventions affect the ability of species and ecosystems to adapt, a deeper understanding on ecosystems and species interactions and evolution in response to climate change is important in order to reduce future biodiversity losses (Nadeau and Urban, 2019). Hard limits for ecological and natural systems are more proximate than for human systems (Chapter 16) (*medium confidence)*. Many terrestrial, freshwater, ocean and coastal ecosystems are currently near or beyond their hard adaptation limits (Chapters 2, 3 and 16).

Many human and natural systems are currently near or beyond their soft adaptation limits (Dow et al., 2013; Chapters 4, 5, 6, 7, 8, and 16). The concept of limits to adaptation is dynamic in terms of the temporal, spatial and contextual dimensions of climate change risks, impacts and responses (Chapter 17; Storch, 2018). Adaptation limits depend on a complex function of interactions between social, ecological, technological and climatic elements, which appear to have thresholds beyond which adaptation can be infeasible and represent limits to adaptation. Such thresholds are endogenous to society and hence contingent on ethics, knowledge, attitudes, culture, governance, institutions and policies (Abrahamson et al., 2009; Tschakert et al., 2017). Since AR5, the evidence on limits to adaptation has been advanced across regions and sectors. Many adaptation constraints (financial, governance, institutional and policy etc.) lead to soft adaptation limits (see Chapter 16 for detailed evidence on constraints and adaptation limits). The ability of actors to overcome these constraints including social constraints to behavioural changes, depends on additional adaptation implementation. (Abrahamson et al., 2009; Di Virgilio et al., 2019; Juan, 2011). Thus, socioeconomic, technological, governance and institutional systems or policies can be changed or transformed in responses to the different dimension of adaptation limits to climate change and extreme events.

When a soft limit is reached, then intolerable risks and impacts may occur, and additional adaptations (incremental or transformational) are required.to reduce or avoid these risks and impacts (Chapters 2, 3, 4, 5, 6, 7, 16 and 17). IPCC SR1.5 defined incremental adaptation that maintains the essence and integrity of a system or process at a given scale whereas transformational adaptation that changes the fundamental attributes of a socio-ecological system in anticipation of climate change and its impacts. When incremental adaptation is insufficient to avoid intolerable risks, transformational adaptation may be able to extend the potential to sustain human and natural systems (IPCC, 2018a; Cross-Chapter Box LOSS in Chapter 17; Klein et al., 2014b). Transformational adaptation can allow a system to extend beyond its soft limits and prevent soft limits from becoming hard limits. This report provides evidence of assessing transformational adaptation in terms of scope, depth, speed and limits to adaptation (Chapter 16).

This report assesses adaptation limits (soft and hard) and residual risks for some actors and systems (Chapter 16). **Residual risk** is the risk that remains following adaptation and risk reduction efforts (SROCC). Residual risk is also used as other terms such as 'residual impacts', 'residual loss and damage' and 'residual damage'. As noted in AR5 WGII, the residual risk is larger or smaller depending on a society's choices about the appropriate level of adaptation and its ability to achieve an appropriate level. The intersection of inequality and poverty presents significant adaptation limits, resulting in residual impacts for vulnerable groups, including women, youth, elderly, ethnic and religious minorities, Indigenous People and refugees (Section 8.4.5). An appropriate level of adaptation, which ideally reflects a balance between the desired level of risk and the actions needed to achieve that level of risk, depends on the solution space, the society's views on climate justice, the tolerance for climate-related risks, the society's tolerance for the costs and other impacts of the actions needed to reduce risk. IPCC'S special reports stated that residual risks rise with increasing global temperatures from 1.5°C to 2°C (SR 1.5) and emerge from irreversible forms of land degradation (SRCCL). Among other risks, this report is evidenced that at risk to coastal flooding from sea level rise, nature-based adaptation measures (e.g., coral reefs, mangroves, marshes) reach hard limits beginning at 1.5ºC of global warming (Chapter 16). Residual risks may lead to exceeding the limits of adaptation, hence, this report underscores on the role of decision-making on transformational adaptation for dealing with residual risk and soft as well as hard adaptation limits (Cross-Chapter Box LOSS in Chapter 17). Section 1.5 addresses transformational adaptation in the context of climate resilient development pathways, since such adaptation is inseparable from mitigation and sustainable development.

1.4.4.2 Emerging importance of loss and damage

The concept of **Loss and Damage** (with capitalized letters, L&D) refers to discussion point under the UNFCCC, which is to "address loss and damage associated with impacts of climate change, including extreme events and slow onset events, in developing countries that are particularly vulnerable to the adverse effects of climate change." Lowercase letters of **losses and damages** refer broadly to harm from (observed) impacts and (projected) risks (IPCC, 2018a). The IPCC report uses the latter for its assessment on loss and damage which may provide useful information for the former. L&D associated with climate change has gained importance supported by the robust scientific evidence on the anthropogenic climate change amplifying frequency, intensity and duration of climate-related hazards (Mechler et al., 2019). Loss and damage associated with those residual losses and damages that are felt beyond the adaptation actions taken implying a sense of limits to adaptation at a given time and spatial contexts (Tschakert et al., 2017). IPCC's special report on climate change and land also underlined the unavoidable loss and damage due to changes in tropical and extratropical cyclones and marine heatwaves where adaptation and resilience limits are being exceeded for the people and ecosystems (IPCC, 2019a; Cross-Chapter Box LOSS in Chapter 17).

Loss and damage has emerged as an important topic in international climate policy (Boyd et al., 2017; Roberts and Pelling, 2016; Surminski and Lopez, 2015) which originated from Small Island Developing States for compensation, related to sea level rise impacts. It has since become formalized under the UNFCCC, through the establishment of the Warsaw International Mechanism (UNFCCC, 2013) and Article 8 of the Paris Agreement (UNFCCC, 2015b). The WIM promotes the implementation of comprehensive risk management approaches, improves understanding of slow onset events, non-economic losses and human mobility (migration, displacement) and enhances action and support, including finance, technology and capacity-building to avert, minimize and address loss and damage associated with climate change impacts particularly vulnerable and developing countries (UNFCCC, 2021). Different actors have defined loss and damage differently in reference to climate change impacts and responses (Boyd et al., 2017; McNamara and Jackson, 2019; Roberts and Pelling, 2016; Surminski and Lopez, 2015). These understanding includes the following: i) an adaptation and mitigation perspective linking all human-induced climate change impacts to potential loss and damage and the mandate to avoid dangerous anthropogenic interference; ii) a risk management perspective emphasising interconnections among disaster risk reduction, climate change adaptation, and humanitarian efforts; iii) a limits to adaptation perspective focused on residual loss and damage beyond adaptation and mitigation; and iv) an existential perspective highlighting inevitable harm and unavoidable transformation for some people and systems. This report assesses the growing literature on loss and damage across sectors and regions linking with adaptation constraints and limits, global warming level and incremental and or transformational adaptation to climate risks (Section 8.3.4, Cross-Chapter Box LOSS in Chapter 17, Box 10.7).

For assessing the projected losses and damages, residual risks also need to be taken into account. The loss and damage associated with the future climate change impacts, beyond the limits to adaptation, is an area of increasing focus, although yet to be fully developed in terms of methods of assessing including non-economic losses and damages as well as identifying means to avoid and reduce both economic (loss of asset, infrastructure, land etc.) and non-economic (loss of societal beliefs and values, cultural heritage, biodiversity and ecosystem services) losses and damages (Andrei et al., 2015; Fankhauser and Dietz, 2014). There is an increasing evidence in economic and non-economic losses due to climate extremes and slow onset events under observed increases in global temperatures (Coronese et al., 2019; Section 8.3.4; Grinsted et al., 2019; Kahn et al., 2019), however assessing non-economic losses and damages is lacking and needs more attention (Serdeczny et al., 2016; Tschakert et al., 2019). The aggregate losses and damages would be higher if non-economic values are considered in such assessment (Laurila-Pant et al., 2015; McShane, 2017). Solutions to reduce or avoid loss and damage need a robust conceptual framework and analysis, focusing the future losses rather than past losses (Preston, 2017) and emphasis on avoiding versus addressing loss and damage, and the role of justice (Boyd et al., 2017), clarity on the detection and attribution (Section 8.2.1, Section 8.3.3), effectiveness of risk management and adaptation (Cross-Chapter Box FEASIB in Chapter 18, Section 1.4), the concepts of risk transfer, liability and financing (Cross-Chapter Box FINANCE in Chapter 17, Section 17.4.2), and the role of transformation (Section 1.5).

1.5 Facilitating Long-Term Transformation

This report highlights that transformative system change is required to meet sustainable development goals (Chapter 18). **Transformation** is defined as "a change in the fundamental attributes of a system including altered goals or values" (SR 1.5). The related concept of **transition** is defined as "the process of changing from one state or condition to another in a given period of time" (IPCC SR 1.5/SRCCL, also see Section 1.5.2).

Many timescales have been assessed that shape the context for any such transformations: including the present, 2030 and mid-century (Cross-Chapter Box CLIMATE in Chapter 1). In the present, significant changes in the climate system have already occurred in many places (WGI) while commensurate adaptation actions have in general been lacking (Chapter 16). By 2030, the SDGs call for significant societal changes, many of which would be more difficult to achieve without significant reductions in climate risk and impacts. By mid-century, global emissions pathways consistent with the Paris Agreement 1.5°C target drop to zero net greenhouse gas emissions with no overshoot and roughly a decade later with overshoot (Cross-Chapter Box CLIMATE in Chapter 1). Pathways consistent with the Paris 2°C target drop to zero net emissions in the latter half of the 21st century. Even in low emission scenarios temperatures, storm intensities, sea levels and other climate parameters are expected to continuing changing for decades (IPCC, 2021).

The concepts of transition and transformation help organize assessments of near and longer-term adaptation actions that may prove feasible and effective in achieving societal goals related to climate and sustainable development.

1.5.1 Understanding Transformation

Over the last two hundred years, human society has undergone a rapid and profound transformation, with population and income per capita expanding by an order of magnitude or more after many millennia of relative stasis in living standards (Dasgupta et al., 2018). The transformations associated with sustainable development and managing climate risk may be of similar scale as these historic transformations. In the past, changes in technologies and economies of this scale are not separate from, but are necessarily embedded alongside changes in political, religious and social relationships (Polanyi, 1957). Future transformation may similarly involve such interlinked social, cultural, economic, environmental, technical and political factors (Chapter 18; Section 1.5.2). Technology-led, market-led or state-led transitions aimed at meeting Paris Agreement and SDGs may fail without integrating dimensions of social justice and addressing the social and political exclusion that prevent the disadvantaged from accessing such improvements and increasing their incomes (Burkett et al., 2014; Scoones et al., 2015). (*medium confidence*)

As used in the global environmental change literature, transformation is a pluralistic concept embracing many interpretations (Box 18.3), but all focus on the general idea of fundamental change in society as opposed to change that is minor, marginal, or incremental. Uses of the term can differ with respect to: 1) how the system undergoing change is conceptualized, 2) the extent to which change is continuous or discontinuous and the time scales involved, 3) the extent to which transformation is guided towards desired goals or emerges without intent and 4) whether the usage focuses on descriptions of societal processes or includes normative judgements as to which outcomes should or should not occur (Feola, 2015) . The literature generally uses transformation as an analytic-descriptive concept, which aims to describe significant change in couple human-natural systems, or as solutions-oriented concept, which aims to inform or contribute to societal change.

The IPCC Fifth Assessment cycle, starting with its Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX), first highlighted the concept of transformation, drawing primarily on the solutions-oriented approaches of O'Brien (2011) and Pelling (2011). This Sixth Assessment report also generally employs transformation as a solutions-oriented concept, with mention in almost all chapters and significant emphasis in the synthesis chapters.

The IPCC Sixth Assessment cycle also highlights the concept of transition, drawn from the sustainability transitions literature (Köhler et al., 2019). The 1.5 Special Report organizes its assessments of feasibility and potential policy actions around transitions in four socio-technical system: energy, land, urban and infrastructure and industrial system (IPCC, 2018b: Chapter 4). This report adds a fifth system transition -- a societal transition focused on attributes that drive innovation, the evolution of patterns of consumption and development and power relationships among societal actors (Section 18.1.4). The AR6 WGIII report is organized around six systems transitions: energy; agricultural, forestry, other land use; urban; buildings; transportation; and industry, which includes supply chains and the circular economy.

The literature offers multiple views on the relationships between transition and transformation (Box 18.3). The 1.5 Special Report suggests that transformation is needed to generate the four system transitions. In many literatures, transformation is considered a more expansive process than transition, with the former less exclusively focused on socio-technical systems and more engaged with questions of power, politics, capabilities, culture, identity and sense-making (Gillard et al., 2016; Hölscher et al., 2018; Linnér and

Wibeck, 2019). This report generally takes this more expansive view of transformation, often to engage with issues of equity, climate justice and large-scale institutional and societal change (Box 18.3).

This WGII report has a particular focus on **transformational adaptation** (Section 1.4.4.1), which it views as laying on a continuum from incremental and transformational with no sharp division between them (Sections 17.2.2.3, 1.5.2).

The IPCC first highlighted the concept of transformational adaptation in the Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX). SREX generally used the phrase transformation to refer to fundamental societal changes that advance climate adaptation, disaster risk management and sustainable development. Transformation was seen as one part of the solution space alongside options such as reducing vulnerability and exposure and increasing resilience for managing risk. WGII of the IPCC Fifth Assessment Report used the phrase transformational adaptation to contrast with incremental adaptation. That report used the former term to refer to: 1) adaptation at large scope or scale, 2) as the type of adaptation that occurs once soft limits have been breached, or 3) change that addresses root causes of vulnerability as well as redressing long-standing inequities. The Fifth Assessment Report's WGIII employed the concepts of transformation and transformation pathways to assess the large-scale societal changes needed to meet greenhouse gas emission reduction goals.

This WGII report focuses on transformational adaptation as one component of climate resilient development in which adaptation, mitigation and development solutions are pursued together to exploit synergies and reduce trade-offs among these actions (Section 1.5.3; Chapter 18). Chapter 16 assesses the extent to which transformational adaptation is currently being implemented, using criteria including the scope, depth and speed of the adaptation actions as well as the extent to which limits to adaptation have been considered (Section 16.3.2.4). Chapter 17 ranks potential adaptation options by where they lie on the incremental to transformational continuum (Section 17.5.1.1.2).

Societal transformation can arise without explicit intent as, arguably, did the industrial revolution and some of the trends re-making today's society (See Section 1.1). In order to help policy-makers achieve societal goals this report seeks to identify the conditions for **deliberate transformations**, that is, those envisioned and intended by at least some societal actors (Linnér and Wibeck, 2019).

Figure 1.9 connects several key concepts that this report employs to help distinguish pathways that lead to deliberative and forced transformations. As shown in the figure, adaptation goals might imply a desired level of adaptation: 1) accessible by actions within the solution space of the existing system or 2) beyond the solution space of the existing system. In the former case, incremental adaptation may stay within soft limits and hold risks to tolerable levels that avoid threatening private or social norms (also see Fig 17.6). In the latter case, deliberate transformational adaptation is necessary to reach the goals. Alternatively, if deliberate transformation does not successfully occur or hard limits are exceeded, the system may nonetheless undergo some type of forced transformation which results in outcomes inconsistent with societal goals. While the figure shows single decision points, multiple actors are involved at each stage. Thus, some people may find themselves coping with what they regard as intolerable risks which are not otherwise avoided. Often such coping situations display significant inequities, with tolerable risks for powerful groups and intolerable ones for marginalized groups.

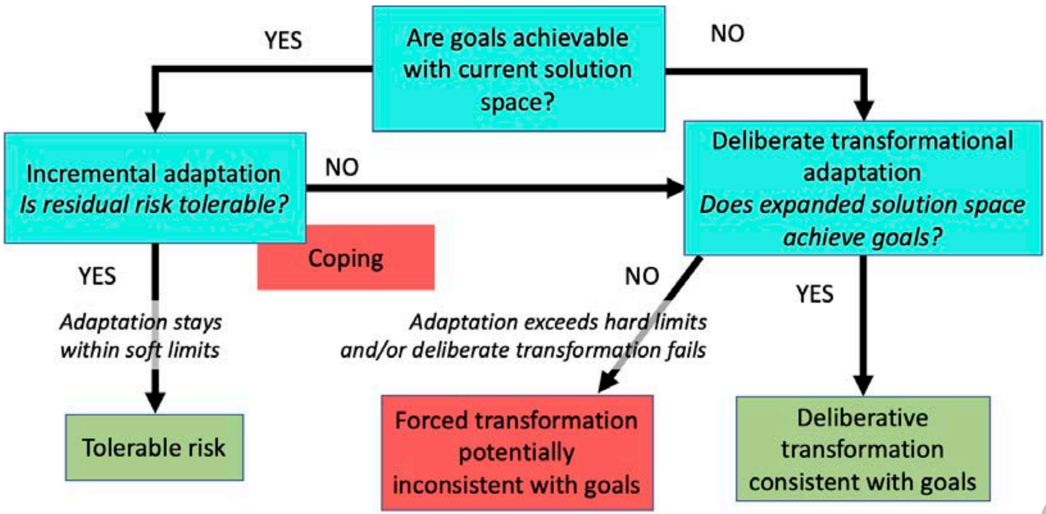

Figure 1.9: **Alternative Pathways to Transformation** Adaptation goals may be accessible by actions within or beyond the existing solution space. In the former case, incremental adaptation may stay within soft limits and hold risks to tolerable levels. In the latter case, deliberate transformational adaptation becomes necessary to achieve goals. If a successful deliberate transformation does not occur, the system may nonetheless undergo a forced transformation. Multiple actors are involved at each stage so that some people may nonetheless find themselves coping with what they regard as intolerable risks.

Multiple narratives describe pathways for pursuing deliberate transformations (Cavanagh and Benjaminsen, 2017). While building on the new "green economy" framing that emerged with the Rio+20 conference in 2012 (De Mello and Dutz, 2012; OECD, 2012; UNEP, 2011), these narratives reflect differing trade-offs among values and differing assumptions about the factors driving system change (see WGIII). The narratives range from "business-as-usual" scenarios focused on modernisation of sectors such as energy, agriculture and use of natural resources to more transformational propositions such as various green new deal proposals (European Commission, 2019), the new climate economy (Global Commission on the Economy and Climate, 2018), and "doughnut economics" (Raworth, 2017). Some literature suggests significant benefits from such new climate economy proposals, claiming tens of trillions in economic benefits, tens of millions of new jobs and close to a million fewer premature deaths from pollution over the coming decade (Global Commission on the Economy and Climate, 2018).

Two contrasting schools of thought, called ecomodernism and degrowth (D'Alisa et al., 2014), offer important bounding narratives for "green economy" approaches that aim achieve the SDGs and Paris Agreement goals.

Ecomodernism aims to decouple GHG emissions and other environmental impacts from GDP growth (Desrochers and Szurmak., 2020)(AR6 WGIII Sect 1.4.1) through three primary strategies: i) 'green' technological innovation, ii) resource efficiency or productivity improvements and iii) the sustainable intensification of land use in both rural and urban areas (Asafu-Adjaye et al., 2015; Isenhour, 2016). Such efforts to mobilize large-scale investment in climate change adaptation and to decouple GDP growth from environmental impacts could generate substantial employment opportunities and open up profitable investment frontiers (Adelman, 2018; Asafu-Adjaye et al., 2015), which could help achieve SDG 8, which calls for accelerated annual growth rates of at least 7 percent in least developed countries and achieve SDG 10, which calls for "income growth of the bottom 40 percent of the population at a rate higher than the national average".

Degrowth proponents question the feasibility of decoupling at a scale and rate sufficient for meeting Paris Agreement goals (Gómez-Baggethun, 2020; Hickel and Kallis, 2020; Kallis, 2017; Parrique et al., 2019). Using precautionary principle-rooted arguments (Latouche, 2001), degrowth aims for the intentional decreases in both GDP and coupled GHG emissions (Kallis, 2011) using policy mechanisms such a "cap and share" framework for distributing emissions permits on an annually declining basis with legislation to prohibit the overshoot of established carbon budgets (Douthwaite, 2012; Kallis et al., 2012). Degrowth thus seeks to minimize reliance on negative emissions technologies, such as the large-scale deployment of

BECCS (e.g., illustrative emissions reduction pathway labelled P4 in IPCC SR1.5, also WGIII Chapter 3) and aims to generate progress toward achieving the SDGs by prioritising redistribution rather than GDP growth. SDGs potentially addressed by degrowth include universal basic income (SDGs 1 and 10), work-sharing to guarantee full employment (SDGs 8 and 10) and shifting taxation burdens from income to resource and energy extraction (SDGs 8 and 12).

The contrasting premises of ecomodernism and degrowth have prompted a series of mutual counterarguments. Degrowth scholars emphasize that global absolute decoupling is currently not proceeding fast enough to meet Paris Agreement targets (Haberl et al., 2020; Moreau et al., 2019; Ward et al., 2016). Ecomodernists point to important progress towards achieving absolute decoupling at the national or regional scale – as shown by Le Quéré et al. (2019) in 18 developed countries – and the future potential of emerging technologies and policy reforms (Asafu-Adjaye et al., 2015)

1.5.2 Enabling Transformation

As one important theme, this Sixth Assessment report assesses who needs to take what actions and when in order that transformations unfold at sufficient speed and scale to meet Paris, SDG and other policy goals. A number of literatures inform these assessments.

Various literatures describe multiple, co-evolving societal elements which organize themselves into stable regimes that, under some circumstance, can undergo significant change. The sustainability transitions literature provides one central focus for understanding such processes and potential intervention points for actors seeking change (Köhler et al., 2019). This literature identifies three, interacting scales: the micro, meso and macro.(Geels, 2004; Köhler et al., 2019) The micro level reflects changing individual choices, attitudes and motivations. The meso reflects socio-technical systems, 'a cluster of elements, including technology, regulations, user practices and markets, cultural meanings, infrastructure, maintenance networks and supply networks' The macro reflects the cultures, institutions, norms, governance and other broad organising features of society. The sustainability transitions literature generally focuses on change that originates and occurs within the meso scale, while the transformation literature focuses on change within and among all scales. This Working Group II report often considers three interacting scales labelled personal, practical and political (O'Brien and Sygna, 2013). Working Group III often employs the multi-level perspectives framework (Geels, 2004) and the more actor-oriented three domains of decision-making framework (Grubb et al., 2014; WGIII Section 1.6.4) to describe related societal scales.

These literatures describe similar processes through which these interacting elements generate significant system change. In the sustainability transitions literature the process begins with a stable system of actors, technologies and institutions (Köhler et al., 2019). Radical innovations begin in niches or protected spaces, sometimes introduced by new entrants or outsiders. Successful innovations expand in scale, scope, and geographically, and ultimately help generate new regimes. Incumbent actors can support or resists innovations through combinations of government policies, economic forces and institutional and behavioural pressures. Such processes can, but need not, follow a common S-curve pattern of initial adoption, take-off, acceleration and stabilisation (Rotmans et al., 2001). The multi-level perspectives literature in WGIII similarly describes innovations as moving from niches to socio-technical regimes, at first mediated by and then potentially altering exogenous socio-technical landscapes (Smith et al., 2010; WGIII Section 1.6.4).

The socio-ecological systems literature, a main source of the resilience concept, focuses on the system elements of society and eco-systems, their interdependence and on how they change in response to shocks (Section 1.2.1.4). Coupled human and natural systems maintain their vital functions through what are called adaptive cycles that begin with growth, reach a period of stasis, experience a disruption, and then reorganize. This repeating cycle can leave the system unchanged or transition it to new states. Human agency can alter system characteristics so that after any disruption the system will reorganize into a different, more desired state; guide the reorganisation in desired directions after a system shock (such as a natural disaster); or provide the shock that catalyses a reorganisation.

These literatures view incremental and transformational change as linked processes. In the transformational adaptation literature, Park et al. (2012) consider incremental and transformational adaptation as two concentric and linked action-learning cycles with similar steps that include monitoring and learning. Systems generally reside in the incremental cycle but can temporarily jump to the transformational cycle before returning to the incremental, albeit in a state with fundamentally changed attributes. Shifts from the incremental to transformational cycle are made possible by knowledge and skills, as well as adjustments to vision, agendas and coalitions achieved through monitoring and learning. The incremental cycle is characterized by reactive responses to external drivers and performance evaluation relative to past performance. Shifts to the transformational cycle are characterized by more pro-active responses and more expansive problem framings.

The socio-ecological and sustainability transitions literature describes transitions as often non-linear, characterized by tipping point behaviour with periods of relative stability interspersed with periods of more rapid change as thresholds are crossed (van Ginkel et al., 2020). Actors seeking transformation may take incremental steps that aim to induce such tipping point behaviour (Otto et al., 2020b). For instance, full accounting of climate risk in insurance and financial lending decisions could similarly act as such social tipping point interventions for adaptation (Hill and Martinez-Diaz, 2019). Transformations need not, however, be equitable or smooth. Historical examples suggest the potential for rigidity traps, in which suppression of innovation and a high degree of connectivity in a system delay an eventual transformation which, when it eventually occurs, unfolds as exceptionally harsh (Hegmon et al., 2008).

Many actors can contribute to launching or blocking significant system change. Pelling et al (2015) highlights power relationships within and among activity spheres that influence the process of transformational adaptation and distribution of risks. In the sustainability transitions literature each set of actors --including those from academia, politics, industry, civil society and households -- brings their own resources, capabilities, beliefs, strategies and interests, which affects their interest, objectives, ability to affect the process and their ability to affect others (Kern and Rogge, 2018).

There is no consensus in the literature on the best means for actors to pursue deliberate transformation (Section 1.5.1) and the extent to which actors can guide the process. The transitions and some transformation literatures derive from a complex systems perspective (Köhler et al., 2019; Section 1.3.1.2; Linnér and Wibeck, 2019) in which behaviours can be understood but not predicted (Mitchell, 2009; Chapter 17). These literatures suggest that interventions in such systems will rarely result in them evolving along some pre-determined pathway. Rather, successful interventions more often resemble iterative processes of action, observation and response, which are described in the literature with terms such as iterative risk management (Section 17.2.1), clumsy solutions (Linnér and Wibeck, 2019; Thompson and Rayner, 1998), probe and response (Chapter 17; French, 2013) and what Young (2017) calls adaptive governance.

These literatures view transformation as a collective action challenge among actors with both common and differing values, interests and capabilities interacting over time with a mix of cooperation and competition (Dasgupta et al., 2018; Young, 2017). Concepts such as radical incremental transformation (Göpel, 2016), direct incrementalism (Grunwald 2007) and progressive incrementalism (Levin et al., 2012) envision strategies in which actors pursue incremental actions in one or more niches that move the current system towards tipping points which, once crossed, will drive the system to a new state (Tàbara et al., 2018). The incremental actions aim to promote learning, remove barriers to change (Baresi et al., 2020; Dasgupta et al., 2018), create a series of wins that generate momentum and generate positive feedbacks (e.g. by creating constituencies) such that the speed and scale of the climate action grows over time (Levin et al., 2012). But incremental strategies can fail to move fast enough; can succumb to path-dependency that locks in initially helpful but long-adverse responses (such as the well-known levee-effect) (Sadoff 2015; Haasnoot 2019); or can result in a transition that meets some goals (e.g., environmental) but not others (e.g., equity). (*high confidence*)

This report describes decision frameworks and tools that can help those involved in such a process – acting independently or collectively - identify, evaluate, seek compromise on, and then implement sequences of solutions that lead to pathways with more desirable outcomes and avoid pathways with less desirable outcomes (Section 17.3.1). For instance, adaptive (also called adaptation) pathways (Cross-Chapter Boxes SLR in Chapter 3 and DEEP in Chapter 17) explicitly chart alternative sequences of actions including near-term steps, indicators to monitor and contingency actions to take if pre-determined monitoring thresholds are breached. Employed in contexts with multiple actors and contested values, adaptive pathways frames deliberate transformation as both a near-term decision problem focused on physical, financial and natural resources as well as a social change process of co-evolving knowledge, policies, institutions, values, rules and norms (Fazey et al., 2016). Transition Management (Loorbach, 2010), rooted in the sustainability transitions literature, supports arenas of actors that co-produce visions of future change, plan pathways and recruit additional actors into the change process.

As a central feature, such frameworks and tools embrace: 1) multiple objectives and measures (Section 1.4.1.2) to help identify and consider trade-offs among parties with a diversity of interests, values and objectives and 2) multiple scenarios enable stress-testing of proposed actions to identify conditions in which they would fail to meet their goals and thus inform consideration of ways to make those actions more robust and resilient over multiple futures in the near- and longer-term (Chapter 17; Cross-Chapter Box DEEP in Chapter 17). A focus on single or overly aggregated measures (Section 1.4.1.2) and single scenarios can privilege some actors' views over others, reduce transparency, and make it more difficult to identify resilient and equitable solutions to complex, deeply uncertain, non-linear and contested problems (Jones et al., 2014; Lempert and Turner, 2020; Renn, 2008; Schoen and and Rein, 1994). (*medium confidence*)

Nonetheless, most concepts of deliberate transformation also emphasize the importance of common goals and principles within a process of goal setting, acting on those goals, monitoring and evaluation and readjustment. Such goals encourage proactive action; help align the activities of multiple, loosely co-ordinated actors (Dasgupta et al., 2018; Göpel, 2016); and provide benchmarks against which to measure progress (Young, 2017). The Paris Agreement and SDGs aim to provide such common goals for the world as a whole and implement what some have described as goal-based as opposed to rule-based governance for galvanising collection action (Kanie and Biermann, 2017; Sachs, 2015). As intended, many public sector, private sector and civil society actors have developed their own goals as that aim to align with the Paris Agreement and the SDGs (see Section 1.1). The existence of goals that helps people envision a future significantly different than present can be one often key difference between decision processes that pursue transformational as opposed to incremental change (Park et al., 2012; Chapter 17). Narratives that help explain where a community is, where it wants to go and how it intends to get there are an important enabler of transformation (Section 1.5.1; Section 1.2.3; Fazey et al., 2020; Linnér and Wibeck, 2019).

1.5.3 Climate-Resilient Development

Adaptation and mitigation can reduce climate-related risks. Implementing these two types of climate action together increases their effectiveness by exploiting synergies and reducing trade-offs among them. In addition, implementing adaptation and mitigation as an integral part of development can similarly make all three more effective (Section 18.2.3). The link between climate change and sustainable development has long been recognized and has been assessed in every Working Group 2 report since AR3. AR5 introduced the concept of climate resilient development to help assess development trajectories that include co-ordinated adaptation and mitigation actions aimed at reducing climate risk.

Building on AR5, this AR6 report expands the focus with increased attention to equity and the processes needed to follow such trajectories. AR6 thus defines **climate resilient development** as "a process of implementing greenhouse gas mitigation and adaptation solutions to support sustainable development for all" (Section 18.1.1). In AR6 WGII, some chapters have a section dedicated to climate resilient development, emphasizing the need for integrative and transformative solutions within a sector or region that address the uneven distribution of climate risks among different groups and geographies, as well as extend the goals of these solutions to more than reducing risk, such as in improving social, economic and ecological outcomes (Sections 2.6.7, 4.1, 5.14.4, 6.4.8, 7.4.3.5, 7.4.5, 10.6, 11.8, 15.7 and 17.6; Boxes 4.7, 13.3 and 8.10). Multiple chapters also employ the concept of climate resilient development to identify and balance trade-offs and make progress on achieving the SDGs (Sections 6.1.3, 7.4.5, 10.6, 13.11, 15.7 and 16.6.4.3; Box 4.7; Chapter 18).

Climate resilient development requires large and equitable changes in human and natural systems. As noted in Section 1.5.1, the SR1.5 finds that four transitions in socio-economic systems - energy, land and ecosystems, urban and infrastructure and industrial – must occur at large scale and rapid rate in order to achieve climate resilient development. This report notes that transitions of such scale, even when beneficial for many people, can also impose significant adverse impacts on others, in particular on marginal and vulnerable populations (Section 18.1.2). This report identifies a fifth socio-economic transition, that in societal systems that "drive innovation, preferences for alternative patterns of consumption and development, and the power relationships among different actors that engage in CRD" (Section 18.1.4). Such societal transitions are necessary to ensure the other four transitions unfold at sufficient speed and scale to meet Paris and Sustainable Development goals as well as to ensure equity in these transitions.

Introduced in the WGII AR5 (Olsson et al., 2014), and further addressed in SR1.5, climate resilient development pathways are trajectories that strengthen sustainable development and efforts to eradicate poverty and reduce inequalities, while promoting fair and equitable reductions of GHG emissions, and serve to steer societies towards low-carbon, prosperous and ecologically safe futures. This report defines a **climate resilient development pathway** as a trajectory in time reflecting a particular sequence of actions and consequences against a background of autonomous developments leading to a specific future situation (Section 18.1.2). Such a pathway emerges from the spatially and temporally distributed choices of many different actors in government, business, civic organizations and households at the individual, community, national and international levels. As such, there exists no single or preferred pathway for climate resilient development and no single best combination of adaptation, mitigation and sustainable development strategies. All pathways involve complex trade-offs and synergies among different actions (Sections 18.1.4, 18.2.2). All pathways are subject to hard-to-predict shocks, both adverse, such as climate disasters, and beneficial, such as new technologies or shifts in public values. The pathway that emerges will represent the results of negotiation, cooperation and competition among actors at many scales whose differing values and objectives would favour differing trajectories (Section 18.1.4). Individual actors at various scales will determine the mix of adaptation, mitigation and development appropriate for their development context and goals, while also influenced by the desire for their collective actions to become consistent with the global policy goals such as those in the Paris Agreement and the SDGs (Section 18.1.2). The norms, institutions and power relationships that mediate such choices determine the extent to which the process unfolds consistent with principles of equity and social justice. (*high confidence*)

Enabling conditions that can accelerate climate resilient development include governance; finance; economy; and science, technology and information (Sections 18.4.2, 18.9.2). The pursuit of equity and justice are both an enabler and an outcome of climate resilient development (Section 18.1.4). Climate resilient development involves a process of action, learning and response (Section 1.5.2), so the capability for such monitoring and iterative risk management also represents an important enabling condition (Section 18.1.4.2). Governments have an important role to play in expanding the solution space, often focusing on technology, policy and finance. Expanding the solution space also requires a broader set of actors. Chapter 18 and other chapters in this report use the climate resilient development concept to highlight the role of citizens, civil society, knowledge institutions, media, investors and businesses and the importance of expanding the arenas of engagement in which they interact.

1.6 Structure of the Report

The IPCC mandate involves the provisioning of available scientific information and evidence to inform climate action by multiple actors, notably governments (including international alliances) in the context of UNFCCC. Increasingly, IPCC assessments also aim to provide valuable information to non-governmental organisations, small and large enterprises and citizens.

Figure 1.10 shows the structure of this report, organized into three sections comprising chapters and cross-chapter papers. This first chapter provides the point of departure for this assessment, defines key concepts, and describes the connections among them.

The next group of chapters assess risks, adaptation and sustainability for systems impacted by climate change from the vantage of seven sectoral chapters, The next group of chapters organizes the assessment from the vantage of seven regional chapters.

In contrast to previous assessments, the current report embeds adaptation in each regional and sectoral chapter rather than in separate adaptation chapters, in order to reflect the increasing prevalence of adaptation and the extent to which many current risk, impacts and vulnerability estimates incorporate adaptation actions already taken. In addition, cross-chapter papers (CCPs) integrate across chapter topics, sectors and regions in particular types of geographies or ecosystems, termed typological regions, such as mountains, cities by the sea, or tropical forests. CCPs are a new element in WGII AR6 included at the request of Governments to highlight and expand relevant material from chapters and beyond into one place to ensure the integrated treatment of particular systems or regions and to improve accessibility of the report to readers.

Finally, section three highlights sustainable development pathways of integrating adaptation and mitigation by three synthesis chapters. The synthesis chapters summarize findings across all the chapters, CCPs and literatures on key risks, decision making options, and climate resilient development pathways that can lead from the current situation to a future more consistent with the stated policy goals. This report also assesses the adaptation options available, the extent to which such options can reduce risk, the effectiveness of current adaptation efforts, and their interactions with mitigation and sustainable development.

[START FAQ1.1 HERE]

FAQ1.1: What are the goals of climate change adaptation?

The goals of climate change adaptation, as a broad concept, are to reduce risk and vulnerability to climate change, strengthen resilience, enhance well-being and the capacity to anticipate, and respond successfully to change. Existing international frameworks provide a high-level direction for coordinating, financing and assessing progress toward these goals. However, specifying the goals for specific adaptation actions is not straightforward because the impacts of climate change affect people and nature in many different ways requiring different adaptation actions. Thereby, goals that accompany these actions are diverse. Goals can relate to health, water or food security, jobs and employment, poverty eradication and social equity, biodiversity and ecosystem services at international, national, and local levels.

Climate change adaptation entails the process of adjustment to actual or expected climate change and its effects in order to moderate harm or exploit beneficial opportunities. At a high level, international frameworks, including the Paris Agreement and the Sustainable Development Goals (SDGs), have come to provide a direction for coordinating, financing and assessing global progress in these terms. The Paris Agreement calls for climate change adaptation actions, referring to these actions as those that reduce risk and vulnerability, strengthen resilience, enhance the capacity to anticipate and respond successfully, and ensure the availability of necessary financial resources, as these processes and outcomes relate to climate change. In addition, the Sustainable Development Goals include 17 targets (with a specific goal SDG 13 on climate action) to fulfil its mission to end extreme poverty by 2030, protect the planet, and build more peaceful, just, and inclusive societies. These goals are difficult to reach without successful adaptation to climate change. Other notable frameworks that identify climate change adaptation as important global priorities include the Sendai Framework for Disaster Risk Reduction, the finance-oriented Addis Ababa Action Agenda and the New Urban Agenda.

While vital for international finance, coordination and assessment, the global goals set forth by these frameworks and conventions do not necessarily provide sufficient guidance to plan, implement or evaluate specific adaptation efforts at the community level. Specifying goals of adaptation is harder than setting goals for reducing emissions of climate-warming greenhouse gas emissions. For instance, emission-reduction effort is ultimately measured by the total amount of greenhouse gases in the Earth's atmosphere. Instead, adaptation aims to reduce risk and vulnerability from climate change and helps to enhance well-being in each individual community worldwide.

Because the impacts of climate change affect people and nature in so many different ways, the specific goals of adaptation depend on the impact being managed and the action being taken . For human systems, adaptation includes actions aimed at reducing a specific risk, such as by hardening a building against flooding, or actions aimed at multiple risks, such as requiring climate risk assessments in financial reporting in anticipation of different kinds of risk. At the local level, communities can take actions that include updating building codes and land use plans, improving soil management, enhancing water use efficiency, supporting migrants and taking measures for poverty reduction. For natural systems, adaptation includes organisms changing behaviours, migrating to new locations and genetic modifications in response to changing climate conditions. The goals for these adaptation actions can relate to health, water or food security, jobs and employment, poverty eradication and social equity, biodiversity and ecosystem services, among others. Articulating the goals of adaptation thus requires engaging with the concepts of equity, justice, and effectiveness at the international, national, and local levels.

[END FAQ1.1 HERE]

[START FAQ1.2 HERE]

FAQ1.2: Is climate change adaptation urgent?

Climate impacts, such as stronger heat waves, longer droughts, more frequent floods, accelerating sea- level rise, and storm surges, are already being observed in some regions, and people around the world are increasingly perceiving changing climates, regarding these changes as significant and considering climate action as a matter of high urgency. Reducing climate risk to levels that avoid threatening private or social norms and ensuring sustainable development will require immediate and long-term adaptation efforts by governments, business, civil society, and individuals at a scale and speed significantly faster than the current trends.

Current observed climate impacts and expected future risks include stronger and longer heat waves, unprecedented droughts and floods, accelerating sea-level rise and storm surges affecting many geographies and communities. People around the world are increasingly perceiving changing climates, regarding these changes as significant and considering climate action as a matter of high urgency. Particularly, marginalised and poor people as well as island and coastal community experience relatively higher risks and vulnerability. The available evidence suggests that current adaptation efforts may be insufficient to help ensure sustainable development and other societal goals in many communities worldwide even under the most optimistic greenhouse gas emissions scenarios.

Climate change adaptation is, therefore, urgent to the extent that meeting important societal goals requires immediate and long-term action by governments, business, civil society, and individuals at a scale and speed significantly faster than that represented by current trends.

[END FAQ1.2 HERE]

[START FAQ1.3 HERE]

FAQ1.3: What constitutes successful adaptation to climate change?

Success of climate change adaptation is dependent on the extent to which relevant actions reduce risk and vulnerability, as well as achieve their respective goals. At a global scale, these goals are set and tracked according to international frameworks and conventions. At smaller scales, such as local and national, goals are dependent on the specific impacts being managed, the actions being taken, and the relevant scale. While success can take shape as uniquely as goals can, the degree to which an adaptation is feasible, effective, and conforms to principles of justice represents important attributes for measuring success across actions. Adaptation responses that lead to increased risk and impacts are considered maladaptation.

Altogether, adaptation success is dependent on the extent to which adaptation actions achieve their respective goals of reducing climate risk, increasing resilience, and pursuing other climate-related societal goals. Viewed globally, successful adaptation consists of actions anticipated to make significant contributions to meeting sustainable development goal such as ending extreme poverty, hunger, and discrimination and reduce risks to ecosystems, water, food systems, human settlements, and health and well-being. Viewed locally, successful adaptation consists of actions that help communities meet their diverse goals including reducing anticipated current and future risks, enhancing capacity to adapt and transform, avoiding maladaptation, yielding benefits greater than costs, serving vulnerable populations, and arising from an inclusive, evidence-based, and equitable decision process.

While success can be unique to an adaptation action, there are important attributes that constitute it as a successful solution. These include the extent to which an action is considered feasible, effective, and conforms to principles of justice.

The degree to which an action is **feasible** is the extent it is appraised as possible and desirable, taking into consideration barriers, enablers, synergies, and trade-offs. These considerations are based on financial or economic, political, physical, historical, and social factors, depending on what is required for an action to be implemented. The degree to which an action is **effective** depends on the extent it reduces climate risk, as well as the extent an action achieves its intended goals or outcomes. An adaptation action can sometimes – usually inadvertently – increase risk or vulnerability for some or all affected individuals or communities. In some cases, such risk increases will be sufficient to call the actions maladaptation. The degree to which an action is **just** is when its outcomes, the process of implementing the action, and the process of choosing the action respects principles of distributive, procedural, and recognitional justice. Distributive justice refers to the different distributions of benefits and burdens of an action across members of society; procedural justice refers to ensuring the opportunity for fairness, transparency, inclusion, and impartiality in the decision-making of an action; and recognitional justice insists on recognizing and including those who are or may be most affected by an action.

These attributes of adaptation success can be assessed throughout the adaptation process of planning, implementation, monitoring and evaluation, adjustment, and learning. However, at the same time, the success of many adaptation actions depend strongly on context and time. For instance, the effectiveness of adaptation will depend on the success of greenhouse gas mitigation efforts, as adaptation has strong synergies and trade-offs with mitigation efforts

[END FAQ1.3 HERE]

[START FAQ1.4 HERE]

FAQ1.4: What is transformational adaptation?

Continuing and expanding current adaptation efforts can reduce some climate risks. But even with emission reductions sufficient to meet the Paris Agreement goals, transformational adaptation will be necessary.

Over six assessment reports, the IPCC has documented transformative changes in the Earth's climate and ecosystems caused by human actions. These changes are now unequivocal and projected to become even more significant in the years and decades ahead. This AR6 report also highlights climate adaptation actions people are taking and can take in response to these significant changes in the climate system.

Some adaptation is incremental, which only modifies existing systems. Other actions are transformational, leading to changes in the fundamental characteristics of a system. For instance, building a seawall to protect a coastal community from flooding might exemplify incremental adaptation. Changing land use regulations in that community and establishing a program of managed retreat might exemplify transformational adaptation. There exists no bright line between incremental and transformational adaptation. Some incremental actions stay incremental. Others may expand the future space of solutions. For instance, including climate risk in mortgages and insurance might at first seem incremental but might lead to more transformational change over time.

Transformation can be deliberate, envisioned and intended by at least some societal actors, or forced, arising without explicit intent.

Deliberate transformational adaptation is not without risks because change can disturb existing power relationships and can unfold in difficult to predict and unintended ways. But transformational adaptation is important to consider because it may be needed to avoid intolerable risks from climate change and may be needed to help meet development goals as articulated in the SDGs. In addition, some type of societal transformation may be inevitable and deliberate rather than forced transformation may bring society closer to its goals.

Some type of transformation may be inevitable because the amount of transformational adaptation needed to avoid intolerable risks depends in part on the level of greenhouse gas mitigation. Low concentration pathways consistent with Paris Agreement goals require deliberate transformations that lead to significant and rapid change in energy, land, urban and infrastructure, and industrial systems. Even with low concentration pathways, some transformational adaptation will be necessary to limit intolerable risks. But with higher concentrations pathways, more extensive transformational adaptation would be required to limit (though not entirely avoid) intolerable risks. In such circumstance, insufficient deliberate transformation could lead to undesirable forced transformations.

[END FAQ1.4 HERE]

[START FAQ1.5 HERE]

FAQ1.5: What is new in this 6th IPCC report on impacts, adaptation and vulnerability?

Since IPCC Fifth Assessment Report, many new sources of knowledge have been employed to provide better understanding of climate change risks, impacts, vulnerability, and also societal responses through adaptation, mitigation and sustainable development. This new, more integrative assessment increasing focuses on risk and solutions, social justice, different forms of knowledge including Indigenous knowledge and local knowledge, role of transformation and the urgency of fast climate actions.

The IPCC Sixth Assessment Report (AR6) plays a prominent role in science-policy–society interactions on the climate issue since 1988, has advanced in important ways of interdisciplinary climate change assessment since AR5. Many new sources of knowledge have been employed to provide better understanding of climate change risks, impacts, vulnerability, and also societal responses through adaptation, mitigation and sustainable development.

This AR6 assessment has increasingly focus on risk and solutions. The risk framing for the first time spans all three working groups, includes risks from the responses to climate change, considers dynamic and cascading consequences, describes with more geographic detail risks to people and ecosystems, and assesses such risks over a range of scenarios. The solutions framing encompasses the interconnections among climate responses, sustainable development, and transformation—and the implications for governance across scales within the public and private sectors. The assessment therefore includes climate-related decision-making and risk management, climate-resilient development pathways, implementation and evaluation of adaptation, and also limits to adaptation and loss and damage.

The AR6 emphases the emergent issue on social justice and different forms of knowledge. As climate change impacts and implemented responses increasingly occur, there is heightened awareness of the ways that climate responses interact with issues of justice and social progress. In this report, there is expanded attention to inequity in climate vulnerability and responses, the role of power and participation in processes of implementation, unequal and differential impacts, and climate justice. The historic focus on scientific literature has also been increasingly accompanied by attention to and incorporation of Indigenous knowledge, local knowledge, and associated scholars.

The AR6 has a more extensive focus on the role of transformation and the urgency of fast climate actions in meeting societal goals. This report assesses extensive literatures with an increasing diversity of topics and geographical areas with more sectoral and regional details. The literature also increasingly evaluates the lived experiences of climate change—the physical changes underway, the impacts for people and ecosystems, the perceptions of the risks, and adaptation and mitigation responses planned and implemented.

The assessment in AR6 has increasingly become integrative across multiple disciplines and combine experts across working groups, chapters, papers and disciplines, such as natural and social sciences, medical and health sciences, engineering, humanities, law, and business administration etc. The emphasis on knowledge for action has also included the role of public communication, stories, and narratives within assessment and associated outreach.

Singer (France/United Kingdom), Jasper Slingsby (South Africa), Stavana E. Strutz (USA), Merritt Turetsky (USA), Beth Turner (Canada), Kenneth Young (USA).

Review Editors: Carol Franco Billini (Dominican Republic/USA), Yakiv Didukh (Ukraine), Andreas Fischlin (Switzerland)

Chapter Scientists: Stavana E. Strutz (USA), Dalila Mezzi-Booth (France)

Date of Draft: 1 October 2021

Notes: TSU Compiled Version

Table of Contents

Executive Summary

Chapter 2, building upon prior assessments[1] provides a global assessment of observed impacts and projected risks of climate change to terrestrial and freshwater ecosystems, including their component species and the services they provide to people. Where possible, differences among regions, taxonomic groups and ecosystems types are presented. Adaptation options to reduce risks to ecosystems and people are assessed.

Observed Impacts

Multiple lines of evidence, combined with strong and consistent trends observed on every continent, make it *very likely*[2] that many observed changes in ranges, phenology, physiology and morphology of terrestrial and freshwater species can be attributed to regional and global climate changes, particularly increases in frequency and severity of extreme events *(very high confidence[3])* {2.3.1; 2.3.3.5; 2.4.2; 2.4.5; Table 2.2; Table 2.3; Table 2.S.1; Cross-Chapter Box EXTREMES this Chapter}. The most severe impacts are occurring in the most vulnerable species and ecosystems, characterized by inherent physiological, ecological or behavioural traits that limit their abilities to adapt and those most exposed to climatic hazards *(high confidence)* {2.4.2.2; 2.4.2.6; 2.4.2.8; 2.4.5; 2.6.1; Cross-Chapter Box EXTREMES this Chapter}.

New studies since AR5 and SR1.5 (now >12,000 species globally) show changes consistent with climate-change. Where attribution was assessed (>4,000 species globally) approximately half of species had shifted their ranges to higher latitudes or elevations and two-thirds of spring phenology had advanced, driven by regional climate changes *(very high confidence).* Shifts in species ranges are altering community make-up, with exotic species exhibiting greater ability to adapt to climate change than natives, especially in more northern latitudes, potentially leading to newly invasive species {2.4.2.3.3}. New analyses demonstrate that prior reports underestimated impacts due to complex biological responses to climate change *(high confidence).* {2.4.2.1; 2.4.2.3; 2.4.2.4; 2.4.2.5; 2.4.5; Table 2.2; Table SM2.1; Table 2.3}

Responses in freshwater species are strongly related to changes in the physical environment *(high confidence)* {2.3.3; 2.4.2.3.2}. Global coverage of quantitative observations in freshwater ecosystems has increased since AR5. Water temperature has increased in rivers (up to 1°C decade^{-1}) and lakes (up to 0.45°C decade^{-1}) {2.3.3.1; Figure 2.2}. Extent of ice cover has declined by 25% and duration by >2 weeks {2.3.3.4; Figure 2.4}. Changes in flow have led to reduced connectivity in rivers (*high confidence*) {2.3.3.2; Figure 2.3}. Indirect changes include alterations in river morphology, substrate composition, oxygen concentrations and thermal regime in lakes (*very high confidence*) {2.3.3.2; 2.3.3.3}. Dissolved oxygen concentrations have typically declined and primary productivity increased with warming. Warming and browning (increase in organic matter) have occurred in boreal freshwaters with both positive and negative repercussions on water temperature profiles (lower vs. upper water)*(high confidence)* and primary productivity (*medium confidence*) and reduced water quality *(high confidence)* {2.4.4.1; Figure 2.5}.

---

[1] Previous IPCC assessments include the IPCC Fifth Assessment Report (AR5) (IPCC, 2013; IPCC, 2014c; IPCC, 2014d; IPCC, 2014a), the Special Report on Global Warming of 1.5°C (SR1.5) (IPCC, 2014b), the Special Report on Ocean and Cryosphere in a Changing Climate (SROCC) (IPCC, 2019b) and the IPCC Sixth Assessment Report Working Group I (AR6 WGI).

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

[3] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

Climate change has increased wildlife diseases *(high confidence).* Experimental studies provide *high confidence* in attribution of observed increased disease severity, outbreak frequency and emergence of novel vectors and their diseases into new areas to recent trends in climate and extreme events. Many vector-borne diseases, and those caused by ticks, helminth worms and Bd (chytrid) fungus, have shifted poleward, upward, and are emerging in new regions *(high confidence).*In the high Arctic and high elevations of Nepal, there is *high confidence* that climate change has driven expansion of vector-borne diseases that infect humans. {2.4.2.7, 7.2.2.1, 9.8.2.4, 10.4.7.1, 12.3.1.4, 13.7.1.2, 14.4.6.4, Cross-Chapter Box ILLNESS this Chapter}

Forest insect pests have expanded northward and severity and outbreak extent has increased in northern North America, northern Eurasia, due to warmer winters reducing mortality and longer growing seasons favouring more generations per year *(high confidence)* {2.4.2.1}

Climate-caused local population extinctions have been widespread among plants and animals, detected in 47% of 976 species examined and associated with increases in hottest yearly temperatures *(very high confidence)* {2.4.2.2}. Climate-driven population extinctions have been higher in tropical (55%), than temperate habitats (39%), higher in freshwater (74%), than in marine (51%) or terrestrial (46%) habitats and higher in animals (50%) than in plants (39%). Extreme heat waves has led to local fish kills in lakes {2.3.3.5}. Intensification of droughts contributes to disappearance of small or ephemeral ponds, which often hold rare and endemic species. {2.4.2.2; Cross-Chapter Box EXTREMES this Chapter}

Global extinctions or near-extinctions have been linked to regional climate change in three documented cases {2.4.2.2}**.** The cloud-forest-restricted Golden toad (*Incilius periglenes*) was extinct by 1990 in a nature preserve in Costa Rica following successive extreme droughts *(medium confidence)*. The white sub-species of the lemuroid ringtail possum (*Hemibelideus lemuroides*) in Queensland, Australia, disappeared after heatwaves in 2005 *(high confidence)*: intensive censuses found only 2 individuals in 2009. The Bramble Cays Melomys (*Melomys rubicola),* was not seen after 2009 and declared extinct in 2016, with SLR and increased storm surge, associated with climate change, the most probable drivers *(high confidence).* The interaction of climate change and chytrid fungus (Bd) has driven many of the observed global amphibian declines and species' extinctions *(robust evidence, high agreement)* {2.4.2.7.1}.

A growing number of studies document genetic evolution within populations in response to recent climate change *(very high confidence).* To date, genetic changes remain within the limits of known variation for species *(high confidence)*. **Controlled selection experiments and field observations indicate that evolution would not prevent a species becoming extinct if its climate space disappears globally *(high confidence).*** Climate hazards outside those to which species are adapted are occurring on all continents (*high confidence*). More frequent and intense extreme events, superimposed on longer-term climate trends, have pushed sensitive species and ecosystems towards tipping points, beyond ecological and evolutionary capacity to adapt, causing abrupt and possibly irreversible changes *(medium confidence)*. {2.3.1; 2.3.3; 2.4.2.6; 2.4.2.8; 2.6.1; Cross-Chapter Box ILNESS this Chapter, Cross-Chapter Box EXTREMES this Chapter}

Since AR5, biome shifts and structural changes within ecosystems have been detected at an increasing number of locations, consistent with climate change and increasing atmospheric CO_2 *(high confidence).* New studies document changes that were projected in prior reports, including upward shifts in the forest/alpine tundra ecotone, northward shifts in the deciduous/boreal forest ecotones, increased woody vegetation in sub-Arctic tundra, and shifts in thermal habitat in lakes. A combination of changes in grazing, browsing, fire, climate, and atmospheric CO_2 are leading to observed woody encroachment into grasslands and savannas, consistent with projections from process-based models driven by precipitation, atmospheric CO_2 and wildfire *(high confidence)*. {2.4.3; Table 2.3; Table 2.S.1; Box 2.1; Figure Box 2.1.1; Table Box 2.1.1} There is high agreement between projected changes in earlier reports and recent observed trends for areas of increased tree death in temperate and boreal forests and of woody encroachment in savannas, grasslands and tundra {2.5.4; Box 2.1; Figure Box 2.1.1; Table Box 2.1.1}. Observed changes impact structure, functioning and resilience of ecosystems, and ecosystem services such as climate regulation (*high confidence*). {2.3; 2.4.2; 2.4.3; 2.4.4, 2.5.4, Figure 2.11, Table 2.5, Box 2.1; Figure Box 2.1.1; Table Box 2.1.1}

Regional increases in area burned by wildfires (up to double natural levels), tree mortality up to 20%, and biome shifts up to 20 km latitudinally and 300 m upslope, have been attributed to anthropogenic climate change in tropical, temperate and boreal ecosystems around the world (*high confidence*), damaging key aspects of ecological integrity. This degrades vegetation survival, habitat for biodiversity, water supplies, carbon sequestration, and other key aspects of the integrity of ecosystems and their ability to provide services for people (*high confidence*). {2.4.3.1, 2.4.4.2, 2.4.4.3, 2.4.4.4; Table 2.3; Table 2.S.1}

B.11 Fire seasons have lengthened on one-quarter of vegetated area since 1979 as a result of increasing temperature, aridity, and drought *(medium confidence)*. **Field evidence shows that anthropogenic climate change has increased the area burned by wildfire above natural levels in western North America from 1984–2017 by double for the Western USA and 11 time higher than natural in one extreme year in British Columbia *(high confidence).*** Burned area has increased in the Amazon, the Arctic, Australia, and parts of Africa and Asia, consistent with, but not formally attributed to anthropogenic climate change. Wildfires generate up to one-third of global ecosystem carbon emissions, a feedback that exacerbates climate change (*high confidence*). Deforestation, peat draining, agricultural expansion or abandonment, fire suppression, and inter-decadal cycles such as the El Niño-Southern Oscillation, can exert a stronger influence than climate change on increasing or decreasing wildfire. {2.4.4.2; Table 2.3; Table 2.S.1; FAQ2.1}. Increases in wildfire from levels to which ecosystems are adapted degrades vegetation, habitat for biodiversity, water supplies, and other key aspects of the integrity of ecosystems and their ability to provide services for people (*high confidence*). {2.4.3.1, 2.4.4.2, 2.4.4.3, 2.4.4.4; Table 2.3; Table 2.S.1}

Anthropogenic climate change has caused drought-induced tree mortality of up to 20% in the period 1945–2007 in three regions in Africa and North America. It has also potentially contributed to over 100 other cases of drought-induced tree mortality across Africa, Asia, Australia, Europe, and North and South America *(high confidence).* Field observations document post-mortality vegetation shifts *(high confidence).* Timber cutting, agricultural expansion, air pollution, and other non-climate factors also contribute to tree death. Climate-change driven increases in forest insect pests have contributed to mortality and changes in carbon dynamics in many temperate and boreal forest areas (*very high confidence*). The direction of changes in carbon balance and wildfires following insect outbreaks depends on the local forest-insect communities (*medium confidence*). {2.4.4.3; Table 2.3; Table 2.S.1}.

Terrestrial ecosystems currently remove more carbon from the atmosphere, 2.5–4.3 Gt y^{-1}, than they emit. Intact tropical rainforests, Arctic permafrost, and other healthy high carbon ecosystems provide a vital global ecosystem service of preventing release of stored carbon *(high confidence).* Terrestrial ecosystems contain stocks of ~3500 GtC in vegetation, permafrost, and soils, three to five times the amount of carbon in unextracted fossil fuels (*high confidence*), and >4 times the carbon currently in the atmosphere (*high confidence*). Tropical forests and Arctic permafrost contain the highest ecosystem carbon, with peatlands following (*high confidence*). Deforestation, draining and burning of peatlands, and thawing of Arctic permafrost due to climate change shifts these ecosystems from carbon-sinks to carbon-sources *(high confidence)*. {2.4.3.6; 2.4.3.8; 2.4.3.9. 2.4.4.4}

Evidence indicates that climate change is affecting many species, ecosystems, and ecological processes that provide ecosystem services connected to human health, livelihoods, and well-being *(medium confidence).* These services include climate regulation, water and food provisioning, pollination of crops, tourism and recreation. It is difficult establish end-to-end attribution from climatic changes to changes in a given ecosystem service and to identify the location and timing of impacts. This limits specific adaptation planning, but protection and restoration of ecosystems could build resilience of service provision.{2.2; 2.3; 2.4.2.7; 2.4.5; 2.6.3; 2.6.4; 2.6.5; 2.6.6; 2.6.7; Cross-Chapter Box NATURAL this Chapter; Cross-Chapter Box ILLNESS this Chapter; Cross-Chapter Box EXTREMES this Chapter; Cross-Chapter Box COVID in Chapter 7; Cross-Chapter Box MOVING PLATE in Chapter 5}

Projected Risks

Climate change increases risks to fundamental aspects of terrestrial and freshwater ecosystems, with the potential for species' extinctions to reach 60% at 5°C GSAT warming (*high confidence*), biome shifts (changes in the major vegetation form of an ecosystem) on 15% (at 2ºC warming) to 35% (at 4ºC warming) of global land (*medium confidence*), and increases in the area burned by wildfire of 35%

(at 2ºC warming) to 40% (at 4ºC warming) of global land (*medium confidence*). {2.5.1; 2.5.2; 2.5.3; 2.5.4; Figure 2.6; Figure 2.7; Figure 2.8; Figure 2.9; Figure 2.11; Table 2.5; Table 2.S.2; Table 2.S.4; Cross-Chapter Box DEEP in Chapter 1; Cross-Chapter Paper 1}

Extinction of species is an irreversible impact of climate change, the risk of which increases steeply with rises in global temperature. It is *likely* that the percentage of species at high risk of extinction (median and maximum estimates) will be 9% (max 14%) at 1.5°C, 10% (max 18%) at 2°C, 12% (max 29%) at 3.0°C, 13% (max 39%) at 4°C and 15% (max 48%) at 5°C (Figure 2.7). Among groups containing largest numbers of species at high risk of extinctions for mid-levels of warming (3.2°C) are: invertebrates (15%), specifically pollinators (12%), amphibians (11%, but salamanders are at 24%) and flowering plants (10%). All groups fare substantially better at 2°C, with extinction projections reducing to <3% for all groups, except salamanders at 7% *(medium confidence)* (Figure 2.8a). Even the lowest estimates of species' extinctions (9%) are 1000x natural background rates. Projected species' extinctions at future global warming levels are consistent with projections from AR4, but assessed on many more species with much greater geographic coverage and a broader range of climate models. {2.5.1.3; Figure 2.6; Figure 2.7; Figure 2.8; Cross-Chapter Box DEEP in Chapter1; Cross-Chapter Paper 1}

Species are the fundamental unit of ecosystems, and increasing risk to species increases risk to ecosystem integrity, functioning and resilience with increasing warming *(high confidence)*. As species become rare, their roles in the functioning of the ecosystem diminishes *(high confidence)*. Loss of species reduces the ability of an ecosystem to provide services and lowers its resilience to climate change *(high confidence)*. At 1.58°C (median estimate), >10% of species are projected to become endangered (sensu IUCN); at 2.07°C (median) >20% of species are projected to become endangered, representing high and very high biodiversity risk, respectively *(medium confidence)*{2.5.4; Figure 2.8b, Figure 2.11; Table 2.5, Table 2.S.4}. Biodiversity loss is projected for more regions with increasing warming, and to be worst in northern South America, southern Africa, most of Australia, and northern high latitudes *(medium confidence)*{2.5.1.3; Figure 2.6}.

Climate change increases risks of biome shifts on up to 35% of global land at ≥4ºC warming, that emissions reductions could limit to <15% for <2ºC warming (*medium confidence*). Under high warming scenarios, models indicate shifts of extensive parts of the Amazon rainforest to drier and lower-biomass vegetation (*medium confidence*), poleward shifts of boreal forest into treeless tundra across the Arctic, and upslope shifts of montane forests into alpine grassland (*high confidence*). Area at high risk of biome shifts from climate change and land use change combined can double or triple compared to climate change alone (*medium confidence*). Novel ecosystems, with no historical analogue, are expected to become increasingly common in future *(medium confidence)*. {2.3, 2.4.2.3.3, 2.5.2; 2.5.4, Figure 2.11; Table 2.5; Table 2.S.4}

Risk of wildfires increases with global temperature *(high confidence)*. With 4ºC warming by 2100 wildfire frequency is projected to have a net increase of ~30% *(medium confidence)*. Increased wildfire, combined with soil erosion due to deforestation, could degrade water supplies *(medium confidence)*. For ecosystems with historically low fire frequencies, a projected 4ºC global temperature rise increases risks of fire, with potential increases in tree mortality and conversion of extensive parts of Amazon rainforest to drier and lower-biomass vegetation *(medium confidence)*. {2.5.3.2; 2.5.3.3}

Continued climate change substantially increases risk of carbon stored in the biosphere being released into the atmosphere due to increases in processes such as wildfires, tree mortality, insect pest outbreaks, peatland drying and permafrost thaw (*high confidence*). These phenomena exacerbate self-reinforcing feedbacks between emissions from high-carbon ecosystems (that currently store ~3030–4090 GtC) and increasing global temperatures. Complex interactions of climate change, land use change, carbon dioxide fluxes, and vegetation changes, combined with insect outbreaks and other disturbances, will regulate the future carbon balance of the biosphere, processes incompletely represented in current earth system models. The exact timing and magnitude of climate-biosphere feedbacks and potential tipping points of carbon loss are characterized by large uncertainty, but studies of feedbacks indicate increased ecosystem carbon losses can cause large future temperature increases *(medium confidence)*. {AR6 WGI 5.4, Table 5.4, Figure 5.29; 2.5.2.7; 2.5.2.8; 2.5.2.9; 2.5.3.2; 2.5.3.3; 2.5.3.4; 2.5.3.5; Figure 2.10; Figure 2.11; Table 2.4; Table 2.5; Table 2.S.2; Table 2.S.4}

Contributions of Adaptation Measures to Solutions

The resilience of biodiversity and ecosystem services to climate change can be increased by human adaptation actions including ecosystem protection and restoration *(high confidence)*. Ecological theory and observations show that a wide range of actions can reduce risks to species and ecosystem integrity. This includes minimising additional stresses or disturbances, reducing fragmentation, increasing natural habitat extent, connectivity and heterogeneity, maintaining taxonomic, phylogenetic and functional diversity and redundancy; and protecting small-scale refugia where microclimate conditions can allow species to persist *(high confidence).* Adaptation also includes actions to aid the recovery of ecosystems following extreme events. Understanding the characteristics of vulnerable species can assist in early warning systems to minimise negative impacts and inform management intervention. {2.3; Figure 2.1; 2.5.3.1, 2.6.2, Table 2.6, 2.6.5, 2.6.7, 2.6.8}.

There is new evidence that species can persist in refugia where conditions are locally cooler, when they are declining elsewhere *(high confidence)* {2.6.2}. Protecting refugia, for example where soils remain wet during drought or fire risk is reduced, and in some cases creating cooler microclimates, are promising adaptation measures {2.6.3; 2.6.5; CCP1; CCP5.2.1}. There is also new evidence that species can persist locally because of plasticity, including changes in phenology or behavioural changes that move an individual into cooler micro-climates, and genetic adaptation may allow species to persist for longer than might be expected from local climatic changes *(high confidence)* {2.4.2.6; 2.4.2.8, 2.6.1}. There is no evidence to indicate that these mechanisms will prevent global extinctions of rare, very localised species at their climatic limits or species inhabiting climate/habitat zones that are disappearing *(high confidence)*. {2.4.2.8, 2.5.1, 2.5.3.1, 2.5.4, 2.6.1, 2.6.2, 2.6.5}

Since AR5, many adaptation plans and strategies have been developed to protect ecosystems and biodiversity but there is limited evidence of the extent to which adaptation is taking place and virtually no evaluation of the effectiveness of adaptation measures in the scientific literature *(medium confidence)*. This is an important evidence gap that needs to be addressed to ensure a baseline is available against which to judge effectiveness and develop and refine adaptation in future. Many proposed adaptation measures have not been implemented (*low confidence*) {2.6.2; 2.6.3; 2.6.4; 2.6.5; 2.6.6; 2.6.8; 2.7}

Ecosystem restoration and resilience building cannot prevent all impacts of climate change, and adaptation planning needs to manage inevitable changes to species distributions, ecosystem structure and processes (*very high confidence*). Actions to manage inevitable change include local modification of microclimate or hydrology, adjustment of site management plans and facilitating the dispersal of vulnerable species to new locations, both by increasing habitat connectivity or by active translocations of species. Adaptation can reduce risks but cannot prevent all damaging impacts so is not a substitute for reductions in greenhouse gas emissions (*high confidence*). {2.2; 2.3; 2.3.1; 2.3.2; 2.4.5; 2.5.1.3; 2.5.1.4; 2.5.2; 2.5.3.1; 2.5.3.5; 2.5.4; 2.6.1; 2.6.2; 2.6.3; 2.6.4; 2.6.5; 2.6.6; 2.6.8; Cross-Chapter Box NATURAL this Chapter}.

Ecosystem-base Adaptation (EbA)can deliver climate change adaptation for people with multiple additional benefits, including for biodiversity (*high confidence*). An increasing body of evidence demonstrates that climatic risks to people, including from flood, drought, fire and over-heating, can be lowered by a range of Ecosystem-based Adaptation techniques in urban and rural areas (*medium confidence*). EbA forms part of a wider range Nature-based Solutions (NbS) actions and some have mitigation co-benefits, including the protection and restoration of forests and other high-carbon ecosystems, as well as agroecological farming practices {2.6.3; 2.6.5; Cross-Chapter Box NATURAL this Chapter}. However, EbA and other NbS are still not widely implemented. {2.2; 2.5.3.1; 2.6.2; 2.6.3; 2.6.4; 2.6.5; 2.6.6, 2.6.7; Table 2.7; Cross-Chapter Box NATURAL this Chapter; Cross-Chapter Paper 1}.

To realise potential benefits and avoid harm, it is essential that EbA is deployed in the right places and with the right approaches for that area, with inclusive governance *(high confidence)*. Interdisciplinary scientific information and practical expertise, including local and Indigenous knowledge, are essential to effectiveness (*high confidence*). There is a large risk of maladaptation where this does not happen (*high confidence*). {1.4.2; 2.2; 2.6; Table 2.7; Box 2.2; Figure Box 2.2.1; Cross-Chapter Box NATURAL this Chapter; Cross-Chapter Paper1; 5.14.2}.

Ecosystem-based Adaptation and other Nature-based Solutions are themselves vulnerable to climate change impacts. They need to take account of climate change adaptation if they are to remain effective and will increasingly be under threat at higher warming levels. Nature-based Solutions cannot be regarded as an alternative to, or a reason to delay, deep cuts in greenhouse gas emissions (high confidence). {2.6.3, 2.6.5; 2.6.7; Cross-Chapter Box NATURAL this Chapter}

Climate Resilient Development

Protection and restoration of natural and semi-natural ecosystems are key adaptation measures in light of clear evidence that damage and degradation of ecosystems exacerbates the impacts of climate change on biodiversity and people (*high confidence*). Ecosystem services that are at threat from a combination of climate change and other anthropogenic pressures include climate change mitigation, flood risk management, food provisioning and water supply (*high confidence*). Adaptation strategies that treat climate, biodiversity and human society as coupled systems will be most effective. {2.3; Figure 2.1; 2.5.4; 2.6.2; 2.6.3; 2.6.7; Cross-Chapter Box NATURAL and Cross-Chapter Box ILLNESS this Chapter}

A range of analyses have concluded that ~30% of Earth's surface needs to be effectively conserved to maintain biodiversity and ecosystem services *(medium confidence)*. Climate change places additional stress on ecosystem integrity and functioning, adding urgency for taking action. Low intensity, sustainable management, including by Indigenous peoples, is an integral part of some protected areas and can support effective adaptation and maintain ecosystem health. Food and fibre production in other areas will need to be efficient, sustainable and adapted to climate change to meet the needs of the human population *(high confidence).* {Figure 2.1; 2.5.4; 2.6.2; 2.6.3; 2.6.7}

Natural ecosystems can provide carbon storage and sequestration at the same time as providing multiple other ecosystem services, including EbA *(high confidence)* but there are risks of maladaptation and environmental damage from some approaches to land-based mitigation (*high confidence*). Plantation forests in areas which would not naturally support forest, including savannas, natural grasslands and temperate peatlands, or replacing native tropical forests on peat soils, have destroyed local biodiversity and created a range of problems, including for water supply, food supply, fire risk and greenhouse gas emissions. Large scale deployment of bioenergy, including Bioenergy with Carbon Capture and Storage (BECCS) through dedicated herbaceous or woody bioenergy crops and non-native production forests can damage ecosystems directly or through increasing competition for land. {2.6.3, 2.6.5, 2.6.6, 2.6.7; Box 2.2; Cross-Chapter Box NATURAL this Chapter; CCP7.3.2; Cross-Working Group Box BIOECONOMY in Chapter 5}.

Terrestrial and aquatic ecosystems and species are often less degraded in lands managed by Indigenous Peoples and local communities than in other lands *(medium confidence).* Including indigenous and local institutions is a key element in developing successful adaptation strategies. Indigenous and local knowledge contain a wide variety of resource-use practices and ecosystem stewardship strategies that conserve and enhance both wild and domestic biodiversity**.** {2.6.5; 2.6.7; Cross-Chapter Box NATURAL this Chapter}

Extreme events are compressing the timeline available for natural systems to adapt and impeding our ability to identify, develop and implement solutions (*medium confidence*). There is now an urgent need to build resilience and assist recovery following extreme events. This, combined with long-term changes in baseline conditions means that implementation of adaptation and mitigation measures cannot be delayed if they are to be fully effective. {2.3; Cross-Chapter Box EXTREMES this Chapter}

2.1 Introduction

2.1.1 *Overview*

Chapter 2: We provide assessments of observed and projected impacts of climate change across species, biomes (vegetation types), ecosystems and ecosystem services, highlighting processes emerging on a global scale. Where sufficient evidence exists, differences in biological responses among regions, taxonomic groups or types of ecosystems are presented, particularly when such differences provide meaningful insights into current or potential future autonomous or human-mediated adaptations. Human interventions that might build resilience of ecosystems and minimise negative impacts of climate change on biodiversity and ecosystem functioning are assessed. Such interventions include adaptation strategies and programmes to support biodiversity conservation and Ecosystem-based Adaptation (EbA). The assessments were done in the context of the Convention on Biological Diversity (CBD) and Sustainable Development Goals (SDGs), whose contributions to climate-resilient development pathways are assessed. This chapter highlights both successes and failures of adaptation attempts and considers potential synergies and conflicts with land-based climate change mitigation. Knowledge gaps and sources of uncertainty are included to encourage additional research.

The Working Group II Summary for Policy Makers of the 5th Assessment Report (WGII AR5 SPM) stated that "many terrestrial and freshwater species have shifted their geographic ranges, seasonal activities, migration patterns, abundances, and species interactions in response to ongoing climate change" (IPCC, 2014e). Based on long-term observed changes across the regions, it was estimated that approximately 20–30% of plant and animal species are at risk of extinction when global mean temperatures rise 2–3°C above preindustrial levels (Fischlin et al., 2007). In addition, WGII AR5 (IPCC, 2014f) broadly suggested that autonomous adaptation by ecosystems and wild species might occur, and proposed human-assisted adaptation to minimise negative climate change impacts.

Risk assessments for species, communities, key ecosystems and their services were based on the Risk Assessment Framework introduced in the IPCC AR5 (IPCC, 2014). Assessments of observed changes in biological systems emphasise detection and attribution of climate change on ecological and evolutionary processes with an emphasis on freshwater ecosystems, and assess ecosystem processes that were lightly assessed in previous reports, such as wildfire. Where appropriate, assessment of interactions between climate change and other human activities is provided.

Land-use and land cover change (LULCC), and unsustainable exploitation of resources from terrestrial and freshwater systems continue to be a major factor of natural ecosystem and biodiversity loss (*high confidence*). Fertiliser input, pollution of waterways, dam construction and extraction of freshwater for irrigation put additional pressure on biodiversity and alter ecosystem function (Shin et al., 2019). Likewise, for biodiversity, invasive alien species have been identified as a major threat, especially in freshwater systems, islands and coastal regions (*high confidence*) (IPBES, 2018b; IPBES, 2018e; IPBES, 2018c; IPBES, 2018d; IPBES, 2019). Climate change and CO_2 are expected to become increasingly important as drivers of change over the coming decades (Ciais et al., 2013; Settele et al., 2014; IPBES, 2019; IPCC, 2019c).

2.1.2 *Points of Departure*

Species diversity and ecosystem function influence each other reciprocally, while ecosystem function forms the necessary basis for ecosystem services (Hooper et al., 2012; Mokany et al., 2016). Drivers of impacts on biodiversity, ecosystem function and ecosystem services have been assessed in reports from IPCC, Food and Agriculture Organization (FAO), IPBES and the Global Environmental Outlook (Settele et al., 2014; FAO, 2018; IPBES, 2018b; IPBES, 2018e; IPBES, 2018c; IPBES, 2018d; IPBES, 2019; UNEP, 2019; Diversity, 2020). Most recently, the IPCC SRCCL provided an assessment on land degradation and desertification, greenhouse gas emissions and food security in the context of global warming (IPCC, 2019c), and the IPBES-IPCC joint report on Biodiversity and Climate Change provided a synthesis of current understanding of the interactions, synergies and feedbacks between biodiversity and climate change (Pörtner et al., 2021). This chapter builds on and expands the results from these assessments.

Assessment of impacts of climate change on freshwater systems has been limited in previous assessments, and interlinkages between terrestrial and freshwater processes have not been fully explored (Settele et al., 2014; IPBES, 2019). Improved treatment of impacts on terrestrial and freshwater systems is critical considering the revisions of international sustainability Goals and Targets, especially the conclusion that many of the proposed post-2020 Biodiversity-targets of the Convention on Biological Diversity (CBD) cannot be met due to climate change impacts (Arneth et al., 2020).

Previous reports highlighted the possibility of new ecosystem states stemming from shifts in thermal regimes, species composition, and energy and matter flows (Settele et al., 2014; Shin et al., 2019). Projecting such "tipping points" (see glossary) has been identified in previous reports as a challenge since neither monitoring programmes nor field studies, nor ecosystem and biodiversity modelling tools capture the underlying species-species and species-climate interactions sufficiently well to identify how biological interactions within and across trophic levels may amplify or dampen shifts in ecosystem states (Settele et al., 2014; Shin et al., 2019). Building on these previous analyses and recent literature, Chapter 2 in this AR6 provides new insights compared to previous assessments by (i) emphasising freshwater aspects, and the interlinkages between freshwater and terrestrial systems, (ii) assessing more clearly the link between biodiversity and ecosystem functioning, (iii) assessing impacts associated with climate change mitigation scenarios versus impacts of climate change, including interactions with adaptation, and (iv) where possible, places findings in context of the United Nations Sustainable Development Goals (SDGs) 2030, and services for human societies.

2.1.3 Guide to Attribution and Traceability of Uncertainty Assessments

For biological systems we use the framework for detection and attribution outlined in AR5 in which attribution of observed biological changes is made not to global, but to local or regional climate changes, (Parmesan et al., 2013; Cramer et al., 2014). However, global distribution of regional responses is desirable to achieve generality, and data in prior reports were concentrated from the northern hemisphere. The critique of "global" studies by (Feeley et al., 2017) argues that their naming is misleading, that most of them are far from global and that considerable geographic and taxonomic bias remains. This bias is diminishing, as data from southern hemisphere regions are added and there is now representation from every continent.

Overall confidence in climate change attribution of a biological change can be increased in multiple ways (Parmesan et al., 2013), of which we list four here. First, confidence rises when the time span of biological records is long, such that decadal trends in climate can be compared with decadal trends in biological response and long-term trends can be statistically distinguished from natural variability. Secondly, confidence can be increased by examining a large geographic area, which tends to diminish the effects of local confounding factors (Parmesan et al., 2013; Daskalova et al., 2020). Third, confidence is increased when there is experimental or empirical evidence of a mechanistic link between particular climate metrics and biological response. Fourth, confidence is increased when particular fingerprints of climate change are documented that uniquely implicate climate change as the causal driver of the biological change (Parmesan and Yohe, 2003). These conditions constitute multiple lines of evidence which, when they converge, can provide *very high confidence* that climate change is the causal driver of an observed change in a particular biological species or system (Parmesan et al., 2013).

Important factors that may confound or obscure effects of climate change are presence of invasive species, changes in land use (LULCC), and, in freshwater systems, eutrophication (IPCC, 2019a). Temporal and spatial scale of the study also affect estimates of impacts. The most extreme published estimates of biological change tend to be derived from smaller areas and/or shorter timeframes (Daskalova et al., 2020), and a recent large global analysis of data for 12,415 species found that differences in study methodology accounted for most of the explained variance in reported range shifts (Lenoir et al., 2020). The importance of land-use change is frequently stressed, but there is a paucity of studies that actually quantify the relative effects of climate change and land-use change on species and communities. Sirami et al. (2017) found only 13 such studies, among which four concluded that effects of land-use change over-rode those of climate change, four found that the two drivers independently affected different species and five found that they acted in synergy.

2.2 Connections of Ecosystem Services to Climate Change

Ecosystems provide services essential for human survival and well-being. The Millennium Ecosystem Assessment defined ecosystem services as "the benefits people obtain from ecosystems" including "provisioning services such as food and water; regulating services such as regulation of floods, drought, land degradation, and disease; supporting services such as soil formation and nutrient cycling; and cultural services such as recreational, spiritual, religious, and other nonmaterial benefits" (Assessment, 2005).

The Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) re-named the concept "nature's contributions to people" and broadened the definition to "the contributions, both positive and negative, of living nature (i.e. diversity of organisms, ecosystems, and their associated ecological and evolutionary processes) to the quality of life for people. Beneficial contributions from nature include such things as food provision, water purification, flood control, and artistic inspiration, whereas detrimental contributions include disease transmission and predation that damages people or their assets" (IPBES, 2019). IPBES modified the concept to include more social viewpoints and broaden analyses beyond narrow economic stock-and-flow valuation approaches (Díaz et al., 2018). IPBES developed a classification of 18 categories of ecosystem services (see Table 2.1).

When anthropogenic climate change affects ecosystems, it can also affect ecosystem services for people. Climate change connects to ecosystem services through three links: climate change—species—ecosystems—ecosystem services. This IPCC chapter assesses these connections through all three links when end-to-end published scientific analyses are available for terrestrial and freshwater ecosystems. This type of robust evidence exists for some key ecosystem services (Section 2.5.4), and is assessed in specific report sections: biodiversity habitat creation and maintenance (Sections 2.4, 2.5), regulation of detrimental organisms and biological processes (Sections 2.4.2.3, 2.4.2.7, 2.4.4, 2.5.3, 2.6.4, Cross-Chapter Box ILLNESS this Chapter), regulation of climate through ecosystem feedbacks in terms of carbon storage (Sections 2.4.4.4, 2.5.2.10, 2.5.3.4, 2.5.3.5) and albedo (Section 2.5.3.5), and provision of freshwater from ecosystems to people (Section 2.5.3.6).

For ecosystem services that do not have published scientific information to establish unambiguous links to climate change, the climate—species—ecosystem links are assessed. Global ecological assessments, including the Global Biodiversity Assessment (Programme, 1995), the Millennium Ecosystem Assessment (Assessment, 2005), and the IPBES Global Assessment Report (IPBES, 2019) have synthesised scientific information on the ecosystem—ecosystem services link, but full assessment from climate change to ecosystem services is often impeded by limited quantitative studies that span this entire spectrum, see (Mengist et al., 2020) for a review of this gap in montane regions.

IPCC and IPBES are collaborating to address gaps in knowledge on the effects of climate change on ecosystem services (Services and Ecosystem, 2021). Table 2.1 provides a guide for finding information on climate change and individual ecosystem services in the IPCC Sixth Assessment Report.

Table 2.1: Connections of ecosystem services to climate change, indicating the 18 categories of nature's contributions to people of the IPBES (IPBES, 2019), the most relevant sections in the IPCC Sixth Assessment Report, and the level of evidence in this report for attribution to anthropogenic climate change of observed impacts on ecosystem services. The order of services in the table follows the order presented by IPBES and does not denote importance or priority. Connections denote observed impacts, future risks, and adaptation. The order of connections follows the relevance or the order of sections.

Ecosystem service	Connections to climate change
Habitat creation and maintenance	Species extinctions (2.4.2.2, 2.5.1.3), Species range shifts (2.4.2.1, 2.4.2.5), Ecological changes in freshwater ecosystems (2.3.3, 2.4.2.3.2, 2.4.4.1, 2.4.4.5.2, 2.5.1.3.2, 2.5.3.5, 2.5.4, 2.5.3.6, 2.5.5.8), Vegetation changes (2.4.3, 2.4.4.2.5, 2.4.4.3, 2.4.4.4, 2.4.4.5.1, 2.5.2, 2.5.3.3), Biome shifts (2.4.3.2, 2.5.4), Wildfire (2.4.4.2, 2.5.3.2), Tree mortality (2.4.4.3, 2.5.3.3) (*robust evidence*)

Pollination and dispersal of seeds and other propagules	Species extinctions (2.4.2.2, 2.5.1.3), Species range shifts (2.4.2.1, 2.4.2.5), Phenology changes (2.4.2.4, 2.4.2.5) (*medium evidence*)
Regulation of air quality	Wildfire (2.4.4.2, 2.5.3.2, Chapter 7), Tree mortality (2.4.4.3, 2.5.3.3) (*medium evidence*)
Regulation of climate	Ecosystem carbon stocks, emissions, and removals (2.4.4.4, 2.5.3.4, IPCC AR6 Working Group I, Chapter 5), Amazon rainforest dieback (2.4.3.6, 2.4.4.3.2, 2.4.4.4.2, 2.5.2.6, 2.5.2.10, 2.5.3.3), Tundra permafrost thaw (2.4.4.4.4, 2.5.2.8, 2.5.3.5, 2.5.4), biome shifts (2.4.3, 2.5.2, 2.5.3.2.2), Wildfire (2.4.4.2, 2.5.3.2), Tree mortality (2.4.4.3, 2.5.3.3), Primary productivity changes (2.4.4.5, 2.5.3.5) (*robust evidence*)
Regulation of ocean acidification	Ocean acidification (IPCC AR6 Working Group I, Chapter 5), Changes in marine species distribution and abundance (Chapter 3) (*robust evidence*)
Regulation of freshwater quantity, location, and timing	Physical changes in freshwater systems (2.3.3), Ecological changes in freshwater ecosystems (2.4.2.3.2, 2.4.4.1, 2.4.4.5.2, 2.5.1.3.2, 2.5.3.7), Tree mortality (2.4.4.3, 2.5.3.3), Freshwater supply from ecosystems (2.5.3.6) (*medium evidence*)
Regulation of freshwater and coastal water quality	Coastal ecosystem changes (Chapter 3), Physical changes in freshwater systems (2.3.3), Ecological changes in freshwater ecosystems (2.4.2.3.2; 2.4.4.1, 2.4.4.5.2, 2.5.1.3.2, 2.5.3.7) (*robust evidence*)
Formation, protection, and decontamination of soils and sediments	Agricultural ecosystem changes (Chapter 5), Physical changes in freshwater systems (2.3.1), Vegetation changes (2.4.3, 2.5.4), Wildfire (2.4.4.2, 2.5.3.2) (*medium evidence*)
Regulation of hazards and extreme events	Coastal ecosystem changes (Chapter 3), Vegetation changes (2.4.3, 2.5.2), Wildfire (2.4.4.2, 2.5.5.2), Summary of hazards (2.3), Cross-Chapter Box EXTREMES this Chapter (*medium evidence*)
Regulation of detrimental organisms and biological processes	Inter-species interactions (2.4.2), Control of disease vectors (2.4.2.7, 2.5.1, 2.6.4), Insect pest infestations (2.4.4.3), Cross-Chapter Box ILLNESS this Chapter (*medium evidence*)
Energy	Forestry plantation changes (Chapter 5), Biomass changes in natural ecosystems (2.4.4.4), Bioeconomy (Cross-Working Group Box BIOECONOMY in Chapter 5), Tree mortality (2.4.4.3, 2.5.3.3) (*limited evidence*)
Food and feed	Agricultural ecosystem changes (Chapter 5), Species extinctions (2.4.2.2, 2.5.1.3), Species range shifts (2.4.2.1), Nature-based services from natural ecosystems (Cross-Chapter Box NATURAL this chapter), shifts in commercial food species Cross-Chapter Box Moving Plate in Chapter 5) (*medium evidence*)
Materials, companionship, and labour	Forestry plantation changes (Chapter 5), Species extinctions (2.4.2.2, 2.5.1.3), Species range shifts (2.4.2.1), Tree mortality (2.4.4.3, 2.5.3.3) (*limited evidence*)
Medicinal, biochemical, and genetic resources	Species extinctions (2.4.2.2, 2.5.1.3), Species range shifts (2.4.2.1) (*limited evidence*)
Learning and inspiration	All observed impacts (2.4) and future risks (2.5) in terrestrial and freshwater ecosystems (*limited evidence*)

Physical and psychological experiences	All observed impacts (2.4) and future risks (2.5) in terrestrial and freshwater ecosystems (*limited evidence*)
Supporting identities	All observed impacts (2.4) and future risks (2.5) in terrestrial and freshwater ecosystems (*limited evidence*)
Maintenance of options	All observed impacts (2.4) and future risks (2.5) in terrestrial and freshwater ecosystems, Nature-based services from natural ecosystems (Cross-Chapter Box NATURAL this Chapter, Cross-Chapter Box DEEP in Chapter 17 *(limited evidence)*

2.3 Hazards and Exposure

In AR6, WGI describes changes in physical climate systems using the term 'climatic impact-drivers' (CIDs), which can have detrimental, beneficial or neutral effects on a system. In contrast, the literature on natural systems tends to focus on hazards, which include natural or human-induced physical events, impacts or trends with the potential to cause negative effects on ecosystems and environmental resources. Hazards are affected by current and future changes in climate, including altered climate variability and extreme events (WGI Chapter 12). Hazards can occur suddenly (e.g., a heat wave or heavy rain event), or more slowly (e.g., land loss, degradation and erosion linked to multiple climate hazards compounding). Observed exposure and risks to protected areas is assessed in Section 2.5.3.1.1. See also Cross-Chapter Box EXTREMES this Chapter.

Non-climatic hazards such as land use change, habitat fragmentation, pollution and invasive species have been the primary drivers of change in terrestrial and freshwater ecosystems in the past (*high confidence*) (Figure 2.1). These impacts have been extensively documented in reports by the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES, 2021). However, whilst climate change has not been the predominant influence to date, its relative impact is increasing (IPCC Special Report on Climate Change and Land (SRCCL)), with greater interactive effects of non-climate and climate hazards now occurring (Birk et al., 2020).

2.3.1 Observed Changes to Hazards and Extreme Events

The major climate hazards at the global level are generally well understood (WGI AR6 Chapter 12; WGI AR6 Interactive Atlas). Increased temperatures and changes to rainfall and runoff patterns; greater variability in temperature, rainfall, river flow and water levels; rising sea-levels and increased frequency of extreme events means that greater areas of the world are being exposed to climate hazards outside those to which they are adapted (*high confidence*) (Lange et al., 2020).

Extreme events are a natural and important part of many ecosystems and many organisms have adapted to cope with long-term and short-term climate variability, within the disturbance regime experienced during their evolutionary history (*high confidence*). However, climate changes, disturbance regimes change and the magnitude and frequency of extreme events such as floods, droughts, cyclones, heatwaves and fire have increased in many regions (*high confidence*). These disturbances affect ecosystem functioning, biodiversity and ecosystem services (*high confidence*) but are, in general, poorly captured in impact models (Albrich et al., 2020b), although this should improve as higher-resolution climate models that better capture smaller-scale processes and extreme events become available (WGI AR6, Chapter 11). Extreme events pose large challenges for Ecosystem-based Adaptation (IPCC Special Reports on Extremes, Section 2.6.3). Ecosystem functionality on which such adaptation measures rely may be altered or destroyed by extreme episodic events (Handmer et al., 2012; Lal et al., 2012; Pol et al., 2017).

There is *high confidence* that the combination of internal variability, superimposed on longer-term climate trends, is pushing ecosystems to tipping points, beyond which abrupt and possibly irreversible changes are occurring (Harris et al., 2018a; Jones et al., 2018; Hoffmann et al., 2019b; Prober et al., 2019; Berdugo et al., 2020; Bergstrom et al., 2021). Increases in the frequency and severity of heatwaves, droughts and aridity, floods, fires and extreme storms have been observed in many regions (Seneviratne et al., 2012; Ummenhofer and Meehl, 2017) and these trends are projected to continue (*high confidence*) (Section 3.2.2.1, Cross-Chapter Box EXTREMES this Chapter, AR6 WGI Chapter 11;, SR1.5, Hoegh-Guldberg et al., 2018b).

While the major climate hazards at the global level are generally well described with high confidence, there is less understanding about the importance of hazards on ecosystems when they are superimposed (Allen et al., 2010; Anderegg et al., 2015; Seidl et al., 2017; Dean et al., 2018), and the outcomes are difficult to quantify in future projections (Handmer et al., 2012). Simultaneous or sequential events (coincident or compounding events) can lead to an extreme event or impact, even if each event is not in themselves extreme (Denny et al., 2009; Hinojosa et al., 2019). For example, the compounding effects of sea-level rise, extreme coastal high tide, storm surge, and river flow can substantially increase flooding hazard and impacts on freshwater systems (Moftakhari et al., 2017). On land, changing rainfall patterns and repeated heat waves may interact with biological factors such as altered plant growth and nutrient allocation under elevated CO_2, affecting herbivory rates and insect outbreaks leading to widespread dieback of some forests (e.g. in Australian *Eucalypt* forests) (Gherlenda et al., 2016; Hoffmann et al., 2019a). Risk assessments typically only consider a single climate hazard without changing variability, potentially underestimating actual risk (Milly et al., 2008; Sadegh et al., 2018; Zscheischler et al., 2018; Terzi et al., 2019; Stockwell et al., 2020;).

Understanding impacts associated with the rapid rate of climate change is less developed and more uncertain than changes in mean climate. High climate velocity (Loarie et al., 2009) is expected to be associated with distribution shifts, incomplete range filling and species extinctions (*high confidence*) (Sandel et al., 2011; Burrows et al., 2014), although not all species are equally at risk from high velocity (see Sections 2.4.2.2, 2.5.1.3). It is generally assumed that the more rapid the rate of change, the greater the impact on species and ecosystems, but responses are taxonomically and geographically variable (*high confidence*) (Kling et al., 2020).

For example, strong dispersers are less at risk, while species with low dispersal ability, small ranges and long lifespans (e.g. many plants, especially trees, many amphibians and some small mammals) are more at risk (Hamann et al., 2015) (IPCC, 2014). This is likely to favour generalist and invasive species, altering species composition, ecosystem structure and function (Clavel et al., 2011; Büchi and Vuilleumier, 2014). The ability to track suitable climates is substantially reduced by habitat fragmentation and human modifications of the landscape such as dams on rivers and urbanisation (*high confidence*). Freshwater systems are particularly at risk of rapid warming given their naturally fragmented distribution. Velocity of change in surface temperature of inland standing waters globally has been estimated as 3.5 ± 2.3 km per decade from 1861 to 2005. This is projected to increase from 2006 to 2099 from between 8.7 ± 5.5 km per decade (RCP 2.6) to 57.0 ± 17.0 km per decade (RCP 8.5) (Woolway and Maberly, 2020). Although the dispersal of aerial adult stage of some aquatic insects can surpass these climate velocities, rates of change under mid- and high emissions scenarios (RCP4.5, RCP6.0, RCP8.5) are substantially higher than known rates of active dispersal of many species (Woolway and Maberly, 2020). Many species, both terrestrial and freshwater, are not expected to be able to disperse fast enough to track suitable climates under mid- and high emissions scenarios (*medium confidence*) (RCP4.5, RCP6.0, RCP8.5; Brito-Morales et al., 2018).

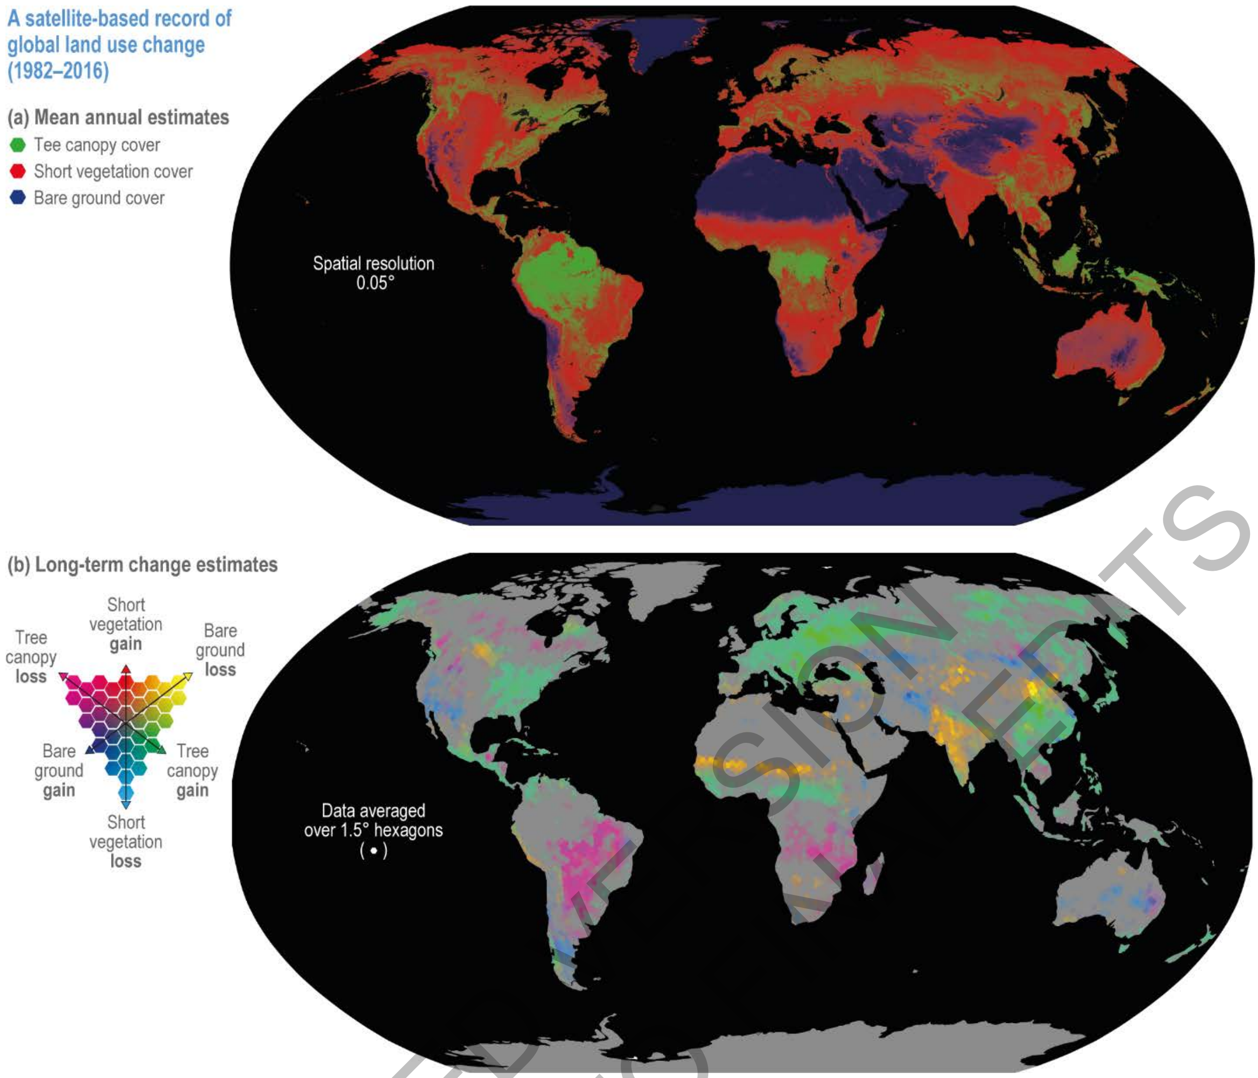

Figure 2.1: Map of global land use change from 1982–2016. Based on satellite records of global tree canopy (TC), short vegetation (SV) and bare ground (BG) cover (from Song et al., 2018). a) Mean annual estimates of cover (% of pixel area at 0.05° resolution). b) Long-term change estimates (% of pixel area at 1.5° resolution), with pixels showing a statistically significant trend (n = 35 years, two-sided Mann–Kendall test, P < 0.05) in TC, SV or BG. The dominant changes are Tree canopy gain with Short vegetation loss; Bare Ground gain with Short vegetation loss; Tree canopy gain with Bare Ground loss; Bare Ground gain with Tree canopy loss; 5, Short vegetation gain with Bare Ground loss; and Short vegetation gain with TC loss. Grey indicates areas with no significant change between 1982–2016.

2.3.2 Projected Impacts of Extreme Events

Understanding of the large-scale drivers and the local to regional feedback processes that lead to extreme events is still limited and projections of extremes and coincident or compounding events remain uncertain (Prudhomme et al., 2014; Sillmann et al., 2017; Hao et al., 2018; Miralles et al., 2019). Extreme events are challenging to model because they are by definition rare and often occur at spatial and temporal scales much finer than the resolution of climate models (Sillmann et al., 2017; Zscheischler et al., 2018). Additionally, the processes that cause extreme events often interact, as is the case for drought and heat events, and are spatially and temporally dependent, for example, as is the case in soil moisture and temperature (Vogel et al., 2017). Understanding feedbacks between land and atmosphere also remains limited. For example, positive feedbacks between soil and vegetation, or between evaporation, radiation and precipitation are important in the preconditioning of extreme events such as heatwaves and droughts, increasing the severity and impact of extreme events (Miralles et al., 2019).

Despite recent improvements in observational studies and climate modelling (Santanello et al., 2015; Stegehuis et al., 2015; PaiMazumder and Done, 2016; Basara and Christian, 2018; Knelman et al., 2019), the potential to quantify or infer formal causal relationships between multiple drivers and/or hazards remains limited, for several reasons (Zscheischler and Seneviratne, 2017; Kleinman et al., 2019; Miralles et al., 2019; Yokohata et al., 2019; Harris et al., 2020). The mechanisms underlying the response are difficult to identify (e.g., response to heat stress, drought, insects), effects vary among species and at different life stages, and an initial stress may influence the response to further stress (Nolet and Kneeshaw, 2018). Additionally, hazards such as drought are often exacerbated by societal, industrial and agricultural water demands, requiring more sophisticated modelling of the physical and human systems (Mehran et al., 2017; Wan et al., 2017). Observations of past compound events may not provide reliable guides to how future events may evolve, because human activity and recent climate change continue to interact to influence both system functioning and the climate state that have not been experienced in the past (see Chapter 11, WGI AR6).

2.3.3 Biologically Important Physical Changes in Freshwater Systems

Physical changes are fundamental drivers of change at all levels of biological organisation, from individual species to communities to whole ecosystems and climate hazards specific to freshwater systems which are not documented elsewhere in AR6 are summarised here.

2.3.3.1 Observed Change in Thermal Habitat and Oxygen Availability

Since AR5, evidence for changes in temperatures of lakes and rivers has continued to increase. Global warming rates for lake surface waters were estimated as 0.21°C to 0.45°C per decade between 1970-2010, exceeding SST trends of 0.09°C per decade between 1980–2017 (*robust evidence, high agreement*) (Figure 2.2; Schneider and Hook, 2010; Kraemer et al., 2015; O'Reilly et al., 2015; Woolway et al., 2020b). Warming of lake surface water temperatures was variable within regions (O'Reilly et al., 2015) but more homogeneous than changes of deep water temperature (Pilla et al., 2020). Because temperature trends in lakes can vary vertically, horizontally, and seasonally, complex changes have occurred in the amounts of habitat available to aquatic organisms at particular depths and temperatures (Kraemer et al., 2021).

Changes in river water temperatures ranged from -1.21 to +1.076 °C per decade between 1901–2010 (*medium evidence, medium agreement*) (Figure 2.2; Hari et al., 2006; Kaushal et al., 2010; Jurgelėnaitė et al., 2012; Li et al., 2012; Latkovska and Apsīte, 2016; Marszelewski and Pius, 2016). The more rapid increase in surface water temperature in lakes and rivers in regions with cold winters (O'Reilly et al., 2015) can in part be attributed to the amplified warming in polar and high latitude regions (*robust evidence, high agreement*) (Figure 2.2b; Screen and Simmonds, 2010; Stuecker et al., 2018).

Shifts in thermal regime: Since AR5 the trend that lake waters mix less frequently continues (Butcher et al., 2015; Adrian et al., 2016; Richardson et al., 2017; Woolway et al., 2017). This results from greater warming of surface temperatures relative to deep water temperatures and the loss of ice during winter which prevents inverse thermal stratification in north temperate lakes *(robust evidence, high agreement)* (Adrian et al., 2009; Winslow et al., 2015; Adrian et al., 2016; Schwefel et al., 2016; Richardson et al., 2017).

Oxygen availability: Increased water temperature and reduced mixing cause a decrease in dissolved oxygen. In 400 lakes, dissolved oxygen in surface and deep waters declined by 4.1 and 16.8%, respectively between 1980 and 2017 (Jane et al., 2021). The deepest water layers are expected to experience an increase in hypoxic conditions by more than 25% due to reduced winter mixing and fewer complete mixing events, with strong repercussions on nutrient dynamics and loss of thermal habitat (*robust evidence, high agreement*) (Straile et al., 2010; Zhang et al., 2015; Schwefel et al., 2016; Adrian et al., 2016; Kraemer et al., 2021).

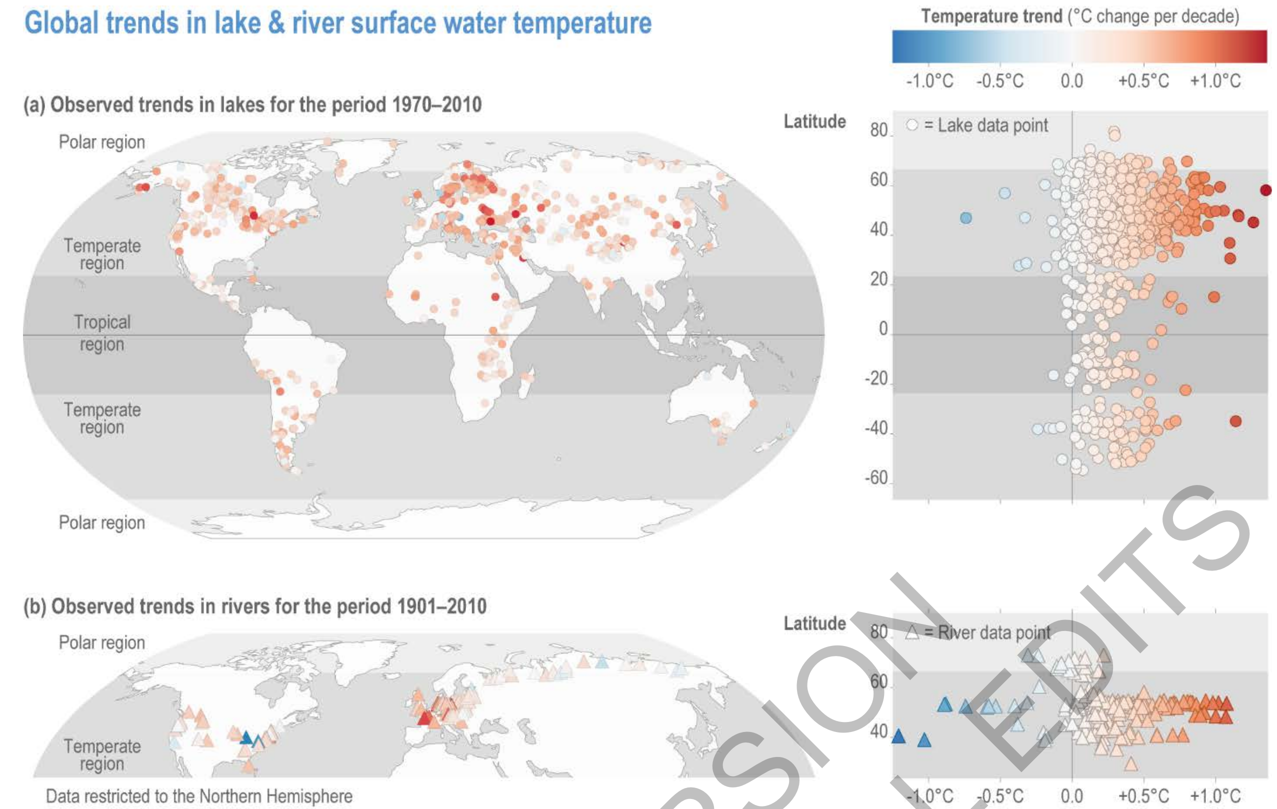

Figure 2.2: Observed global trends in lake and river surface water temperature. a) Left panel: Map of temperatures of lakes (1970-2010). b) Left panel: Map of temperatures of rivers (1901–2010). Note that the trends of river water temperatures are not directly comparable within rivers or directly comparable to lakes since time periods are not consistent across river studies. Right panels in a) and b) depict water temperature trends along a latitudinal gradient highlighting the above average warming rates in northern Polar Regions (polar amplification). Data sources for lakes: (O'Reilly et al., 2015; Carrea and Merchant, 2019; Woolway et al., 2020a; Woolway et al., 2020b). Data sources for rivers: (Webb and Walling, 1992; Langan et al., 2001; Daufresne et al., 2004; Moatar and Gailhard, 2006; Lammers et al., 2007; Patterson et al., 2007; Webb and Nobilis, 2007; Durance and Ormerod, 2009; Kaushal et al., 2010; Pekárová et al., 2011; Jurgelėnaitė et al., 2012; Markovic et al., 2013; Arora et al., 2016; Latkovska and Apsīte, 2016; Marszelewski and Pius, 2016; Jurgelėnaitė et al., 2017).

2.3.3.2 Observed Changes in Water Level

Depending on how the intensification of the global water cycle affects individual lake water budgets, the amount of water stored in specific lakes may increase, decrease, or have no substantial cumulative effect (Notaro et al., 2015; Pekel et al., 2016; Rodell et al., 2018; Busker et al., 2019; Woolway et al., 2020b). The magnitude of hydrological changes that can be assuredly attributed to climate change remains uncertain (Hegerl et al., 2015; Gronewold and Rood, 2019; Kraemer et al., 2020). Attribution of water storage variation in lakes due to climate change is facilitated when such variations occur coherently across broad geographic regions and long timescales, preferably absent other anthropogenic hydrological influences (Watras et al., 2014; Kraemer et al., 2020). There is increasing awareness that climate change contributes to the loss of small temporary ponds, which cover a greater global area than lakes (Bagella et al., 2016).

Lakes fed by glacial meltwater are growing in response to climate change and glacier retreat (*robust evidence*, *high agreement*) (Shugar et al., 2020). Water storage increases on the Tibetan Plateau (Figure 2.3a) have been attributed to changes in glacier melt, permafrost thaw, precipitation and runoff, in part as a result of climate change (Huang et al., 2011; Meng et al., 2019; Wang et al., 2020a). *High confidence* in attribution of these trends to climate change is supported by long-term ground survey data and observations from the GRACE satellite mission (Ma et al., 2010; Rodell et al., 2018; Kraemer et al., 2020).

In the Arctic, lake area has increased in regions with continuous permafrost and decreased in regions where permafrost is thinner and discontinuous *(robust evidence, high agreement)* (see Chapter 4; Smith et al., 2005; Andresen and Lougheed, 2015; Nitze et al., 2018; Mekonnen et al., 2021).

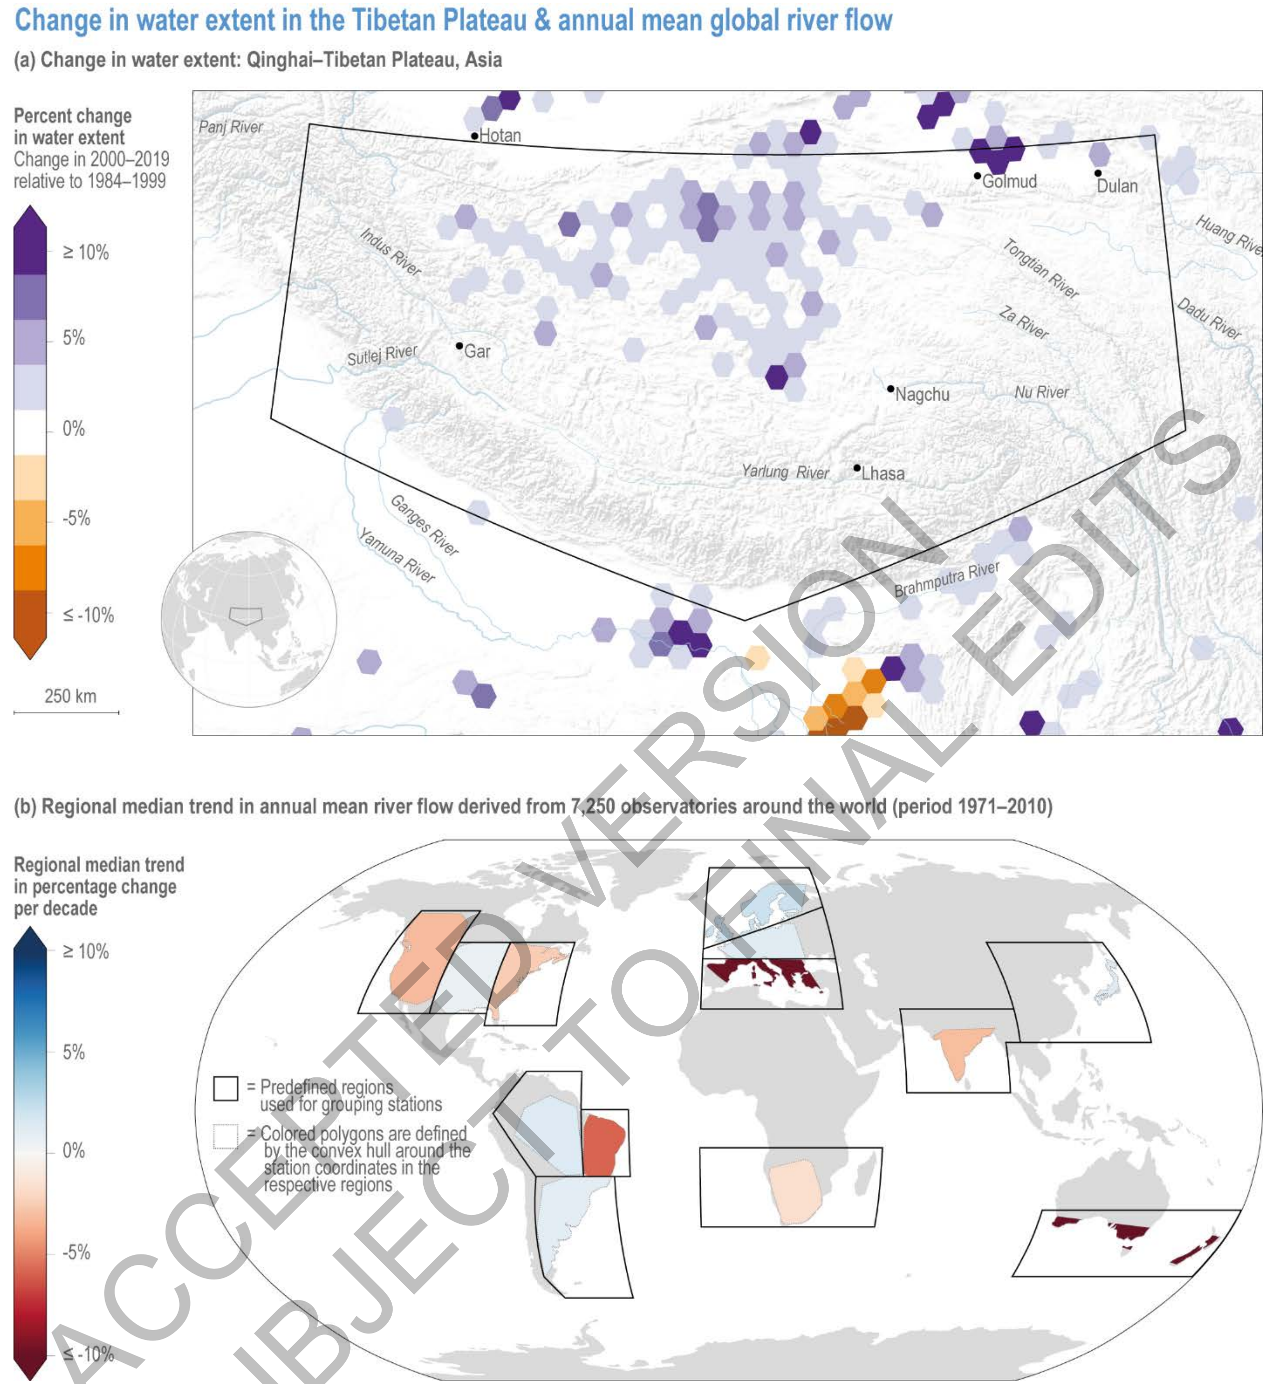

Figure 2.3: Change in water extent in the Tibetan Plateau and annual mean global river flow. a) Changes in water storage on the Tibetan Plateau. Map of the Qinghai-Tibetan Plateau, Asia showing the percent change in surface water extent from 1984-2019 based on LANDSAT imagery. Increases in surface water extent in this region are mainly caused by climate-change mediated increases in precipitation and glacial melt (Source: EC JRC/Google; (Pekel et al., 2016). b) Global map of the median trend in annual mean river flow derived from 7250 observatories around the world (period 1971–2010). Some regions are drying (northeast Brazil, southern Australia, and the Mediterranean) and others are wetting (northern Europe) mainly caused by large-scale shifts in precipitation, changes in factors that influence evapotranspiration and alterations of the timing of snow accumulation and melt driven by rising temperatures (Source: Gudmundsson et al., 2021).

2.3.3.3 Observed Changes in Discharge

Analysis of river flows from 7,250 observatories around the world covering the years 1971 to 2010 and identified spatially complex patterns, with reductions in northeastern Brazil, southern Australia and the

Mediterranean and increases in northern Europe (*medium evidence, medium agreement*) (Figure 2.3b; Gudmundsson et al., 2021). More than half of global rivers undergo periodic drying that reduces river connectivity (*medium evidence, medium agreement*). Increased frequency and intensity of droughts may cause perennial rivers to become intermittent and intermittent rivers to disappear (*medium evidence, medium agreement*), threatening freshwater fish in habitats already characterised by heat and droughts (Datry et al., 2016; Schneider et al., 2017; Jaric et al., 2019). In high altitude/latitude streams, reduced glacier and snowpack extent, earlier snowmelt and altered precipitation patterns, attributed to climate change, have increased flow intermittency (Vorosmarty et al., 2010; Siebers et al., 2019; Gudmundsson et al., 2021) Patterns in flow regimes can be directly linked to a variety of processes shaping freshwater biodiversity, hence any climate-change induced changes on flow regimes and river connectivity are expected to alter species composition, as well as having societal impacts (See Chapter 3 of IPCC SR1.5; Bunn and Arthington, 2002; Thomson et al., 2012; Chessman, 2015; Kakouei et al., 2018)

2.3.3.4 Observed Loss of Ice

Studies since AR5 have confirmed ongoing and accelerating loss of lake and river ice in the northern hemisphere (*robust evidence, high agreement)* (Figure 2.4). In recent decades, systems have been freezing later in winter and thawing earlier in spring, reducing ice duration by >2 weeks per year and leading to increasing numbers of years with loss of perennial ice cover, leading to intermittent ice-cover or even absence of ice (Adrian et al., 2009; Kirillin et al., 2012; Paquette et al., 2015; Adrian et al., 2016; Park et al., 2016; Roberts et al., 2017; Sharma et al., 2019). The global extent of river ice declined by 25% between 1984 and 2018 (Yang et al., 2020). This trend has been more pronounced at higher latitudes, consistent with enhanced polar warming (large geographic coverage) (Du et al., 2017). Empirical long-term and remote sensing data gathered in an increasingly large number of freshwater systems supports *very high confidence* in attribution of these trends to climate change. For declines of glaciers, snow and permafrost see AR6 WGII Chapter 4 and SROCC report.

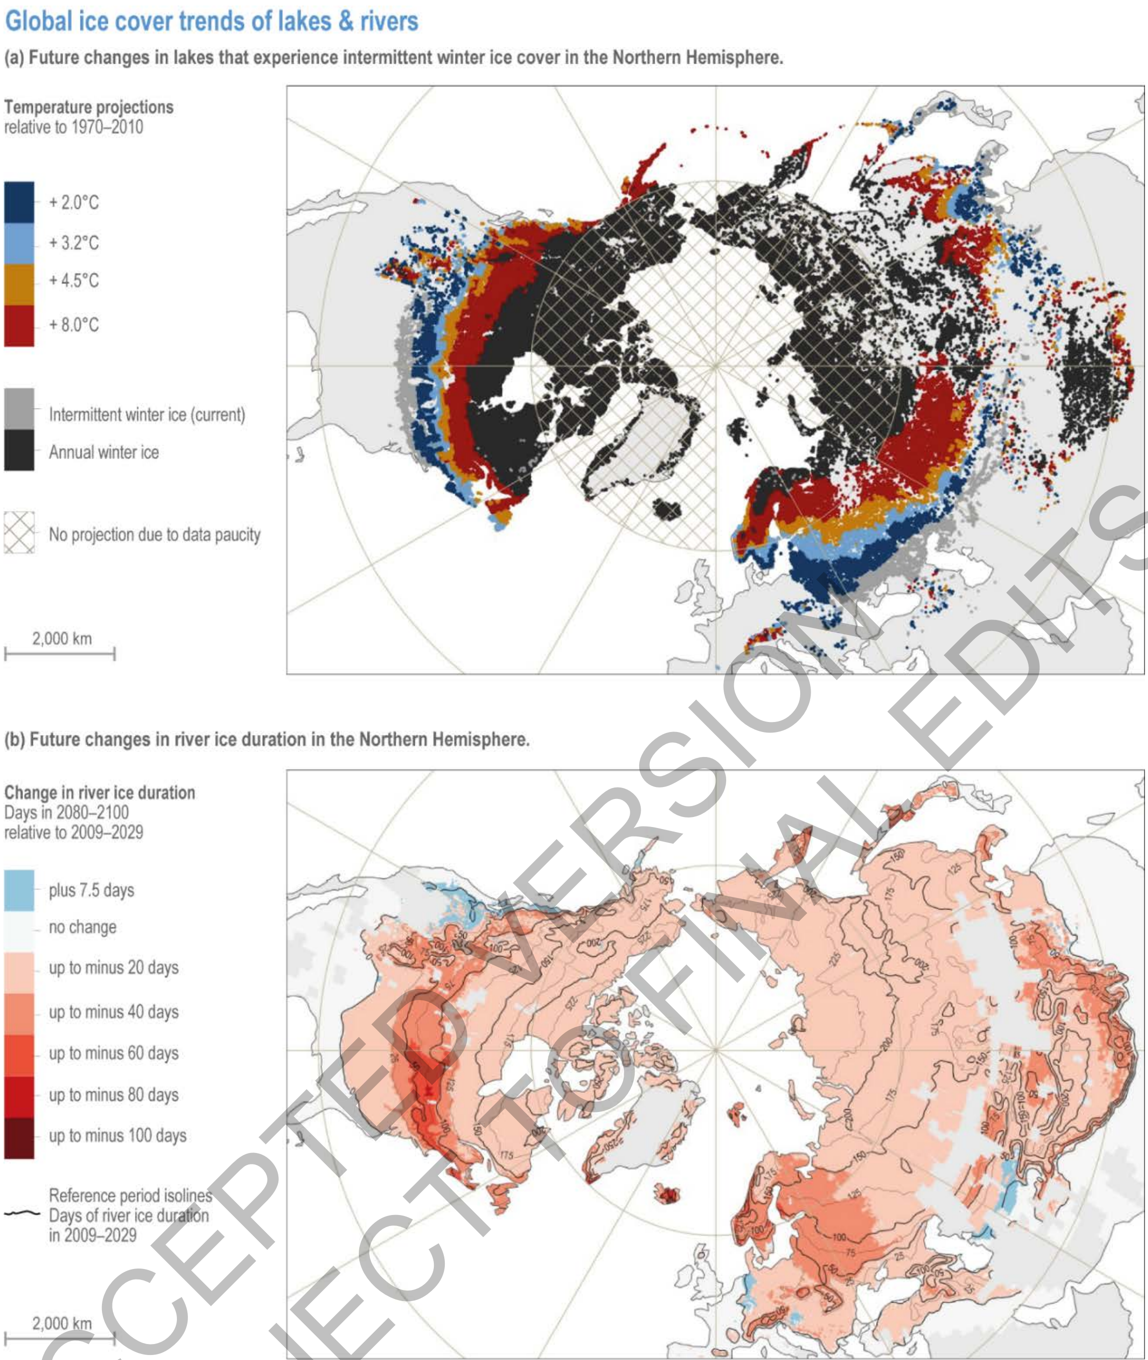

Figure 2.4: Global ice cover trends of lakes and rivers. a) Spatial distribution of current (light grey areas) and future (coloured areas) Northern Hemisphere lakes that may experience intermittent winter ice cover with climate warming. Projections were based on current conditions (1970-2010) and four established air temperature projections (Data source: (Sharma et al., 2019). b) Spatial distribution of projected change in Northern Hemisphere river ice duration under the RCP 4.5 emission scenario by 2080-2100 relative to the period 2009-2029. White areas refer to rivers without ice cover in the period 2009-2029 (zero days). Reference period isolines indicate river ice duration in the period 2009-2029. Coloured areas depict loss of ice duration in days. Blue areas depict a projected increase in river ice duration. Grey land areas indicate a lack of Landsat-observable rivers (Data source: Yang et al., 2020).

2.3.3.5 Extreme Weather Events and Freshwater Systems

Since AR5, numerous drastic short-term responses have been observed in lakes and rivers, both to expected seasonal extreme events and to unexpected supra-seasonal extremes extending over multiple seasons. Consequences for ecosystem functioning are not well understood (Bogan et al., 2015; Death et al., 2015; Stockwell et al., 2020). Increasing frequencies of severe floods and droughts attributed to climate change are major threats for river ecosystems (Peters et al., 2016; Alfieri et al., 2017). While extreme floods cause massive physical disturbance, moderate floods can have positive effects, providing woody debris that contributes to habitat complexity and diversity, flush fine sediments, dissolving organic carbon and providing important food sources from terrestrial origins (Peters et al., 2016; Talbot et al., 2018). Droughts reduce river habitat diversity and connectivity, threatening aquatic species, especially in deserts and arid regions (Bogan et al., 2015; Death et al., 2015; Ledger and Milner, 2015; Jaric et al., 2019).

Rivers already stressed by human activities such as urban development and farming on floodplains are prone to reduced resilience to future extreme events (*medium confidence*) (Woodward et al., 2016; Talbot et al., 2018). Thus, potential for floods to become catastrophic for ecosystem services are exacerbated by land-use changes (Peters et al., 2016; Talbot et al., 2018). However, biota can recover rapidly from extreme flood events if river geomorphology is not reformed. If instream habitat is strongly affected, recovery, if it occurs, takes much longer, resulting in decline in biodiversity (*medium confidence*) (Thorp et al., 2010; Death et al., 2015; Poff et al., 2018).

However, not all extreme events will have a biological impact, depending in particular on the timing, magnitude, frequency of events and the antecedent conditions (Bailey and van de Pol, 2016; Stockwell et al., 2020; Jennings et al., 2021; Thayne et al., 2021). For instance, an extreme wind event may have little impact on phytoplankton in a lake, which was fully mixed prior to the event. Conversely, storm effects on phytoplankton communities may compound when lakes are not yet recovered from a previous storm or if periods of drought alternate with periods of intense precipitation (*limited evidence*) (Leonard, 2014; Stockwell et al., 2020).

In summary, extreme events (heat waves, storms, loss of ice) affect lakes in terms of water temperature, water level, light, oxygen concentrations and nutrient dynamics, that in turn affect primary production, fish communities and greenhouse gas emissions *(high confidence)*. These impacts are modified by levels of solar radiation, wind speed and precipitation (Woolway et al., 2020a). Droughts have negative impact on water quality in streams and lakes by increasing water temperature, salinity, the frequency of algal blooms and contaminant concentrations, and reducing concentrations of nutrients and dissolved oxygen (*medium confidence*) (Peters et al., 2016; Alfieri et al., 2017) (Woolway et al., 2020a). Understanding how these pressures subsequently cascade through freshwater ecosystems will be essential for future projections of their resistance and resilience towards extreme events (Leonard, 2014; Stockwell et al., 2020). See Table SM2.1 for specific examples of observed changes.

2.3.3.6 Projected Changes in Physical Characteristics of Lakes and Rivers

Given the strength of relationship between past GAST and warming trends at lake surfaces (Figure 2.2; section 2.3.3.1), and projected increases in heatwaves, surface water temperatures are projected to continue to increase (Woolway et al., 2021). Mean May to October lake surface temperatures in 46,557 European lakes were projected to be 2.9°, 4.5°, and 6.5°C warmer by 2081-2099 compared to historic (1981-1999) under RCPs 2.0, 6.0, and 8.5, respectively (Woolway et al., 2020a). Under RCP 2.6, average lake heatwave intensity increases from 3.7° to 4.0°C and average duration from 7.7 to 27.0 days, relative to the historical period (1970-1999). For RCP 8.5, warming increases to 5.4°C and duration increases dramatically to 95.5 days (*medium confidence*) (Woolway et al., 2021).

Worldwide alteration of lake mixing regimes in response to climate change are projected (Kirillin, 2010). Most prominently, monomictic lakes–undergoing one mixing event in most years–will become permanently stratified, while lakes that are currently dimictic–mixing twice per year–will become monomictic by 2080-2100 (*medium confidence*) (Woolway and Merchant, 2019). Nevertheless, predicting mixing behavior remains an important challenge and attribution to climate change remains difficult (Schwefel et al., 2016; Bruce et al., 2018).

Under climate projections of 3.2°C warming, 4.6% of the ice covered lakes in the northern hemisphere could switch to intermittent winter ice cover (Figure 2.4a; Sharma et al., 2019). Unfrozen and warmer lakes lose more water to evaporation (Wang et al., 2018b). By 2100, global annual lake evaporation will increase by 16%, relative to 2006-2015, under RCP 8.5 (Woolway et al., 2020b). Moreover, melting of ice decreases the ratio of sensible to latent heat flux, thus channelling more energy into evaporation (*medium confidence*)

(Wang et al., 2018b). Between 2009-2029 and 2080-2100, average river ice duration is projected to decline by 7.3 and 16.7 days under the RCP 4.5 and RCP 8.5 (Figure 2.4b; Yang et al., 2020).

Projections of lake water are limited by the absence of reliable, long-term, homogenous, and spatially resolved hydrologic observations (Hegerl et al., 2015). This uncertainty is reflected in the widely divergent projections for lake water storage in response to future climate changes in individual lakes (Angel and Kunkel, 2010; Malsy et al., 2012) (MacKay and Seglenieks, 2012; Notaro et al., 2015). Selecting models that perform well when comparing hindcasted to observed past water storage variation often does little to reduce water storage projection uncertainty (Angel and Kunkel, 2010). This wide range of potential changes complicates lake management. For information on observed and projected changes in the global water cycle and hydrological regimes for streams, lakes, wetland, groundwater and their implications on water quality and societies, see Chapter 4 of WGII and Chapter 8 of WGI. For the role of weather and climate extremes on the global water cycle, see Chapter 11 of WGI.

In summary, with ongoing climate warming and an increase in the frequency and intensity of extreme events, observed increases in water temperature, losses of ice and shifts in thermal regime, are projected to continue (*high confidence*).

Cross-Chapter Box EXTREMES: Ramifications of Climatic Extremes for Marine, Terrestrial, Freshwater and Polar Natural Systems

Authors: Rebecca Harris (Australia, Chapter 2, CCP3), Philip Boyd (Australia, Chapter 3), Rita Adrian (Germany, Chapter 2), Jörn Birkmann (Germany, Chapter 8), Sarah Cooley (USA, Chapter 3), Simon Donner (Canada, Chapter 3), Mette Mauritzen (Norway, Chapter 3), Guy Midgley (South Africa, Chapter 16); Camille Parmesan (France/USA/United Kingdom, Chapter 2), Dieter Piepenburg (Germany, Chapter 13, CCP6), Marie-Fanny Racault (United Kingdom/France, Chapter 3), Björn Rost (Germany, Chapter 3, CCP6), David Schoeman (Australia, Chapter 3), Maarten van Aalst (The Netherlands, Chapter 16).

Introduction

Extreme events are now causing profound negative effects across all realms of the world (marine, terrestrial, freshwater and polar) (*medium confidence*) (WGI, Chapter 9, 11; WGII AR6 Section 2.3.1, 2.3.2, 2.3.3.5, Chapter 3, Chapters 9–12). Changes to population abundance, species distributions, local extirpations and extinctions are leading to long-term, potentially irreversible shifts in the composition, structure and function of natural systems (*medium confidence*) (Frolicher and Laufkotter, 2018; Harris et al., 2018a; Maxwell et al., 2019; Smale et al., 2019). These effects have widespread ramifications for ecosystems and the services they provide – physical habitat, erosion control, carbon storage, nutrient cycling and water quality, with knock-on effects on tourism, fisheries, forestry and other natural resources (Kaushal et al., 2018; Heinze et al., 2021; Pörtner et al., 2021).

Increasingly, the magnitude of extreme events is exceeding values projected for mean conditions for 2100, regardless of emissions scenario (Figure Cross-Chapter Box EXTREMES.1). This has collapsed the timeline organisms and natural communities have to acclimate or adapt to climate change (*medium confidence)*. Consequently, rather than having decades to identify, develop and adopt solutions, there is now an urgent need to build resilience and assist recovery following extreme events.

Recent extremes highlight characteristics that enable natural systems to resist or recover from events, helping natural resource managers to develop solutions to improve resilience of natural communities and identify limits to adaptation (Bergstrom et al., 2021).

Marine Heatwaves

Consensus is emerging that anthropogenic climate change has significantly increased the likelihood of recent marine heat waves (MHWs) (*medium confidence*) (WGI AR6, Chapter 9; Oliver et al., 2018). A widespread

MHW occurred in the NE Pacific between 2013–2015, with upper ocean temperature anomalies of up to 6.2°C relative to 2002-2012 (Gentemann et al., 2017). This event, termed the "Blob", enhanced surface water stratification, decreasing nutrient supply, primary and community production, leading to widespread changes to open ocean and coastal ecosystems, with geographical shifts of key species across trophic levels, mass strandings of marine mammals, seabird mortalities and closures of commercially important fisheries (Cavole et al., 2016; Piatt et al., 2020). The heatwave reappeared in 2019 ("Blob 2.0") (Amaya et al., 2020), with similarly high temperature anomalies extending from Alaska to California, but the ecological effects of this event are expected to differ because the Blob originated in winter, and Blob2.0 intensified in summer (Amaya et al., 2020). Modelling suggests rapid shifts in the geographic distributions of important fish species in response to MHWs (Cheung & Frölicher, 2020), with projected decreased biomass and distributional shifts of fish at least four times faster and larger than the effects of decadal-scale mean changes throughout the 21st century under RCP8.5 *(high confidence*) (Cheung & Frölicher, 2020). Marine heatwaves can also dramatically increase CH4 emissions from oceans, a significant positive feedback on global warming (See also Chapter 3; Borges et al., 2019).

The Arctic region is warming more than twice as fast as the global mean, and polar organisms and ecosystems are likely to be particularly vulnerable to heatwaves due to their specific thermal niches and physiological thresholds and the lack of poleward 'refugia' (*high confidence*). The consequences of MHWs are exacerbated by concomitant sea-ice melting and freshening of surface waters, leading to secondary effects due to osmotic stress and failing pH homeostasis. Since sea-ice associated organisms are often critical components of polar food chains, cascading effects up to top predators are expected. In 2015–2016 a MHW occurred in the Gulf of Alaska/Bering Sea (Walsh et al., 2018) which was unprecedented in terms of surface temperatures and ocean heat content, geographical extent, depth range and persistence, impacting the entire marine food web. Persistent warming favoured some phytoplankton species and triggered one of the largest algal blooms recorded in this region, with concomitant oyster farm closures due to uncommon paralytic shellfish poisoning events (Walsh et al., 2018). There were also massive die-offs of common murres (*Uria aalge*) and puffins (*Fratercula cirrhata)*, attributed to starvation resulting from warming-induced effects on food supply (Jones et al., 2019). A 2017 survey found a 71% decline in abundance of Pacific cod (*Gadus macrocephalus*) since 2015, likely due to an increase in metabolic demand and reduced prey supply during the MHWs (Barbeaux et al., 2020).

Terrestrial Heatwaves

Heatwaves are now regularly occurring that exceed the physiological thresholds of some species, including birds and other small endotherms such as flying-foxes (*high confidence)* (Sections 2.4.2.2, 2.4.2.6). Heatwaves in Australia, North America and southern Africa have caused mass mortality events due to lethal hyperthermia and dehydration (Saunders et al., 2011; Conradie et al., 2020; McKechnie et al., 2021), reducing fitness (du Plessis et al., 2012; Andrew et al., 2017; Sharpe et al., 2019; van de Ven et al., 2019; van de Ven et al., 2020), breeding success and recruitment (Kennedy et al., 2013; Wiley and Ridley, 2016; Ratnayake et al., 2019) and affecting daily activity and geographic distributions (Albright et al., 2017). They also place enormous demands on wildlife management agencies and pose human health risks (Welbergen et al., 2008).

Recent mortality events affected 14 species of bird and fruit bats (*Epomophorus wahlbergi*) in South Africa when maximum air temperatures exceeded 43–45°C in 2020 (McKechnie et al., 2021). Passerine birds seem more vulnerable to lethal hyperthermia due to the relative inefficiency of panting to lose heat (McKechnie et al., 2021) and their small size, as heat tolerance generally increases with body mass (McKechnie et al., 2017). Several mass mortality events of flying-foxes (*Pteropus poliocephalus, P. alecto*) have occurred in eastern Australia when maximum air temperatures exceeded 42℃ (Welbergen et al., 2008). Nineteen such events occurred between 1994 and 2008, compared to three events prior to 1994. In January 2002, maximum temperatures exceeded the 30-year average mean daily maximum by up to 16.5℃ and killed more than 3500 individuals (Welbergen et al., 2008). In 2014, an estimated 45,500 flying-foxes died in a single day, when average maximum temperatures were 8°C or more above average (Meteorology, 2014). Drought compounds the impacts, as mortality increases when water availability is low (Welbergen et al., 2008; Mo and Roache, 2020; McKechnie et al., 2021).

Antarctica encountered its first recorded heatwave in 2020. Record-high temperatures occurred in East Antarctica (Robinson et al., 2020), with a maximum (9.2°C) temperature ~7°C above the mean maximum, and minimum temperatures > 0°C. Record-high temperatures (18.3°C) were also recorded in West Antarctica (Robinson et al., 2020). It is too soon to know the impacts on polar life, but such abrupt heating is expected to have wide-ranging effects on biota, from flash-flooding and dislodgement of plants, to excess melt waters supplying moisture to arid polar ecosystems (CCP Polar). Heatwaves in Siberia in 2016, 2018 and 2020, with air temperature anomalies >6°C, were associated with extensive wildfires, pest infestations and melting permafrost (Overland and Wang, 2021).

Freshwater Extremes

Heatwaves, storms and floods affect the thermal regime and biogeochemical functioning of lakes and rivers (Woolway and Merchant, 2017; Vicente-Serrano et al., 2020). Extreme heatwaves lead to abnormally high water temperatures (Till et al., 2019) and reduce mixing of lakes (Woolway et al., 2021), causing a decrease in oxygen and deep-water oxygen renewal (Zhang et al., 2015). Ectotherms such as fish and invertebrates are particularly susceptible to such temperature and oxygen stress (Stoks et al., 2014). Their metabolic demands increase with rising temperature and suitable habitat is eroded due to both high temperatures and lower oxygen concentrations in lakes and rivers. Till et al. (2019) attributed 502 fish kill events in Wisconsin lakes (USA) to warmer summers in lakes that experienced abnormally high water temperatures. Such events are predicted to double by 2041–2059 and increase fourfold by 2081–2099 compared to historical levels (Till et al., 2019). This anticipated increase in die-offs may facilitate warm-water fish species displacing cool-water species (Hansen et al., 2017; Jennings et al., 2021). Floods mobilise nutrients and sediment, and aid dispersal of invasive species in rivers (Death et al., 2015), while drought extremes reduce river connectivity, threatening biodiversity in rivers (Section 2.3.3.5; Tickner et al., 2020).

Learnings from Recent Extremes

These examples show that the impact of an extreme event is a function of its characteristics and those of the exposed ecosystem. The timing, frequency, absolute magnitude and geographic extent of the extreme event, relative to antecedent conditions, the life-cycle, resistance and resilience of the natural community, all determine the biological response (Figure Cross-Chapter Box EXTREMES.2; Hillebrand et al., 2018; Gruber et al., 2020). Impacts appear to be greater when extreme events occur more frequently, particularly when the interval between events is insufficient to allow recovery to previous population sizes (e.g. frequent fire, coral bleaching), or coincides with vulnerable life cycle stages, even when populations are adapted to cope with such disturbances. Events occurring over large spatial areas reduce the potential for recolonisation from nearby populations (e.g. regional droughts causing widespread declines). Often the magnitude of extreme events exceeds historical levels, so organisms are less likely to be adapted to them, particularly when several extremes coincide (e.g. high water temperatures, drought) (Duke et al., 2017). When hazards occur simultaneously (compound events), impacts of extremes can be substantially aggravated, triggering cascading effects in ecosystems (Gruber et al., 2020).

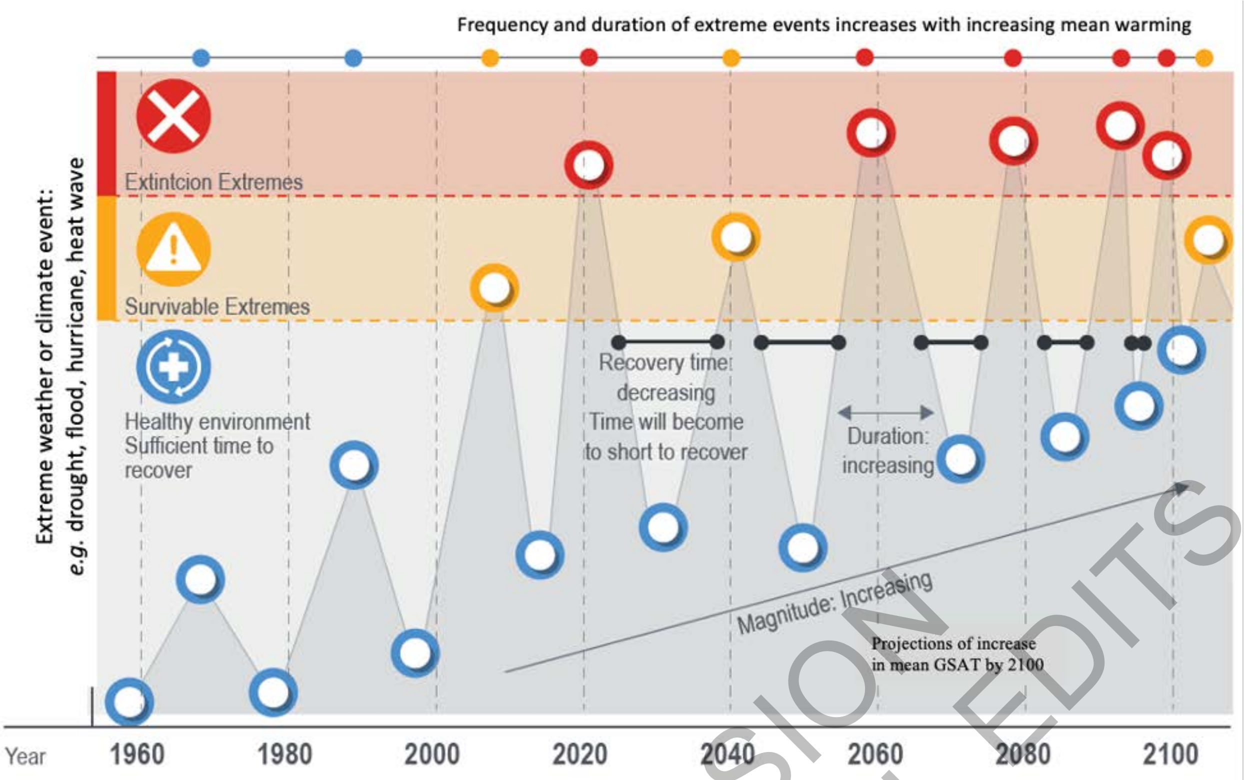

Figure Cross-Chapter Box EXTRMES.1: A conceptual illustration of how extinction risk is affected by changes in the frequency, duration and magnitude of extreme weather or climate events (e.g,. drought, fire, flood, heatwaves). Many organisms have adapted to cope with long-term and short-term climate variability, but as the magnitude and frequency of extreme events increases, superimposed on the long-term climate trend, the threshold between survivable extreme weather events (yellow) and extremes that have high risk of causing population or species extinctions (red) is crossed more frequently. This can lead to local extinction events with insufficient time between to enable recovery, resulting in long-term, irreversible changes to the composition, structure and function of natural systems. When the extreme event occurs over a large area relative to the distribution of a species (e.g., a hurricane impacting an island which is the only place a given species occurs), a single extreme event can drive the global extinction of a species.

Several characteristics of natural systems are associated with greater vulnerability to extreme events (Figure Cross-Chapter Box EXTREMES.2), knowledge of which can inform solutions to build resilience and aid recovery (Robinson et al., 2020). Resilience can be built prior to an event by minimising additional disturbances, such as water extraction from river systems, pollution of aquatic systems, land-use change and fragmentation. Managing landscapes to reduce fragmentation and increase habitat extent, connectivity and heterogeneity, by increasing the number and extent of reserves, may provide local refugia from extreme events and enhance post-event recolonisation, but may be less effective for marine systems (Chapter 3, Section 3.6). Maintaining taxonomic, phylogenetic and functional diversity is important, as more diverse systems may be more stable in the face of disturbance (Pimm, 1984; García-Palacios et al., 2018).

Several characteristics increase vulnerability: low or narrow thermal tolerances, high habitat specificity, low dispersal ability, long generation times, low competitive ability and lifecycle constraints that limit recovery or recolonisation. Populations living close to one or more limiting factors near range edges are also vulnerable (Arafeh-Dalmau et al., 2019). Understanding these characteristics can inform management intervention to aid recovery following an extreme event. For instance, knowledge of the flying-fox's physiological temperature threshold led to successful interventions, including misting of populations to reduce mortality (Mo and Roache, 2020) and the development of a 'heat stress forecaster', an online tool which uses weather forecasts to identify roosts at risk of extreme heat events (Ratnayake et al., 2019). This early-warning system increases the preparedness of wildlife management and conservation agencies, enabling efficient allocation of management resources towards locations that are likely to be most affected. Monitoring following extreme events can help identify immediate impacts and the potential for cascading interactions, such as changes to competitive interactions following range shifts, impacts on freshwater ecosystems following wildfires and the spread of invasive species. Ongoing monitoring of recovery and effectiveness of management intervention is important, focussing on habitat-forming species (eg. kelp, corals, dominant tree species) and keystone species (eg. filter feeders, macrophytes, top predators), as the loss of these species can lead to ecosystem tipping points, beyond which the system may not recover (Section 2.5.3; SROCC Chapter 6, Section 3.4.4.1; AR6 sectoral chapters, Chapter 3 section 3.4.4.1.4). The acute impacts of extreme events, in addition to the chronic stress of changing mean conditions, are accelerating and amplifying the biological effects of climate change. This amplification is being observed globally and in all realms where life exists. Extreme events are compressing the timeline available for natural systems to adapt and impeding our ability to identify, develop and adopt solutions. Recent events highlight the urgent need to mitigate global greenhouse gas emissions and identify solutions to halt accelerating impacts on natural systems (Díaz et al., 2020).

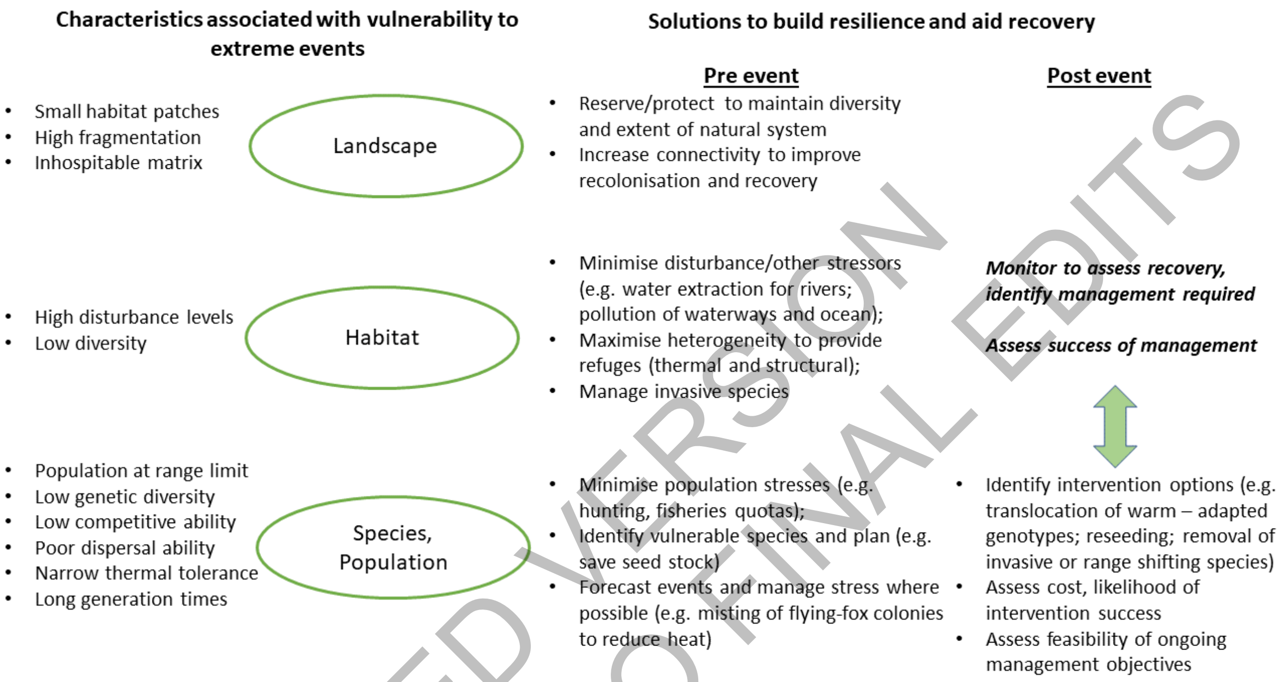

Figure Cross-Chapter Box EXTREMES.2: Characteristics of natural systems that affect vulnerability and help identify solutions – both prior to and after extreme events - to build resistance, resilience and recovery.

[END CROSS-CHAPTER BOX EXTREMES HERE]

2.4 Observed Impacts of Climate Change on Species, Communities, Biomes, Key Ecosystems and their Services

2.4.1 Overview

Global meta-analyses of terrestrial systems in AR3 and AR4 concentrated on long time frames (>20 years) and findings from relatively undisturbed areas, where confidence in attributing observed changes to climate change is high. Recent global and regional meta-analyses (AR5 and later) have been broader, including data from degraded and disturbed areas and studies with shorter time frames (Tables 2.2a,b).

By the time of AR5, >4000 species with long-term observational data had been studied in the context of climate change (Parmesan, 2006; Parmesan and Hanley, 2015). Since then, hundreds of new studies have been added, leading to higher confidence in climate change attribution (Table 2.2; Scheffers et al., 2016; Wiens, 2016; Cohen et al., 2018; Feeley et al., 2020). Freshwater habitats have been under-represented in prior reports, but new long-term data sets, coupled with laboratory and field experiments, are improving our understanding and this assessment stresses observations from lakes and streams. As numbers of studies increase and data is increasingly extracted from areas with high LULCC, attribution is more difficult as habitat loss and fragmentation are known major drivers of changes in terrestrial and freshwater species (IPBES) (Gardner and Finlayson, 2018; Grill et al., 2019; Zarfl et al., 2019; Tickner et al., 2020).

2.4.2 Observed Responses to Climate Change by Species and Communities (Freshwater and Terrestrial)

2.4.2.1 Observed Range Shifts Driven by Climate Change

Poleward and upward range shifts were already attributable to climate warming with *high confidence* in AR5. Publication of observed range shifts in accord with climate change have accelerated since AR5 and strengthened attribution. Ongoing latitudinal and elevational range shifts driven by regional climate trends are now well-established globally across many groups of organisms, and attributable to climate change with *very high confidence* due to very high consistency across a now very large body of species and studies and in-depth understanding of mechanisms underlying physiological and ecological responses to climate drivers (Table 2.2; Table 2.3, Table SM2.1;Pöyry et al., 2009; Chen et al., 2011; Grewe et al., 2013; Gibson-Reinemer and Rahel, 2015; MacLean and Beissinger, 2017; Pacifici et al., 2017; Anderegg et al., 2019b). Range shifts stem from local extinctions along warm-range-boundaries (Anderegg et al., 2019b), as well as from colonisation of new regions at cold-range-boundaries (Ralston et al., 2017).

Many studies since AR4 have tended not to be designed as attribution studies, particularly recent large scale, multispecies meta-analyses. That is, all data available were included in such studies (from both undisturbed and from highly degraded lands, and including very short term datasets of <20 years) with little attempt to design the studies to differentiate effects of climate change from effects of other potential confounding variables. These studies tended to find greater lag and lower proportion of species changing in directions expected from climate change, with authors concluding that LULCC, particularly habitat loss and fragmentation, was impeding wild species from effectively tracking climate change (Lenoir and Svenning, 2015; Rumpf et al., 2019; Lenoir et al., 2020).

Unprecedented outbreaks of spruce beetles occurring from Alaska to Utah in the 1990s were attributed to warm weather that, in Alaska, facilitated a halving of the insect's life cycle from two years to one (Logan et al., 2003). Milder winters and warmer growing seasons were likewise implicated in poleward range expansions and increasing outbreaks of several forest pests (Weed et al., 2013), leading to the current prediction that 41% of major insect pest species will increase their damage further as climate warms, and only 4% will reduce their impacts, while the rest will show mixed responses (Lehmann et al., 2020).

During their range shifts, forest pests remain climate-sensitive. For example, the distribution of Western Spruce Budworm is limited at its warm range edges by adverse effects of mild winters on overwinter survival, and at its cool range limits by ability to arrive at a cold-resistant stage before winter arrives (Régnière and Nealis, 2019). We might therefore expect tree mortality from insect outbreaks to be most severe in sites climatically less suitable for the plants, where plants would be under more stress. However, (Jaime et al., 2019), using separate SDMs (MaxEnt) for the insects and plants, found that mortality of Scots Pine from bark beetles was highest in sites most climatically suitable for the trees as well as for the insects. In a study of tree mortality in California, bark beetles selectively killed highly-stressed fir trees but killed pines according to their size, irrespective of stress status (Stephenson et al., 2019).

Range shifts in a poleward and upward direction, following expected trajectories given the local and regional climate trends, are strongly occurring in freshwater fish populations in North America (Lynch et al., 2016b), Europe (Comte and Grenouillet, 2013; Gozlan et al., 2019) and Central Asia (Gozlan et al., 2019). Cold water fish, such as coregonids and smelt have been negatively affected at the equatorial borders of their distributions (Jeppesen et al., 2012). Upward elevational range shifts in rivers and streams have been observed. Systematic shifts towards higher elevation and upstream were found for 32 stream fish species in France following regional variation in climate change (Comte and Grenouillet, 2013). Bull trout (*Salvelinus confluentus*) in Idaho (USA), were estimated to have lost 11–20% (8–16% decade^{-1}) of the headwater stream lengths necessary for cold water spawning and early juvenile rearing, with the largest losses occurring in the coldest habitats (Isaak et al., 2010). Range contractions of the same species have been found in the Rocky Mountain watershed (Eby et al., 2014). Likewise, the distribution of the stonefly *Zapada glacier*, endemic to alpine streams of Glacier National Park in Montana (USA), has been reduced over several decades by upstream retreat to higher, cooler sites as water temperatures have increased and glacial masses decreased (Giersch et al., 2015).

The melting of glaciers has led to a change in water discharge associated with community turnover in glacier-fed streams (Cauvy-Fraunié and Dangles, 2019). For instance, glacier-obligate macroinvertebrates have started disappearing when glacial cover drops below approximately 50% (*robust agreement, high confidence)*, reviewed in (Hotaling et al., 2017). For freshwater invertebrates, no meaningful trends have been detected in geographic extent or population size for most species (Gozlan et al., 2019).

An invasive freshwater cyanobacterium in lakes*, Cylindrospermopsis raciborskii,* originating from the tropics, has spread to temperate zones over the last few decades due to climate change-induced earlier increase of water temperature in spring (Wiedner et al., 2007), aided by a competitive advantage in eutrophic systems (Ekvall et al., 2013; Urrutia-Cordero et al., 2016).

2.4.2.2 Observed Local Population and Global Species' Extinctions Driven by Climate Change

Disappearances of local populations within a species range are more frequent and better documented than whole species' extinctions, and attribution to climate change is possible for sites with minimal confounding non-climatic stressors. Changes of temperature extremes are often more important to these local extinction rates than changes of mean annual temperature (see Sections 2.3.1, 2.3.2, 2.3.3.5, 2.4.2.6, Cross-chapter Box EXTREMES this Chapter; Parmesan et al., 2013). In a study of 538 plant and animal species, sites with local extinctions were associated with smaller changes of mean annual temperature but larger and faster changes of hottest yearly temperatures than sites where populations persisted (Román-Palacios and Wiens, 2020). Near warm range limits, 44% of species had suffered local extinctions. In both temperate and tropical regions, sites with local extinction had greater increases in maximum temperatures than those without (T_{max} increased 0.456°C and 0.316°C vs. T_{mean} increase of 0.153 °C and 0.061 °C for temperate (n=505 sites) and tropical (n=76 sites), respectively, $P < 0.001$) (Román-Palacios and Wiens, 2020).

Wiens (2016) assumed that population extinctions were primarily driven by climate change when they occurred at elevational or latitudinal "warm edge" range limits, and were in relatively undisturbed sites that were stated by authors to be under increasing climatic stress. By this criterion, climate-caused local extinctions were widespread among plants and animals, detected in 47% of 976 species examined. The percentage of species suffering these extinctions was higher in the tropics (55%), than in temperate habitats (39%), higher in freshwater (74%), than in marine (51%) or terrestrial (46%) habitats and higher in animals (50%) than in plants (39%). The difference between plants and animals varied with latitude: in the temperate zone a much higher proportion of animals than plants suffered range-limit extinctions (38.6% of 207 animal species versus 8.6% of 105 plants, $p < 0.0001$) while at tropical sites local extinction rates were (nonsignificantly) higher in plants (59% of 155 species) than in animals (52% of 349 species), the reverse of their temperate zone relationship. Rates varied among animal groups, from 35% in mammals through 43% in birds to 56% in insects and 59% in fish (Wiens, 2016).

Freshwater population extinctions are mainly due to habitat loss, introduction of alien species, pollution, over-harvesting (Gozlan et al., 2019; IPBES, 2019) and climate change induced epidemic diseases (Pounds et al., 2006)(see Section 2.4.2.7.1). Climate warming particularly through intensification and severity of droughts, contributes to the disappearance of small ponds, which hold rare and endemic species (Bagella et al., 2016). Systematic data on the extent and biology of small ponds is, however, lacking at a global scale. Extreme heat waves can lead to large local fish kills in lakes (see Section 2.3.3.5), when water temperature and oxygen concentrations surpass critical thresholds, threatening cold water fish and amphibians (Thompson et al., 2012). Evidence for a local extinction of some invertebrate species with a 1.4°–1.7°C rise in mean annual stream winter temperature from 1981–2005 was reported in (Abrahams et al., 2013). Population declines of specialist species in glacier-fed streams, such as the non-biting midge *Diamesa davisi* (Chironomidae), can be attributed to glacier retreat given climate change (Cauvy-Fraunié and Dangles, 2019), and the flatworm *Crenobia alpina* (Planariidae) has been reported as locally extinct in the Welsh Llyn Brianne river (Durance and Ormerod, 2010; Larsen et al., 2018).

Many high montane possums in Australia have low physiological tolerance to heatwaves, with death occuring due to heat-driven dehydration at temperatures exceeding 29°–30°C for >4–5 hours over several days (Meade et al., 2018; Turner, 2020), with major declines recorded for several species, and population extinctions at lower elevations, since the early 2000s (Chandler, 2014; Weber et al., 2021).

Two terrestrial and freshwater species have gone extinct, with climate change implicated as a key driver. The cloud-forest-restricted Golden toad (*Incilius periglenes*) was extinct by 1990 in a nature preserve in Costa Rica, driven by successive extreme droughts. This occurred in the absence of chytridiomycosis infection, caused by the fungal pathogen *Batrachochytrium dendrobatidis* (BD), verified during field censuses of golden toad populations in the process of extinction and through genetic analyses of museum specimens, although Bd was present in other frog species in the region *(medium evidence, high agreement)* (Pounds et al., 1999; Pounds et al., 2006; Puschendorf et al., 2006; Richards-Hrdlicka, 2013). The interaction between expansion of chytrid fungus globally and local climate change is implicated in the extinction of a wide range of tropical amphibians (see Section 2.4.2.7.1 Case study 2 *Chytrid fungus and climate change*).

The Bramble Cay Melomys *(Melomys rubicola)*, the only mammal endemic to the Great Barrier Reef, inhabited a small (five hectare) low-lying (<3m high) cay in the Torres Strait Islands, Australia. Recorded having a population size of several hundred in 1978, this mammal has not been seen since 2009 and was declared extinct in 2016 (Gynther et al., 2016). SLR, documented increases in storm surge and in tropical cyclones, driven by climate change, led to multiple inundations of the island in the 2000s. Between 1998 and 2014, herbacious vegetation, the food resource for the BC Melomys, declined by 97% in area (from 2.2 ha down to 0.065 ha), and from 11 plant species down to two (Gynther et al., 2016; Watson, 2016; Woinarski, 2016; Woinarski et al., 2017). The island was unihabited with few non-climatic threats, providing *high confidence* in attribution of extinction of the BC Melomys to climate change-driven increases in frequency and duration of island inundation (Turner and Batianoff, 2007; Woinarski et al., 2014; Gynther et al., 2016; Watson, 2016; Woinarski et al., 2017).

In the IUCN Red List (IUCN, 2019), 16.2% of terrestrial and freshwater species (n=3,777 species) that are listed as endangered, critically endangered or extinct in the wild (n=23,251 species) list climate change or severe weather as one of their threats.

[START FAQ2.1 HERE]

FAQ2.1: Will species go extinct with climate change and is there anything we can do to prevent it?

Climate change is already posing major threats to biodiversity and the most vulnerable plants and animals are likely to go extinct. If climate change continues to worsen, it is expected to cause many more species to go extinct unless we take actions to improve the resilience of natural areas, through protection, connection and restoration. We can also help individual species that we care most about by reducing the stress they are under from other human activities, and even helping them move to new places as their climate space shifts and they need to shift to keep up.

Climate change has already caused some species to go extinct, and is likely to drive more species to extinction. Species have always gone extinct in the history of our planet but human activities causing climate change are accelerating this process. For instance, recent research predicts that one-third of all plant and animal species could be extinct by 2070 if climate change continues as it is. Species can adapt to some extent to these rapidly changing climate patterns. We are seeing changes in behaviour, dispersal to new areas as the climate becomes more suitable, and genetic evolution. However, these changes are small, and adaptations are limited. Species that cannot adapt beyond their basic climate tolerances (ability to survive extremes of temperature or rainfall) or successfully reproduce in a different climate environment from what they have evolved in, will simply disappear. In the Arctic for example, sea ice is melting and will likely disappear in summer time within a century. This means that the animals that have evolved to live on sea ice - polar bears and some seals and sea lions - will go extinct.

Fortunately, there are some things we can do to help. We can take actions to assist, protect and conserve natural ecosystems and prevent the loss of our planet's endangered wildlife, such as:

"Assisting" species' migration: This has many names, "assisted colonisation", "assisted translocation", "assisted migration", "assisted movement". In effect, it is about helping endangered species to move to a new area with a good habitat for them to survive. "Passive" assisted colonisation focuses on helping species move themselves, whilst the most "active" form implies picking up individuals and transporting them to a new location. This is different from re-introductions that are already a normal part of conservation programs. Climate-driven translocations are moving plants or animals to an area where they have never lived historically, a new location that is now suitable for them due to climate change.

This active form of "assisted colonisation" has been controversial, because exotic species can become invasive when they are moved between continents or oceans. For example, no one would advocate moving polar bears to Antarctica, as they would likely fest on native penguins, thus causing another conservation problem. However, moving species only a few hundred kilometers avoids most adverse outcomes, and that is often all that is needed to help a wild plant or animal cope with climate change. In extreme cases, another type of assisted adaptation is to preserve species until we get climate change under control and can reintroduce them to the wild. This might include moving them into zoos or into seed or frozen embryo banks.

Extending protected zones and their connectivity: Species' ability to move to new locations and track climate change are very limited – in particular, when a habitat has been turned into a crop field or a city. To help them move between their natural habitats, we can increase the connectedness of protected areas or simply create small patches or corridors of semi-wild nature within a largely agricultural or inhabited region, that encourages wildlife to move through an area, and in which they are protected from hunting and poisons. Those semi-wild protected areas can be very small, like the hedgerows between fields in England, that provide both habitats for many flowers, birds, insects and corridors to move between larger protected areas. Alternatively, it can just be an abandoned field that is now growing "weeds" without pesticides, hunting or farming. For instance, in the United States of America, private landowners get a tax break by making their land a "wildlife conservation" area using no pesticide, not cutting weeds too often, putting up brush piles and bird boxes for nesting, and providing a water source.

Assisting, protecting and conserving natural ecosystems would help enhance biodiversity overall as well as already endangered species. Diverse plant and animal communities are more resilient to disturbances, including climate change. A healthy ecosystem also recovers more quickly from extreme events, such as floods, droughts and heat waves that are a part of human-driven climate change. Healthy ecosystems are critical to prevent species' extinctions from climate change, but are also important for human health and well-being, providing clean, plentiful water, cleaning the air, providing recreation and holiday adventures, and making people feel happier, calmer and more contented.

[END FAQ2.1 HERE]

2.4.2.3 Observed Changes in Community Composition Driven by Climate Change

2.4.2.3.1 Overall patterns of community change

The most common type of community change takes the form of in situ decreases of cold-adapted species and increases of warm-adapted species (Bowler et al., 2017; Hughes et al., 2018; Kuhn and Gégout, 2019; Feeley et al., 2020). This process has lead to increases of species richness on mountaintops and decreased richness at adjacent lower elevations *(medium evidence, high agreement)* (Forister et al., 2010; Steinbauer et al., 2018). Observed shifts in community composition have consequences for species' interactions. Such indirect effects of climate change have been shown to often have greater impacts on species than direct effects of climate itself, particularly for higher level consumers (Ockendon et al., 2014).

Like other responses, analyses indicated responses were lagging behind the change expected from regional warming, and thereby accumulating 'climate debt.' Examples of climate debt, measured from community composition changes, come from birds and butterflies in Europe (Devictor et al., 2012) and from lowland forest herbaceous plants in France (Bertrand et al., 2011). The French study found that larger debts occurred in communities with warmer baseline conditions and that some of the apparent debt stemmed from species' ability to tolerate warming in situ. Geothermal streams have provided evidence about community structure and ecosystem function in high temperatures. A study of 14 such habitats reported simplified the food-web structures and shortened pathways of energy flux between consumers and resources (*high confidence*) (O'Gorman et al., 2019).

Prominent changes in freshwater community composition, such as increases in cyanobacteria and warm tolerant zooplankton species, loss of cold water fish, gain in thermo-tolerant fish and macroinvertebrates and gain in floating macrophytes, are occurring (*medium evidence, high agreement*, *medium confidence)* (Adrian et al., 2016; Hossain et al., 2016; Short et al., 2016; Huisman et al., 2018; Gozlan et al., 2019). Changes in relative species abundances, species composition and biodiversity due to warming trends and non-climate driven changes are to be expected in lakes and rivers globally. However, thus far empirical evidence and mechanistic understanding to inform modelling is too limited to draw general conclusions about the nature of current and future climate change driven changes within entire food webs on a global scale (Urban et al., 2016).

2.4.2.3.2 Freshwater mechanistic drivers and responses

Physical changes in lakes (see Section 2.3.3) have affected primary production (see Section 2.4.4.5.2), algal bloom formation and composition, zooplankton and fish size distribution and species composition (Urrutia-Cordero et al., 2017; Gozlan et al., 2019; Seltmann et al., 2019). Declines in abundance of cold-stenothermal species (particularly Arctic charr, *Salvelinus alpinus, coregonids* and smelt) and increases in eurythermal fish (e.g. the thermo-tolerant carp *Cyprinus carpio*, common bream, pike perch, roach and shad) have been observed in northern temperate lakes associated with warming trends (*high agreement*, *medium confidence*) (Jeppesen et al., 2012; Jeppesen et al., 2014). These changes increase predation pressure on zooplankton and reduce grazing pressure on phytoplankton, which may result in higher phytoplankton biomass (De Senerpont Domis et al., 2013; Jeppesen et al., 2014; Adrian et al., 2016). Reduction in lake mixing lowers the concentration of nutrients in the epilimnion and may lead to higher silicon to phosphorous ratios negatively affecting diatom growth (Yankova et al., 2017) or overall primary productivity (see Section 2.4.4.5.2).

In as study of 1,567 lakes across Europe and North America, (Kakouei, 2021) identified climate change as the major driver of increases in phytoplankton biomass in remote areas with minimal LULCC. Greater temperature variability can be more important than long-term temperature trends as a driver of zooplankton biodiversity (Shurin et al. (2010). Reductions of winter severity attributed to anthropogenic climate change are increasing winter algal biomass, and motile and phototropic species at the expense of mixotrophic species (Özkundakci et al., 2016; Hampton et al., 2017).

Tropical lakes are prone to loss of deep-water oxygen due to lake warming with negative consequences for their fisheries and their biodiversity (Lewis Jr, 2000; Van Bocxlaer et al., 2012). Many ancient tropical lakes (Malawi, Tanganyika, Victoria, Titicaca, Towuti and Matano) hold thousands of endemic animal species (Vadeboncoeur et al., 2011).

Observed climate-change effects on freshwater invertebrates are variable (Knouft and Ficklin, 2017). In glacier-fed streams globally, climate change has caused community turnover and changes in abundances in terms of increased generalist and decreased specialist species abundances (Lencioni, 2018; Cauvy-Fraunié and Dangles, 2019). In turn, dragonflies in flowing waters, monitored during the warming period from 1988 through 2006 in Europe, did not show consistent changes in their distribution (Grewe et al., 2013), reviewed in (Knouft and Ficklin, 2017). Long-term trends in species composition and community structure of stream macroinvertebrates, specifically a general trend for decreases in species characteristic of cold, fast-flowing waters and increases of thermophilic species typical of stagnant or slow-moving waters, have been attributed to climate change (*high agreement, high confidence*) (Daufresne et al., 2007; Chessman, 2015). A study of 14 geothermal streams reported simplified food-web structures and shortened pathways of energy flux between consumers and resources (O'Gorman et al., 2019). Macrophytes benefit from rising water temperatures, but increased shading from increased phytoplankton biomass could offset this (see 2.5.3.6.2 for projections; Hossain et al., 2016; Short et al., 2016;Zhang et al., 2017a).

2.4.2.3.3 Emergence of novel communities and invasive species

As climate change is increasing the movements of species into new areas, there is concern about how exotic species are being impacted, either by becoming invasive or by already invasive species gaining even more advantage over native species. Modeling predicts that effects of climate warming on food web structure and stability favour success of invading species (Sentis et al., 2021). Both simulated warming experiments (Zettlemoyer et al., 2019) and long-term observations (Losos et al., 2010) have found phenologies of exotic species to respond more adaptively to warming than those of natives, and in the long-term observations the success of exotics was attributed to their greater phenological responsiveness. In an expert assessment of the future relative importance of different drivers of the impacts of biological invasions, climate change was named as the most important driver in polar regions, the second most important in temperate regions (after trade/transport) and the third most important in the tropics (after trade/transport and human demography/migration) (Essl et al., 2020).

However, not all exotic species become invasive. As novel climate conditions develop, novel communities made up of new combinations of species are emerging as populations and species adapt and shift ranges differentially, not always with negative consequences (*high confidence*) (Dornelas et al., 2014; Evers et al., 2018; Teixeira and Fernandes, 2020). Novel communities differ in composition, structure, function and evolutionary trajectories, as the proportion of specialists and generalists, native, introduced and range shifting species changes and species interactions are altered, ultimately affecting ecosystem dynamics and functioning (Lurgi et al., 2012; Hobbs et al., 2014; Heger and van Andel, 2019 Towards an Integrative). The exact nature of novel communities is difficult to predict because species-level uncertainties propagate at the community level due to ecological interactions (Williams and Jackson, 2007), but observations, experimental mesocosms (Bastazini et al., 2021); and theoretical models (Lurgi et al., 2012; Sentis et al., 2021) provide support that they will continue to emerge with climate change.

2.4.2.4 Observed Phenological Responses to Climate Change

With advances in remote sensing, quality and quantity of phenological data are rapidly increasing (Piao et al., 2019). Since AR5, numbers of studies have increased substantially with consistent conclusions in response to warming, including advancement of spring events and lengthening of growing seasons in temperate regions (through a combination of advancement of spring events and to a lesser extent, retardation of autumn events) *(robust evidence, high agreement)* (Table 2.2, Table 2.3, Table SM2.1; Menzel et al., 2020). In the tropics, by contrast, precipitation changes have more strongly influenced phenology than temperature changes (Cohen et al., 2018). A meta-analysis comparing observed phenological advances in birds with expectations from warming of local climates concluded that the advances fell short of expectation and that substantial phenological climate debt had been generated (Radchuk et al., 2019).

Taxonomic groups have differed in their responses (Parmesan, 2007; Thackeray et al., 2010), and a few have completely abstained from the general trends—for example, seabirds continue to breed with their pre-climate-change phenologies (Keogan et al., 2018). Newer reviews and analyses reveal differences in responses among continents and across time intervals (Piao et al., 2019). Mean advance in days per decade was 5.5 in China, and 3.0–4.2 in Europe but only 0.9 in North America (Piao et al., 2019). Mean values for retardation of autumn leaf fall, which can be more influenced by photoperiod and less by temperature than spring leaf-out, were 0.36 days per decade in Europe (Menzel et al., 2020), 2.6 days per decade in China and around 3 days per decade in the USA *(medium evidence, high agreement)* (Piao et al., 2019).

The rapid rates of advance of spring events in the 1990s slowed down in the 2000s and stalled or even reversed in some regions (Menzel et al., 2020). Wang et al. (2019) noted, from remote sensing, that during the 'global warming hiatus' from 1998–2012, there were no global trends in either Spring green-up or autumn colouring. Annual crops, for which timing is determined by farmers, were an exception. When natural systems were advancing fast prior to 1998, farmers advanced more slowly, but during the natural 'hiatus', farmed crops advanced faster than wild plants and cultivated trees (Menzel et al., 2020). In a long (67 year) European time series (Menzel et al., 2020), autumn leaf colouring showed delays attributed to winter & spring warming in 57% of observations (mean delay 0.36 days per decade); spring & summer phenologies advanced in 89% of wild plants despite decreased winter chilling, with c.60% of trends significant and 'strongly attributable' to winter & spring warming; and growing season length increased in 84% of cases (mean lengthening 0.26 days yr^{-1}) (Table 2.2).

Changes in freshwater systems are consistent with changes in terrestrial systems: earlier timing of spring phytoplankton and zooplankton development and earlier spawning by fish, as well as extension of the growing season are occurring *(robust evidence, high agreement)* (Adrian et al., 2009; De Senerpont Domis et al., 2013; Adrian et al., 2016; Thackeray et al., 2016). Phenological changes in lakes have been related to rising water temperatures, reductions of ice cover and prolongation of thermal stratification (increasing evidence and agreement since AR5; *very high confidence*). Crozier and Hutchings (2014) reviewed phenological changes in fish and documented that changes in the timing of migration and reproduction, age at maturity, age at juvenile migration, growth, survival and fecundity were associated primarily with changes in temperature. The median return time of Atlantic salmon among rivers in Newfoundland and Labrador advanced by 12 to 21 days over the past decades, associated with overall warmer conditions (Dempson et al., 2017).

2.4.2.5 Observed Complex Phenological and Range Shift Responses

Early meta-analyses tested the straightforward hypotheses that warming should shift timing earlier and ranges poleward. Once these trends had been established, exceptions to them became foci of study. For example, some plants in northern regions of the northern hemisphere were retarding their spring flowering instead of advancing it as expected with warming. These turned out to be species requiring vernalisation (winter chilling) to speed spring development. For these plants, phenological changes result from combined effects of advancement caused by spring warming and retardation caused by winter warming. Incorporating this level of complexity into analyses revealed that a greater proportion of species were responding to climate change than estimated under the simple expectation that warming should always cause advancement (92% responding vs 72% from earlier analyses) (Cook et al., 2012).

Animal species can show vernalisation equivalent to that in plants (Stålhandske et al., 2017). However, a semi-global meta-analysis across terrestrial animals failed to detect delaying effects of warming winters (Cohen et al., 2018). The same animal-based meta-analysis contrasted phenological changes in temperate-zone animals, which are principally explained by changes of temperature, with those at lower latitudes, which follow changes of precipitation (Cohen et al., 2018).

Vitasse et al. (2018), working with Alpine trees, found that phenological delay with increasing elevation had declined from 34 days per 1,000 m in the 1960s to 22 days per 1,000 m, greatly reducing the differences in timing between trees growing at different elevations. This reduction was greatest after warmer winters, suggesting winter warming as a principal cause of the overall trend.

Lian et al. (2020) observed that earlier spring leaf-out in the Northern Hemisphere is causing increases in evapotranspiration that are not fully compensated by increased precipitation. The consequence is increased soil moisture deficit in summer, expected to exacerbate impacts of heatwaves as well as drought stress. In Arctic freshwater ecosystems, Heim et al. (2015) demonstrated the importance of seasonal cues for fish migration, which can be impacted by climate change due to reduced stream connectivity and fragmentation, earlier peak flows, and increased evapotranspiration.

Precipitation has also been implicated in exceptions to the rule that ranges should be shifting to higher elevations. In dry climates, increases of precipitation accompanying climate warming can facilitate downslope range shifts (Tingley et al., 2012).

Multiple responses can co-occur. Hällfors et al (Hällfors et al., 2021), in a study of 289 lepidoptera in Finland, found 45% had either shifted their ranges northward or advanced their flight season with warming. The 15% of species that did both (shifting northward by 113.1 km and advancing flight period by 2.7 days per decade, on average, over a 20 year period) had the largest population increases, and the 40% of species that showed no response had the largest population declines.

Table 2.2: Global Fingerprints of Climate Change Impacts across Wild Species. Updated from (Parmesan and Hanley, 2015). For each dataset, a response for an individual species or functional group was classified as (1) no response (no significant change in the measured trait over time), (2) if a significant change was found, the response was classified as either consistent or not consistent with expectations from local or regional climate trends. Percentages are approximate and estimated for the studies as a whole. Individual analyses within the studies may differ. The specific metrics of climate change analysed for associations with biological change vary somewhat across studies, but most use changes in local or regional temperatures (e.g. mean monthly T or mean annual T), with some using precipitation metrics (e.g. total annual rainfall). For example, a consistent response would be poleward range shifts in areas that are warming. Probability (P) of getting the observed ratio of consistent: not consistent responses by chance was <10-13 for (Parmesan and Yohe, 2003; Root et al., 2003; Root et al., 2005; Poloczanska et al., 2013) and was <0.001 for Rosenzweig 2008 (source=publication) (Parmesan and Yohe, 2003; Root et al., 2003; Root et al., 2005; Rosenzweig et al., 2008; Poloczanska et al., 2013). Test were all binomial tests against p=0.5, performed by Parmesan.

[INSERT TABLE 2.2 HERE.]

2.4.2.6 Observed Changes to Physiology and Morphology Driven by Climate Change

Impacts on species physiology in terrestrial and freshwater systems have been observed and attributed to climate change (*medium confidence*), including changes in tolerances to high temperatures (Healy and Schulte, 2012; Gunderson and Stillman, 2015; Deery et al., 2021), increased metabolic costs of living under elevated temperatures (Scheffers et al., 2016) and shifts in sex ratios in species with temperature-dependent sex determination (e.g. masculinisation of lizard populations (Schwanz and Janzen, 2008; Schwanz, 2016; Edmands, 2021) and feminisation of turtle populations (Telemeco et al., 2009)). Skewed sex ratios can lead to mate shortages, reduced population growth and adaptive potential, and increased extinction risk, because genetic diversity decreases as fewer individuals mate and heterozygosity is lost (Mitchell and Janzen, 2010; Edmands, 2021).

Behavioural plasticity such as nest-site selection can provide a partial buffer from the effects of increasing temperature, but there are environmental and physical limits to this plasticity (*medium confidence*) (Refsnider and Janzen, 2016; Telemeco et al., 2017). Plasticity in heat tolerance (e.g. due to reversible acclimation or acclimatisation) can also potentially compensate for rising temperatures (Angilletta Jr, 2009), but ectotherms have relatively low acclimation in thermal tolerance and acclimation is expected to only slightly reduce overheating risk in even the most plastic taxa (*low confidence*) (Gunderson and Stillman, 2015).

Geographic variation in thermal tolerance plasticity is expected to influence species vulnerability and range shifts in response to climate change (Gunderson and Stillman, 2015; Sun et al., 2021). In many ectotherms, plasticity in thermal tolerance increases towards the poles, as thermal seasonality increases (Chown et al., 2004), contributing to higher vulnerability to warming in tropical organisms (*low confidence*) (Huey et al., 2009; Campos et al., 2021). Some species have evolved extreme upper thermal limits at the expense of plasticity, reflecting an evolutionary trade-off between these traits (Angilletta et al., 2003; Stillman, 2003). The most heat-tolerant species, such as those from extreme environments, may therefore be at greater risk of warming because of an inability to physiologically adjust to thermal change (*low confidence*) (Bozinovic et al., 2011; Overgaard et al., 2014; Magozzi and Calosi, 2015).

Physiological changes have observable impacts on morphology, such as changes to body size (and length of appendages) and colour changes in butterflies, dragonflies, and birds (*medium confidence*) (Galeotti et al., 2009; Karell et al., 2011), but trends are not always linear or consistent across realms, taxonomic groups or geographic regions (Gotanda et al., 2015). Some morphological changes arise in response to environmental changes rather than as the result of genetic adaptation or selection for an optimum body type. For example, dietary changes associated with climate change have led to changes in chipmunk skull morphology (Walsh et al., 2016).

Decreased body size has been suggested as a general response of species to climate change in freshwater species given the temperature related constraints of metabolism with increasing body size. Reduced body size in response to global warming has been documented for freshwater bacteria, plankton and fish, as well as a shift towards smaller species (*low confidence*) (Daufresne et al., 2009; Winder et al., 2009; Jeppesen et al., 2010; Crozier and Hutchings, 2014; Jeppesen et al., 2014; Farmer et al., 2015; Rasconi et al., 2015; Woodward et al., 2016). However, the lack of systematic empirical evidence in freshwaters and confounding effects such as interactions between temperature, nutrient availability and predation limit generalisations about body size effects (Pomati et al., 2020 Nutrients).

Evidence is weak for a consistent reduction in body size across taxonomic groups in terrestrial animals (*low confidence*) (Siepielski et al., 2019). Decreased body size in warmer climates (as higher surface area to volume ratios maximise heat loss) is expected based on biogeographic patterns such as Bergmann's Rule, but both increases and decreases have been documented in mammals, birds, lizards and invertebrates and attributed to climate change (Teplitsky and Millien, 2014; Gotanda et al., 2015; Gardner et al., 2019; Hill et al., 2021). Contrasting patterns (increased body size) may be due to short-term modifications in selection pressures (e.g. changes to predation and competition), variation in life histories or a result of interactions with climate variables other than temperature (e.g. changes to food availability with rainfall changes) and other disturbances (Yom-Tov and Yom-Tov, 2004; Gardner et al., 2019; Wilson et al., 2019) or body size measurements (linear vs. volumetric dimensions) (Salewski et al., 2014).

Several lines of evidence suggest evolution of melanism in response to climate change (*low confidence*), with colour changes associated with thermoregulation being demonstrated in butterflies (Zeuss et al., 2014; MacLean et al., 2016; MacLean et al., 2019a), beetles (de Jong and Brakefield, 1998; Brakefield and de Jong, 2011; Zvereva et al., 2019), dragonflies (Zeuss et al., 2014) and phasmids (Nosil et al., 2018). Such changes may represent decreased phenotypic diversity and, potentially, genetic diversity (*low confidence*), but the consequences of climate change on the genetic structure and diversity of populations have not been widely assessed (Pauls et al., 2013). Simplistically, the thermal melanism hypothesis suggests that lighter (higher reflectance) individuals should have increased fitness and therefore be selected for in a warmer climate (Clusella-Trullas et al., 2007). However, several biotic (e.g thermoregulatory requirements, predator avoidance, signalling) and abiotic (e.g. UV, moisture, interannual variability) factors interact to influence changes in colour, making attribution to climate change across species and broad geographic regions difficult (Kingsolver and Buckley, 2015; Stuart-Fox et al., 2017; Clusella-Trullas and Nielsen, 2020).

Interactions between morphological changes and changes to phenology may facilitate or constrain adaptation to climate change (*medium confidence*) (Hedrick et al., 2021). For example, advancing phenology in migratory species may impose selection on morphological traits (e.g. wing length) to increase migration speed. If advancing spring phenology results in earlier breeding, this may offset the effect of rising temperatures in the breeding range and reduce the effect of increasing temperature on body size (Zimova et al., 2021). A study of 52 species of North American migratory birds, based on more than 70,000 specimens, showed that spring migration phenology has advanced over the past 40 years, concurrent with widespread shifts in morphology (reduced body size and increased wing length), perhaps to compensate for the increased metabolic cost of flight as body size decreases (Weeks et al., 2020).

A lack of understanding of physiological constraints and mechanisms remains a barrier to predicting many of the ecological effects of climate change (Bozinovic et al., 2011; Vázquez et al., 2017; González-Tokman et al., 2020). Many behavioural, morphological and physiological responses are highly species and context specific, making generalisations difficult (Bodensteiner et al., 2021). Recent advances in mechanistic understanding (from experiments), in process-based modeling that includes microclimates and developmental processes (Carter and Janzen, 2021) and in sophistication of niche models (Kearney et al., 2009) have improved projections, but comprehensive tests of geographic patterns and processes in thermal tolerance and plasticity are still lacking, with studies limited to a few phylogenetically restricted analyses showing mixed results (Gunderson and Stillman, 2015). Improved understanding of the mechanistic basis for observed geographic patterns in thermal tolerance and plasticity is needed to identify species' physiological limits, the potential for adaptation and the presence of evolutionary trade-offs, which will strongly influence population declines, species range shifts, invasive interactions and success of conservation interventions (Cooke et al., 2021; Ryan and Gunderson, 2021).

2.4.2.7 Observed Impacts of Climate Change on Diseases of Wildlife and Associated Impacts on Humans

Assessment of changes in diseases of terrestrial and freshwater wild organisms was scarce in WGII AR4, AR5, IPCC SR1.5 and IPCC SRCCL. Most emerging infectious diseases (EIDs) are zoonoses, that is, transmissible between humans and animals, and climate sensitive (Woolhouse et al., 2001; Woolhouse and Gowtage-Sequeria, 2005; McIntyre et al., 2017; Salyer et al., 2017). WGII AR4 found weak to moderate evidence that disease vectors and their diseases had changed their distributions in concert with climate change, but attribution studies were lacking. In WGII AR5 Chapter 11, geographic expansion of a few vector borne diseases (VBDs) to higher latitudes and elevations had been detected and associated with regional climate trends, but non-climatic drivers were not assessed well, leading to only a *medium confidence* in attribution) (IPCC, 2014). Here we build upon previous assessments by focusing on changes in population dynamics and geographic distributions of diseases of wildlife, and those of humans and domestic animals that are also harbored, amplified, and transmitted by wild animal reservoir hosts and vectors.

Increased disease incidence is correlated with regional climatic changes and is expected from underlying biology of relationships between temperature, precipitation, and disease ecology (*robust evidence, high agreement*) (Norwegian Polar Institute, 2009; Tersago et al., 2009; Tabachnick, 2010; Paz, 2015; Dewage et al., 2019; Deksne et al., 2020; Shocket et al., 2020; Couper et al., 2021). Whether increases in diseases in wild and domestic animals correspond to increased disease risk in nearby human populations is complicated by potential buffering effects of the local medical system, healthcare access, socio-economic status, education, behaviours and general health of the human population (see also Chapter 7 and Cross-Chapter Box ILLNESS this Chapter).

2.4.2.7.1 Direct effects of climate on reproduction, seasonality, growing season length and transmission of pathogens, vectors, and hosts

VBDs require arthropod vector hosts (e.g., insects or ticks), while other infectious diseases (e.g., fungi, bacteria, and helminths) have free-living life stages and/or complex life cycles that require intermediate hosts (e.g., snails), all of which have temperature-driven rates of development and replication/reproduction *(robust evidence, high agreement)* (Mordecai et al., 2013; Liu-Helmersson et al., 2014; Moran and Alexander, 2014; Bernstein, 2015; Marcogliese, 2016; Ogden and Lindsay, 2016; Mordecai et al., 2017; Short et al., 2017; Caminade et al., 2019; Cavicchioli et al., 2019; Mordecai et al., 2019; Liu et al., 2020; Rocklöv and Dubrow, 2020). Additionally, microbes such as bacteria thermally adapt to temperature changes through multiple mechanisms, indicating that warming will not reduce antibiotic resistance (MacFadden et al., 2018; Pärnänen et al., 2019; Shukla, 2019; McGough et al., 2020; Rodriguez-Verdugo et al., 2020).

There is increasing evidence for a role of extreme events in disease outbreaks (Tjaden et al., 2018; Bryson et al., 2020). Heat waves have been associated with outbreaks of helminth pathogens, especially in subarctic and Arctic areas. For example, a severe outbreak of microfilaremia, a vector-borne disease spread by mosquitoes and flies, plagued reindeer in northern Europe following extreme high temperatures (Laaksonen et al., 2010). More frequent and severe extreme events such as floods, droughts, heat waves, and storms can either increase or decrease outbreaks, depending upon the region and disease (*robust evidence, high agreement*) (Anyamba et al., 2001; Marcheggiani et al., 2010; Brown and Murray, 2013; Paz, 2015; Boyce et al., 2016; Wu et al., 2016b; Wilcox et al., 2019; Nosrat et al., 2021). Heavy precipitation events have been shown to increase some infectious diseases with aquatic life cycle components such as mosquito-borne, helminth, and rodent-borne diseases (*robust evidence, high agreement*) (Anyamba et al., 2001; Zhou et al., 2005; Wu et al., 2008; Brown and Murray, 2013; Anyamba et al., 2014; Boyce et al., 2016). Conversely, flooding also increases flow rate and decreases parasite load and diversity in other aquatic wildlife (Hallett and Bartholomew, 2008; Bjork and Bartholomew, 2009; Marcogliese, 2016; Marcogliese et al., 2016) and can reduce mosquito abundance by flushing them out of the system (Paaijmans et al., 2007; Paz, 2015).

Droughts reduce aquatic habitat of some mosquito species while simultaneously increasing the availability of stagnant standing pools of water that are ideal breeding habitats for other species, such as dengue vector *Aedes* mosquitos *(medium evidence, medium agreement)* (Chareonviriyaphap et al., 2003; Chretien et al., 2007; Padmanabha et al., 2010; Trewin et al., 2013; Paz, 2015). Extreme drought has been associated with an increase in bluetongue virus haemorrhagic disease in wildlife in eastern North America, though mechanisms were not identified (Christensen et al., 2020). Heatwaves in some regions, especially coastal regions, increased parasitism and decreased host richness and abundance leading to population crashes (Larsen and Mouritsen, 2014; Mouritsen et al., 2018). Changes in temperature and precipitation, especially extreme events, can alter community structure (Larsen et al., 2011) by increasing or decreasing parasites and their host organisms and even altering host behavior in ways advantageous to parasites (Macnab and Barber, 2012).

Climate change not only affects the occurrence of pathogens and their hosts in geographic space but also the temporal patterns of disease transmission. Warmer winters allow greater overwinter survival of arthropod vectors which, coupled with lengthened tranmission seasons, drive increases in vector population sizes, pathogen prevalence, and hence proportion of vectors infected *(robust evidence, high agreement)* (Laaksonen et al., 2009; Molnár et al., 2013; Waits et al., 2018). For example, a parasitic nematode lung worm (*Umingmakstrongylus pallikuukensis)* has shortened its larval development time in half (from two years to one year), which has increased infection rates in North American muskoxen (Norwegian Polar Institute, 2009).

Case study 1: Climate change impacts on pathogenic helminths in Europe

Parasitic helminth worms can reduce growth and yield, or kill livestock, and infect humans and wildlife, leading to health, agricultural and economic losses (Fairweather, 2011; Charlier et al., 2016; Charlier, 2020). Attribution of increased helminth disease incidence and risk to climate change is stronger than for most human diseases because of long-term records and careful analysis of other anthropogenic drivers (e.g. land use change, agricultural/livestock intensification, and antihelminthic intervention and resistance) (van Dijk et al., 2008; van Dijk et al., 2010; Fox et al., 2011b; Martínez-Valladares et al., 2013; Charlier et al., 2016; Innocent et al., 2017; Mehmood et al., 2017).

In Europe, evidence from laboratory studies, long term surveillance, statistical analyses, and modelling shows that multiple helminth pathogens and their host snails have extended their transmission windows and have increased survival, fecundity, growth and abundances (*robust evidence, high agreement)*. Furthermore, they have expanded or shifted their ranges poleward due to increases in temperature, precipitation and humidity (*robust evidence, high agreement*) (Lee et al., 1995; Pritchard et al., 2005; Poulin, 2006; van Dijk et al., 2008; van Dijk et al., 2010; Fairweather, 2011; Fox et al., 2011b; Martínez-Valladares et al., 2013; Bosco et al., 2015; Caminade et al., 2015; Caminade et al., 2019). These documented changes in climate, hosts and pathogens have been linked to higher disease incidence and more frequent outbreaks in livestock across Europe (*high confidence*) (Bosco et al., 2015).

Case study 2: Chytrid fungus and climate change

Infection by the chytrid fungus, *Batrachochytrium dendrobatidis* (Bd), can cause chytridiomycosis in amphibians. Bd is widely distributed globally and has caused catastrophic disease in amphibians, associated with declines of 501 species and extinctions of a further 90 species, primarily in tropical regions of the Americas and Australia (Scheele et al., 2019; Fisher and Garner, 2020). Bd successfully travelled with high-elevation Andean frog species as they expanded their elevational ranges upward, driven by regional warming, to > 5200 m (Seimon et al., 2017).

New findings since AR5 from controlled laboratory experiments (manipulating temperature, humidity and water availability), intensive analyses of observed patterns of infection and disease in nature, and modeling studies have led to an emerging consensus that interactions between chytrids and amphibians are climate-sensitive, and that the interaction of climate change and Bd has driven many of the observed global amphibian declines and species' extinctions *(robust evidence, high agreement)* (Rohr and Raffel, 2010; Puschendorf et al., 2011; Rowley and Alford, 2013; Raffel et al., 2015; Sauer et al., 2018; Cohen et al., 2019a; Sauer et al., 2020; Turner et al., 2021).

The "thermal mismatch hypothesis" posits that vulnerability to disease should be higher at warm temperatures in cool-adapted species and higher at cool temperatures in warm-adapted species and is generally supported. However, the most recent studies reveal more complex mechanisms underlying amphibian-disease-climate change dynamics, including variation in thermal preferences among individuals in a single amphibian population *(robust evidence, high agreement)* (Zumbado-Ulate et al., 2014; Sauer et al., 2018; Cohen et al., 2019b; Neely et al., 2020; Sauer et al., 2020).

Bd is not universally harmful—it has been recorded as endemic in frog populations that did not suffer disease, where it may be commensal rather than parasitic (Puschendorf et al., 2006; Puschendorf et al., 2011; Rowley and Alford, 2013). Projections of future impacts are difficult, as the virulence of Bd is variable across Bd populations and dependent upon the evolutionary and ecological histories, and evolutionary potentials, of both the local amphibian populations and the endemic or invading Bd *(robust evidence, high agreement)* (Retallick et al., 2004; Daskin et al., 2011; Puschendorf et al., 2011; Phillips and Puschendorf, 2013; Rowley and Alford, 2013; Zumbado-Ulate et al., 2014; Sapsford et al., 2015; Voyles et al., 2018; Bradley et al., 2019; Fisher and Garner, 2020; McMillan et al., 2020). Further, specific local habitats might serve as regional climate refugia from chytrid infection (e.g. hot and dry) *(medium evidence, high agreement)* (Zumbado-Ulate et al., 2014; Cohen et al., 2019b; Neely et al., 2020; Turner et al., 2021).

2.4.2.7.2 Effects on geographic distribution and connectivity patterns of pathogens

As species' geographic ranges and migration patterns are modified by climate change (Section 2.4.2.1, Table 2.2), pathogens accompany them. Diverse vectors and associated parasites, pests, and pathogens of plants and animals are being recorded at higher latitudes and elevations in conjunction with regional temperature increases and precipitation changes *(robust evidence, high agreement),* although analysis of realized disease incidence often lacks inclusion of non-climatic vs climate drivers, compromising attribution (Ollerenshaw and Rowlands, 1959; Purse et al., 2005; Laaksonen et al., 2010; van Dijk et al., 2010; Alonso et al., 2011; Genchi et al., 2011; Pinault and Hunter, 2011; Jaenson et al., 2012; Loiseau et al., 2012; Kweka et al., 2013; Medlock et al., 2013; Dhimal et al., 2014a; Dhimal et al., 2014b seasonal; Siraj et al., 2014; Khatchikian et al., 2015; Hotez, 2016a; Hotez, 2016b; Bett et al., 2017; Mallory and Boyce, 2017; Strutz, 2017; Booth, 2018; Dumic and Severnini, 2018; Carignan et al., 2019; Gorris et al., 2019; Le et al., 2019; Stensgaard et al., 2019b snails and; Brugueras et al., 2020; Gilbert, 2021).

At least six major VBDs affected by climate drivers have recently emerged in Nepal and are now considered endemic, with climate change implicated as a primary driver as LULCC has been assessed to have a minimal influence on these diseases (*high confidence*) (Table SM2.1). There is *increasing evidence* that climate warming has extended the elevational distribution of *Anopheles, Culex* and *Aedes* mosquito vectors above 2,000 m in Nepal *(limited evidence, high agreement)* (Dahal, 2008; Dhimal et al., 2014a; Dhimal et al., 2014b; Dhimal et al., 2015) with similar trends being recorded in neighboring Himalayan regions *(medium evidence, high agreement)* (Phuyal et al., 2020; Dhimal et al., 2021). Host animals in novel areas may be immunologically naive, and therefore more vulnerable to severe illness (Bradley et al., 2005; Hall et al., 2016).

Case study 3: Arctic and subarctic disease expansion and intensification

High Arctic regions have warmed by more than double the global average, >2°C in most areas (see Sections 2.3.1.1.2, Figure 2.11, and Atlas 11.2.1.2, in WGI). Experimental, field ecology studies and computational models in Arctic and subarctic regions indicate that milder winters have reduced mortality of vectors and reservoir hosts and increased their habitat as forested taiga expands into previously treeless tundra (Table SM2.1; Parkinson et al., 2014). Warmer temperatures and longer seasonal windows have allowed faster reproduction/replication, accelerated development, and increased the number of generations per year of pathogens, vectors and some host animals, that in turn increase the populations of disease organisms and disease transmission (Sections 2.4.2.4, 2.4.4.3.3). Ticks, mosquitos, culicoides biting midges, deer flies, horseflies, and simuliid black flies that transmit a variety of pathogens are being documented in high-latitude regions at higher numbers or where they have been historically absent (*robust evidence, high agreement*) (Waits et al., 2018; Caminade et al., 2019; Gilbert, 2021). In concert with these poleward shifts of hosts and vectors, pathogens, particularly tick-borne pathogens and helminth infections, have increased dramatically in incidence and severity from once rare occurrences and have appeared in new regions (*robust evidence, high agreement, very high confidence*) (Caminade et al., 2019; Gilbert, 2021).

Zoonoses and VBDs that have been historically rare or never documented in Arctic and subarctic regions of Europe, Asia, and North America, such as anthrax, cryptosporidiosis, elaphostrongylosis, filariasis (Huber et al., 2020), tick-borne encephalitis, and tularemia (Evander and Ahlm, 2009; Parkinson et al., 2014; Pauchard et al., 2016), are spreading poleward and increasing in incidence *(robust evidence, high agreement, very high confidence)* (Table SM2.1; Omazic et al., 2019). Recent anthrax outbreaks and mass mortality events among humans and reindeer, respectively, have been linked to abnormally hot summer temperatures that caused permafrost to melt and exposed diseased animal carcasses, releasing thawed, highly infectious, *Bacillus anthracis* spores *(medium evidence, medium agreement)* (Ezhova et al., 2019; Hueffer et al., 2020; Ezhova et al., 2021). Multiple contributing factors conspired over different time scales to compound a 2016 anthrax outbreak occurring on the Yamal peninsula: (i) rapid permafrost thawing for 5 years preceding the outbreak; (ii) thick snow cover the year before the outbreak insulated the warmed permafrost and kept it from re-freezing; and (iii) anthrax vaccination rates had decreased or ceased in the region (Ezhova et al., 2019; Ezhova et al., 2021). These precursors converged with an unusually dry and hot summer that: (i) melted permafrost, creating an anthrax exposure hazard; (ii) increased the vector insect population; and (iii) weakened the immune systems of reindeer thus increasing their susceptibility (Waits et al., 2018; Hueffer et al., 2020).

Warmer temperatures have increased blood-feeding insect harassment of reindeer with compounding consequences: (1) increased insect bite rates lead to higher parasite loads, (2) time spent by raindeer in trying to escape biting flies reduces foraging while simulataneously increasing energy expenditure, (3) the combination of (1) and (2) lead to poor body condition, that subsequently leads to (4) reduced winter survival and fecundity (Mallory and Boyce, 2017). As temperatures warm and connectivity increases between the Arctic and the rest of the world, tourism, resource extraction, and increased commercial transport will create additional risks of biological invasion by infectious agents and their hosts (Pauchard et al., 2016). These increases in introduction risk compounded with climate change have already begun to harm indigenous peoples dependent on hunting and herding livestock (horses and reindeer) that are suffering increased pathogen infection (Deksne et al., 2020; Stammler and Ivanova, 2020).

2.4.2.7.3 Biodiversity-disease links

Anthropogenic impacts, such as disturbances caused by climate change, can reduce biodiversity through multiple mechanisms and increase disease risk to humans *(limited evidence, low agreement)* but more research is needed to understand the underlying mechanisms (Civitello et al., 2015; Young et al., 2017b; Halliday et al., 2020; Rohr et al., 2020; Glidden et al., 2021). Known wildlife hosts of human-shared pathogens and parasites overall comprise a greater proportion of local species richness (18–72% higher) and abundance (21–144% higher) in sites under substantial human use (agricultural and urban lands) compared with nearby undisturbed habitats (Gibb et al., 2020).

Exploitation of wildlife and degradation of natural habitats have increased opportunities for ‘spill over’ of pathogens from wildlife to human populations and increased emergence of zoonotic disease epidemics and pandemics *(robust evidence, high agreement)*; animal and human migrations driven by climate change have added to this increased risk *(medium evidence, medium agreement)* (see Section 2.4.2.1, Chapter 8, Cross-Chapter Box MOVING PLATE in Chapter 5; Patz et al., 2004; Cleaveland et al., 2007; Karesh et al., 2012; Altizer et al., 2013; Allen et al., 2017; Plowright et al., 2017; Olivero et al., 2017; Faust et al., 2018; Carlson et al., 2020; Gibb et al., 2020; Hockings et al., 2020; IPBES, 2020; Volpato et al., 2020; Glidden et al., 2021). Agricultural losses and subsequent food scarcity, that is increasing due to climate change, can also lead to an increase in the use of bushmeat, and, hence increase risk of diseases jumping from wild animals to humans *(medium evidence, high agreement)* (Brashares et al., 2004; Leroy et al., 2004; Wolfe et al., 2004;

Rosen and Smith, 2010; Kurpiers et al., 2016).

2.4.2.7.4 Implications for humans of changes in diseases in wild animals

Changes in temperature, precipitation, humidity, and extreme events have been associated with more frequent disease outbreaks, increases in disease incidence and severity, and novel disease and vector emergence into new areas for wild animals, with a mechanistic understanding of the roles of these drivers from experimental studies providing *high confidence* for the role of climate change. However, attribution of how this has impacted human infectious diseases remains difficult, and definitive attribution studies are lacking. The specific role of recent climate change is difficult to examine in isolation for most regions where human disease incidence has also been affected by land use change (particularly agricultural and urban expansion), changes in public health access and measures, socio-economic changes, increased global movements of people, and changes in vector and rodent control programs, supporting *medium confidence* in the role of climate change driving observed changes in human diseases globally. Exceptions are in areas noted above (Arctic, subarctic, and high elevation regions), in which climate change fingerprints are strong and/or concurrent changes in non-climatic drivers are less pronounced than in other regions (*high confidence* for climate change attribution) (see Table SM2.1, Sections 5.5.1.3, 7.2.2.1, Cross-Chapter Box ILLNESS this Chapter; Harvell et al., 2002; Norwegian Polar Institute, 2009; Tersago et al., 2009; Tabachnick, 2010; Altizer et al., 2013; Garrett et al., 2013; Paz, 2015; Wu et al., 2016b; Caminade et al., 2019; Dewage et al., 2019; Coates and Norton, 2020; Deksne et al., 2020; Shocket et al., 2020; Couper et al., 2021; Gilbert, 2021).

[START FAQ2.2 HERE]

FAQ2.2: How does climate change increase the risk of diseases?

Climate change is contributing to the spread of diseases in both wildlife and humans. Increased contact between wildlife and human populations increases disease risk and climate change is altering where pathogens that cause diseases and the animals that carry them live. Disease risk can often be reduced by improving health care and sanitation systems, training the medical community to recognize and treat potential new diseases in their region, limiting human encroachment into natural areas, limiting wildlife trade, and promoting sustainable and equitable socioeconomic development.

Diseases spread between humans and animals are called zoonoses. Zoonoses comprise nearly two-thirds of known human infectious diseases and the majority of newly emerging infectious diseases (EIDs). COVID-19 is the most recent zoonosis and has killed millions of people globally while devastating economies. The risk posed by EIDs has increased because of: (1) movement of wild animals and their parasites into new areas via climate change, global trade, and travel; (2) human intrusion into and conversion of natural areas for agriculture, livestock, industrial/raw materials extraction, and housing; (3) increased wildlife trade and consumption; (4) increased human mobility resulting from global trade, war/conflicts, and migration made faster and farther by fossil fuel powered travel; and (5) widespread antimicrobial use, which can promote antibiotic resistant infections (Figure FAQ2.3.1).

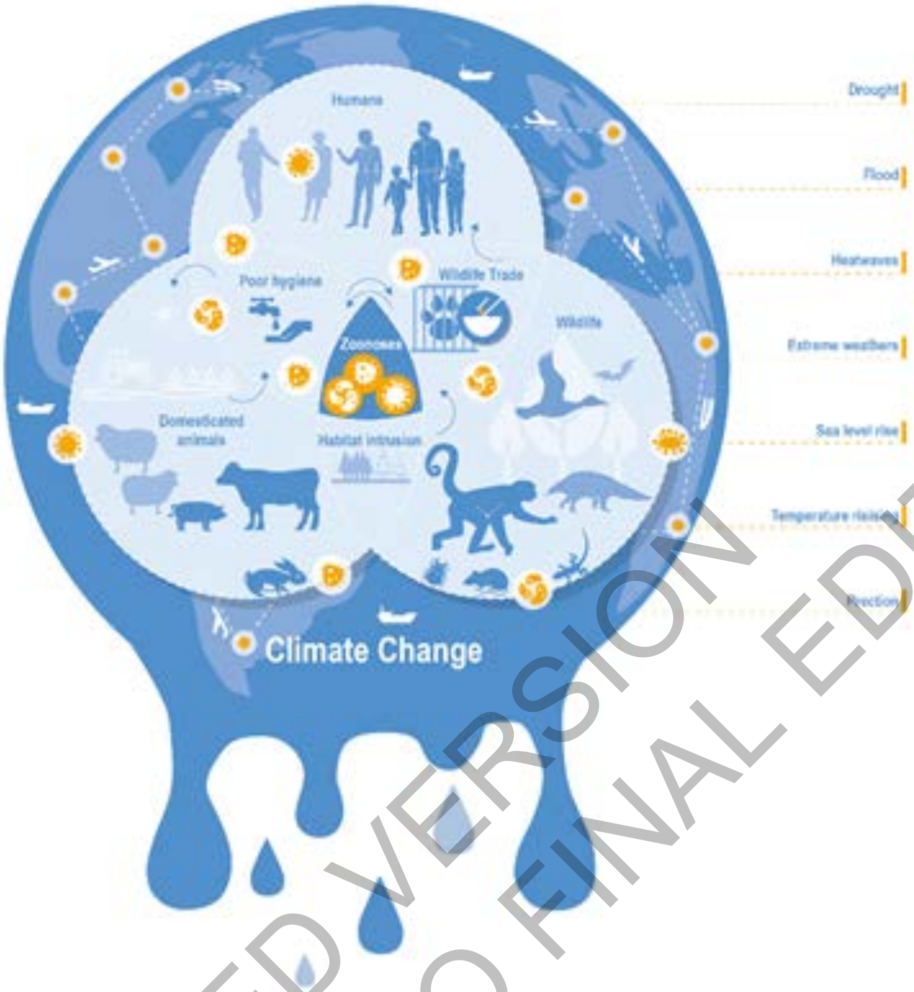

Figure FAQ2.2.1: How diseases move from the wild into human populations. Climate change may increase diseases in nature, but whether or not this leads to an increase in disease risk for humans depends upon a range of societal, infrastructure and medical buffers that form a shield protecting humans.

Climate change further increases risk by altering pathogen and host animal (1) geographic ranges and habitats; (2) survival, growth, and development; (3) reproduction and replication; (4) transmission and exposure (5) behavior; and (6) access to immunologically naïve animals and people who lack infection resistance. This can lead to novel disease emergence in new places, more frequent and larger outbreaks, and longer or shifted seasons of transmission. Climate change is making it possible for many EIDs to colonize historically colder areas that are becoming warmer and wetter in temperate and polar regions and in mountains. Vector-borne diseases (VBDs) are diseases spread by vectors such as mosquitoes, sand flies, kissing bugs, and ticks. For example, ticks that carry the virus that causes tick-borne encephalitis have moved into northern subarctic regions of Asia and Europe. Viruses like dengue, chikungunya, and Japanese encephalitis are emerging in Nepal in hilly and mountainous areas. Novel outbreaks of *Vibrio* bacteria seafood poisoning are being traved to the the Baltic States and Alaska where they were never documented before. Many scientific studies show that infectious disease transmission and the number of individuals infected depends on rainfall and temperature; climate change often makes these conditions more favourable for disease transmission.

Climate change can also have complicated, compounding, and contradictory effects on pathogens and vectors. Increased rainfall creates more habitat for mosquitoes that transmit diseases like malaria but too much rain washes away the habitat. Decreased rainfall also increases disease risk when people without reliable water access use containers to store water in that mosquitos, such as the vectors of dengue fever, *Aedes aegypti* and *Ae. albopictus,* use for egg laying. Hotter temperatures also increase mosquito bite rate, parasite development, and viral replication! Certain species of snails are intermediate hosts for many helminth worm parasites that make humans, livestock, and wild animals sick. When it gets hot, the snails can produce two to three times as many infective larvae but if it becomes too hot many pathogens and their vectors cannot survive or reproduce.

Humans also contract zoonoses directly through their skin, mucus membranes, and lungs when eating or butchering animals, or coming into contact with pathogen shed in the air, urine, or faeces that contaminates water, food, clothing, and other surfaces. Any activity that increases contact with wildlife, especially in high biodiversity regions like the tropics and subtropics, increases disease risk. Climate change-related disease emergence events are often rare but may become more frequent. Fortunately, there are ways to reduce risks and protect our health, as described below.

Habitat and biodiversity protection: Encroachment of humans into natural areas, due to expansion of agriculture and livestock, timber harvests, resource extraction, and urban development has increased human contact with wild animals, and creates more opportunities for disease spillover (transmission from an animal to a new species, including humans). By conserving, protecting, and restoring wild habitats, we can build healthier ecosystems that provide other services, such as clean air, clean and abundant water, recreation, spiritual value, and well-being, as well as reduced disease spillover. If humans must go into wild areas or hunt, they should take appropriate precautions such as wearing protective clothing, using insect repellant, performing body checks for vectors like ticks, and washing hands and clothing well.

Food resilience: Investing in sustainable agroecological farming will alleviate the pressure to hunt wild animals and reduce the conversion of more land to agriculture/livestock use. Stopping illegal animal trading and poaching and decreasing reliance on wild meats and products made from animal parts will reduce direct contact with potentially infected animals. This has the added benefit of increasing food security, nutrition, improving soil, reducing erosion, preserving biodiversity, and mitigating climate change.

Disease prevention and response: The level of protection against infection is linked directly to the level of development and wealth of a country. Improved education, high-quality medical and veterinary systems, high food security, proper sanitation of water and waste, high housing quality, and disease surveillance and alarm systems dramatically reduce disease risk and improve health. Utilizing a One Biosecurity or One Health framework further improves resilience. Sharing knowledge within communities, municipalities, regional, and between national health authorities globally is important to assessing, preventing and responding to outbreaks and pandemics more efficiently and economically.

Humans are facing many direct or indirect challenges because of climate change. Increasing EIDs is one of our greatest challenges, due to our ever-growing interactions with wildlife and the climatic changes creating new disease transmission patterns. COVID-19 is a current crisis, and follows other recent EIDs: SARS, HIV/AIDS, H1N1 influenza, Ebola, Zika, and West Nile fever. EIDs have accelerated in recent decades, making it clear that new societal and environmental approaches to wildlife interactions, climate change, and health are urgently needed to protect our current and future well-being as a species.

[END FAQ2.2 HERE]

2.4.2.8 Observed Evolutionary Responses to Climate Change

Prior sections document species' tendencies to retain their climate envelopes by some combination of range shift and phenological change. However, this tracking of climate change can be incomplete, causing species or populations to experience hotter conditions than those to which they are adapted and thereby incur 'climate debts' (Devictor et al., 2012). The importance of population-level debt is illustrated by a study in which estimated debt values were correlated with population dynamic trends in a North American migratory songbird, the Yellow Warbler, *Setophaga petechia.* Populations that were genetic outliers for their local climate space had larger population declines (greater debt) than populations with genotypes closer to the average values for that particular climate space. Debt values were estimated from genomic analyses independent of the population trends, and were distributed across the species' range in a mosaic, not simply concentrated at range margins, rendering the results robust to being confounded by broad-scale geographical trends (Bay et al., 2018).

In the absence of evolutionary constraints, climate debts can be cancelled by genetically-based increases in thermal tolerance and ability to perform in high ambient temperatures. In species already showing local adaptation to climate, populations currently living at relatively cool sites should be able to evolve to adopt traits of populations currently at warmer sites, as their local experience of climate changes (Singer, 2017; Socolar et al., 2017).

An increasing number of studies document evolutionary responses to climate change in populations not at warm range limits (Franks and Hoffmann, 2012). Organisms with short generation times should have higher capacity to genetically track climate change than species with long generation times, such as mammals (Boutin and Lane, 2014). Indeed, observed evolutionary impacts have been mainly documented in insects, especially at expanding range margins (Chuang and Peterson, 2016) where evolutionary changes have been documented of dispersal ability (Thomas et al., 2001) and host specialisation (Bridle et al., 2014; Lancaster, 2020).

Away from range margins, individual populations experiencing regional warming have evolved diverse traits related to climate adaptation. For example, pitcher-plant mosquitos (*Wyeomyia smithii)* in Pacific NW America have evolved to wait for shorter day lengths before initiating diapause. This adaptation to lengthening summers enables them to delay overwintering until later and add an extra generation each year (Bradshaw and Holzapfel, 2001). Among 26 populations of *Drosophila subobscura* studied on three continents, 22 experienced climate warming across two or more decades, and 21 of those 22 showed increasing frequencies of chromosome inversions characteristic of populations adapted to hot climates (Balanya et al., 2006).

However, for populations already at their warm range limits, their ability to track climate change in situ would require evolving to survive and reproduce outside their species' historical climate envelope, which is not supported by experimental or observational evidence *(medium evidence, high agreement)* (Singer, 2017). Whether or not they can do so depends on the level of 'niche conservatism' operating at the species level (Lavergne et al., 2010). If a species' whose range limits are determined by climate finds itself completely outside of its traditional climate envelope, extinction is expected in the absence of 'evolutionary rescue' (Bell and Gonzalez, 2009; Bell et al., 2019). To investigate the evolutionary potential enabling a species to survive in a novel climate entirely outside its traditional climate envelope, experiments have been carried out on ectotherms testing thermal performances, thermal tolerances, and their evolvabilities (Castaneda et al., 2019; Xue et al., 2019). Tests of thermal performance have been complicated as both long-term acclimation and transgenerational effects occur (Sgro et al., 2016). However, the results to date have been consistent: despite widespread local adaptation to climate across species' ranges, substantial constraints exist to the evolution of greater stress tolerance (e.g. high temperatures and drought) at warm range limits *(medium evidence, high agreement)* (Hoffmann and Sgro, 2011; MacLean et al., 2019b). For example, as temperature was experimentally increased, the amount of genetic variance in fitness of *Drosophila melanogaster* decreased: in hot environments, flies had low evolvability (Kristensen et al., 2015). The hypothesis that heat stress tolerance is evolutionarily constrained is further supported by experiments in which 22 Drosophila species drawn from tropical and temperate climes were subjected to extremes of heat and cold. They differed as expected in cold tolerances, but not in heat tolerances nor in temperatures at which optimal performances were observed (MacLean et al., 2019b).

Plasticity in acclimating to thermal regimes helps organisms adapt to environmental change. The form and extent of plasticity can vary among populations experiencing different climates (Kelly, 2019) and generate phenotypic values outside the prior range for the species, but plasticity itself has not yet been observed to evolve in response to climate change (Kelly, 2019). Relevant genetic changes in nature (e.g. affecting heat tolerance) have not yet been shown to alter the boundaries of existing genetic variation for any species. Evolutionary rescue of entire species has not yet been observed in nature, nor is it expected based upon experimental and theoretical studies *(medium evidence, high agreement)*.

Hybridisation between closely related species has increased in recent decades as one species shifts its range boundaries and positions itself more closely to the other—hybrids between polar bears and brown bears have been documented in northern Canada (Kelly et al., 2010). In North American rivers, hybridisation between invasive rainbow trout and native cutthroat trout has increased in frequency as the rainbow trout expanded into warming waters (Muhlfeld et al., 2014). Whether climate-changed induced hybridisations can generate novel climate adaptations remains to be seen.

In summary, with present knowledge, evolution is not expected to be sufficient to prevent whole species' extinctions if a species' climate space disappears *(high confidence)*.

2.4.3 Observed Changes in Key Biomes, Ecosystems and their Services

2.4.3.1 Detection and Attribution for Observed Biome Shifts

Attribution for biome (major vegetation form of an ecosystem) shifts is complex because of their extensive, sometimes continental, spatial scale (Whittaker, 1975; Olson et al., 2001; Woodward et al., 2004); and therefore, non-climatic factors strongly influence biome spatial distributions (Ellis and Ramankutty, 2008).

The most robust attribution studies use data from individual locations with minimal confounding factors, particularly recent land use change, and scale up by analysing multiple locations across a long zone between biomes. As with individual species, multiple lines of evidence increase confidence (Hegerl et al., 2010; Parmesan et al., 2013). Multivariate statistical analyses aid attribution studies by allowing the assessment of relative weights among multiple factors, including variables related to climate change (Gonzalez et al., 2012). However, drivers often have strong, significant interactions with one another, complicating quantitative assessment of the strength of individual drivers (Parmesan et al., 2013). In these cases, manipulative experiments are critical in assessing attribution to climate change drivers.

Certain biomes exhibit a relatively stronger relationship to climate; for example, Arctic tundra generally has a distinct ecotone with boreal conifer forest (Whittaker, 1975). In these areas, attribution of biome shifts to climate change are relatively straightforward, if human land use change is minimal. However, other biomes, such as many grassland systems, are not at equilibrium with climate (Bond et al., 2005). In these systems their evolutionary history (Keeley et al., 2011; Strömberg, 2011; Charles-Dominique et al., 2016), distribution, structure and function have been shaped by climate and natural disturbances, such as fire and herbivory (Staver et al., 2011; Lehmann et al., 2014; Pausas, 2015; Bakker et al., 2016; Malhi et al., 2016). Disturbance variability is an inherent characteristic of grassland systems and suitable “control” conditions are seldom available in nature. Furthermore, due to the integral role of disturbance, these biomes have been widely affected by long-term and widespread shifts in grazing regimes, large-scale losses of mega-herbivores and fire suppression policies (Archibald et al., 2013; Malhi et al., 2016; Hempson et al., 2017). It is necessary to conduct climate change attribution on a case-by-case basis for grasslands; such assessments are complex as direct climate change impacts from either inherent variation within disturbance regimes or directional changes in background disturbances are difficult to separate (detailed in Sections 2.4.3.2.1; 2.4.3.2.2; 2.4.3.5). Confidence in assessments is increased when observed trends are supported by mechanistic understanding of responses identified by physiological studies, manipulative field experiments, greenhouse studies and lab experiments (Table SM2.1).

2.4.3.2 Global Patterns of Observed Biome Shifts Driven by Climate Change

2.4.3.2.1 Observed biome shifts predominantly driven by climate change

Th IPCC Fifth Assessment Report and a meta-analysis found that vegetation at the biome level shifted poleward latitudinally and upward altitudinally due to anthropogenic climate change at 19 sites in boreal, temperate, and tropical ecosystems from 1700 to 2007 (Gonzalez et al., 2010a; Settele et al., 2014). In these areas, temperature increased 0.4° to 1.6ºC above the pre-industrial period (Gonzalez et al., 2010a; Settele et al., 2014). Field research since the IPCC Fifth Assessment Report detected additional poleward and upslope biome shifts over periods of 24 to 210 years at numerous sites (described below) but were not directly attributed to anthropogenic climate change as the studies were not designed nor conducted properly for attribution.

Many of the recently detected shifts were nevertheless consistent with climate change temperature increases and observed in areas lacking agriculture, livestock grazing, timber harvesting, or other anthropogenic land uses. For example, in the Andes Mountains in Ecuador, a biome shift was detected by comparing a survey by Alexander von Humboldt in 1802 to a re-survey in 2012, making this the longest time span in the world for this type of data (Morueta-Holme et al., 2015) and 2017 (Moret et al., 2019). During 210 years, temperature increased 1.7ºC (Morueta-Holme et al., 2015) and the upper edge of alpine grassland shifted upslope 100–450 m (Moret et al., 2019).

Other biome shifts consistent with climate change and not substantially affected by local land use include northward shifts of deciduous forest into boreal conifer forest in Canada (5 km between 1970–2012, (Sittaro et al., 2017) and 20 km between 1970–2014, (Boisvert-Marsh et al., 2019)) and northward shifts of temperate conifer into boreal conifer forest in Canada (21 km between 1970–2015, (Boisvert-Marsh and de Blois, 2021)). Research detected upslope shifts of boreal and sub-alpine conifer forest into alpine grassland at 143 sites on four continents (41 m, 1901–2018, (Lu et al., 2021)) and individual sites in Canada (54 m, 1900–2010, (Davis et al., 2020)), China (300 m, 1910–2000 (Liang et al., 2016); 33 m, 1985–2014, (Du et al., 2018)), Nepal (50 m, 1860–2000, (Sigdel et al., 2018)), Russia (150 m, 1954–2006, (Gatti et al., 2019)) and the United States (19 m, 1950–2016, (Smithers et al., 2018); 38 m, 1953–2015, (Terskaia et al., 2020)). Other upslope cases include shifts of temperate conifer forest in Canada (Jackson et al., 2016) and the United States (Lubetkin et al., 2017), temperate deciduous forest in Switzerland (Rigling et al., 2013) and temperate shrubland in the United States (Donato et al., 2016).

In summary, anthropogenic climate change has caused latitudinal and elevational biome shifts in at least 19 sites in boreal, temperate, and tropical ecosystems between 1700 and 2007, where temperature increased 0.4° to 1.6ºC above the pre-industrial period (*robust evidence, high agreement*). Additional cases of 5 to 20 km northward and 20 to 300 m upslope biome shifts between 1860 and 2016, under approximately 0.9ºC mean global temperature increase above the pre-industrial period, are consistent with climate change (*medium evidence, high agreement*).

2.4.3.2.2 Observed biome shifts from combined land use change and climate change

Research has detected biome shifts in areas where agriculture, fire use or suppression, livestock grazing, timber and fuelwood harvesting, or other local land use actions substantially altered vegetation, in addition to changes in climatic factors and CO_2 fertilisation. These studies were not designed or conducted in a manner to make climate change attribution possible, although vegetation changes are consistent with climate change: for example, a global review of observed changes in treelines found that 2/3 of treelines globally have shifted upslope in elevation over the past 50 years or more (Hansson, 2021, a review of).

Upslope and poleward forest shifts have occurred where timber harvesting or livestock grazing was abandoned, allowing regeneration of trees at sites in Canada (Brice et al., 2019; Wang et al., 2020b), France (Feuillet et al., 2020), Italy (Vitali et al., 2017), Spain (Ameztegui et al., 2016), the United States (Wang et al., 2020b) and mountain areas across Europe (Cudlin et al., 2017). Intentional use of fire drove an upslope forest shift in Peru (Bush et al., 2015) while mainly human-ignited fires drove conversion of shrubland to grassland in a drought-affected area of the United States (Syphard et al., 2019b). In eastern Canada, timber harvesting and wildfire drove conversion of mixed conifer-broadleaf forests to broadleaf-dominated forests (Brice et al., 2020; Wang et al., 2020b).

Shrub encroachment onto savanna has occurred at numerous sites, particularly across the Southern Hemisphere, mainly between 1992 and 2010 (Criado et al., 2020). Globally, overgrazing initiates shrub encroachment by reducing grasses more than woody plants, while fire exclusion maintains the shrub cover (D'Odorico et al., 2012; Caracciolo et al., 2016; Bestelmeyer et al., 2018). The magnitude of woody cover change in savannas is not correlated to mean annual temperature change (Criado et al., 2020), however, higher atmospheric CO_2 increases shrub growth in savannas (Nackley et al., 2018; Manea and Leishman, 2019). A global remote sensing analysis of biome changes from all causes, including agricultural and grazing expansion and deforestation, estimated that 14% of pixels changed between 1981 and 2012, although this approach can overestimate global changes since it uses a new biome classification system, which doubles the conventional biome classifications (Higgins et al., 2016). In addition to climate change, land use change causes vegetation changes at the biome level (*robust evidence, high agreement*).

2.4.3.3 Observed Changes in Deserts and Arid Shrublands

Divergent responses to anthropogenic climate change are occurring within and across arid regions, depending on time period, location, detection methodology and vegetation type (see Cross-Chapter Paper 3). Emerging shifts in ecosystem structure, functioning and biodiversity are supported by evidence from modelled impacts of projected climate and CO_2 levels. While observed responsiveness of arid vegetation productivity to rising atmospheric CO_2 (Fensholt et al., 2012b) may offset risks from reduced water availability (Fang et al., 2017), climate- and CO_2 driven changes are key risks in arid regions, interacting with habitat degradation, wildfire, and invasive species (Hurlbert et al., 2019).

Widespread vegetation greening, as projected in AR4, is occurring in arid shrublands (Zhang et al., 2019a; Maestre et al., 2021) as a result of increases in leaf area, woody cover and herbaceous production at desert-grassland interfaces (Gonsamo et al., 2021). Plant productivity in arid regions has increased (Fensholt et al., 2012b) because of improved water use efficiency associated with elevated CO_2 (Norby and Zak, 2011; Donohue et al., 2013; Burrell et al., 2020; Gonsamo et al., 2021) *(medium evidence, high agreement)*, altered rainfall seasonality and amount (Rohde et al., 2019; Zhang et al., 2019a) *(robust evidence, high agreement),* increases in temperature (Ratajczak et al., 2014; Wilcox et al., 2018)*(robust evidence, high agreement)* and heavy grazing (*robust evidence, high agreement*) with relative importance differing among locations (Donohue et al., 2013; Caracciolo et al., 2016; Archer et al., 2017; Hoffmann et al., 2019b; Rohde et al., 2019). Woody plant encroachment into arid shrublands is occurring in North America (Caracciolo et al., 2016; Archer et al., 2017), southern Africa (du Toit and O'Connor, 2014; Ward et al., 2014; Masubelele et al., 2015a; Hoffman et al., 2019; Rohde et al., 2019) (*high confidence*) and Central Asia (Li et al., 2015) (*low confidence*). In North America, sagebrush steppe changes have been attributed to increases in temperature and earlier snowpack melt (Wuebbles et al., 2017; Mote et al., 2018; Snyder et al., 2019).

Non-native grasses are invading the sagebrush steppes (cold deserts) in North America (Chambers et al., 2014) attributed to warming (Bradley et al., 2016; Hufft and Zelikova, 2016). In the eastern semi-desert (Karoo) of South Africa, annual rainfall increases and a rainfall seasonality shift (du Toit and O'Connor, 2014) are increasing grassiness as arid grasslands expand into semi-desert shrublands (du Toit et al., 2015; Masubelele et al., 2015b; Masubelele et al., 2015a) causing fire in areas seldom burned (Coates et al., 2016).

Drought, warming, and land management interactions have caused vegetation mortality (see section 2.4.4.3) and reduced vegetation cover in shrublands as projected by AR4 (Burrell et al., 2020). Increased heat and drought are causing succulent species health and abundance to decline (Musil et al., 2009; Schmiedel et al., 2012; Aragón-Gastélum et al., 2014; Koźmińska et al., 2019). Hot droughts especially reduce population resilience (*medium confidence*) (Koźmińska et al., 2019).

2.4.3.4 Observed Changes in Mediterranean-Type Ecosystems

Since AR5, Settele et al. (2014) found that all five Mediterranean-Type Ecosystems (MTEs) of the world experienced extreme droughts within the past decade, with South Africa and California reporting the worst on record (*robust evidence, high agreement*) (Diffenbaugh et al., 2015; Williams et al., 2015a; Garreaud et al., 2017; Otto et al., 2018; Sousa et al., 2018). Climate change is causing these droughts to become more frequent and severe (*medium evidence, medium agreement*) (AghaKouchak et al., 2014, Garreaud et al 2017 The 2010-2015 megadrought , AR6 WGI Chpt 11; Otto et al., 2018).

MTEs show a range of direct responses to various forms of water deficit, but have also been affected by increasing fire activity linked to drought (Abatzoglou and Williams, 2016), and interactions between drought or extreme weather and fire, affecting post-fire ecosystem recovery (Slingsby et al., 2017). Responses include shifts in functional composition (Acácio et al., 2017; Syphard et al., 2019a), decline in vegetation health (Hope et al., 2014; Asner et al., 2016a), decline or loss of characteristic species (White et al., 2016; Stephenson et al., 2019), shifts in composition towards more drought- or heat-adapted species and declining diversity (also see Section 2.4.4.3; Slingsby et al., 2017.; Harrison et al., 2018).

Declines in plant health and increased mortality in MTEs associated with drought have been widely documented (*robust evidence, high agreement*) (Section 2.4.4.3). Remote sensing studies show drought associated mortality in postfire vegetation regrowth in the Fynbos of South Africa (Slingsby et al., 2020b), reduced canopy health in forests within MTE zones of South Africa (Hope et al., 2014), and declines in canopy water content in forests of California (Asner et al., 2016a). Several studies reported climate-associated responses of dominant or charismatic species. High mortality in the Clanwilliam Cedar between 1931 to 2013 occurred at lower, hotter elevations in the Fynbos of South Africa (White et al., 2016). Drought reduced growth and increased mortality of the holm oak, *Quercus ilex,* in the Iberian Peninsula of Spain, Natalini et al. (2016). Portuguese shrublands experienced losses of many deciduous and evergreen oak species, and increasing dominance of to pyrophytic xeric trees (Acácio et al., 2017). The 2012–2015 drought in California caused: high canopy foliage die-back of the Giant Sequoia (*Sequoiadendron giganteum*) (Stephenson et al., 2019), increased the dominance of oaks relative to pines resulting from increased water deficit, and large-scale mortality from drought and insect pest outbreak interactions (McIntyre et al., 2015; Fettig et al., 2019).

Species distribution or community composition changes have contributed to declines in diversity and/or shifts towards more drought- or heat-adapted species (*medium evidence, high agreement*). Two conifer species (*Pinus longaeva*, *P. flexilis*) shifted upslope 19 m from 1950 to 2016 in the Great Basin, USA, (Smithers et al., 2018). Reduced winter precipitation caused native annual forbs to recede resulting in long-lasting and potentially unidirectional reductions in diversity in a Californian grassland (Harrison et al., 2018). More frequent extreme hot and dry weather between 1966 and 2010 caused declines in diversity during the post-fire regeneration phase in the Fynbos of South Africa (Slingsby et al., 2017) resulting in shifts towards species with higher temperature preferences (Slingsby et al., 2017). In Italy, Del Vecchio et al. (2015) observed increases in plant cover and thermophilic species in coastal foredune habitats between 1989 and 2012.

In southern California, USA, areas of forest and woody shrublands are shifting to grasslands, driven by a combination of climate and land use factors such as increased drought, fire ignition frequency and increases in nitrogen deposition (*robust evidence, high agreement*) (Jacobsen and Pratt, 2018; Park et al., 2018; Park and Jenerette, 2019; Syphard et al., 2019b).

The effects of climate change on heat, fuel, and wildfire ignition limitations show spatial and temporal variation globally (see Section 2.3.6.1), but there have been a number of observed impacts in MTEs (*medium evidence, high agreement*). Climate change has caused increases in fuel aridity and area burned by wildfire across the western United States from 1985 to 2015 (Abatzoglou and Williams, 2016). Local and global climatic variability led to a 4 year decrease in the average fire return time in Fynbos, South Africa when comparing fires recorded between 1951 to 1975 and 1976 to 2000 (Wilson et al., 2010). For Chile, González et al. (2018) reported a significant increase in the number, size, duration and simultaneity of large fires during the 2010 to 2015 "megadrought" when compared to the 1990 to 2009 baseline.

2.4.3.5 Observed Changes in Savanna and Grasslands

Savannas consist of coexisting trees and grasses in the tropics and temperate regions (Archibald et al., 2019). The global trend of woody encroachment reported in AR5 (Settele et al., 2014) is continuing *(robust evidence, high agreement, very high confidence)* (see Table 2.S.1), with increases occurring in: temperate savannas in North America (10-20% per decade) (Archer et al., 2017), tropical savannas in South America (8% per decade), Africa (2.4% per decade) and Australia (1% per decade) (O'Connor et al., 2014; Espírito-Santo et al., 2016; Skowno et al., 2017; Stevens et al., 2017; McNicol et al., 2018; Venter et al., 2018; Rosan et al., 2019). Additionally, forest expansion into mesic savannas reported in AR5 (Settele et al., 2014), is continuing in Africa, South America and Southeastern Asia (Marimon et al., 2014; Keenan et al., 2015; Baccini et al., 2017; Ondei et al., 2017; Stevens et al., 2017; Aleman et al., 2018; Rosan et al., 2019). Extreme high rainfall anomalies also contributed to an increase in herbaceous and foliar production in the Sahel (Brandt et al., 2019; Zhang et al., 2019a).

New studies since AR5, using multiple study designs (experimental manipulations in lab and field, meta-analyses and modelling), attribute climate change increases in woody cover to elevated atmospheric CO_2 (Donohue et al., 2013; Nackley et al., 2018; Quirk et al., 2019) and increased rainfall amount and intensity *(robust evidence, high agreement)* (Venter et al., 2018; Xu et al., 2018b; Zhang et al., 2019a). Direct quantification of climate change drivers is confounded with local land use changes such as fire suppression (Archibald, 2016; Venter et al., 2018), heavy grazing (du Toit and O'Connor, 2014; Archer et al., 2017), removal of native browsers, and specifically loss of mega-herbivores in Africa *(medium evidence, medium agreement)* (Asner et al., 2016b; Daskin et al., 2016; Stevens et al., 2016; Davies et al., 2018). The relative importance of the climate- and non-climate-related causes of woody plant vary between regions, but there is general agreement that climate change impacts, specifically, increasing rainfall and rising CO_2, are frequent and strong contributing factors of woody cover increase *(robust evidence, high agreement*).

Extensive woody cover increases in non-forested biomes is reducing grazing potential (Smit and Prins, 2015), and changing the carbon stored per unit land area (González-Roglich et al., 2014; Puttock et al., 2014; Pellegrini et al., 2016; Mureva et al., 2018) and hydrological characteristics (Honda and Durigan, 2016; Schreiner-McGraw et al., 2020). Woody cover encroachment also reduces biodiversity by threatening fauna and flora adapted to open ecosystems (Ratajczak et al., 2012; Smit and Prins, 2015; Pellegrini et al., 2016; Andersen and Steidl, 2019).

The global extent of grasslands is declining significantly because of climate change *(medium confidence)*. In temperate and boreal zones, where about half of treelines are shifting, they are overwhelmingly expanding poleward and upward, with accompanying loss of montane grassland (*robust evidence, high agreement*); whereas tropical treelines have been generally stable *(medium evidence, medium agreement)* (Harsch et al., 2009; Rehm & Feeley 2015; Silva et al., 2016; Andela et al., 2017; Song et al., 2018; Aide et al., 2019; Gibson and Newman, 2019). The Eurasian steppes experienced a 1% increase in woody cover per decade since 2000 (Liu et al., 2021) and Inner Mongolian grasslands in China experienced broad encroachment as well (Chen et al., 2015). Climatic drivers of woody expansion in temperature limited grasslands, particularly alpine grasslands, are most frequently attributed to warming (*robust evidence, high agreement, high confidence*) (D'Odorico et al., 2012; Hagedorn et al., 2014), increases in water and nutrient availability from thawing permafrost (*medium evidence, high agreement*) (Zhou et al., 2015b; Silva et al., 2016) and rising CO_2 (*medium evidence, medium agreement*) (Frank et al., 2015; Aide et al., 2019). Interactions between land use changes: land abandonment, grazing management shifts, and fire suppression, and climate change are contributing factors (Liu et al., 2021)

Remote sensing shows overall increasing trends in both the annual maximum NDVI and annual mean NDVI in global grasslands ecosystems between 1982 and 2011 (Gao et al., 2016). Multiple lines of evidence indicate that changes in grassland productivity are positively correlated with increases in mean annual precipitation (Hoover et al., 2014; Brookshire and Weaver, 2015; Gang et al., 2015; Gao et al., 2016; Wilcox et al., 2017; Wan et al., 2018). Increasing temperatures positively impact grassland production and biomass, especially in temperature limited regions (Piao et al., 2014; Gao et al., 2016). However, grasslands in hot areas are expected to decrease production with increases in temperature *(limited evidence, low agreement)* (Gang et al., 2015). Nevertheless, grassland responses to warming and drought are being ameliorated by increasing CO_2 and associated improved water use efficiency (Roy et al., 2016). For example, in a cool temperate grassland experiment, warming led to a longer growing season and elevated CO_2 further extended growing by conserving water, which enabled most species to remain active longer (*medium evidence, medium agreement)* (Reyes-Fox et al., 2014).

2.4.3.6 Observed Changes in Tropical Forest

Overall declines of tropical forest cover (Kohl et al., 2015; Liu et al., 2015; Baccini et al., 2017; Harris et al., 2021), with declines more than triple the gains (Harris et al., 2021) have been driven primarily by deforestation and land conversion (*robust evidence, high agreement*) (Lewis et al., 2015; Curtis et al., 2018; Espaciais, 2021). In opposition to this general trend, expansion of tropical forest cover into savannas and grasslands has occurred in Africa, South America, and Australia (Baccini et al., 2017; Aleman et al., 2018; Staver, 2018) (Marimon et al., 2014; Ondei et al., 2017; Stevens et al., 2017; Rosan et al., 2019).

Specific examples of climate-change driven range shifts of tropical deciduous forests upslope into alpine grasslands have been documented in the Americas (Chacón-Moreno et al., 2021; Jiménez-García et al., 2021) and in Asia (Sigdel et al., 2018). However, treeline behaviours are diverse. A study in Nepal recorded that treeline fomed by *Abies spectabilis* had been stable for more than a century, while the upper limit of large shrubs (*Rhododendron campanulatum*) had been advancing (Mainali et al., 2020). In both the Andes (Harsch et al., 2009) and Himalaya (Singh et al., 2021) most treelines have been stable, leading (Rehm & Feeley 2015) to postulate a "grass ceiling" that has been difficult for trees to penetrate. The treeline shifts that have occurred are probably driven by interactions between changing land-use, such as fire suppression, and climate changes such as increased rainfall, warming and elevated CO_2 either through CO_2 fertilisation or increases in water-use efficiency (*medium evidence, medium agreement)* (Cernusak et al., 2013; Huang et al., 2013; Van Der Sleen et al., 2015; Yang et al., 2016).

Increases in productivity of tropical forests (Gatti et al., 2014; Brienen et al., 2015; Baccini et al., 2017), Africa and SE Asia (Qie et al., 2017) have been attributed to elevated CO_2 *(robust evidence, medium agreement)* (Ballantyne et al., 2012; Brienen et al., 2015; Sitch et al., 2015; Yang et al., 2016; Mitchard, 2018). The rates of these increases have been slowing down in the central Amazon (Brienen et al., 2015; de Meira Junior et al., 2020) and SE Asia (Qie et al., 2017). In contrast, the carbon sink (and hence rate of biomass gain) in intact African forests was stable until 2010 and has only recently started to decline, indicating asynchronous carbon sink saturation in Amazonia and Africa, the difference driven by rates of tree mortality (Hubau et al. 2020). At a global level (Hubau et al 2020) argue that the carbon sink associated with intact tropical forests peaked in the 1990s and is now in decline.

Declines in productivity are most strongly associated with warming (Sullivan et al., 2020), reduced growth rates during droughts (Bennett et al., 2015; Bonai et al., 2016; Corlett, 2016), drought related mortality (Brando et al., 2014; Zhou et al., 2014; Brienen et al., 2015; Corlett, 2016; McDowell et al., 2018), fire (Liu et al., 2017), and cloud-induced radiation-limitation *(robust evidence, high agreement)* (Deb Burman et al., 2020). Increases in frequency and severity of droughts and shorter tree residence times due to increases in growth rates caused by elevated CO_2 may be additional interactive factors increasing tree mortality (Malhi et al., 2014; Brienen et al., 2015). Vulnerability to drought varies between tree species and sizes with large, long-lived trees at highest risk of mortality (McDowell et al., 2018; Meakem et al., 2018). Mortality risk also varies between forest types with seasonal rainforests appearing most vulnerable to drought (Corlett, 2016).

Lianas (long-stemmed woody vines) generally negatively impact trees, significantly reducing the growth of heavily infested trees (Reis et al., 2020). They would benefit from climate change and disturbance (LingZi et al., 2014; Hodgkins et al., 2018). The extent of their suitable niche can increase (Taylor and Kumar, 2016), thereby decreasing forest biomass accumulation *(robust evidence, high agreement*) (van der Heijden et al., 2013; Fauset et al., 2015; Estrada-Villegas et al., 2020).

Climate change continues to degrade forests by reducing resilience to pests and diseases, increasing species invasion, facilitating pathogen spread (Malhi et al., 2014; Deb et al., 2018) and intensifying fire risk and potential die-back (Lapola et al., 2018; Marengo et al., 2018). Drought, temperature increases and forest fragmentation interact to increase the prevalence of fires in tropical forests (*robust evidence, high agreement*). Warming increases water stress in trees (Corlett, 2016) and together with forest fragmentation, dramatically increases desiccation of forest canopies—resulting in deforestation that then leads to even hotter and drier regional climates (Malhi et al., 2014; Lewis et al., 2015). Warming and drought increase invasion of grasses into forest edges and increase fire risk (*robust evidence, high agreement*) (Brando et al., 2014; Balch et al., 2015; Lewis et al., 2015). Droughts and fires additively increase mortality and, consequently, reduce canopy cover and aboveground biomass (Cross-Chapter Paper 7; Brando et al., 2014, 2020; Balch et al., 2015; Lewis et al., 2015).

2.4.3.7 Observed Changes in Boreal and Temperate Forests

The IPCC Fifth Assessment Report found increased tree mortality, wildfire and plant phenology changes in boreal and temperate forests (Settele et al., 2014). Expanding on those conclusions, this Assessment, using analyses of causal factors, attributes to anthropogenic climate change the following observed changes in boreal and temperate forests in the 20th and 21st centuries: upslope and poleward biome shifts at sites in Asia, Europe, and North America (Section 2.4.3.2.1); range shifts of plants (Section 2.4.2.1); earlier blooming and leafing of plants (Section 2.4.2.4); poleward shifts in tree-feeding insects (Section 2.4.2.1); increases in insect pest outbreaks (Section 2.4.4.3.3); increases in area burned by wildfire in western North America (Section 2.4.4.2.1); increased drought-induced tree mortality in western North America (Section 2.4.4.3.1); and thawing of permafrost that underlies extensive areas of boreal forest (IPCC Sixth Assessment Report, Working Group I, Chapter 2, Section 2.4.3.9). Atmospheric CO_2 from anthropogenic sources has also increased net primary productivity (Section 2.4.4.5.1). In summary, anthropogenic climate change has caused substantial changes to temperate and boreal forest ecosystems, including biome shifts and increases in wildfire, insect pest outbreaks, and tree mortality, at a global mean surface temperature increase of 0.9º C above the pre-industrial period (*robust evidence, high agreement*).

Other changes detected in boreal forests and consistent with, but not formally attributed to climate change, include increased wildfire in Siberia (Section 2.4.4.2.3), long-lasting smoldering belowground fires in Canada and the United States (Scholten et al., 2021), tree mortality in Europe (Section 2.4.4.3.3), and post-fire shifts of boreal conifer to deciduous broadleaf tree species in Alaska (Mack et al., 2021). From 1930 to 1960, boreal forest growth became limited more by precipitation than temperature in the Northern Hemisphere (Babst et al., 2019).

For some vegetation changes, land use and land management changes have exerted more influence than climate change. These include upslope and poleward forest shifts in Europe following abandonment of timber harvesting or livestock grazing (Section 2.4.3.2.2), changes in wildfire in Europe affected by fire suppression, fire prevention, and agricultural abandonment (Section 2.4.4.2.3), and forest species composition changes in Scotland due to nitrogen deposition from air pollution (Hester et al., 2019). Remote sensing suggests that the area of temperate and boreal forests increased in Asia and Europe between 1982 and 2016 (Song et al., 2018) and in Canada between 1984 and 2015 (Guindon et al., 2018), but forest plantations and regrowth are probable drivers (Song et al., 2018).

2.4.3.8 Observed Changes in Peatlands

Globally, peatland ecosystems store approximately 25% (600±100 GtC) of the world's soil organic carbon (Yu et al., 2010; Page et al., 2011; Hugelius et al., 2020) and 10% of the world's freshwater resources (Joosten and Clarke, 2002), despite only occupying 3% of the global land area (Xu et al., 2018a). The long-term role of northern peatlands in the carbon cycle was mentioned for the first time in IPCC AR4 (IPCC, 2007b), while SR1.5 briefly mentioned the combined effects of climate and land-use change on peatlands (IPCC, 2018b). New evidence confirms that climate change, including extreme weather events (e.g., droughts; Section 8.3.1.6), permafrost degradation (Section 2.3.2.5), sea-level rise (Section 2.3.3.3), and fire (Section 5.4.3.2) (Henman and Poulter, 2008; Kirwan and Mudd, 2012; Turetsky et al., 2015; Page and Hooijer, 2016; Swindles et al., 2019; Hoyt et al., 2020; Hugelius et al., 2020; Jovani-Sancho et al., 2021; Veraverbeke et al., 2021), superimposed on anthropogenic disturbances (for example, draining for agriculture or mining; Section 5.2.1.1), has led to rapid losses of peatland carbon across the world (*robust evidence, high agreement*) (Page et al., 2011; Leifeld et al., 2019; Hoyt et al., 2020; Turetsky et al., 2020; Loisel et al., 2021). Other essential peatland ecosystem services, such as water storage and biodiversity, are also being lost worldwide (*robust evidence, high agreement*) (Bonn et al., 2014; Martin-Ortega et al., 2014; Tiemeyer et al., 2017).

The switch from carbon sink to source in peatlands globally is mainly attributable to changes in water table depth, regardless of management or status (*robust evidence, high agreement*) (Lafleur et al., 2005; Dommain et al., 2011; Lund et al., 2012; Cobb et al., 2017; Evans et al., 2021; Novita et al., 2021). Across the temperate and tropical biomes, extensive drainage and deforestation have caused widespread water table drawdowns and/or peat subsidence, as well as large CO_2 emissions (*medium evidence, high agreement*). Climate change is compounding these impacts (*medium evidence, medium agreement*). For example, in Indonesia, the highest emissions from drained tropical peatlands were reported in the extremely dry year of the 1997 El Niño (810–2570 TgC yr^{-1}) (Page et al., 2002) and the 2015 fire season (380 TgC yr^{-1}) (Field et al., 2016). These prolonged dry seasons have also led to tree die-offs and fires, which are relatively new phenomena in these latitudes (*medium evidence, high agreement*) (Cole et al., 2015; Mezbahuddin et al., 2015; Fanin and van der Werf, 2017; Taufik et al., 2017; Cole et al., 2019). Low soil moisture contributes to increased fire propagation (see Cross-Chapter Box 5, and Section 12.4.2.2; Dadap et al., 2019), causing long-lasting fires responsible for smoke and haze pollution (*robust evidence, high agreement*) (Ballhorn et al., 2009; Page et al., 2009; Gaveau et al., 2014; Huijnen et al., 2016; Page and Hooijer, 2016; Hu et al., 2018; Vadrevu et al., 2019; Niwa et al., 2021). Increases in fires and smoke lead to habitat loss and negatively impact regional faunal populations (*limited evidence, high agreement*) (Neoh et al., 2015; Erb et al., 2018b; Thornton et al., 2018).

In large lowland tropical peatland basins that are less impacted by anthropogenic activities (i.e., Amazon and Congo river basins), the direct impact of climate change is that of a decreased carbon sink (*limited evidence,* *medium agreement*) (Roucoux et al., 2013; Gallego-Sala et al., 2018; Wang et al., 2018a; Dargie et al., 2019; Ribeiro et al., 2021). As for the temperate and boreal regions, climatic drying also tends to promote peat oxidation and carbon loss to the atmosphere (*medium evidence, medium agreement*) (section 2.3.1.3.4) (Helbig et al., 2020; Zhang et al., 2020). In Europe, increasing mean annual temperatures in the Baltic, Scandinavia, and Continental Europe (Section 12.4.5.1) have led to widespread lowering of peatland water tables at intact sites (Swindles et al., 2019), *Sphagnum* moss desiccation and die off (Bragazza, 2008; Lees et al., 2019), and increased fire intensity and frequency resulting in rapid carbon loss (Davies et al., 2013; Veraverbeke et al., 2021). Nevertheless, longer growing seasons and warmer, wetter climates have increased carbon accumulation and promoted thick deposits regionally, as reported for some North American sites (*limited evidence, medium agreement*) (Cai and Yu, 2011; Shiller et al., 2014; Ott and Chimner, 2016).

In high-latitude peatlands, the net effect of climate change on the permafrost peatland carbon sink capacity remains uncertain (Abbott et al., 2016; McGuire et al., 2018b; Laamrani et al., 2020; Loisel et al., 2021; Sim et al., 2021; Väliranta et al., 2021). Increasing air temperatures have been linked to permafrost degradation and altered hydrological regimes (Section 2.3.3.2, Figure 2.4a, 2.4.3.9, and Box 5.1), which have led to rapid changes in plant communities and biogeochemical cycling (*robust evidence, high agreement*) (Liljedahl et al., 2016; Swindles et al., 2016; Voigt et al., 2017; Zhang et al., 2017b; Voigt et al., 2020; Sim et al., 2021). In many instances, permafrost degradation triggers thermokarst land subsidence associated with local wetting (*robust evidence, high agreement*) (Jones et al., 2013; Borge et al., 2017; Olvmo et al., 2020; Olefeldt et al., 2021). Permafrost thaw in peatland-rich landscapes can also cause local drying through increased hydrological connectivity and runoff (Connon et al., 2014). In the first decades following thaw, increases in methane, CO_2, and nitrous oxide emissions have been recorded from peatland sites, depending on surface moisture conditions (Schuur et al., 2009; O'Donnell et al., 2012; Elberling et al., 2013; Matveev et al., 2016; Euskirchen et al., 2020; Hugelius et al., 2020). Conversely, some evidence suggests increased peat accumulation after thaw (Jones et al., 2013; Estop-Aragonés et al., 2018; Väliranta et al., 2021). There is also a need to consider the impact of wildfire on permafrost thaw, due to its effect on soil temperature regime (Gibson et al., 2018), wildfire as a}, as fire intensity and frequency have increased across the boreal and Arctic biomes (*limited evidence, high agreement*) (Kasischke et al., 2010; Scholten et al., 2021).

Unfortunately, the CO_2 emissions from degrading peatlands is contributing to climate change in a positive feedback loop (*robust evidence, high agreement)*. In the midlatitudes, widespread anthropogenic disturbance led to large historical GHG emissions and current legacy emissions of 0.15 PgC yr^{-1} between 1990 and 2000 (*limited evidence, high agreement*) (Maljanen et al., 2010; Tiemeyer et al., 2016; Drexler et al., 2018; Qiu et al., 2021). About 80 million ha of peatlands have been converted to agriculture, equivalent to 72 PgC emissions between 850–2010 CE (Leifeld et al., 2019; Qiu et al., 2021). In southeast Asia, an estimated 20–25 Mha of peatlands have been converted to agriculture with carbon currently being lost at a rate of ~155 ± 30 MtC yr^{-1} (Miettinen et al., 2016; Leifeld et al., 2019; Hoyt et al., 2020). Extensive deforestation and drainage have caused widespread peat subsidence and large CO_2 emissions at a current average of ~10 ± 2 t ha^{-1} yr^{-1} (excluding fires, (Hoyt et al., 2020)), with values estimated from point subsidence measurements being as high as 30–90 t CO_2 ha^{-1} yr^{-1} locally (*robust evidence, high agreement*) (Wösten et al., 1997; Matysek et al., 2018; Swails et al., 2018; Evans et al., 2019; Conchedda and Tubiello, 2020; Anshari et al., 2021). On balance, at the global scale, increases in GHG emissions from peatlands have primarily come from the compounded effects of land-use change, drought, and fire, with emissions from some thawing permafrost peatlands (*robust evidence, high agreement*).

2.4.3.9 Observed Changes in Polar Tundra

Warming at high latitudes, documented in both AR4 and AR5, is leading to earlier snow and sea ice melt and longer growing seasons (WGI AR6) which are continuing to alter tundra plant communities (*medium evidence, high agreement)* (Post et al., 2009; Gauthier et al., 2013). Woody encroachment and increases in vegetation productivity observed in both AR4 and AR5 are widespread and continuing. Both experiments and monitoring indicate that climate warming is causing increases in shrub, grass and sedge abundance, density, frequency and height, with decreases in mosses and/or lichens *(robust evidence, high agreement)* (Myers-Smith et al., 2011; Bjorkman et al., 2018; Bjorkman et al., 2019). Shrub growth is climate-sensitive and greater in years with warmer growing seasons (Myers-Smith et al., 2015). Plant species that prefer warmer conditions are increasing (Elmendorf et al., 2015; Bjorkman et al., 2018), plant cover is increasing and bare ground is decreasing in long-term monitoring plots (Bjorkman et al., 2019; Myers-Smith et al., 2019). Animals such as moose, beavers and songbirds may already be responding to these vegetation changes by expanding their ranges northward or upslope into shrub tundra (Boelman et al., 2015; Tape et al., 2016a; Tape et al., 2016b; Tape et al., 2018).

In addition to direct warming, indirect effects of climate change such as thawed permafrost, altered hydrology and enhanced nutrient cycling (as observed in AR4 and AR5) continue and are causing pronounced vegetation changes *(medium evidence, medium agreement)* (Schuur et al., 2009; Natali et al., 2012). Soil moisture status influences temperature sensitivity of plant growth and canopy heights (Myers-Smith et al., 2015; Ackerman et al., 2017; Bjorkman et al., 2018). In tundra ecosystems permafrost thawing can decouple below-ground plant growth dynamics from above-ground dynamics, with below-ground root growth continuing until soils refreeze in autumn (Cross-Chapter Paper 6; Iversen et al., 2015; Blume-Werry et al., 2016; Radville et al., 2016).

2.4.4 Observed Changes in Ecosystem Processes and Services

2.4.4.1 Observed Browning of Rivers and Lakes

In boreal coniferous areas there has been an increase in terrestrial derived dissolved organic carbon (DOC) transport into rivers and lakes, which has caused increased opacity and shift toward a brown colour (browning). This process was not given much attention in AR5 even though it is a consequence of climate change: hydrological intensification, greening of the Northern Hemisphere, and degradation of carbon sinks in peatlands *(robust evidence, high agreement*) (Solomon et al., 2015; Catalán et al., 2016; Crowther et al., 2016; de Wit et al., 2016; Finstad et al., 2016; Creed et al., 2018; Hayden et al., 2019) factors that enhance terrestrial productivity, alter vegetation communities, and affect the hydrological control on production and transport of DOC (Weyhenmeyer et al., 2016). Non climate-related drivers of browning are: declining atmospheric sulphur deposition, forestry practices and land-use changes (see Table 2.S.1 for detail).

Browning creates a positive feedback by absorbing photosynthetically active radiation accelerating upper water (epilimnetic) warming (Solomon et al., 2015). Browning of lakes leads to shallower and more stable thermoclines and thus, overall deep water cooling (Solomon et al., 2015; Williamson et al., 2015) and can provoke a transition of the seasonal mixing regime from a mixed lake (polymictic) to one that is seasonally stratified (Kirillin and Shatwell, 2016).

The ecological responses of browning need to be considered as concomitant effects of climate change and nutrient status. Results from long-term, large-scale lake experiments were variable, showing both strong synergistic effects (Urrutia-Cordero et al., 2016) and no significant effects of browning on plankton community food webs (Rasconi et al., 2015). Browning has driven a shift from auto- to heterotrophic/mixotrophic-based production (Wilken et al., 2013; Urrutia-Cordero et al., 2017) and supports heterotrophic metabolism of the bacterial community (Zwart et al., 2016). Browning may also accelerate primary production through input of nutrients associated with DOM in nutrient poor lakes and increase cyanobacteria, which better cope with low light intensities (Huisman et al., 2018) and toxin levels (Urrutia-Cordero et al., 2016). However, the synergistic impacts of browning and climate change on aquatic communities depends on regional precipitation patterns (Weyhenmeyer et al., 2016), watershed type (de Wit et al., 2016), and food chain length (Hansson et al., 2013). Quantitative attribution of browning to climate change remains difficult (*medium evidence, medium confidence*).

In summary, new studies since AR5 have explicitly estimated the effects of warming and browning on freshwaters in boreal areas with complex positive and negative repercussions on water temperature profiles (lower vs upper water) (*high confidence*) and primary production (*medium confidence*).

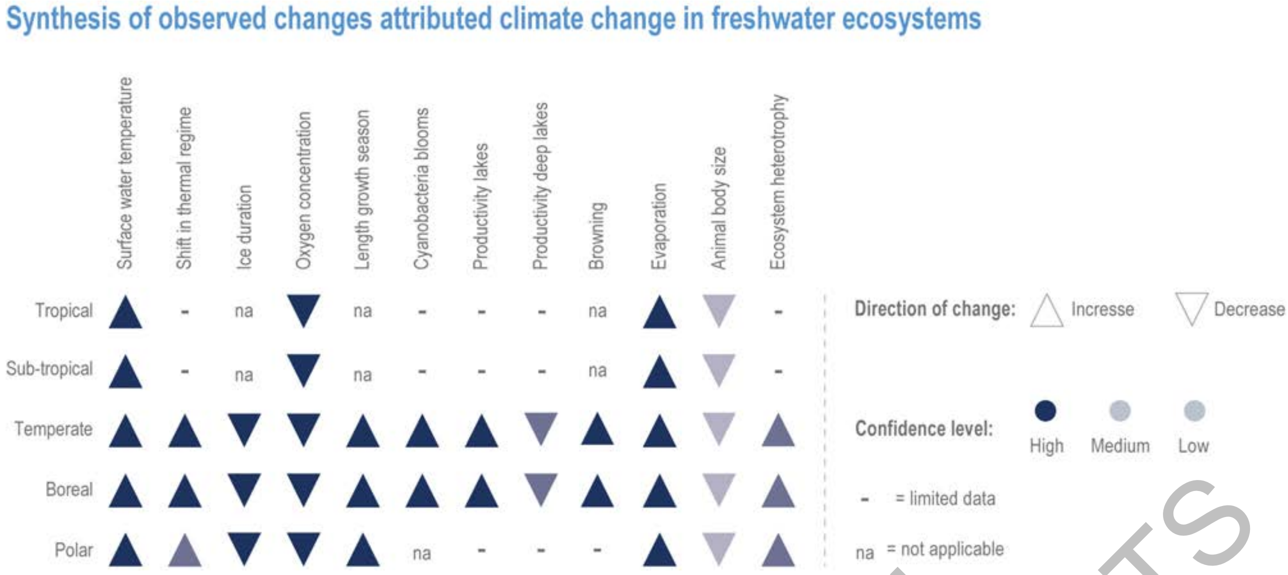

Figure 2.5: Large scale observed changes in freshwater ecosystems attributed to climate change over more than four decades. For description and references, see 2.3.3, 2.4.2, and 2.5.3.6.2.

2.4.4.2 Observed Changes in Wildfire

2.4.4.2.1 Detection and attribution of observed changes in wildfire

Wildfire is a natural and essential component of many forest and other terrestrial ecosystems. Excessive wildfire, however, can kill people, cause respiratory disease, destroy houses, emit carbon dioxide, and damage ecosystem integrity (see Section 2.4.4.2, 2.4.4.4). Anthropogenic climate change increases wildfire by exacerbating its three principal driving factors—heat, fuel, and ignition (Moritz et al., 2012; Jolly et al., 2015). Non-climatic factors also contribute to wildfires—in tropical areas fires are set intentionally to clear forest for agricultural fields and livestock pastures (Bowman et al., 2020b). Urban areas and roads create ignition hazards. Governments in many temperate zone countries implement policies to suppress fires, even natural ones, producing unnatural accumulations of fuel in the form of coarse woody debris and high densities of small trees (Ruffault and Mouillot, 2015; Hessburg et al., 2016; Andela et al., 2017; Balch et al., 2017; Lasslop and Kloster, 2017; Aragao et al., 2018, (Kelley et al., 2019). Globally, 4.2 million km^2 of land per year burned on average from 2002 to 2016 (Giglio et al., 2018) with the highest fire frequencies in the Amazon rainforest, deciduous forests and savannas in Africa, and deciduous forests in northern Australia (Earl and Simmonds, 2018; Andela et al., 2019).

Since the IPCC Fifth Assessment Report and the IPCC Special Report on Land, published research has detected increases in the area burned by wildfire, analysed relative contributions of climate and non-climate factors, and attributed burned area increases above natural levels to anthropogenic climate change in one part of the world – western North America (*robust evidence, high agreement)* (Abatzoglou and Williams, 2016; Partain et al., 2016; Kirchmeier-Young et al., 2019; Mansuy et al., 2019; Bowman et al., 2020b). Across the western United States, increases in vegetation aridity due to higher temperatures from anthropogenic climate change doubled burned area from 1984 to 2015 over what would have burned due to non-climate factors, including unnatural fuel accumulation from fire suppression, with the burned area attributed to climate change accounting for 49% (32–76%, 95% confidence interval) of cumulative burned area (Abatzoglou and Williams, 2016). Anthropogenic climate change has doubled the severity of a southwest North American drought from 2000 to 2020 that has reduced soil moisture to its lowest levels since the 1500s (Williams et al., 2020), driving half of the increase in burned area (Abatzoglou and Williams, 2016; Holden et al., 2018; Williams et al., 2019). In British Columbia, Canada, the increased maximum temperatures due to anthropogenic climate change increased burned area in 2017 to its highest extent in the 1950–2017 record, seven to eleven times the area that would have burned without climate change (Kirchmeier-Young et al., 2019). In Alaska, USA, the high maximum temperatures and extremely low relative humidity due to anthropogenic climate change accounted for 33–60% of the probability of wildfire in 2015, when the area burned was the second highest in the 1940–2015 record (Partain et al., 2016). In protected areas of Canada and the United States, climate factors (temperature, precipitation, relative humidity, evapotranspiration) accounted for 60% of burned area from local human and natural ignitions from 1984 to 2014, outweighing local human factors (population density, roads, and built area) (Mansuy et al., 2019).

In summary, field evidence shows that anthropogenic climate change has increased the area burned by wildfire above natural levels across western North America in the period 1984–2017, at global mean surface temperature increases of 0.6ºC –0.9ºC, increasing burned area up to 11 times in one extreme year and doubling burned area over natural levels in a 32 year period (*high confidence*).

2.4.4.2.2 Observed changes in wildfire globally

For global terrestrial area as a whole, wildfire trends vary depending on the time period of analysis. From 1900 to 2000, global average fire frequency, based on field data, increased 0.4% but the change was not statistically significant, (Mouillot and Field, 2005; Gonzalez et al., 2010b). Fire frequency increased on one-third of global land, mainly from burning for agricultural clearing in Africa, Asia, and South America, slightly less than the area of fire frequency decrease, mainly from fire suppression across Australia, North America, and Russia (Gonzalez et al., 2010b). Analyses of the Global Fire Emissions Database document that from 1996 to 2015, global burned area decreased at a rate of –0.7% y^{-1} (Forkel et al., 2019) but the change was not statistically significant, (Giglio et al., 2013). From 1998 to 2015, global burned area decreased at a rate of $-1.4 \pm 0.5\%\ y^{-1}$ (Giglio et al., 2013; Andela et al., 2017). The area of fire increases was a third of the area of decreases, due to reduction of vegetation cover from agricultural expansion and intensification (Andela et al., 2017) and increased precipitation (Forkel et al., 2019). Furthermore, much of the decreasing trend derives from two years: 1998 with high burned area and 2013 with low burned area (Forkel et al., 2019). Wildfire does not show a clear long-term trend for the world as a whole because of increases and decreases in different regions (*medium evidence, medium agreement*).

Where global average burned area has decreased in the past two decades, higher correlations of rates of change in burning to human population density, cropland area, and livestock density than to precipitation indicate that agricultural expansion and intensification were main causes (Andela et al., 2017). The global decrease of fire frequency from 2000 to 2010 is correlated to increasing human population density (Knorr et al., 2014). The fire-reduction effect of reduced vegetation cover following expansion of agriculture and livestock herding can counteract the fire-increasing effect of increased heat of climate change (Lasslop and Kloster, 2017; Arora and Melton, 2018; Forkel et al., 2019). The reduction of burning needed after the initial clearing for agricultural expansion drives much of the decline in fire in the tropics (Andela et al., 2017; Earl and Simmonds, 2018; Forkel et al., 2019). The human influence on fire ignition can be seen through the decrease documented on holy days (Sundays and Fridays), traditional religious days of rest (Earl et al., 2015). Overall, human land use exerts an influence on wildfire trends for global terrestrial area as a whole that can be stronger than climate change (*medium confidence*).

2.4.4.2.3 Observed changes in wildfire in individual regions

While burned area has increased in parts of Asia, Australia, Europe, and South America, published research has not yet attributed the increases to anthropogenic climate change (*medium evidence, high agreement*).

In the Amazon, deforestation for agricultural expansion and the degradation of forests adjacent to deforested areas cause wildfire in moist humid tropical forests not adapted to fire (*robust evidence, high agreement*) (Fonseca et al., 2017; van Marle et al., 2017; da Silva et al., 2018; da Silva et al., 2021; dos Reis et al., 2021; Libonati et al., 2021). Roads facilitate deforestation, fragmenting the rainforest and increasing the dryness and flammability of vegetation (Alencar et al., 2015). Extreme droughts that occur during warm phases of the El Niño-Southern Oscillation (ENSO) and the Atlantic Multidecadal Oscillation combine with the degradation of vegetation to cause extreme fire events (*robust evidence, high agreement*) (Fonseca et al., 2017; Aragao et al., 2018; da Silva et al., 2018; Burton et al., 2020; dos Reis et al., 2021; Libonati et al., 2021). In the State of Roraima, Brazil, distance to roads, infrastructure that enables deforestation, and ENSO were the two factors most explaining fire occurrence in the extreme 2015–2016 fire season (Fonseca et al., 2017). From 1973 to 2014, burned area increased in the Amazon, coinciding with increased deforestation (van Marle et al., 2017). In the State of Acre, Brazil, burned area increased 36-fold from 1984 to 2016, with 43% burned area in agricultural and livestock settlement areas (da Silva et al., 2018). In 2019, the extreme fire year 2019, 85% of the area burned in the Amazon occurred in areas deforested in 2018 (Cardil et al., 2020). Even though relatively higher moisture in 2019 led to burning below the 2002–2019 average across most of South America, burning in areas of recent deforestation in the Amazon were above the 2002-2019 average, indicating that deforestation, not meteorological conditions, triggered the 2019 fires (Kelley et al., 2021; Libonati et al., 2021). Furthermore, from 1981 to 2018, deforestation in the Amazon reduced moisture inputs to the lower atmosphere, increasing drought and fire in a self-reinforcing feedback (Xu et al., 2020). In the Amazon, deforestation exerts an influence on wildfire that can be stronger than climate change (*robust evidence, high agreement*).

In Australia, burned area increased significantly between the periods 1950–2002 and 2003–2020 in the southeast state of Victoria, with the area burned in the 2019–2020 bushfires the highest on record (Lindenmayer and Taylor, 2020). In addition to the deaths of dozens of people and destruction of thousands of houses, the 2019–2020 Australia bushfires burned almost half of the area protected for conservation in Victoria and two-thirds of forests allocated for timber harvesting (Lindenmayer and Taylor, 2020), wildlife, and extensive areas of habitat for threatened plant and animal species (Geary et al., 2021). Generally, past timber harvesting did not lead to more severe fire canopy damage (Bowman et al., 2021). Across Southeastern Australia, the fraction of vegetated area that burned increased significantly in eight of the 32 bioregions from 1975 to 2009 but decreased significantly in three bioregions (Bradstock et al., 2014). Increases in four bioregions were correlated to increasing temperature and decreasing precipitation. Decreases in burned area occurred despite increased temperature and decreased precipitation. Analyses of climate across Australia from 1950 to 2017 (Dowdy, 2018; Harris and Lucas, 2019) and during periods with extensive fires in 2017 in eastern Australia (Hope et al., 2019), in 2018 in Northeastern Australia (Lewis et al., 2020), and in period 2019-2020 in Southeastern Australia (Abram et al., 2021; van Oldenborgh et al., 2021) indicate that temperature and drought extremes due to the El Niño-Southern Oscillation, Southern Annular Mode, and other natural interdecadal cycles drive interannual variability of fire weather. While the effects of interdecadal climate cycles on fire are superimposed on long-term climate change, the relative importance of anthropogenic climate change in explaining changes in burned area in Australia remains unquantified (*medium evidence, high agreement*).

In Africa, the rate of change of burned area for the continent as a whole ranged from a non-statistically significant –0.45% y^{-1} from 2002 to 2016 (Zubkova et al., 2019) to a significant –1.9% y^{-1} from 2001 to 2016 (Wei et al., 2020). Burned area decreases coincided with areas of agricultural expansion or areas where drought reduced fuel loads (Zubkova et al., 2019; Wei et al., 2020). It is possible, however, that the 500 m spatial resolution of Modis remote sensing fire data underestimates burned area in Africa by half by missing small fires (Ramo et al., 2021). In the Serengeti-Mara savanna of east Africa, burned area showed no significant change from 2001 to 2014, although an increase in domestic livestock would tend to reduce the grass cover that fuels savanna fires (Probert et al., 2019).

In Mediterranean Europe, burned area for the region as a whole decreased from 1985 to 2011 (Turco et al., 2016), although burned area for Spain did not show a significant long-term increase from 1968 to 2010 (Moreno et al., 2014) while burned area for Portugal in 2017 was the highest in the period 1980–2017 (Turco et al., 2019). Increased summer maximum temperature and decreased soil moisture explained most of observed burned area, suggesting a contribution of climate change, but fire suppression, fire prevention, agricultural abandonment, and reforestation, and reduction of forest area exerted even stronger influences on burned area than climate across Mediterranean Europe (*robust evidence, high agreement*) (Moreno et al., 2014; Turco et al., 2017; Viedma et al., 2018; Turco et al., 2019).

In the Arctic tundra and boreal forest, where wildfire has naturally been infrequent, burned area showed statistically significant increases of ~50% y^{-1} across Siberia, Russia, from 1996 to 2015 (Ponomarev et al., 2016) and 2% y^{-1} across Canada from 1959 to 2015 (Hanes et al., 2019). Wildfire burned ~ 6% of the area of four extensive Arctic permafrost regions in Alaska, USA, eastern Canada, and Siberia from 1999 to 2014 (Nitze et al., 2018). In boreal forest in the Northwest Territories, Canada, and Alaska, USA, the area burned by wildfire increased at a statistically significant rate of 6.8% y^{-1} in the period 1975–2015, (Veraverbeke et al., 2017), with smouldering belowground fires that lasted through the winter covering ~1% of burned area in the period 2002-2016 (Scholten et al., 2021). While burned area was correlated to temperature and reduced precipitation in Siberia (Ponomarev et al., 2016; Masrur et al., 2018) and to lightning, correlated with temperature and precipitation in the Northwest Territories and Alaska (Veraverbeke et al., 2017), no attribution analyses have examined relative influences of climate and non-climate factors.

In Indonesia, deforestation and draining of peat swamp forests dries out the peat, providing substantial fuel for fires (Page and Hooijer, 2016). Extreme fire years in Indonesia, including 1997, 2006, and 2015, coincide with extreme heat and aridity during the warm phase of the El Niño-Southern Oscillation (Field et al., 2016). Fire-resistant forest in 2019 covered only 3% of peatlands and 4.5% of non-peatlands on Sumatra and Kalimantan (Nikonovas et al., 2020).

In Chile, burned area in the summer of 2016–2017 was 14 times the mean for the period 1985–2016 and the highest on record (Bowman et al., 2019). While that extreme fire year coincided with the highest daily mean maximum temperature in the period 1979–2017 (Bowman et al., 2019), in central Chile, the area of highest fire activity, burned area from 1976 to 2013 showed highest correlation to precipitation cycles of the El Niño-Southern Oscillation and temperature cycles of the Antarctic Oscillation (Urrutia-Jalabert et al., 2018).

Overall, burned area has increased in the Amazon, the Arctic, Australia, and parts of Africa and Asia, consistent with, but not formally attributed to anthropogenic climate change (*medium evidence, high agreement*). Deforestation, peat draining, agricultural expansion or abandonment, fire suppression, and interdecadal cycles such as the El Niño-Southern Oscillation exert a stronger influence than climate change on wildfire trends in numerous regions outside of North America (*high confidence*).

2.4.4.2.4 Observed changes in fire seasons globally

IPCC AR6 Working Group 1, Chapter 12, has assessed fire weather, while this chapter assesses burned area and fire frequency. The global increases in temperature of anthropogenic climate change have increased aridity and drought, lengthening the fire weather season (annual period with a heat and aridity index greater than half of its annual range) on one-quarter of global vegetated area and increasing average fire season length by one-fifth, from 1979 to 2013 (Jolly et al., 2015). Climate change has contributed to increases in the fire weather season or the probability of fire weather conditions in the Amazon (Jolly et al., 2015), Australia (Dowdy, 2018; Abram et al., 2021; van Oldenborgh et al., 2021), Canada (Hanes et al., 2019), central Asia (Jolly et al., 2015), East Africa (Jolly et al., 2015), and North America (Jain et al., 2017; Williams et al., 2019; Goss et al., 2020). In forest areas, the burned area is correlated to fuel aridity, a function of temperature; in non-forest areas, the burned area is correlated to high precipitation in the previous year, which can produce high grass fuel loads (Abatzoglou et al., 2018). Fire use in agriculture and livestock raising or other factors have generated a second fire season on approximately one-quarter of global land where fire is present, despite sub-optimal fire weather in the second fire season (Benali et al., 2017). In summary, anthropogenic climate change, through a 0.9ºC surface temperature increase since the pre-industrial period, has lengthened or increased the frequency of periods with heat and aridity that favour wildfire on up to one-quarter of vegetated area, since 1979 (*robust evidence, high agreement*).

2.4.4.2.5 Observed changes in post-fire vegetation

Globally, fire has contributed to biome shifts (Section 2.4.3.2) and tree mortality (Section 2.4.4.2, 2.4.4.3) attributed to anthropogenic climate change. Research since the IPCC Fifth Assessment Report has also found vegetation changes from wildfire due to climate change. Through increased temperature and aridity, anthropogenic climate change has driven post-fire changes in plant regeneration and species composition in South Africa (Slingsby et al., 2017) and tree regeneration in the western United States (Davis et al., 2019b). In the Fynbos vegetation of the Cape Floristic Region, South Africa, post-fire heat and drought and legacy effects of exotic plant species reduced native plant species regeneration, decreasing species richness 12% from 1966 to 2010 and shifting the average temperature tolerance of species upward by 0.5ºC (Slingsby et al., 2017). In burned areas across the western United States, the increasing heat and aridity of anthropogenic climate change from 1979 to 2015 pushed low-elevation ponderosa pine (*Pinus ponderosa*) and Douglas-fir (*Pseudotsuga menziesii*) forests across critical thresholds of heat and aridity that reduced post-fire tree regeneration by half (Davis et al., 2019b). In the Southwestern United States of America, where anthropogenic climate change has caused drought (Williams et al., 2019) and increased wildfire (Abatzoglou and Williams, 2016), high-severity fires have converted some forest patches to shrublands (Barton and Poulos, 2018). Field evidence shows that anthropogenic climate change and wildfire together have altered vegetation species composition in the Southwestern USA and in the Cape floristic region, South Africa, reducing post-fire natural regeneration and species richness of tree and other plant species, between 1966 and 2015, at global mean surface temperature increases of 0.3-0.9ºC (*medium evidence, high agreement*).

[START FAQ2.3 HERE]

FAQ2.3: Is climate change increasing wildfire?

In the Amazon, Australia, North America, Siberia, and other regions, wildfires are burning wider areas than in the past. Analyses show that human-caused climate change has driven the increases in burned area in the forests of western North America. Elsewhere, deforestation, fire suppression, agricultural burning, and short-term cycles like El Niño can exert a stronger influence than climate change. Many forests and grasslands naturally require fire for ecosystem health but excessive wildfire can kill people, destroy homes, and damage ecosystems.

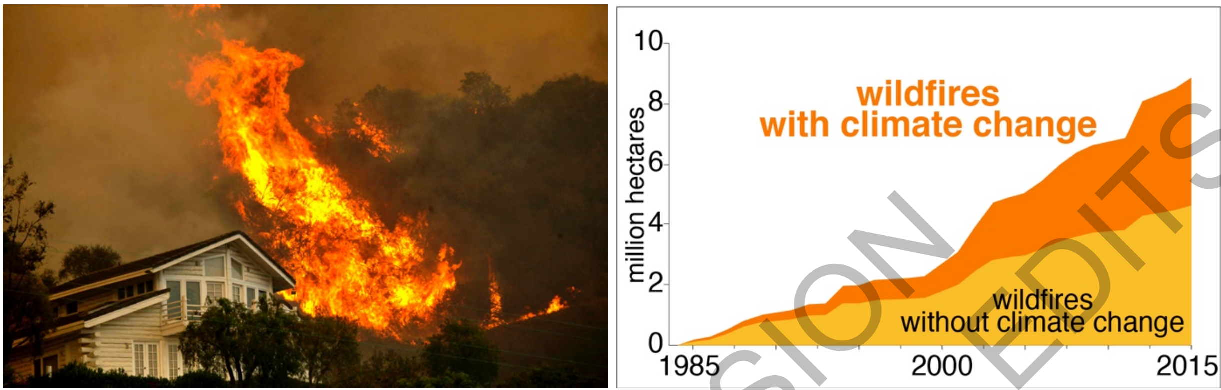

Figure FAQ2.3.1: (a) Springs Fire, May 2, 2013, Thousand Oaks, California, USA (photo by Michael Robinson Chávez, Los Angeles Times). (b) Cumulative area burned by wildfire in the western U.S., with (orange) and without (yellow) the increased heat and aridity of climate change (Abatzoglou and Williams, 2016).

Wildfire is a natural and essential part of many forest, woodland, and grassland ecosystems, killing pests, releasing plant seeds to sprout, thinning out small trees, and serving other functions essential for ecosystem health. Excessive wildfire, however, can kill people, cause breathing illnesses from the smoke, destroy homes (Figure FAQ2.1a), and damage ecosystems.

Human-caused climate change increases wildfire by intensifying its principal driving factor – heat. The heat of climate change dries out vegetation and accelerates burning. Non-climate factors also cause wildfires. Agricultural companies, small farmers, and livestock herders in many tropical areas cut down forests and intentionally set fires to clear fields and pastures. Cities, towns, and roads increase the number of fires that people ignite. Governments in many countries suppress fires, even natural ones, producing unnatural accumulations of fuel in the form of coarse woody debris and dense stands of small trees. The fuel accumulations cause particularly severe fires that burn into tree crowns.

Evidence shows that human-caused climate change has driven increases in the area burned by wildfire in the forests of western North America. Across the western U.S., the higher temperatures of human-caused climate change doubled burned area from 1984 to 2015, compared with what would have burned without climate change (Figure FAQ2.1b). The additional area burned, 4.9 million hectares, is greater than the land area of Switzerland. In this region, human-caused climate change has driven a drought from 2000 to 2020 that is the most severe since the 1500s, severely increasing the aridity of vegetation. In British Columbia, Canada, the higher maximum temperatures of human-caused climate change increased burned area in 2017 to its widest extent in the 1950–2017 record, seven to eleven times the area that would have burned without climate change. Moreover, in national parks and other protected areas of Canada and the U.S., climate factors explained the majority of burned area from 1984 to 2014, with climate factors (temperature, rainfall, aridity) outweighing local human factors (population density, roads, and urban area).

In other regions, wildfires are also burning wider areas and occurring more often. This is consistent with climate change but analyses have not yet shown if climate change is more important than other factors. In the Amazon, deforestation by companies, farmers, and herders who cut down and intentionally burn rainforests to expand agricultural fields and pastures causes wildfires even in relatively moister years. Drought exacerbates these fires. In Australia, much of the southeastern part of the continent has experienced extreme wildfire years, but analyses suggest that El Niño, a heat phenomenon that cycles up and down periodically, is more important than long-term climate change. In Indonesia, intentional burning of rainforests for oil palm plantations and El Niño seem to be more important than long-term climate change. In Mediterranean Europe, fire suppression seems to have prevented any increasing trend in burned area but suppression and abandonment of agricultural lands have allowed fuel to build up in some areas and contribute to major fires in years of extreme heat. In Canada and Siberia, wildfires are now burning more often in permafrost areas where fire had been rare, but analyses are lacking on the relative influence of climate change. For the world as a whole, satellite data indicate that the vast amount of land that converted from forest to farmland from 1998 to 2015 actually decreased total burned area. Nevertheless, the evidence from the forests of western North America shows that human-caused climate change has, on one continent, clearly driven increases in wildfire.

[END FAQ2.3 HERE]-

2.4.4.3 Observed Changes in Tree Mortality

2.4.4.3.1 Observed tree mortality globally

Anthropogenic climate change can cause tree mortality directly through increased aridity or drought (Section 2.4.4.3.3) or indirectly through wildfire (Section 2.4.4.2.1) and insect pests (Section 2.4.4.3.3). Catastrophic failure of the plant hydraulic system, in which a lack of water causes the xylem to lose hydraulic conductance, is the principal mechanism of drought-induced tree death (Anderegg et al., 2016; Adams et al., 2017; Anderegg et al., 2018; Choat et al., 2018; Menezes-Silva et al., 2019; Brodribb et al., 2020).

Up through the IPCC Fifth Assessment Report (Settele et al., 2014), detection and attribution analyses had found that anthropogenic climate change, with global temperature increases of 0.3°-0.9ºC above the pre-industrial period and increases in aridity exceeding the effects of local non-climate change factors, caused three cases of drought-induced tree mortality of up to 20% in the period 1945-2007, in western North America (van Mantgem et al., 2009), the African Sahel (Gonzalez et al., 2012), and North Africa (le Polain de Waroux and Lambin, 2012). Increased wildfire and pest infestations, driven by climate change, also contributed to the North American tree mortality (van Mantgem et al., 2009). In addition, a meta-analysis of published cases found that drought consistent with, but not formally attributed, to climate change, had caused tree mortality at 88 sites in boreal, temperate and tropical ecosystems (Allen et al., 2010), with 49 additional cases found by the IPCC Fifth Assessment report (Settele et al., 2014).

Since the IPCC Fifth Assessment Report (Settele et al., 2014), global meta-analyses have found at least 15 (Allen et al., 2015) and 25 (Hartmann et al., 2018) additional sites of drought-induced tree mortality around the world. These and other global analyses found more rapid mortality than previously (Allen et al., 2015), rising background mortality (Allen et al., 2015), mortality increasing with drought severity (Greenwood et al., 2017), mortality of tropical trees increasing with temperature (Locosselli et al., 2020), mortality increasing with tree size for many species (Bennett et al., 2015), mortality predominantly at the dry edge of species ranges (Anderegg et al., 2019a), and three-fourths of drought-induced mortality cases leading to a change in the dominant species (Batllori et al., 2020). Multiple non-climate factors contribute to tree mortality, including timber cutting, livestock grazing, and air pollution (Martinez-Vilalta and Lloret, 2016). Globally, tropical dry forests lost, from all causes, 95,000 km^2, 8% of their total area, from 1982 to 2016, the most extensive area of mortality of any biome (Song et al., 2018).

In summary, anthropogenic climate change has caused drought-induced tree mortality up to 20% in the period 1945-2007 in western North America, the African Sahel, and North Africa, through global temperature increases of 0.3°–0.9ºC above the pre-industrial period and increases in aridity, and contributed to over 100 other cases of drought-induced tree mortality in Africa, Asia, Australia, Europe, and North and South America (*high confidence*). Field observations document accelerating mortality rates, rising background mortality, and post-mortality vegetation shifts (*high confidence*). Water stress, leading to plant hydraulic failure, is the principal mechanism of drought-induced tree mortality. Timber cutting, agricultural expansion, air pollution, and other non-climate factors also contribute to tree death.

2.4.4.3.2 Observed tree mortality in tropical ecosystems

In the Brazilian Amazon, deforestation to clear agricultural land comprises the principal cause of tree mortality, reducing forest cover an average of 13,900 km^2 y^{-1} from 1988 to 2020 (Espaciais, 2021). In addition, an annual average temperature increase of 1.2ºC from 1950 to 2018 (Marengo et al., 2018) contributed to mortality in a set of 310 Amazon field plots of ~40% from 1983 to 2011 (Brienen et al., 2015). In another set of plots, mortality among newly recruited trees of mesic genera increased and drought-tolerant genera became more abundant from 1985 to 2015 (Esquivel-Muelbert et al., 2019). In other plots, tree mortality did not show a statistically significant change from 1965 to 2016 but rose abruptly in severe drought years, mainly during warm phases of the El Niño-Southern Oscillation (ENSO) (Aleixo et al., 2019). Nearly half the area of the Amazon has experienced extremely dry conditions during ENSO warm phases, which can cause extensive wildfire (Section 2.4.4.2.3). Wildfire can increase tree mortality rates by >600% above rates in non-burned areas, with the higher mortality persisting up to a decade after a fire (Silva et al., 2018; Berenguer et al., 2021). Climate change has contributed to tree mortality in Amazon rainforest (*medium evidence, medium agreement*).

In the African Sahel field research has continued to detect tree mortality, ranging from 20% to 90% in the period 1965-2018 (Kusserow, 2017; Trichon et al., 2018; Dendoncker et al., 2020), and declines in tree biodiversity, with local losses of tree species up to 80% in the period 1970-2014 (Hanke et al., 2016; Kusserow, 2017; Ibrahim et al., 2018; Dendoncker et al., 2020), consistent with, but not formally attributed to climate change. In Algeria, mortality of Atlas cedar (*Cedrus atlantica*) increased from 1980 to 2006, coinciding with a ~1ºC spring temperature increase, but non-climate factors were not examined (Navarro-Cerrillo et al., 2019). Across southern Africa, nine of the 13 oldest known baobab trees (*Adansonia digitata*), 1100–2500 years old, have died since 2005, although the causes are unknown (Patrut et al., 2018). In South Africa, savanna trees experienced an order of magnitude increase in mortality, related, but not formally attributed to decreased rainfall (Case et al., 2019). In Tunisia, insect infestations related, but not formally attributed to, hotter temperatures led to mortality of cork oaks (*Quercus suber*) (Bellahirech et al., 2019).

2.4.4.3.3 Observed tree mortality in boreal and temperate ecosystems

The most extensive research on tree mortality since the IPCC Fifth Assessment Report has occurred in the western United States, where anthropogenic climate change accounts for half the magnitude of a drought from 2000 to 2020 that has been the most severe since the 1500s (Williams et al., 2020) and for one-tenth to one-quarter of the magnitude of the 2012-2014 period of the severe 2012-2016 drought in California (Williams et al., 2015a). Across the western United States, anthropogenic climate change doubled tree mortality between 1955 and 2007 (van Mantgem et al., 2009). Lodgepole pine (*Pinus contorta*) mortality increased 700% from 2000 to 2013 (Anderegg et al., 2015) and piñon pine (*Pinus edulis*) experienced over 50% mortality from 2002 to 2014 (Redmond et al., 2018). In California montane conifer forest, anthropogenic climate change increased tree mortality one-quarter (Goulden and Bales, 2019). One-quarter of trees died in some areas with mortality rates of ponderosa pine (*Pinus ponderosa*) and sugar pine (*Pinus lambertiana*) increasing up to 700% of pre-drought rates (Stephenson et al., 2019; Stovall et al., 2019). Substantial field evidence shows that anthropogenic climate change has caused extensive tree mortality in North America (*robust evidence, high agreement*).

In western North America, increased infestations of bark beetles and other tree-feeding insects that benefit from increased winter temperatures (IPCC AR6 WGI 3.3.1.1) and longer growing seasons (IPCC AR6 WGI 2.3.4.3.1) have killed drought-stressed trees (Section 2.4.2.1; Anderegg et al., 2015; Kolb et al., 2016; Lloret and Kitzberger, 2018; Redmond et al., 2018; Stephens et al., 2018; Fettig et al., 2019; Restaino et al., 2019; Stephenson et al., 2019). Increasing temperatures have allowed bark beetles to move further north and higher in elevation, survive through the winter at sites where they would previously have died, and reproduce more often (Raffa et al., 2008; Bentz et al., 2010; Jewett et al., 2011; Macfarlane et al., 2013; Raffa et al., 2013; Hart et al., 2017; Stephenson et al., 2019; Teshome et al., 2020; Koontz et al., 2021). Under warmer conditions, some insects that were previously innocuous have become important agents of tree mortality (Stephenson et al., 2019; Trugman et al., 2021). Field observations show mixed effects of bark beetle-induced tree mortality on subsequent fire-caused tree mortality (Andrus et al., 2016; Meigs et al., 2016; Candau et al., 2018; Lucash et al., 2018; Talucci and Krawchuk, 2019; Wayman and Safford, 2021). From 1997 to 2018, ~5% of western U.S. forest area died from bark beetle infestations (Hicke et al., 2020). In most circumstances, trees that have been weakened by drought are more vulnerable to being killed by bark beetles (Anderegg et al., 2015; Kolb et al., 2016; Lloret and Kitzberger, 2018; Redmond et al., 2018;

Stephens et al., 2018; Fettig et al., 2019; Restaino et al., 2019; Stephenson et al., 2019; Koontz et al., 2021). Climate change has contributed to bark beetle infestations that have caused much of the tree mortality in North America (*robust evidence, high agreement*) (Section 2.4.2.1).

Across Europe, rates of tree mortality in field inventories from 2000 to 2012 were highest in Spain, Bulgaria, Sweden, and Finland, positively correlated to maximum winter temperature and inversely correlated to spring precipitation (Neumann et al., 2017). Tree mortality in Austria, the Czech Republic, Germany, Poland, Slovakia, and Switzerland doubled from 1984 to 2016, correlated to intensified logging and increased temperatures (Senf et al., 2018). Drought-related tree mortality rates from 1987 to 2016 were highest in Ukraine, Moldova, southern France, and Spain (Senf et al., 2020). Climate contributed to tree mortality across Europe from 1958 to 2001 (Seidl et al., 2011). In addition, insect infestations related to higher temperatures (Okland et al., 2019) have caused extensive mortality of Norway spruce (*Picea abies*) across nine European countries (Marini et al., 2017; Mezei et al., 2017). Across the Mediterranean Basin, a combination of drought, wildfire, pest infestations, and livestock grazing has driven tree mortality (Penuelas and Sardans, 2021). Climate change has contributed to tree mortality in Europe (*high agreement, medium confidence*). (Section 2.4.2.1)

2.4.4.3.4 Tree mortality and fauna

A global meta-analysis of 631 cases of bird and mammal abundance changes in areas of tree mortality found increasing abundance in a set of 186 bird species with increasing mortality and no trend in mammal abundance (Fleming et al., 2021). Ground-nesting, ground foraging, tree hole nesting, and bark foraging increased most, while nectar-feeding and foliage-gleaning birds declined. Invertebrates, especially ground-foraging predators and detritivores, decreased.

2.4.4.4 Observed Terrestrial Ecosystem Carbon

2.4.4.4.1 Observed terrestrial ecosystem carbon globally

Terrestrial ecosystems contain stocks of 450 Gt (380–540 Gt) carbon in vegetation, 1700 Gt ± 250 Gt carbon in soils, and 1400 Gt ± 200 Gt carbon in permafrost (Hugelius et al., 2014; Batjes, 2016; Jackson et al., 2017; Strauss et al., 2017; Erb et al., 2018a; Xu et al., 2021). Ecosystem carbon stocks, totaling 3030–4090 GtC (from lowest and highest estimates above) substantially exceed the ~900 Gt carbon in unextracted fossil fuels (see Chapter 5 of WGI).

Deforestation, draining of peatlands, expansion of agricultural fields, livestock pastures, and human settlements, and other land use changes emitted carbon at a rate of 1.6 ± 0.7 Gt y^{-1} from 2010 to 2019, (Friedlingstein et al., 2020), of which wildfires and peat burning emitted 0.4 ± 0.2 Gt y^{-1} from 1997 to 2016 (van der Werf et al., 2017). Anthropogenic climate change has caused a portion of these emissions through increases in wildfire (Section 2.4.4.2.1) and tree mortality (Section 2.4.4.3.1) but the fraction of the total remains unquantified. Land use change produced ~15% of global anthropogenic emissions, from fossil fuels and land (Friedlingstein et al., 2020). Terrestrial ecosystems removed carbon from the atmosphere through plant growth at a rate of -3.4 ± 0.9 Gt y^{-1} from 2010 to 2019 (Friedlingstein et al., 2020).

Tropical deforestation and draining and burning of peatlands produce almost all of the carbon emissions from land use change (Houghton and Nassikas, 2017; Friedlingstein et al., 2020), while forest growth accounts for two-thirds of ecosystem carbon removals from the atmosphere (Pugh et al., 2019b). Global terrestrial ecosystems comprised a net sink of -1.9 ± 1.1 Gt y^{-1} from 2010 to 2019 (Friedlingstein et al., 2020), mainly due to growth in forests (Harris et al., 2021; Xu et al., 2021), mitigating ~31% of global emissions from fossil-fuel burning and land use change (Friedlingstein et al., 2020).

In summary, terrestrial ecosystems contain 3000-4000 Gt carbon in vegetation, permafrost, and soils, three to five times the amount of carbon in unextracted fossil fuels, and 4.4 times the carbon currently in the atmosphere (*robust evidence, high agreement*). Tropical deforestation, draining and burning of peatlands and other land use changes emit 0.9-2.3 Gt y^{-1} of carbon, ~15% of global emissions from fossil fuel and ecosystems (*robust evidence, high agreement*). Terrestrial ecosystems currently remove more carbon from the atmosphere, 2.5-4.3 Gt y^{-1}, than they emit, so tropical rainforests, Arctic permafrost, and other ecosystems provide the global ecosystem service of naturally preventing carbon from contributing to climate change (*high confidence*).

2.4.4.4.2 Observed stocks in high-carbon terrestrial ecosystems

The ecosystem that attains the highest aboveground carbon density in the world is coast redwood (*Sequoia sempervirens*) forest, in California, USA, with 2600 ± 100 t ha^{-1} carbon (Van Pelt et al., 2016). The ecosystem with the second highest documented carbon density in the world is mountain ash (*Eucalyptus regnans*) forest in Victoria, Australia, with ~1900 t ha^{-1} (Keith et al., 2009). Within the tropics, tropical evergreen broadleaf forests (rainforests) in the Amazon, the Congo, and Indonesia attain the highest carbon densities, reaching a maximum of 230 t ha^{-1} in the Amazon (Mitchard et al., 2014) and the Congo (Xu et al., 2017). Temperature increases reduce tropical rainforest aboveground carbon density 9.1 t ha^{-1} per degree Celsius, through reduced growth and increased mortality (Sullivan et al., 2020).

Tropical forests contain the largest vegetation carbon stock in the world, with 180–250 Gt of above- and belowground carbon (Saatchi et al., 2011; Baccini et al., 2012; Avitabile et al., 2016). The Amazon contains a carbon stock of 45–60 Gt (Baccini et al., 2012; Mitchard et al., 2014; Englund et al., 2017).

Ecosystems with high soil carbon densities include peat bogs in Ireland, with up to 3000 t ha^{-1} (Tomlinson, 2005), Cuvette Centrale swamp forest peatlands in Congo, with an average of ~2200 t ha^{-1} (Dargie et al., 2017), Arctic tundra, with an average of ~900 t ha^{-1} (Tarnocai et al., 2009), and mangrove peatlands in Kalimantan, Indonesia, with an average of 850 ± 320 t ha^{-1} (Murdiyarso et al., 2015). Arctic permafrost contains 1400 Gt ± 200 Gt to 3 m depth, the largest soil carbon stock in the world (Hugelius et al., 2014). Globally, peatlands contain 470–620 Gt carbon (Page et al., 2011; Hodgkins et al., 2018) of which boreal and temperate peatlands contain 415 ± 150 Gt (Hugelius et al., 2020) and tropical peatlands 80–350 Gt (Page et al., 2011; Dargie et al., 2017; Gumbricht et al., 2017; Ribeiro et al., 2021). Other analyses increase the upper estimates for boreal and temperate peatlands to 800-1200 Gt (Nichols and Peteet, 2019; Mishra et al., 2021b).

Tropical forests and Arctic permafrost contain the highest ecosystem carbon stocks in aboveground vegetation and soil, respectively, in the world (*robust evidence, high agreement*). These ecosystems form natural sinks that prevent the emission to the atmosphere of 1400-1800 Gt carbon that would otherwise increase the magnitude of climate change (*high confidence*).

2.4.4.4.3 Biodiversity and observed terrestrial ecosystem carbon

High biodiversity and ecosystem carbon generally occur together, with rainforests in the Amazon, the Congo, and Indonesia containing the largest aboveground vegetation carbon stocks (Saatchi et al., 2011; Baccini et al., 2012; Avitabile et al., 2016) and the highest vascular plant species richness (Kreft and Jetz, 2007) in the world. Aboveground ecosystem carbon and animal species richness show high correlation but also high spatial variability (Strassburg et al., 2010). Aboveground carbon is correlated to genus richness globally (Cavanaugh et al., 2014), but to species richness only in local areas (Poorter et al., 2015; Sullivan et al., 2017). Species richness generally increases vegetation productivity in the humid tropics while tree abundance increases productivity in drier conditions (Madrigal-Gonzalez et al., 2020). Across the Amazon, ~1% of tree species contain 50% of the aboveground carbon, due to abundance and maximum height (Fauset et al., 2015). Aboveground carbon in tropical forest shows positive correlations to vertebrate species richness (probability values not reported) (Deere et al., 2018; Di Marco et al., 2018). In logged and burned tropical forest in Brazil, species richness of plants, birds, and beetles increased with carbon density up to ~100 t ha^{-1} (Ferreira et al., 2018).

National parks and other protected areas, which, in June 2021, covered 15.7% of global terrestrial area (UNEP-WCMC, 2021), contain ~90 Gt carbon in vegetation and ~150 Gt carbon in soil (one-fifth and one-tenth, respectively, of global stocks) and remove carbon from the atmosphere at a rate of ~0.5 Gt y^{-1} (one-sixth of global removals) (Melillo et al., 2016). The most strictly protected areas contain carbon at higher densities, but illegal deforestation and fires in some protected areas emit 38 ± 17 Mt y^{-1} globally (Collins and Mitchard, 2017). In the Amazon, protected areas store more than half of the aboveground vegetation carbon stock of the region but account for only one-tenth of net emissions (Walker et al., 2020). Conservation of high biodiversity areas, particularly in protected areas, protects ecosystem carbon, prevents emissions to the atmosphere, and reduces the magnitude of climate change (*high confidence*).

2.4.4.4.4 Observed emissions and removals from high-carbon terrestrial ecosystems

Most global deforestation is occurring in tropical forests (Pan et al., 2011; Liu et al., 2015; Houghton and Nassikas, 2017; Erb et al., 2018a; Li et al., 2018; Harris et al., 2021), primarily for clearing of agricultural land (Hong et al., 2021), causing primary tropical forest to comprise a net source of carbon to the atmosphere from 2001 to 2019 (emissions to the atmosphere 0.6 Gt y^{-1}, removals from the atmosphere -0.5 Gt y^{-1}, net 0.1 Gt y^{-1}) (Harris et al., 2021). While wildfires emitted an average of 0.4 ± 0.2 Gt y^{-1} carbon from 1997 to 2016 (van der Werf et al., 2017), individual fire seasons can emit the same magnitude, such as the 0.4 Gt carbon from the Amazon fires of 2007 (Aragao et al., 2018), 0.5 Gt carbon from the Amazon fires of 2015-2016 (Berenguer et al., 2021) and 0.2 Gt from the Australia fires of 2019-2020 (Shiraishi and Hirata, 2021). So, wildfires account for up to one-third of annual average ecosystem carbon emissions, while major fire seasons can emit up to two-thirds of global ecosystem carbon emissions (*medium evidence, medium agreement*).

Primary boreal and temperate forests also comprised net sources in the period 2001-2019, but, when including all tree age classes, boreal, temperate, and tropical forests were net sinks, as growth exceeded permanent forest cover losses (Harris et al., 2021), though boreal and temperate forests are much stronger sinks (Pan et al., 2011; Liu et al., 2015; Houghton and Nassikas, 2017). Estimates of carbon removals from remote sensing may provide more accurate estimates of boreal forest carbon balances than earth system models, which overestimate regrowth after forest and timber (Wang et al., 2021a). Mortality of boreal forest in British Columbia from mountain pine beetle infestations converted 374 000 km^2 from a net carbon sink to a net carbon source (Kurz et al., 2008). Modeling suggests that a potential increase in water-use efficiency and regrowth could offset the losses in part of the forest mortality area (Giles-Hansen et al., 2021).

The Amazon as a whole was a net carbon emitter from 2003 to 2008 (Exbrayat and Williams, 2015; Yang et al., 2018b), primarily due to expansion of agricultural and livestock areas, which caused over two-thirds of deforestation from 1990 to 2005 (De Sy et al., 2015; De Sy et al., 2019). Four sites in the Amazon also showed net carbon emissions from 2010 to 2018, from deforestation and fire (Gatti et al., 2021). In the Amazon, deforestation emitted 0.17 ± 0.05 Gt y^{-1} carbon from 2001 to 2015 (Silva Junior et al., 2020) while fires emitted 0.12 ± 0.14 Gt y^{-1} carbon from 2003 to 2015 (Aragao et al., 2018). An analysis of the Amazon carbon loss from deforestation and degradation estimated a loss of 0.5 Gt y^{-1} from 2010 to 2019, with degradation accounting for three-fourths (Qin et al., 2021). Intact old-growth Amazon rainforest has been a net carbon sink (Hubau et al., 2020) but may have become a net carbon source from 2010 to 2019 (Qin et al., 2021).

In Indonesia and Malaysia, draining and burning of peat swamp forests for oil palm plantations emitted 60 – 260 Mt y^{-1} carbon from 1990 to 2015, converting peatlands in that period from a carbon sink to a source (Miettinen et al., 2017; Wijedasa et al., 2018; Cooper et al., 2020). Deforestation of mangrove forests emitted 10–30% of deforestation emissions in Indonesia from 1980 to 2005 (Donato et al., 2011; Murdiyarso et al., 2015), even though mangroves comprised only 3% of Indonesia primary forest area in 2000 (Margono et al., 2014; Murdiyarso et al., 2015).

In North America, wildfire emitted 0.1 ± 0.02 Gt y^{-1} of carbon from 1990 to 2012, but regrowth was slightly greater to produce a net sink (Chen et al., 2017). In California, USA, two-thirds of the 70 Mt carbon emissions from natural ecosystems from 2001 to 2010 came from the 6% of the area that burned (Gonzalez et al., 2015). Anthropogenic climate change caused up to half of the burned area (Section 2.4.4.2.1).

In the Arctic, anthropogenic climate change has thawed permafrost (Guo et al., 2020), leading to carbon emissions of 1.7 ± 0.8 Gt y^{-1} in the winter from 2003 to 2017 (Natali et al., 2019). Wildfires in Arctic tundra in Alaska from ~1930 to 2010 caused up to 0.5 m of permafrost thaw (Brown et al., 2015), exposing peatland carbon (Brown et al., 2015; Gibson et al., 2018), including soil carbon deposits up to 1600 years old (Walker et al., 2019).

Tropical deforestation, draining and burning of peatlands, and thawing of Arctic permafrost due to climate change have caused those ecosystems to emit more carbon to the atmosphere than they naturally remove through vegetation growth (*high confidence*).

2.4.4.5 Observed Changes in Primary Productivity

2.4.4.5.1 Observed changes in terrestrial primary productivity

The difference between photosynthesis by plants (gross primary productivity [GPP]) and plant energy use through respiration is the net growth of plants (net primary productivity [NPP]), which removes CO_2 from the atmosphere and mitigates emissions from deforestation and other land use changes (Section 2.4.4.4). Global terrestrial NPP has exceeded land use emissions since the early 2000s, making terrestrial ecosystems a net carbon sink (Friedlingstein et al., 2020).

Global terrestrial NPP increased 6% from 1982 to 1999, through increased temperature and increased solar radiation in the Amazon from decreased cloud cover (Nemani et al., 2003), then decreased 1% from 2000 to 2009, because of extensive droughts in the southern hemisphere (Zhao and Running, 2010). From 1999 to 2015, increased aridity caused extensive declines in the Normalized Difference Vegetation Index (NDVI) globally, particularly semi-arid ecosystems (Huang et al., 2016), indicating widespread decreases in NPP (Yuan et al., 2019).

Global terrestrial GPP increased 2% from 1951 to 2010 and continued increasing at least through 2016, with increased atmospheric CO_2 showing a greater influence than natural factors (Li et al., 2017; Fernandez-Martinez et al., 2019; Liu et al., 2019a; Cai and Prentice, 2020; Melnikova and Sasai, 2020). Global forest area increased 7% from 1982 to 2016, mainly from forest plantations and regrowth in boreal and temperate forests in Asia and Europe (Song et al., 2018), while regrowth in secondary forests > 20 years old, mainly in boreal, temperate, and sub-tropical regions, generated a net removal of 7.7 Gt y^{-1} CO_2 from the atmosphere from 2001 to 2019 (Harris et al., 2021). Vegetation growth that exceeds the modelled CO_2 fertilisation, gaps in field data, and incomplete knowledge of plant mortality and soil carbon responses introduce uncertainties into quantifying the magnitude of CO_2 fertilisation (Walker et al., 2021). A combination of CO_2 fertilisation of global vegetation and secondary forest regrowth has increased global vegetation productivity (*medium evidence, medium agreement*).

The relative increase in GPP per unit of atmospheric CO_2 increase declined from 1982 to 2015, indicating a weakening of any CO_2 fertilisation effect (Wang et al., 2020c). Increased growth from CO_2 fertilisation has begun to shorten the life span of trees due to a trade-off between growth rate and longevity, based on analyses of tree rings of 110 species around the world (Brienen et al., 2020). Furthermore, water availability controls the magnitude of NPP (Beer et al., 2010; Jung et al., 2017; Yu et al., 2017), including water from precipitation (Beer et al., 2010), soil moisture (Stocker et al., 2019), groundwater storage (Humphrey et al., 2018; Madani et al., 2020a), and atmospheric vapour (Novick et al., 2016; Madani et al., 2020b). Drought stress reduced NPP across tropical forests from 2000 to 2015 (Zhang et al., 2019b) and GPP in the tropics from 1982 to 2016 (Madani et al., 2020b). Drought stress has also reduced GPP in some semi-arid and arid lands (Huang et al., 2016; Liu et al., 2019a). In addition, nitrogen and phosphorus constrain CO_2 fertilisation (Terrer et al., 2019), though phosphorus limitation of tropical tree growth is species-specific (Alvarez-Clare et al., 2013; Thompson et al., 2019). NPP has decreased during some time periods and in some regions where drought stress has exerted a greater influence than increased atmospheric CO_2 (*medium evidence, high agreement*).

2.4.4.5.2 Observed changes in freshwater ecosystem productivity

Temperature affects primary productivity through moderating phytoplankton growth rates, ice cover, thermal stratification and growing season length (Rühland et al., 2015; Richardson et al., 2018). Global warming has reinforced eutrophication, especially cyanobacteria blooms (Wagner and Adrian, 2009; Kosten et al., 2012; O'Neil et al., 2012; De Senerpont Domis et al., 2013; Adrian et al., 2016; Visser et al., 2016; Huisman et al., 2018) (*very high confidence).* Conversely*,* warming can reduce cyanobacteria in hypertrophic lakes (Richardson et al., 2019). Freshwater cyanobacteria may benefit directly from elevated CO_2 concentrations (Visser et al., 2016; Ji et al., 2017; Huisman et al., 2018; Richardson et al., 2019).

Macrophyte growth in freshwaters is likely to increase with rising water temperatures, atmospheric CO_2 and precipitation (*robust evidence*, *high agreement*) (Dhir, 2015; Hossain et al., 2016; Short et al., 2016; Reitsema et al., 2018). Nonetheless, primary productivity in rivers is variable and unpredictable (Bernhardt et al., 2018) because seasonal variations in temperature and light are uncorrelated, frequent high flow events reduce biomass of autotrophs and droughts can strand and desiccate autotrophs.

In large, nutrient-poor lakes warming-induced prolonged thermal stratification can reduce primary production (*medium evidence*) (Kraemer et al., 2017). Warming may reduce phytoplankton concentrations when temperature-induced increases in consumption of phytoplankton outpace increases in phytoplankton production (De Senerpont Domis et al., 2013). These decreases in productivity may be under-recognised responses to climate change.

Summary: Evidence is *robust* for increase in primary production with warming trends, but increases or declines of algae cannot entirely be attributed to climate change; they are lake specific and modulated through weather conditions, lake morphology, salinity, land-use and restoration, and biotic interactions (*medium evidence*, *medium confidence*) (O'Beirne et al., 2017; Velthuis et al., 2017; Rusak, 2018; Ho et al., 2019).

2.4.5 Conclusions on Observed Impacts

The consistency of patterns of biological change with expectations from regional or global warming processes, coupled with an understanding of underlying processes, the coherence of these patterns at both regional and global scales, all form multiple lines of evidence (Parmesan et al., 2013) that it is *very likely* that observed range shifts and phenological changes in individual species can be attributed to regional and global climate changes *(very high confidence)* (Section 2.4.2, Table 2.2; Table 2.3; Table SM2.1; Parmesan et al., 2013).

Global and regional meta-analyses of diverse systems, habitats and taxonomic groupings document that approximately half of all species with long-term records have shifted their ranges poleward and/or upward in elevation and ~2/3 have advanced their timing of spring events (phenology) (Section 2.4.2, Table 2.2; Parmesan and Hanley, 2015; Parmesan, 2019). Changes in abundance tend to match predictions from climate warming, with warm-adapted species significantly out-performing cold-adapted species in warming habitats (Feeley et al., 2020) and the composition of local communities becoming more 'thermophilised' i.e., experiencing 'increase in relative abundance of heat-loving or heat-tolerant species' (Section 2.4.2.3; Cline et al., 2013; Feeley et al., 2020).

New studies since AR5, with more sophisticated analyses designed to capture complex responses, indicate that past estimates of the proportion of species impacted by recent climate change have been underestimates due to their unspoken assumptions that local or regional warming should lead solely to poleward/upward range shifts and advancements of spring timing (Duffy et al., 2019). More complex analyses have documented cases of winter warming driving delayed spring timing of northern temperate species due to chilling requirements, and increased precipitation driving species' range shifts downslope in elevation, and eastward and westward in arid regions *(high confidence).* Further new studies have shown that phenological changes have, in some cases, successfully compensated for local climate change and reduced degree of range shifts *(medium confidence).* Limited number of studies of this type make it difficult to estimate the generality of these effects globally (Section 2.4.2.5, Table 2.2).

Responses in freshwater species are consistent with responses in terrestrial species, including poleward and upward ranges shifts, earlier timing of spring plankton development, earlier spawning in fish, and extension of the growing season. Observed changes in freshwater species are strongly related to anthropogenic climate change driven changes in the physical environment (e.g. increased water temperature, reduced ice cover, reduced mixing in lakes, loss of oxygen, reduction in river connectivity). While evidence is high for an increase in primary production in nutrient rich lakes with warming trends (*high confidence*), increasing or declining algal formations are lake specific and modulated through variability in weather conditions, lake morphology, changes in salinity, stoichiometry, land-use and restoration measures, and food web interactions. In boreal coniferous forest, there has been an increase in terrestrial derived dissolved organic matter transported into rivers and lakes as a consequence of climate change (that has induced increases in run-off and greening of the northern hemisphere), as well as to changes in forestry practices. This has caused waters to become brown resulting in an acceleration of upper water warming and an overall cooling of deep water *(high confidence).* Browning may accelerate primary production through input of nutrients associated with DOM in nutrient poor lakes and increase cyanobacteria growth, which better cope with low light intensities (*medium confidence*) (Sections 2.4.2.1, 2.4.2.2, 2.4.2.3, 2.4.2.4).

Field research since the IPCC Fifth Assessment Report has detected biome shifts at numerous sites, poleward and upslope, that are consistent with increased temperatures and altered precipitation patterns driven by climate change, and support prior studies that attributed such shifts to anthropogenic climate change *(high confidence).* These new studies help fill prior geographic and habitat gaps, for example documenting upward shifts in the forest/alpine tundra ecotone in the Andes, Tibet and Nepal, and northward shifts in the deciduous/boreal forest ecotones in Canada. Globally, woody encroachment into open areas (grasslands, arid regions and tundra) is *likely* being driven by climate change and increased CO_2 in concert with changes in grazing and fire regime *(medium confidence)* (Section 2.4.3).

Climate change has driven or is contributing to increased tree mortality directly through increased aridity or drought and indirectly through increased wildfire and insect pests in many locations *(high confidence).* Analyses of causal factors have attributed increasing tree mortality at sites in Africa and North America to anthropogenic climate change and field evidence has detected tree mortality from drought, wildfire, and insect pests in temperate and tropical forests around the world *(high confidence)*. Water stress, leading to plant hydraulic failure, is ~~the~~ a principal mechanism of drought-induced tree mortality, along with indirect effects of climate change mediated through community interactions *(high confidence)* (Section 2.4.4.3).

Terrestrial ecosystems sequester and store globally critical stocks of carbon but these stocks are at risk from deforestation and climate change (*high confidence*). Tropical deforestation, draining, and burning of peatlands produce almost all of the carbon emissions from land use change. In the Arctic, increased temperatures have thawed permafrost at numerous sites, dried some areas, and increased fire, causing net emissions of carbon from soils *(high confidence)* (Sections 2.4.4.4, 2.5.3.4).

Globally, increases in temperature, aridity, and drought have increased the length of fire seasons and doubled potentially burnable area *(medium confidence)*. Increases in burnt area have been attributed to anthropogenic climate change in North America *(high confidence).* In parts of Africa, Asia, Australia, and South America, area burned have also increased, consistent with anthropogenic climate change. Deforestation, peat burning, agricultural expansion or abandonment, fire suppression, and inter-decadal cycles, strongly influence fire occurrence. Areas with the greatest increases in fire season length include the Amazon, western North America, western Asia, and East Africa. (Section 2.4.4.2)

The changes we have observed, and project to continue, in biodiversity and ecosystem health pose a risk of declines in human health and well-being: e.g. tourism, recreation, food, livelihoods and quality of life *(medium confidence).* Clear attribution of these impacts is often not possible, but inference can be made by comparison of observed changes in biodiversity / ecosystem health and known services from those particular ecosystems.

Table 2.3: Confidence in detecting and attributing observed changes in terrestrial and freshwater species and systems to climate change. Lines of evidence for attribution of observed changes to climate change and increased CO2 are used to support stated confidence in attribution of key statements on observed biological changes to climate change and increased atmospheric CO2. Icons represent lines of evidence. This is a summary table that is fully detailed in Table SM2.1 in Supplementary Material.

Lines of evidence:

Paleo data	Experiment	Long-term observations
Fingerprint of climate change response	Models	Complex statistical analysis

Key statement	Region	Period	Lines of evidence	Climate change attribution

About half of all species where land use change has been minimal have shifted their ranges, with 80–90% of movements being in the direction expected from regional warming trends – i.e. poleward and upward.	Global	Range 20 - 260 years		*robust evidence high agreement very high confidence*
Downslope elevational shifts and east-west shifts (shown for trees and birds) have been associated with regional increases in precipitation where precipitation has been shown to be the principal driver of a range boundary	USA	~ 40–60 years		*limited evidence, high agreement, medium confidence*
About two- thirds of all species with long-term (>20 years) records have shifted the timing of spring events in directions expected from regional winter and spring warming.	Global	Varies by study. Range: 20–400 years		*robust evidence high agreement very high confidence*
Winter chilling-depending species have delayed or not changed spring events despite spring warming countered by winter warming. When these species are taken into account, it is estimated that 92% of species in these studies have responded to regional warming trends	Northern Europe and USA	Varies by study. Range = 26–46 years		*medium evidence high agreement high confidence*
Anthropogenic climate change, acting through increased heat and aridity at global mean surface temperature increases of 0.6-0.9ºC, has increased the area burned by wildfire over natural levels, increasing burned area up to 11 times in one extreme year and doubling over natural levels in a 32-year period	western north America	1984–2017		*robust evidence high agreement high confidence*
Anthropogenic climate change has caused drought-induced tree mortality of up to 20% in three regions, through global mean surface temperature increases of 0.3-0.9ºC above the pre-industrial period and increases in aridity, more than non-climate change factors	North America and Africa	ca. 1945–2007		*medium evidence high agreement medium confidence*
Anthropogenic climate change has caused latitudinal and elevational vegetation biome shifts in at least 19 sites in boreal, temperate, and tropical ecosystems, between 1700 and 2007, through local temperature increases of 0.4 to 1.6ºC above the pre-industrial period more than non-climate change factors	Global	1500–2007		*robust evidence high agreement high confidence*
Anthropogenic climate change and wildfire together have altered vegetation species composition in at least two regions, reducing post-fire natural regeneration and species richness of tree and other plant species, at global mean surface temperature increases of 0.3-0.9ºC	western North America, Africa	1966–2015		*medium evidence high agreement medium confidence*

Beetles & moths shifting poleward and upward has brought new pest species into some forests; warming winters and longer growing season has increased destructive outbreaks of beetles and moths in temperate and boreal forests	North America, Europe	Varies by study		*medium-high confidence*
Exotic species are responding differently from native species in both abundance changes and phenological changes, but not in a consistent fashion	North America			*low/medium evidence low agreement*
The most cold-adapted species are generally declining in population abundances and contracting their ranges poleward and upward: (e.g. sea-ice dependent, mountain-top restricted, upper headwaters, coldest lakes)	Arctic, Himalayas , Antarctic, Alps			*medium confidence*
Diseases of both wildlife and humans have emerged into new areas they have not been in historically	Global	past 20–100 years		*medium confidence*
Warming has amplified the trophic state lakes are already in. Eutrophic lakes have become more productive while oligotrophic lakes tend to become more nutrient limited	Global	Past 20–50 years		*robust evidence high agreement high/medium confidence*
Woody encroachment into open (grassland, desert) systems has occurred, with climate change as one of the drivers, along with changes in grazing and other land uses	Global			*medium confidence*
In boreal, coniferous areas changes in forestry practices and climate change have caused an increase in terrestrial derived dissolved organic matter (DOM) transport into rivers and lakes leading to their browning	Boreal	Past decades		*robust evidence high agreement high confidence*
Climate change induced warming leads to shifts in thermal regime of lakes	Global	Past decades		*robust evidence high agreement high confidence*
Climate change causes gains and losses in freshwater water level	Global	Past decades		*limited evidence low confidence*
Greenhouse gas emissions from freshwater ecosystems are equivalent to around 20% of global burning fossil-fuel CO_2 emission	Global	Past decades		*medium evidence medium agreement medium/low confidence*
In lakes weather extremes in wind, temperature, precipitation and loss of ice foremost affect the thermal regime with repercussions on water temperature, transparency, oxygen and nutrient dynamics, affecting ecosystem functionality	North America, Europe	Varies by study		*medium/limited evidence high agreement medium/low confidence*

Climate change induced warming leads to shifts in thermal regime of rivers and streams; lowland rivers show a stronger thermal response than high-altitude, cold-water receiving streams	North America, Europe	Past decades		*robust evidence medium agreement high confidence*
Loss of biodiversity in streams can be directly attributed to climate change through increased water temperatures, hydrological changes such as increased peak discharges, flow alteration and droughts	Global	Past decades		*high agreement very high confidence*
Climate change is causing range shifts of freshwater fish	North America Europe	Past decades		*high agreement, high confidence*

2.5 Projected Impacts and Risk for Species, Communities, Biomes, Key Ecosystems and their Services

Under the Risk Assessment Framework that was introduced in AR5 (2014), risk means the probability of harmful consequences resulting from climate change. It results from the interaction of vulnerability, exposure, and hazard (see Chapter 1) and can be represented as the probability of occurrence of hazardous events or trends multiplied by the impacts if these events or trends occur (IPCC, 2014). The Framework defines vulnerability as a pre-existing condition, incorporating the extent to which species or ecosystems are susceptible to, or unable to cope with, adverse effects of climate change. Vulnerable species have limited adaptive capacity stemming from physiological and behavioural constraints, limited dispersal abilities and restricted resource requirements or capacities for distributional and genetic changes (Foden et al., 2019) (Foden et al., 2013; Cizauskas et al., 2017). Traits that render entire ecosystems vulnerable are harder to define, but it is clear that vulnerabilities are high in the coldest habitats, in those with limited geographic ranges such as low-lying islands, and in specialized, restricted habitats such as serpentine outcrops in California (Anacker and Harrison, 2012) and dry meadows in Fennoscandia and Tibet (Yang et al., 2018a). Ecosystem vulnerability can depend critically on the fates of plants that function as 'foundation species,' providing community biomass aboveground and below, structuring habitat for fauna and providing ecosystem services such as erosion control (Camac et al., 2021).

2.5.1 Projected Changes at Species and Community Levels

2.5.1.1 Assessment of Models and Sources of Uncertainties

Methods for projecting impacts of climate change on biodiversity can be classified into three types: 1) statistical models such as species distribution models (Elith and Leathwick, 2009); 2) mechanistic or process–based models (Chuine and Régnière, 2017) and 3) trait–based models (Pacifici et al., 2015). It is only recently that models have been developed looking at smaller levels of warming. such as 1.5°C (Hoegh-Guldberg et al., 2018a; Warren et al., 2018).

Species distribution models (SDMs) or niche-based models assess potential geographic areas of suitable climate for the species in current conditions and then project them into future conditions (Trisurat, 2018; Vieira et al., 2018). There are limitations in all models and it is critical that modellers understand the assumptions, proper parameterization, and limitations of each model technique, including differences among climate models, emission scenarios or representative concentration pathways, and baselines (Araujo et al., 2019). Several systems automate development of SDMs, including R-packages (e.g., (Beaumont et al., 2016; Hallgren et al., 2016), development of other model types (Foden et al., 2019) and aid in use of climate model data (Suggitt et al., 2017), including allowing for connectivity constraints (Peterson et al., 2013). Buisson et al. (2010) found most variation in model outputs stem from differences in design, followed by GCMs.

Mechanistic approaches, also known as process-based models, project species' responses to climate changes by explicitly incorporating known biological processes, thresholds and interactions (Morin and Thuiller, 2009; Maino et al., 2016). Mechanistic models are able to accommodate a broad range of climate change impact mechanisms and include species-specific characteristics such as dispersal distances, longevity, fecundity, genetic evolution, phenotypic plasticity. However, sufficient knowledge is available for only a few well-studied species. Species traits have been used to more broadly estimate potential climate change impacts (Foden et al., 2013; Cizauskas et al., 2017).

Most models are at large scales (20 km–50 km), and so cannot capture micro-climatic refugia generated by diversities of slope aspect, elevation or shade (Suggitt et al., 2015; Suggitt et al., 2018). In analyzing records of 430 climate-threatened and range-declining species in England, (Suggitt et al., 2015; Suggitt et al., 2018) showed that topographic diversity reduced population declines most strongly in areas experiencing the most local warming and in species most sensitive to warming. In these circumstances topographic diversity reduced population extinction risk by 22% for plants and by 9% for insects.

None of the modelling techniques are predictions of the future; they are projections of possible futures. To date, few studies have validated model performance against observations, and many of these have been on islands, reducing ability to generalize (Fordham et al., 2018). Species' models should be considered as hypotheses of what a future world might look like if the climate projections came to pass. Suggestions have been made on how to start bringing more biotic interactions into species distribution models (Early and Keith, 2019), but limited basic ecological understandings of interactions, along with limits on computation and funding, constrain how far and how fast these modelling techniques can advance.

2.5.1.2 Risk Assessment and non-modelling approaches

In order to add realism and reliability to risk assessments at the species and community levels, non-modelling approaches based on known biological traits or processes, as well as on expert opinion (Camac et al., 2021), are used to temper model outputs with ground-based validation. Trait-based assessment approaches use species' biological characteristics as predictors of sensitivity, adaptive capacity and extinction risk due to climate change. Climate exposure can be estimated using GIS-based modelling, statistical programs or expert judgment (Chin et al., 2010). These trait-based approaches are widely applied to predict responses of biodiversity to climate change because they do not require modelling expertise nor detailed distibutional data (Pacifici et al., 2015; Willis et al., 2015). Most of these methods have not been independently validated and do not allow direct comparison of vulnerability and risk among taxonomic groups.

Some studies have combined two or three approaches for climate change risk assessment of biodiversity in order to capture the advantages of each and avoid their limitations. Warren et al. (2013) used combinations of SDMs and trait-based approaches to estimate the proportions of species losing their climatically suitable ranges under the various future scenarios of climate and dispersal rate. Similarly, spatial projections of climate change exposure were combined with traits to assess vulnerability of sub-Saharan amphibians (Garcia et al., 2014). Laurance et al. (2012) combined 31 functional groups of species and 21 potential drivers of environmental change to assess both the ecological integrity and threats for tropical protected areas on a global scale. Keith et al. (2014) used a combination of three approaches (SDMs-trait-mechanistic) to determine how long before extinction a species would become eligible for listing as threatened based on the IUCN Red List criteria.

2.5.1.3 Risk of Species' Extinctions

2.5.1.3.1 Overview

This assessment of current findings is of studies across a range of taxa and modelling techniques. Extinction risk estimates whether or not a particular species may be at risk of extinction over the coming decades if climatic trends continue and usually does not take into account other human-induced stressors (e.g. invasive species or pollution). It is not a prediction that a species will definitely go extinct, because even complete loss of a species' range is projected, the scale of the model cannot estimate persistence in micro-climatic refugia (Suggitt et al., 2015; Suggitt et al., 2018). Individuals and populations can survive after conditions for successful reproduction are gone, leading to a lagged decline, called 'extinction debt' (Alexander et al., 2018). Therefore, range loss is an established criterion for assessing endangerment status and risk of extinction. As a species range becomes smaller and occupied habitats become more isolated, the likelihood of a single stochastic event causing extinction increases. It is this combination of projected loss of climatically suitable space and additional stressors (especially LULCC of critical habitat) that is expected to drive future extinctions.

The IUCN Red List Criteria (IUCN, 2019) classifies a species as 'critically endangered' if it has suffered a range loss of ≥80%, with a resulting likelihood of extinction of >50% in the near term (10-100 years, depending upon generation time). A species is classified as 'endangered' if it has suffered a range loss of ≥50%, with a resulting likelihood of extinction of >20% in the near term (10-100 years).

2.5.1.3.2 Projections for freshwater biodiversity

Lakes, rivers and freshwater wetlands cover approximately 7.7–9.1 % of global land surface area; (Lehner et al., 2008; Fluet-Chouinard et al., 2015; Allen and Pavelsky, 2018), and hold 9.5% of the Earth's described animals (Balian et al., 2008), with climate change indicated as a threat for 50–75% of fish (Xenopoulos et al., 2005; Darwall and Freyhof, 2015 who). Climate change is cited as a primary factor in species' extinction risk, through changes in water temperatures, stream flow, loss of cold water habitat, increased variability of precipitation, and increased disease risk from warming temperatures (*high evidence, high agreement, high confidence*) (Knouft and Ficklin, 2017; Pletterbauer et al., 2018; Reid et al., 2019; Jaric et al., 2019), adding to stress from overexploitation and LULCC (Craig et al., 2017; IPBES, 2019 Global assessment report).

Increased frequency of stream drying events, reducing hydrologic connectivity and limiting access of native fishes to spawning habitats is projected for RCP 8.5 in Colorado, USA (*medium evidence, medium agreement*) (Jaeger et al., 2014). Cold-water habitats and associated obligate species are particularly vulnerable and losses in these habitats have been both documented and projected, for example in salmonids (Santiago et al., 2016; Fullerton et al., 2017; Merriam et al., 2017). River networks are projected to lose connections to cold tributary refugia, that are important thermal refuges for cold water species *(robust evidence, high agreement)* (Isaak et al., 2016) during low flows (Merriam et al., 2017).

Community turnovers are expected in freshwaters as cold-adapted species lose and warm-adapted species gain climatically suitable habitat (Domisch et al., 2011; Domisch et al., 2013; Shah et al., 2014). While a number of warm-adapted species may experience range expansions, the majority of species are predicted to lose climatically suitable areas by on average 38–44%, depending on the emission scenario (A2a and B2a) (*medium evidence*) (Domisch et al., 2013).

Molluscs are projected to be the most at risk group, given their limited dispersal capability (Woodward et al., 2010). Mediterranean freshwater fish are especially susceptible to climate change due to increasing flood and drought events and risks of surpassing critical temperature thresholds (Santiago et al., 2016; Jaric et al., 2019). In southern Europe, aquatic insects (Ephemeroptera, Plecoptera, and Trichoptera) are endangered by climate change (Conti et al., 2014). European protected areas are not expected to be sufficient under warming to provide habitat for the majority of rare molluscs and fish (Markovic et al., 2014). Observed trends agree with model projections in direction, but magnitude remains uncertain (*medium evidence, medium agreement, medium confidence*). (see Figure 2.8 for extinction risk globally for dragonflies, amphibians and turtles).

Regional threats from climate change have been reported for 40% of amphibians in China, (Wu, 2020), 33% of European freshwater fish species (Janssen et al., 2016) and 56-69% of Odonates in Australia, (Bush et al., 2014b). Assessment of site-specific extirpation likelihoods for 88 aquatic insect taxa projected that climate-change induced hydrological alteration would result in a 30–40% loss of taxa in warmer, drier ecoregions and 10–20% loss in cooler, wetter ecoregions (*medium evidence*) (Pyne and Poff, 2017). In Africa's Albertine Rift, 51% (n=551) of fish are expected to be impacted by climate change, with 5.5% at high risk due to their sensitivity and poor adaptative capability (*high agreement*) (Carr et al., 2013).

The GLOBIO-Aquatic model (Janse et al., 2015 a) links models for demography, economy, land use changes, climate change, nutrient emissions, a global hydrological model and a global map of water bodies. It projects that changes in both water quality (eutrophication) and quantity (flow) will generate negative relations in freshwater ecosystems between persistence of species originally present in each community and a constellation of stressors, including harmful algal blooms. Under 4°C rise by 2050, mean abundance of species is projected to decline by 70% in running water and 80% in standing water (*medium evidence, high agreement, medium confidence*) (Janse et al., 2015 a).

2.5.1.3.3 Global projections of extinction risk

In prior reports, risk assessed from the literature was generally based on estimates of overall range contractions with climate change. In AR4, extinction risk was carefully quantified: 'There is *medium confidence* that approximately 20–30% of species assessed so far are *likely* to be at increased risk of extinction if increases in global average warming exceed 1.5–2.5°C (relative to 1980 to 1999). As global average temperature increase exceeds about 3.5°C, model projections suggest significant extinctions (40–70% of species assessed) around the globe.' These estimates approximately correspond to 50% reductions in range size (IPCC, 2007a). AR5 stated 'a large fraction of terrestrial and freshwater species face increased extinction risk under projected climate change during and beyond the 21st century, especially as climate change interacts with other pressures ... (*high confidence*)' (Field et al., 2014). A series of multi-species and global analyses have been published since AR5, using both statistical models and trait-based approaches.

In this Chapter, risk to species, with implications for ecosystems, is assessed using three different approaches. First is an assessment of the geographic distributions of species' losses at different levels of GAST warming, termed 'biodiversity loss, measured as the proportion of species within a given location becoming classified as 'endangered' or 'critically endangered' (sensu IUCN). This measure provides estimates of which sites are at most risk of losing substantial numbers of species locally, leading to degradation of that ecosystems' ability to function. Second is an assessment of risk of proportions of species' becoming extinct globally at different levels of GAST warming, measured using the IUCN criteria for 'critically endangered', and termed 'species' extinction risk'. This measure is closest to assessing the complete loss of a species in the wild, and can be used to compare to past (paleo) extinction rates. Third is an assessment of proportions of species becoming rare or endangered globally (not just locally), and is the foundation for the Burning Embers on biodiversity risk in Figure 2.11. These three approaches provide complementary information of the overall risks to biodiversity and ecosystem integrity under different warming levels.

Biodiversity risk, estimated as the proportion of species in a given area projected to become endangered (sensu IUCN), is projected to affect a greater number of regions with increasing warming, with about one-third of land area risking loss of >50% of species currently inhabiting those ecosystems. Species' losses are projected to be worst in the northern South America, southern Africa, most of Australia, and northern high latitudes *(medium confidence)* (Figure 2.6).

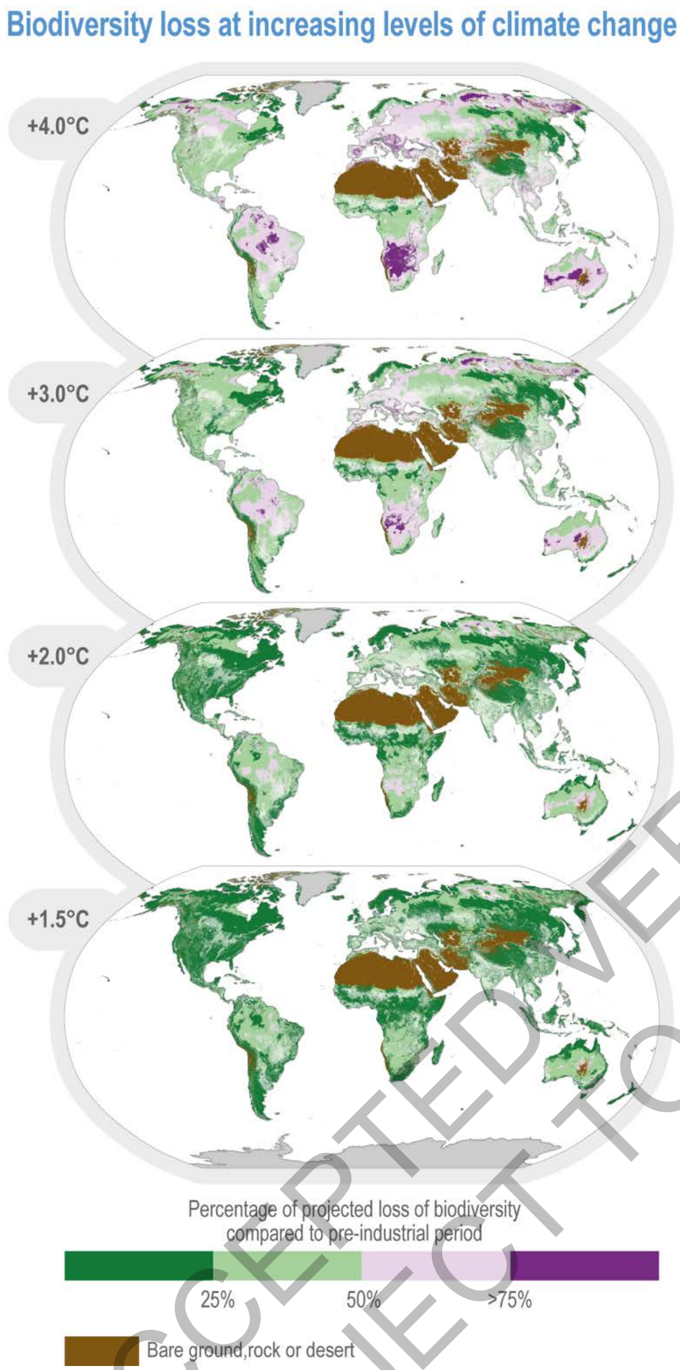

Figure 2.6: Biodiversity loss at increasing levels of climate change. The higher the percent of species projected to lose suitable climate in a given area, the higher the risk to ecosystem integrity, functioning and resilience to climate change. Warming levels are based on global levels (GSAT) above pre-industrial temperatures. Colour shading represent proportion of species for which the climate is projected to become unsuitable within a given pixel across their current distributions at a given GSAT warming level, based on the data underpinning (Warren et al., 2018) (modelled n=119,813 species globally, with no dispersal, averaged over 21 CMIP5 climate models). Areas shaded in green are above the 50% biodiversity loss threshold, meaning that <50% of species in that area are projected to go locally extinct. Areas shaded in pink and purple represent significant risk of biodiversity loss (areas where climates become unsuitable, rendering them locally extinct, for >50% and >75% of species, respectively). The maps of species richness remaining have been overlaid with a landcover layer (2015) from the European Space Agency Climate Change Initiative. This landcover layer leaves habitats classified by the ESA as natural as being transparent, cities as black, water as blue, permanent snow/ice as white and bare/rock as dark brown. Areas with a landcover identified as agriculture are 5% transparent, such that potential species richness remaining if the land had not been converted to agricultural shows as pale shading of the legend colours (very pale pink or very pale green). These paler areas represent biodiversity loss due to habitat destruction, but with a potential to be restored, with green shading having potential for restoration to higher species richness than pink and purple shadings.

Risk of species' becoming extinct globally was estimated as the probability of loss of suitable climate space rendering it critically endangered (sensu IUCN). It is *likely* that the percentage of species at high risk of extinction (median and maximum estimates) will be 9% (max 14%) at 1.5°C, 10% (max 18%) at 2°C, 12% (max 29%) at 3.0°C, 13% (max 39%) at 4°C and 15% (max 48%) at 5°C (Figure 2.7). Among groups containing largest numbers of species at high risk of extinctions for mid-levels of projected warming (3.2°C) are: invertebrates (15%), specifically pollinators (12%), amphibians (11%, but salamanders are at 24%) and flowering plants (10%) (Figure 2.8a). All groups fare substantially better at 2°C, with extinction projectionsreducing to <3% for all groups, except salamanders at 7% *(medium confidence)* (Figure 2.8a). Even the lowest estimates of species' extinctions (9%) are 1000x natural background rates (Section 2.5.4; De Vos et al., 2015). Projected species' extinctions at future global warming levels are in accord with projections from AR4, assessed on much larger numbers of species with much greater geographic coverage and a broader range of climate models. (Figure 2.7; Figure 2.8)

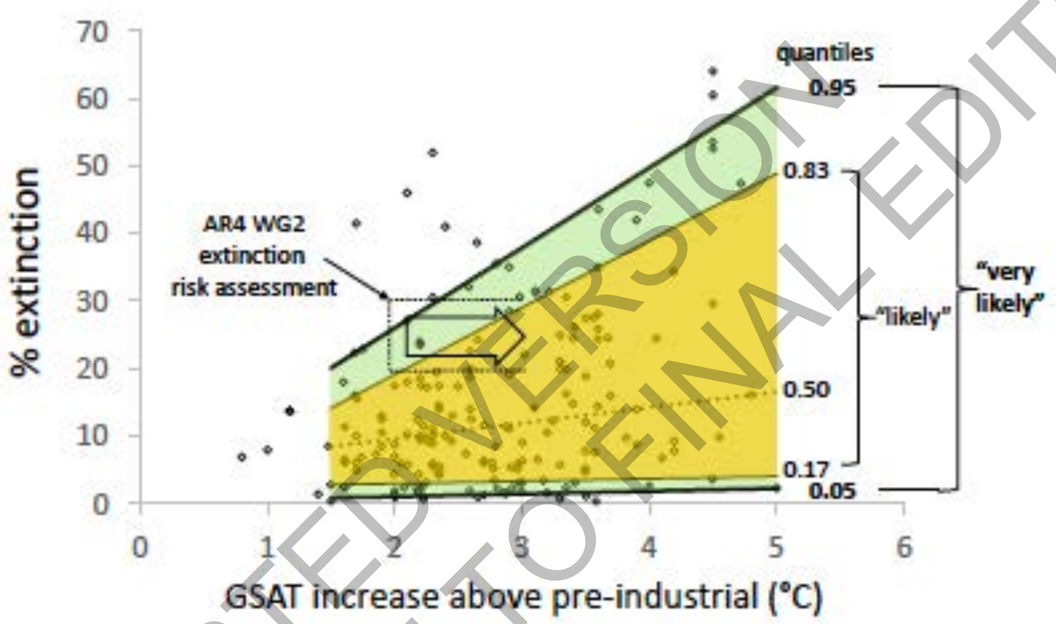

Figure 2.7: Synthesis of modelled climate-driven extinction risk studies. The relationship between modelled projections of extinction (expressed as a proportion of species at risk of extinction assessed in individual studies) and GSAT increase above the pre-industrial average. Data (global sample size n = 178 modelled estimates) were sourced from a number of sources, including digitization of data points in Figure 2 in the synthetic analysis of (Urban, 2015), note: unweighted for sample size, n = 126); Table 4.1 of the AR4 WG2 chapter 2 (Fischlin et al., 2007), n = 40; (Hannah et al., 2020) n = 6); and (Warren et al., 2018) n = 6). The. Quantile regression (which is robust to the non-normal distribution of the response variable, and less sensitive to data outliers) was used to fit quantile estimates for levels relevant to informing *"likely"* (between the 0.17 and 0.83 quantiles, shaded in orange) and "very likely" ranges (between the 0.05 and 0.95 quantiles, shaded in green) relating extinction risk to GSAT increase (Quantile regression implemented using the Barrodale and Roberts algorithm in XLSTAT). The roughly equivalent estimate of this risk as expressed in AR4 (Fischlin et al., 2007) is indicated by the dotted block indicating the medium confidence statement "Approximately 20 to 30% of plant and animal species assessed so far (in an unbiased sample) are likely to be at increasingly high risk of extinction as global mean temperatures exceed a warming of 2 to 3°C above preindustrial levels *(medium confidence)."* This box is open on the right-side because AR4 estimates stipulated temperatures at or exceeding given levels.

Projections of extinction risk by taxa are presented both for risk of becoming critically endangered (losing ≥80% of suitable climate habitat, Figure 2.8a) and endangered (losing ≥50% of suitable climate habitat, Figure 2.8b). The percentages of species projected at risk of becoming endangered (or worse) was 49% for insects, 44% for plants, and 26% for vertebrates at ~3°C global rise in temperature (Warren et al., 2018). Those estimates dropped considerably at lower levels of warming, down to 18%, 16%, and 8% at 2°C; and 6%, 8% and 4% at 1.5°C (Warren et al., 2018); thus not entirely dis-similar to the numbers in AR4 (Figure 2.7). Figure 2.8 shows the benefits of dispersal in offsetting extinction risk in birds, mammals, butterflies, moths and dragonflies. While dispersal may benefit individual species, it poses additional risks to communities and ecosystems as interactions between species are changed or eliminated.

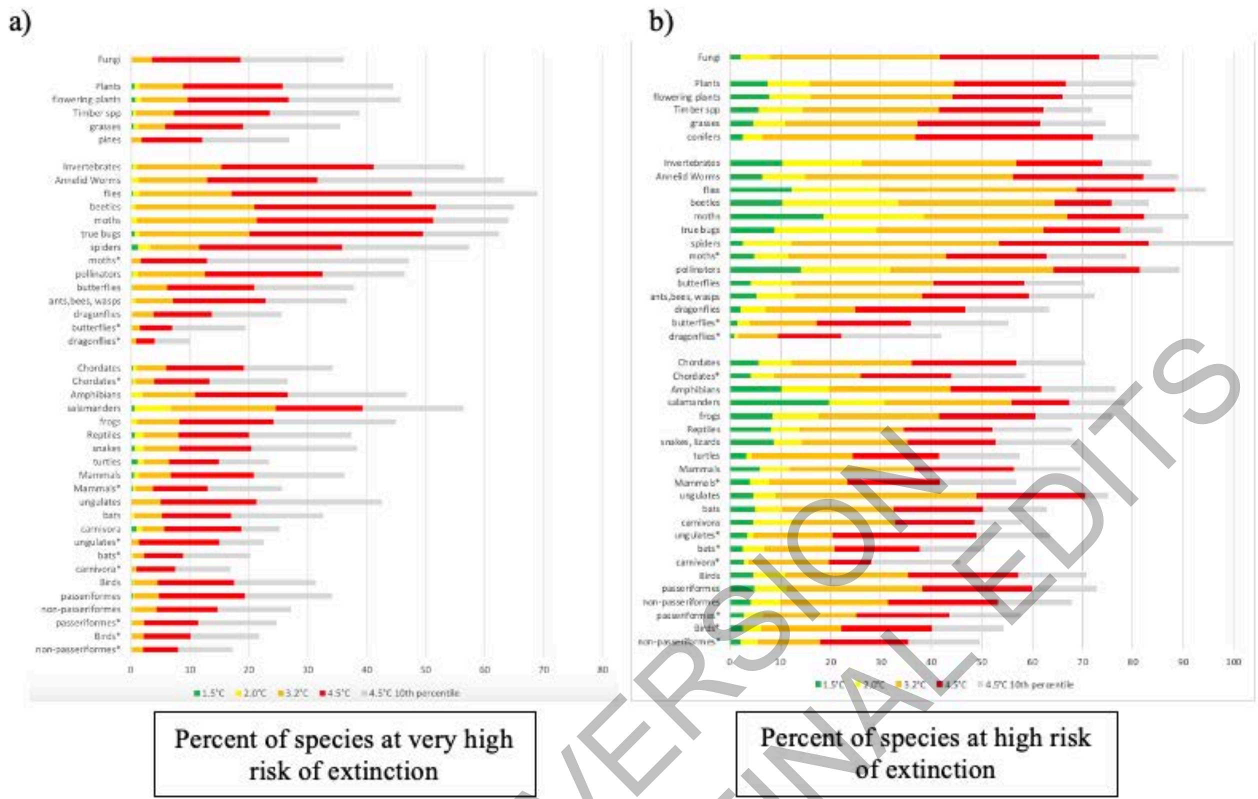

Figure 2.8: Percent of species of different groups classified as being under risk of extinction. a) Percent of the species group listed projected to be at very high risk of extinction, corresponding to the IUCN Red List criteria for a species classified as "critically endangered" (version 3.1) through losing >80% of its climatically suitable range area. b) Percent of the species group listed projected to be at high risk of extinction, corresponding to the IUCN Red List criteria for a species classified as "endangered" (version 3.1) through losing >50% of its climatically suitable range area. For a) and b), values calculated from the underlying data underpinning (Warren et al., 2018). Values for each temperature are the mean values across 21 CMIP5 models. The grey band represents the high-end of extinction risk from the 10th percentile of the climate models to show the maximum range of values while the low end (90th percentile, 1.5°C) is not shown as it is too small to appear on the plots. Taxa marked with * represent potential benefits from adaptation, specifically dispersal at realistic rates (Warren et al., 2018); those with no * have dispersal rates that are essentially not detected in the spatial resolution of the models (20 km). See (Warren et al., 2018) for caveats and more details. Sample size for each group is as follows: Invertebrates (33949), Annelid Worms (155), Butterflies (1684), Moths (6910), Dragonflies (599), Pollinators (1755), Spiders (2212), Beetles (7630), True Bugs (1728), Bees/Ants/Wasps (5914), Flies (4809), Plants (72399), Flowering Plants (52310), Conifers (340), Timber spp (1328), Grasses (3389), Fungi (16187), Vertebrates (12642), Mammals (1769), Carnivores (107), Ungulates (80), Bats (500), Birds (7968), Passeriformes (4744), Non-passeriformes (3224), Amphibians (1055), Frogs (887), Salamanders (163), Reptiles (1850), Snakes (1741), Turtles (94).

For local biodiversity loss, at 1.58°C (median estimate), >10% of species are projected to become endangered (sensu IUCN); at 2.07°C (median) >20% of species are projected to become endangered, representing high and very high biodiversity risk, respectively *(medium confidence)* (see Section 2.5.4; Figure 2.11; Table 2.5, Table 2.S.4).

Using data from geological time scales, Song et al. (2021) predicted that a warming of 5.2 °C above pre-industrial would result in mass extinction comparable to that of the five mass extinctions over the past 540 My, on the order of 70–85% of species going extinct, in the absence of non-climatic stressor. Mathes et al. (2021) found evidence in the geological record that short-term rapid warming, on top of long-term warming trends, increases extinction risk by up to 40% over that expected from the long-term trend alone, with a biodiversity 'memory' up to 60 Myr, indicating an additonal risk of multi-decadal overshoot.

Most of the large-scale studies that have been performed are for losses based on climate alone (Figures 2.6, 2.7, 2.8). However, climate is rarely the only stressor affecting species survival. Habitat loss is currently the largest driver of range loss and extinction risk for most species (IUCN). Communities in different regions are becoming more similar to each other as species tolerant of human activities prosper and spread, with many rare and endemic species already having been driven extinct, primarily by LULCC (Pimm et al., 2006). Thus, it will likely be the interaction of climate change and habitat conversion (often also being driven by climate change) that will ultimately determine the risk and ability to survive of many species.

2.5.1.4 Changing Risks of Diseases

Multiple studies predict increases in disease incidence or geographic and phenological changes of pathogens, vectors, and reservoir host species due to climate change with or without other non-climatic variables (González et al., 2010; Moo-Llanes et al., 2013; Roy-Dufresne et al., 2013; Liu-Helmersson et al., 2014; Laporta et al., 2015; Ryan et al., 2015; Haydock et al., 2016; Hoover and Barker, 2016; Prist et al., 2017; Blum and Hotez, 2018; Dumic and Severnini, 2018; Hundessa et al., 2018; Ryan et al., 2019; Ryan et al., 2021). However, models predicting changes in infectious disease risk are complex and sometimes produce conflicting results and lack consensus (Caminade et al., 2014; Giesen et al., 2020). For example, malaria is projected to increase in some regions of Africa, Asia, and South America by the end of the 21st century if public health interventions are not sufficient, but malaria is also forecasted to decrease in some of the higher risk areas (Peterson, 2009; Caminade et al., 2014; Ryan et al., 2015; Khormi and Kumar, 2016; Leedale et al., 2016; Murdock et al., 2016; Endo and Eltahir, 2020; Mordecai et al., 2020).

While malaria risk is predicted to decrease in some lowland tropical areas as temperatures become too hot for vector or parasite development, other, warmer-adapted diseases like dengue and Zika, transmitted by *Aedes aegypti*, are predicted to increase (Ryan et al., 2019; Ryan et al., 2021). In more temperate regions, arboviruses and other vector-borne diseases with wider thermal breadths, such as West Nile fever, Ross River fever, and Lyme disease, are predicted to increase with climate warming (Ogden et al., 2008; Leighton et al., 2012; Shocket et al., 2018; Shocket et al., 2020; Couper et al., 2021), and drought can exacerbate these effects of temperature (Paull et al., 2017).

A global analysis of 7346 wildlife populations and 2021 host-parasite combinations found that organisms adapted to cool and mild climates are likely to experience increased risks of outbreaks with climate warming while warm-adapted organisms may experience lower disease risk, providing further support for predictions that climate change will increase infectious disease transmission in higher latitude regions across a taxonomically diverse array of pathogens (*robust evidence, high confidence*) (Cohen et al., 2020). A study examining the future risk of arboviruses (chikungunya, dengue, yellow fever, and Zika viruses) spread by *Aedes aegypti* and *Ae. albopictus* projected increased disease risk due to interactions of multiple variables, including increased human connectivity, urbanisation and climate change (Kraemer et al., 2019), although vector species' ranges broaden only slightly (Campbell et al., 2015).

In sum, climate change is expected to expand and redistribute the burden of vector-borne and other environmentally-transmitted diseases by shifting many regions toward the thermal optima of vector-borne disease transmission for multiple parasites, increasing transmission, while pushing temperatures above optima and toward upper thermal limits for other vectors and pathogens, decreasing transmission (Mordecai et al., 2019; Mordecai et al., 2020). These effects are mediated by other human impacts such as land use change, mobility, socio-economic conditions, and vector and pathogen control measures (Parham et al., 2015; Tjaden et al., 2018).

2.5.2 Projected Changes at Level of Biomes and Whole Ecosystems

2.5.2.1 Global Overview, Assessment of Ecosystem-level Models, and Sources of Uncertainties

Shifts in terrestrial biome and changes in ecosystem processes in response to climate change are most frequently projected with dynamic global vegetation models (DGVMs), or land-surface models that form part of Earth System Models, which use gridded climate variables, atmospheric CO_2 concentration and information on soil properties as input variables. Since AR5, most of DGVMs have been upgraded to capture carbon-nitrogen cycle interactions (e.g. Le Quéré et al., 2018), many also include a representation of wildfire, and fire-vegetation interactions (Rabin et al., 2017), and a small number now also accounts for land management (such as wood removal from forests, crop fertilisation harvest of irrigation (Arneth et al., 2017). Other forms of disturbance, such as tree mortality in response to, for example, episodic weather extremes or insect pest outbreaks, are relatively poorly represented, or not at all, although they demonstrably impact calculated carbon cycling (Pugh et al., 2019a). Simulated biome shifts are generally in agreement in projecting broad patterns at the global scales, but vary greatly regarding the simulated trends in historical and future carbon uptake or losses, both regionally and globally (WGI, Chapter 5 AR6; Chang et al., 2017).

Similar to other models, models to project large-scale changes in vegetation and ecosystem processes have to deal with structural uncertainty (associated with the choice and the representation of processes in models), input-data uncertainty (associated with variability in initial conditions and parameter values) and error propagation (associated with coupling models) (Rounsevell et al., 2019). The IPBES methodological assessment report on scenarios and models of biodiversity and ecosystem services provides a comprehensive overview over the relevant issues (Ferrier et al., 2016).

In order to assess the model's performance, most models have been individually evaluated against a range of observations. Moreover, in the annual updates of the global carbon budgets a model has to meet a small set of basis criteria to have its output included (Le Quéré et al., 2018). More systematic benchmarking approaches have also been proposed that utilise a range of different data sets (Kelley et al., 2013; Chang et al., 2017), in order to assess multiple simulated processes. These methods in principle allow to assign quality scores to models based on their overall performance (Kelley et al., 2013). So far, this scoring does not yet allow a clear quality ranking of models since the individual DGVMs tend to score well for some variables and badly for others. A recent comparison of global fire-vegetation model outputs was also able to clearly identify outliers when using a formalised benchmarking and scoring approach (Hantson et al., 2020). However, benchmarking does not address sources of uncertainty and it would be advisable to perform "perturbed-physics" experiments, in which multiple model parameters are varied in parallel more frequently, as a means to test parameter-value uncertainty (Wramneby et al., 2008; Booth et al., 2012; Lienert and Joos, 2018).

Species diversity impact ecosystem functioning and hence ecosystem services (Hooper et al., 2012; Mokany et al., 2016). So far, however, integrated modelling of ecosystem processes and biodiversity across multiple trophic levels and food webs is in its infancy (Harfoot et al., 2014). Whether or not enhanced integration of state, function, and functional diversity across multiple trophic levels in models will markedly alter projections of how ecosystems respond to climate change thus remains an open research question.

Beyond simulating dynamically biome shifts and carbon cycling, which are important aspects of climate regulation, DGVMs can also provide information on a number of variables closely linked to other ecosystem services, such as water availability, air quality or food provisioning (Krause et al., 2017; Rabin et al., 2020). However, they are not intended to provide a comprehensive assessment of ecosystem services. For these, other approaches applied, but to date these are mostly applied on regional scales and are only weakly dynamic (Ferrier et al., 2016).

2.5.2.2 Projected Changes Globally at the Biome Level

Climate change and the associated change in atmospheric CO_2 levels already exacerbate other human-caused impacts on structure and composition of land and freshwater ecosystems, such as land-use change, nitrogen deposition, of pollution. The relative importance of these drivers for ecosystems over the coming decades will likely differ between biomes, but climate change and atmospheric CO_2 will be pervasive unless we manage to rapidly limit fossil-fuel emissions and warming (*high confidence*) (Pereira et al., 2010; Warren, 2011; Ostberg et al., 2013; Davies-Barnard et al., 2015; Pecl et al., 2017; Ostberg et al., 2018). Global vegetation and Earth system models agree on climate-change driven shifts of biome boundaries potentially of hundreds of km over this century, combined with several substantial alterations that take place within biomes (e.g., changes in phenology, canopy structure and functional diversity, etc.). Large discrepancies exist between models and between scenarios regarding the region and the speed of change (Gonzalez et al., 2010b; Pereira et al., 2010; Pecl et al., 2017), but robust understanding is emerging in that the degree of impact increases in high emission and warming scenarios (*high confidence)* (Figure 2.9).

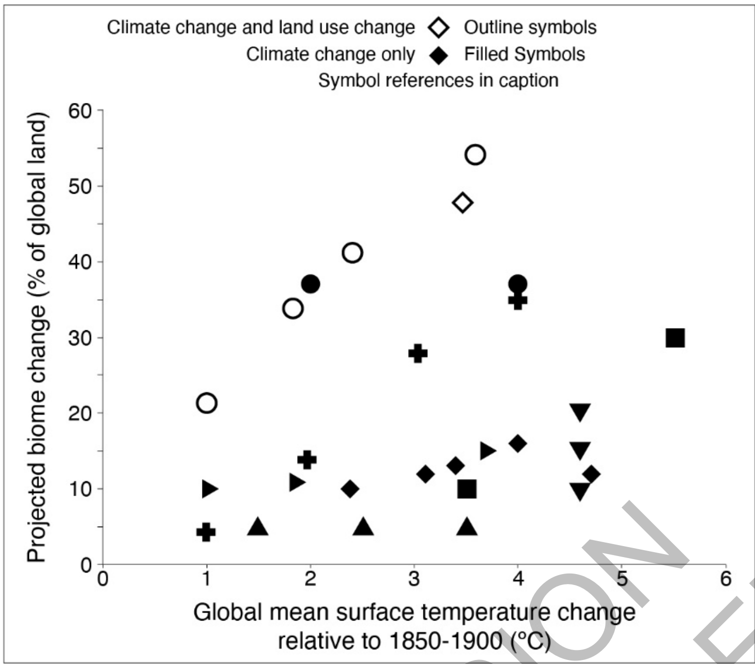

Figure 2.9: Projected fraction of global terrestrial area that could experience a biome shift by 2100, due to climate change (filled symbols) or a combination of climate change and land use change (outline symbols), from publications in Supplementary Table 2.S.3 (Projected vulnerabilities and risks of ecosystems to biome shifts). Circle filled (Bergengren et al., 2011), square filled (Alo and Wang, 2008), diamond filled (Gonzalez et al., 2010b), triangle up filled (Scholze et al., 2006), triangle down filled (Sitch et al., 2008), triangle on side filled (Li et al., 2018), cross filled (Warszawski et al., 2013), circle outline (Ostberg et al., 2018), diamond outline (Eigenbrod et al., 2015).

Substantial changes in vegetation structure and ecosystem processes are already happening (see section 2.4). Many of these observations have already been projected to take place as early as at least IPCC AR3 (Rosenzweig et al., 2007), and can they now be increasingly tested for their robustness with observational evidence. These multiple changes in response to warming (and changes in precipitation and increasing atmospheric CO_2 levels that go hand-in-hand with the warming) are further expected for already relatively small additional temperature increases, in particular in cold (boreal, tundra) regions, as well as in dry regions (*high confidence*): alterations of 2–47% of the areal extent of terrestrial ecosystems in scenarios of <2°C warming above pre-industrial have been projected, increasing drastically with higher-warming scenarios (Warren, 2011; Wårlind et al., 2014). More recent work, applying also probabilistic methods confirm the risk of drastic changes in vegetation cover (e.g. forest to non-forest or vice versa) at the end of the 21st century even for ca. 2°C warming scenarios, especially in tundra, and in tropical forest and savannah regions, with more subtle changes (within a given biome types) likely to occur in all regions (Ostberg et al., 2013; Ostberg et al., 2018). Model studies have found 5–20% of terrestrial ecosystems affected by warming ca. 2–3ºC, increasing to above one-third at a warming of 4–5ºC (Ostberg et al., 2013; Warszawski et al., 2013).

In general, vegetation types are projected to be moving into their 'neighbouring' climates, depending on whether temperature or precipitation is expected to be the predominant factor, and how vegetation interacts with the increasing CO_2 levels in the atmosphere (Wårlind et al., 2014; Scheiter et al., 2015; Schimel et al., 2015; Huntzinger et al., 2017). For instance, boreal or temperate forest vegetation is simulated to migrate polewards, closed tropical (moist) forest is expected to transition towards dry tropical forest types, while climate-driven degradation might expand arid vegetation cover (Sections 2.5.4.2.1-2.5.4.2.5) However, 'novel ecosystems', that is, communities with no current or historical equivalent because of the novel combinations of abiotic conditions under climate change, are expected to be increasingly common in the future (*medium confidence)* although the regions where these novel ecosystems might emerge are still disputed (Reu et al., 2014; Radeloff et al., 2015; Ordonez et al., 2016). The possibility of these novel ecosystems and the communities that live within them poses challenges to current modelling of ecosystem shifts, and will require new approaches to conservation that are designed to adapt to rapid changes in species composition and ensuing conservation challenges.

2.5.2.3 Risk to Arid Regions

Shifts in arid system structure and functioning that have been observed to date (section 2.4.3.3) are projected to continue and include widespread woody plant encroachment, notably in savanna systems in Africa, Australia and South America, and attributed to interacting land use change, climate change, and CO_2 fertilisation effects (Fensholt et al., 2012a; Fang et al., 2017; Stevens et al., 2017). Arid Mongolian Steppe grassland did not respond to experimentally elevated CO_2 (Song et al., 2019). Woody encroachment is projected to continue or not reverse in North American drylands (Caracciolo et al., 2016), and in southern African arid ecosystems (Moncrieff et al., 2014b). Dryland woody encroachment may increase carbon stocks, depending on emissions scenario (Martens et al., 2021), but reduce soil water and biodiversity of grassland-dependent species diversity (Archer et al., 2017). Warm season (C4) grass expansion into arid shrublands risks sudden ecosystem transformation due to introduced wildfire (Bradley et al., 2016), a risk anticipated for grass-invaded desert ecosystems of Australia and south-western United States (Horn and St. Clair, 2017). Novel fire regimes in grassy shrublands have enhanced grass cover locally in southern African Nama-Karoo (du Toit et al., 2015).

Range retractions are projected for endemic plants in southern Africa (Young et al., 2016) and dry woodlands in Morocco (Alba-Sánchez et al., 2015). Increasing thermal stress is projected to increase woody plant mortality in Sonoran Desert ecosystems (Munson et al., 2016), and facilitate perennial grass replacement by xeric shrubs in the south-western USA (Bestelmeyer et al., 2018). Ecological effects may occur rapidly when extreme events compound long-term trends (Hoover et al., 2015), but evolve more slowly as opportunity costs accumulate due to warming (Cross-Chapter Paper 3; Cunningham et al., 2021).

2.5.2.4 Risk to Mediterranean-type Systems

All Mediterranean Type Ecosystems (MTEs) show *high confidence* in projected increases in the intensity and frequency of hot extremes and decreases in the intensity and frequency of cold extremes and *medium confidence* in increasing ecological drought due to increased evapotranspiration (all regions) and reduced rainfall (excluding California, where model agreement is low) (see Chapter 11 of WG1). Projections also show a robust increase in the intensity and frequency of heavy precipitation in the event of 2° C warming or more for MTEs in South Africa, the Mediterranean Basin and California, but are less clear for Australia and Chile (see Chapter 11 of WG1).

MTEs are characterised by the distinctive seasonal timing of precipitation and temperature and disruption of this regime is likely to be critical for their maintenance. Unfortunately, projections of changes in rainfall seasonality have received less attention and are far more uncertain than many other aspects of climate change (Pascale et al., 2016; Breinl et al., 2020), limiting our ability to predict the ecological consequences of climate change in MTEs. Responses to experimental manipulation of rainfall seasonality show potential for shifts in plant functional composition and diversity loss, but results vary with soil type (van Blerk et al., 2021).

Unfortunately, global and regional scale dynamic vegetation models show poor performance for large areas of MTEs, because they do not characterise shrub and CAM-photosynthetic plant functional types well (Moncrieff et al., 2015). Furthermore, the grain of these models are too coarse for quantifying impacts to many vegetation formations which are patchy or of limited extent (e.g. forests). There is *high confidence* that observations of high mortality in trees and other growth forms, reduced reproductive and recruitment success, range shifts, community shifts towards more thermophilic species, and type conversions are set to continue, either due to direct climate impacts through drought and other extreme weather events, or their interaction with factors like fire and pathogens (Sections 2.4.3.6; 2.4.4.2; 2.4.4.3; 2.5.4.2.4; 2.5.5.2).

Fire is a key driver across most MTEs due to summer-dry conditions. Climate projections for the MTEs translate into high confidence that periods of low fuel moisture will become more severe and prolonged and that episodes of extreme fire weather will become more frequent and severe (see Chapter 11, Section 8.3 WGI). This will lead to the birth of novel fire regimes in MTEs characterised by an increase in the probability of greater burned area and extreme wildfire events (e.g. megafires), with associated loss of human life and property, and long-term impacts on ecosystems and accelerating the possible loss of resilience and capacity to recover (Abatzoglou and Williams, 2016; González et al., 2018; Boer et al., 2020; Moreira et al., 2020; Nolan et al., 2020; Duane et al., 2021; Gallagher et al., 2021).

Fire is virtually certain to have additional impacts through compound events (AR6 WGI Chapter 11.8). Extreme postfire weather is extremely likely to continue to impact diversity (Slingsby et al., 2017), retard vegetation regrowth (Slingsby et al., 2020a) and accelerate vegetation shifts (Batllori et al., 2019). Any increases in the intensity and frequency of heavy precipitation are highly likely to compromise soil stability in recently burnt areas (Morán-Ordóñez et al., 2020). The impacts of fire often depend on interactions with non-climatic factors such as habitat fragmentation (Slingsby et al., 2020b), management (Steel et al., 2015) or the spread of flammable exotic plantation forestry and invasive species (Kraaij et al., 2018; McWethy et al., 2018). Managing these factors provides opportunities for adaptation and mitigation (Moreira et al., 2020).

Human adaptation and mitigation responses to climate change may create additional threats to MTEs. MTEs have dry summers by definition, posing a challenge for the year-round supply of water to growing human populations and agriculture. With recent major droughts in all MTEs (Section 2.4.3.6), there is increasing reliance on groundwater for bulk water supply (Kaiser and Macleod, 2018). The majority of groundwater systems have exceeded or are rapidly approaching their environmental flow limits (de Graaf et al., 2019), threatening human populations and ecosystems that depend on these systems for their persistence through unfavourable climatic conditions (McLaughlin et al., 2017 Plants). Similarly, much of the MTEs are open shrublands and grasslands and proposed extensive tree-planting to sequester atmospheric CO_2 could result in loss of biodiversity and threaten water security (Doblas-Miranda et al., 2017; Bond et al., 2019).

2.5.2.5 Risk to Grasslands and Savannas

Worldwide, woody cover is increasing in savannas (Buitenwerf et al., 2012; Donohue et al., 2013; Stevens et al., 2017), as a result interactions of elevated CO_2 combined with altered fire and herbivory impacts (i.e. from land-use change; see Section 2.4.3.5; CCP3.2; Venter et al., 2018; Wu et al., 2021). In some regions, altered climate may also contribute (CCP3.2). Elevated CO_2 benefits plants with C3 photosynthesis (often woody plants), more than C4 species (Moncrieff et al., 2014a; Scheiter et al., 2015; Knorr et al., 2016a). Increases in woody vegetation in grassy ecosystems could provide some carbon increase (*medium confidence*) (Zhou et al., 2017; Mureva et al., 2018), but is expected to decrease biodiversity (Smit and Prins, 2015; Abreu et al., 2017; Andersen and Steidl, 2019), decrease water availability (Honda and Durigan, 2016; Stafford et al., 2017) and alter ecosystem services like grazing and wood provision (*high confidence*) (Anadon et al., 2014).

The relative importance of climate, disturbance (e.g. fire/herbivory) and plant feedbacks in shaping present and future savanna distribution vary between continents (Lehmann et al., 2014), which makes projections of changing biome extent challenging (Moncrieff et al., 2016). It has been shown that simulation studies that do not account of CO_2 interactions and only consider climate change impacts do not realistically capture the future distribution of savannas (*high confidence)* (Higgins and Scheiter, 2012; Moncrieff et al., 2016; Scheiter et al., 2020). Due to the continued strong effect of CO_2 on tree (and shrub) to grass ratios in future, models suggest a loss of savanna extent and conversion into closed canopy forest/thicket and an expansion of savanna-type vegetation into arid grasslands (Wårlind et al., 2014; Moncrieff et al., 2016). In arid savannas and their interface to grasslands, survival of woody vegetation (which may be stimulated to grow by increasing CO_2) will depend l on their capacity to survive potentially more severe and frequent droughts (Sankaran and Staver, 2019). Across a range of models, for RCP4.5 future climate change and CO_2 concentrations, savanna expanse declined by around 50% (converting to closed canopy systems) by 2070 in Africa and South America, 25% in Asia with small changes in Australia (Moncrieff et al., 2016; Kumar et al., 2021). Future fire spread is expected to be reduced with increased woody-dominance (Scheiter et al., 2015; Knorr et al., 2016b; Scheiter et al., 2020), feeding back to further increase tree to grass ratios (*high confidence)*.

Like the tropical forest biome, savannas are at large risk, given the projected climate changes in combination with land-use change (see Cross Chapter Paper 3). About 50% of Brazilian Cerrado has been transformed to agriculture and pastures (Lehman and Parr, 2016), and African savannas have been proposed to follow a similar tropical agricultural revolution pathway in order to enhance agronomical prosperity (Ryan et al., 2016). In fact, indirect climate change impacts arising from mitigation efforts on land may be particularly perilous to savannas: extensive tree-planting to restore ecosystems and remove CO_2 from the atmosphere, as pledged, for example, under the African Forest Restoration Initiative, could lead to carbon losses, loss of biodiversity and damage ecosystem's water balance if trees are planted in what naturally are grasslands or savannas (Box 2.2, FAQ2.6; Bond et al., 2019).

2.5.2.6 Risk to Tropical Forest

Key factors affecting the future distribution of tropical humid and dry forests are amounts and seasonalities of precipitation, increased temperatures, prolonged droughts and droughted-moderated fires (*robust evidence, high agreement*) (Bonai et al., 2016; Corlett, 2016; Lyra et al., 2017; Anderson et al., 2018; da Silva et al., 2018; Fontes et al., 2018; O'Connell et al., 2018; Aguirre-Gutiérrez et al., 2019; Bartlett et al., 2019; Brando et al., 2019; Stan and Sanchez-Azofeifa, 2019). Probability of severe drought is projected to quadruple in natural areas in Brazil with above 2°C warming (Barbosa and Lakshmi Kumar, 2016; Marengo et al., 2020). Most multi-model studies assuming rapid economic growth/business-as-usual scenarios (A2, A1B, RCP8.5) show an increase in future woody biomass and areas of woody cover towards the end of the 21st century in the temperate regions (Boit et al., 2016; Nabuurs et al., 2017) and in tropical forests in East Africa (Ross et al., 2021) but decrease in the remaining tropical regions (Anadón et al., 2014; Boit et al., 2016; Lyra et al., 2017; Nabuurs et al., 2017; Maia et al., 2020). Terrestrial species are predicted to shift to cooler temperatures and higher elevations (Pecl et al., 2017). Tropical species are more susceptible to climate warming than temperate species (Rehm and Feeley, 2016; Sentinella et al., 2020). This susceptibility will be exacerbated by road-building increasing ease of access into forests (Brinck et al., 2017; Taubert et al., 2018; Bovendorp et al., 2019; Senior et al., 2019). Furthermore, most tropical cloud forest species are unable to invade grasslands and this will increase risk of extinctions in tropical cloud forests (Rehm and Feeley, 2015).

Sea level rise as the result of climate change is likely to influence mangroves in all regions, with greater impact on North and Central America, Asia, Australia, and East Africa than West Africa and South America (*robust evidence, high agreement*) (Alongi, 2015; Ward et al., 2016). On a small scale, mangroves are potentially moving landward (Di Nitto et al., 2014), while on a large scale they will continue to expand poleward (Alongi, 2015).

Most simulations predict a significant geographical shifts of transition areas between tropical forests and savanna in the tropical and subtropical Americas and Himalayas (Anadón et al., 2014) (Rashid et al., 2015). Forest die-back, as postulated for the Amazon region, does not occur in the majority of simulations (Malhi et al., 2009; Poulter et al., 2010; Rammig et al., 2010; Higgins and Scheiter, 2012; Huntingford et al., 2013; Davies-Barnard et al., 2015; Sakschewski et al., 2016; Wu et al., 2016a). Model projections of future biodiversity in tropical forests are rare. Arguably, species are most vulnerable to climate change effects in higher altitudes or at the dry end of tropical forest occurrence (*medium evidence, medium agreement*) (Krupnick, 2013; Nobre et al., 2016; Trisurat, 2018). Tropical lowlands are expected to lose plant species as temperatures rise above species' heat tolerance but could also generate novel communities of heat tolerant species (*robust evidence, high agreement*) (Colwell et al., 2008; Trisurat et al., 2009; Trisurat et al., 2011; Krupnick, 2013; Zomer et al., 2014a; Zomer et al., 2014b; Sullivan et al., 2020; Pomoim et al., 2021).

Statistical models that correlate data on species abundance with information on human pressures (such as land-use change (Srichaichana et al., 2019), population density (Leclère et al., 2020) hunting (Mockrin et al., 2011) found for tropical and sub-tropical forests that birds, invertebrates, mammals and reptiles show a decline in their probability of presence with declining forest cover, which is particularly pronounced in forest specialists or narrow-ranged species (Newbold et al., 2014). Different soil fauna groups showed different responses in abundance and diversity to climate change conditions (Coyle et al., 2017; Facey et al., 2017) but these changes can impact decomposition rates and biogeochemical cycles (*medium evidence, low agreement*).

Invasive plant species are predicted to expand upward by 500-1,500m in the Western Himalaya (Thapa et al., 2018), and by 6-35% per year from the current extent in South America (*robust evidence, high agreement*) (Bhattarai and Cronin, 2014). Global assessment (Wang et al., 2017) also revealed that ecoregions of high elevation tropical forests and sub-tropical coniferous forests have high risk of invasive plant expansion in the low CO_2 emission scenarios, with negative impacts on ecosystem functioning and local livelihoods (Shrestha et al., 2019).

The impact of unsustainable land use on tropical forests continues in all regions (see Cross-Chapter Paper 7). Projected climate changes will not only cause impacts on biodiversity but also on the livelihoods of affected people (*robust evidence, high agreement*). Increased drought drives crop failures that cause local communities to expand agricultural area by further clearing native forests (Desbureaux and Damania, 2018). Climate change is projected to enlarge the area of suitability for booming tree crops such as oil palm, acacia, Eucalyptus, and rubber (Koninck et al., 2011; Cramb et al., 2015; Nath, 2016; Hurni et al., 2017; Li et al., 2017; Varkkey et al., 2018). An increase of 8% in area of rubber plantations in Yunnan province, China, between 2002–2010 to higher altitude due to decreased environmental limits, potentially increases pressure on remaining biodiversity both within and outside of protected areas (Zomer et al., 2014a). As a consequence, the suitable area for mammals is projected to be reduced by 47.7% (RCP 2.6) and 67.7% (RCP8.5) by 2070, with large variability depending on the different species (See also Cross-Chapter Paper 7; Brodie, 2016).

2.5.2.7 Risk to Boreal and Temperate Forests

As in the Arctic, warming substantially exceeding the global average has already been observed for the northern parts of the temperate and boreal forest zone (Gauthier et al., 2015), and is projected to continue (see Chapter 4 of WGI, see Cross-Chapter Paper 6). As a consequence, boreal tree species are expected to move northwards (or in mountain regions: upwards) into regions dominated by tundra, unless constrained by edaphic features, and temperate species are projected to grow in regions currently occupied by southern boreal forest (*high confidence)*. In both biomes, deciduous trees are simulated to increasingly grow in regions currently dominated by conifers (Wårlind et al., 2014; Boulanger et al., 2017). These simulation results have been supported by observational examples. In Eastern Siberia, fire disturbance of larch-dominated forest was followed by recovery to birch-dominated forest (Stuenzi and Schaepman-Strub, 2020). In Alberta Lodgepole Pine (*Pinus contorta*) lost its dominant status after attacks by Mountain Pine Beetles (*Dendroctonus ponderosae*) caused the canopy to switch to non-pine conifers and broadleaved trees (Axelson et al., 2018). In contrast to the examples above, some boreal forests have proven resilient to disturbances, including to recent unprecedented spates of insect attacks (Campbell et al., 2019a; Prendin et al., 2020).

Reforestation, either natural or anthropogenic, leads to summer cooling and winter warming of the ground, while forest thinning or removal by fire has the reverse effects and deepens the upper layer free of permafrost (Stuenzi et al., 2021a). Interactions between permafrost and vegetation are important. For example, trees in East Siberian taiga obtained water mostly from rain in wet summers and mostly from permafrost meltwater in dry summers (Sugimoto et al., 2002), suggesting that these forests will be particularly vulnerable to combination of drought with retraction further underground of permafrost under climate warming.

2.5.2.8 Risk to Peatland Systems

The overall effect of climate change on the extent of northern peatlands is still debated (*limited evidence, low agreement*). It is expected that climate change will drive high-latitude peatland expansion poleward of their present distribution due to warming, permafrost degradation, and glacier retreat, which could provide new land and conditions favourable for peat development (*limited evidence, medium agreement*) (Zhang et al., 2017b), as seen during the last deglacial warming (*robust evidence, high agreement)* (MacDonald et al., 2006; Jones and Yu, 2010; Ratcliffe et al., 2018). Peatland area loss (shrinking) near the southern limit of their current distribution or in areas where the climate becomes unsuitable is also expected (*medium evidence, medium agreement*) (Section 2.3.4.3.2; Finkelstein and Cowling, 2011 temperature, and; Gallego-Sala and Colin Prentice, 2013; Schneider et al., 2016; Müller and Joos, 2020), though these peatlands could persist if moisture is maintained via peatlands' self-regulating capacity. In Western Canada, a study suggests that peatlands may persist until 2100, even though the climate will be less suitable (Schneider et al., 2016). Simulations suggest that climate change driven increases in temperature and atmospheric CO_2 could drive reductions in the northern peatland area up to 18% (SSP1-2.6), 41% (SSP2-4.5), and 61% (SSP5-8.5) by 2300 (Müller and Joos, 2020). This is in contrast with findings of northern peatland persistence and expansion under RCP2.6 and RCP6.0 scenarios during 1861–2099 by another modelling study (Qiu et al., 2020). In the tropics, the only available study suggests peatland area will increase until 2300, mainly due to the CO_2 fertilisation effect (Müller and Joos, 2020).

The combination of climate and land-use change represents a substantial risk to peatland carbon stocks, but full assessment is impeded because peatlands are yet to be included in Earth System models (*limited evidence, high agreement)* (Loisel et al., 2021). It is expected that the carbon balance of peatlands globally will switch from sink to source in the near future (2020–2100), mainly because tropical peatland emissions, together with those from climate change -driven permafrost thaw, will likely surpass the carbon gain expected from climate change-driven enhanced plant productivity in the northern high latitudes (Gallego-Sala et al., 2018; Chaudhary et al., 2020; Turetsky et al., 2020; Loisel et al., 2021), mainly because of groundwater drawdown *(robust evidence, medium agreement)* (Hirano et al., 2014; Brouns et al., 2015; Cobb et al., 2017; Itoh et al., 2017; Evans et al., 2021). The overall northern peatland carbon sink has been simulated to persist for at least 300 years under RCP2.6, but not under RCP8.5 (Qiu et al., 2020).

Increases in fire extent, severity, and duration are expected in all peatland regions in the future due to temperature increases (Section 4.3.1.1), changes in precipitation patterns (section 4.3.1.2), and increases in ignition sources (such as lightning) (Section 5.4.3.2), with associated rapid carbon losses to the atmosphere *(medium evidence, high agreement)* (Dadap et al., 2019; Chen et al., 2021a; Nelson et al., 2021). For example, drought has been linked to fires in SE Asian peatlands (Field et al., 2009) and there are predicted decreases in mean summer precipitation (10-30%) for high and low RCPs, particularly over the Indonesian region by mid and late twenty-first century (Section 12.4.2.2; Tangang et al., 2020; Taufik et al., 2020). During wet years, the fire probability in Indonesian peatlands also significantly increases (+15-40 %) when July-October temperatures surpass 0.5°C anomalies compared to a 1995-2015 baseline (Fernandes et al., 2017). Overall, current evidence suggests that peat carbon losses via fire have the potential to be equal to, or greater than, losses due to human peatland drainage and disturbance (*limited evidence, high agreement*) (Turetsky et al., 2015).

In permafrost peatlands, studies differ, with some projecting net loss ~~or~~ and others net gain of carbon (*medium evidence, low agreement*) (Estop-Aragonés et al., 2018; Hugelius et al., 2020; Loisel et al., 2021; Väliranta et al., 2021). In some permafrost peatlands, prolonged and warmer growing seasons due to climate change (section 2.3.4.3.1), along with increases in nitrogen deposition since 1850 (Lamarque et al., 2013), are promoting plant primary productivity. Other studies indicate increased nitrogen-mediated sequestration could be exceeded by increased decomposition due to climate-change-driven warming and fire (*medium evidence, low agreement*) (Natali et al., 2012; Vonk et al., 2015; Keuper et al., 2017; Burd et al., 2018; Estop-Aragonés et al., 2018; Gallego-Sala et al., 2018; Serikova et al., 2018; Wild et al., 2019; Chaudhary et al., 2020; Hugelius et al., 2020).

Any climate change or human-driven degradation of peatlands will also entail losses in water storage (*limited evidence, high agreement*) (Wooster et al., 2012 drought and; Hirano et al., 2015; Cole et al., 2019; Taufik et al., 2019) and biodiversity (Harrison, 2013; Lampela et al., 2017; Renou-Wilson et al., 2019). The environmental archive contained in peat that preserves records of vegetation, hydrology, climate change, pollution and/or human disturbances is also lost as the peatlands degrade (Greiser and Joosten, 2018). (Kasischke and Turetsky, 2006; MacDonald et al., 2006; Turunen, 2008; Field et al., 2009; Flannigan et al., 2009; Jones and Yu, 2010; Kasischke et al., 2010; Peterson et al., 2010; Finkelstein and Cowling, 2011 temperature, and; Rooney et al., 2012; Gallego-Sala and Colin Prentice, 2013; Lamarque et al., 2013; Hirano et al., 2014; Brouns et al., 2015; Turetsky et al., 2015; Miettinen et al., 2016; Schneider et al., 2016; Cobb et al., 2017; Fernandes et al., 2017; Itoh et al., 2017; Gallego-Sala et al., 2018; Greiser and Joosten, 2018; Ratcliffe et al., 2018; Dadap et al., 2019; Leifeld et al., 2019; Chaudhary et al., 2020; Hoyt et al., 2020; Müller and Joos, 2020; Qiu et al., 2020; Tangang et al., 2020; Taufik et al., 2020; Turetsky et al., 2020; Chen et al., 2021a; Evans et al., 2021; Loisel et al., 2021; Nelson et al., 2021; Qiu et al., 2021)

2.5.2.9 Risk to Polar Tundra Ecosystems

For boreal-tundra systems, AR5 projected transformation of species composition, land cover and permafrost extent, decreasing albedo and increasing greenhouse gases emission *(medium confidence)*. The Special Report on Global Warming of 1.5°C classified tundra and boreal forests as particularly vulnerable to degradation and encroachment of woody shrubs *(high confidence)*. The Special Report on Oceans and Cryosphere (SROCC) projected climate-related changes to arctic hydrology, wildfire and abrupt thaw, *(high confidence)* and broad disappearance of arctic near-surface permafrost in this century, with important consequences for global climate *(very high confidence).* Chapter 2 of AR6 has focused on new key findings about observed and projected changes in tundra vegetation and related hydrology, with implications for feedbacks to the climate system.

Due to the rapid warming in high northern latitudes, Arctic tundra is one of the terrestrial biomes where climate change impacts are already clearly visible (Settele et al., 2014; Uboni et al., 2016). Climate models project that warming for the Arctic is likely to continue at more than double the global rate. Compared to the period 1995–2014, mean annual surface air temperatures in Arctic tundra are projected to increase by 7.9°–10°C by the end of the century for scenarios of high greenhouse gas emissions (RCP 7.0 and 8.5). For scenarios of low greenhouse gas emissions (RCP 1.9 and 2.6), the projected increase is 2.6°–3.2°C (see Chapter 4 pf WGI). The Arctic is also projected to have among the largest increases in precipitation globally, although there is high uncertainty in these projections. In contrast to climate change, land use change is projected to be very low in Arctic tundra systems (van Asselen and Verburg, 2013).

Models of vegetation response to climate project acceleration in coming decades of observed increases in shrub dominance and boreal forest encroachment that have been driven by recent warming (Settele et al., 2014), leading to a shrinking of the area of tundra globally (*medium confidence)* (Mod and Luoto, 2016; Gang et al., 2017). Simulating changes in tundra vegetation is complicated by permafrost dynamics (e.g. formation of thaw ponds), changes in precipitation, or low nutrient availability, which may promote abundance of graminoids (van der Kolk et al., 2016). The changes in vegetation, when combined with warming and increased precipitation effects on soil thawing and carbon cycling, are projected to modify greenhouse gas emissions and have biophysical feedbacks to regional and global climate. Large uncertainty in modelled carbon cycle changes arises from differences between the vegetation models (Nishina et al., 2015; Ito et al., 2016). In addition, climate change is expected to strongly interact with other factors, such as fire, to further increase uncertainty in projections of tundra ecosystem function (Jiang et al., 2017).

2.5.2.10 Committed Impacts of Climate Change on Terrestrial Ecosystems and Implications of Overshoot

Projections point to potentially large changes of canopy structure and composition within and across the terrestrial biomes in response to climate change and changes in atmospheric CO_2. These changes will contribute to altered ecosystem carbon uptake and losses, biophysical climate feedbacks (Sections 2.3.2; 2.4.4; 2.5.3.2; 2.5.3.3. 2.5.3.4, 2.5.3.5, Figure 2.10, Table 2.4), and multiple other ecosystem services (Sections 2.5.3, 2.5.4), as well as for biodiversity (Sections 2.4.2, 2.4.3, 2.4.4, 2.4.5, 2.5.1.3, 2.5.1.4, 2.5.2, Figure Box 2.1.1, Table Box 2.1.1, Table SM2.4). Until now, most studies project changes over next decades until the end of this century.

However, there is an increasing body of literature that has found continued, longer-term responses of ecosystems to climate change, so-called 'committed changes,' that arise from lags that exist in many systems. Many processes in ecosystems take more than a few decades to quasi-equilibrate to environmental changes. Therefore, trends of changing vegetation cover identified in simulations of transient warming continue to show up in simulations that hold climate change at low levels of warming (*medium confidence)* (Boulton et al., 2017; Pugh et al., 2018; Scheiter et al., 2020). Such changes, which could tip ecosystems into an alternative state, could also be triggered by a ‘warming overshoot’ – if global warming were to exceed a certain threshold, even if mean temperatures afterwards decline again (Albrich et al., 2020a).

For instance, even if warming achieved by 2100 remained constant after 2100, such committed responses continue to occur. These include: (1) continued Amazon forest loss (Boulton et al., 2017), consistent with results in (Pugh et al., 2018) that found continued tropical forest cover loss across a range of models and simulation set-ups, and (2) across Africa, an increased shift towards woody C3 vegetation was found in equilibrium state, the overall response depending on the atmospheric CO_2 concentration (Scheiter et al., 2020). In Pugh et al. (2018), the opposite was found for boreal forest cover, which showed a strong committed increase. The committed changes in vegetation composition correspond to large committed changes in terrestrial carbon uptake and losses (Boulton et al., 2017; Pugh et al., 2018; Scheiter et al., 2020), and would plausibly also appear in other ecosystem functioning and services. These studies point to the importance of having not only a multi-decadal but also a multi-century perspective when exploring the impacts of political decisions on climate change mitigation taken now. Even if climate-warming targets are met, published evidence so far suggests that fundamental changes in some ecosystems are *likely* as these correspond to well-understood ecosystem physiological responses that trigger long-term changes in composition.

[START BOX 2.1 HERE]

Box 2.1: Assessing Past Projections of Ecosystem Change Against Observations

To assess future climate change impacts on ecosystems we use models to project their future distribution. Comparing the trends in the observed changes against the projections can help assess the strength of the model projections. In this box, we compare observed trends of changes in ecosystem structure to projections highlighted in previous IPCC reports (specifically AR3 (IPCC, 2001), AR4 (Fischlin et al., 2007) and AR5 (Settele et al., 2014). We use this to assess how well the projections are matching up with observed changes. The map represents studies documenting observed changes in common plant functional groups (e.g. trees, grasses, shrubs). Studies, documenting changes in plant functional groups, were collated from published papers in natural and semi-natural areas. Studies were included if climate change, or interactions between climate change and land use showed a causal link to the observed change. Studies were excluded if the changes only from landscape/land use transformation (e.g. deforestation). In each paper, we recorded the geographical location, the type of functional change and noted the causes. Observed changes are plotted onto a biome map derived from the WWF ecoregions database (Olson et al., 2001). Trends in changing plant functional types are good indicators of potential biome shifts and are used to assess how observations match up with projections.

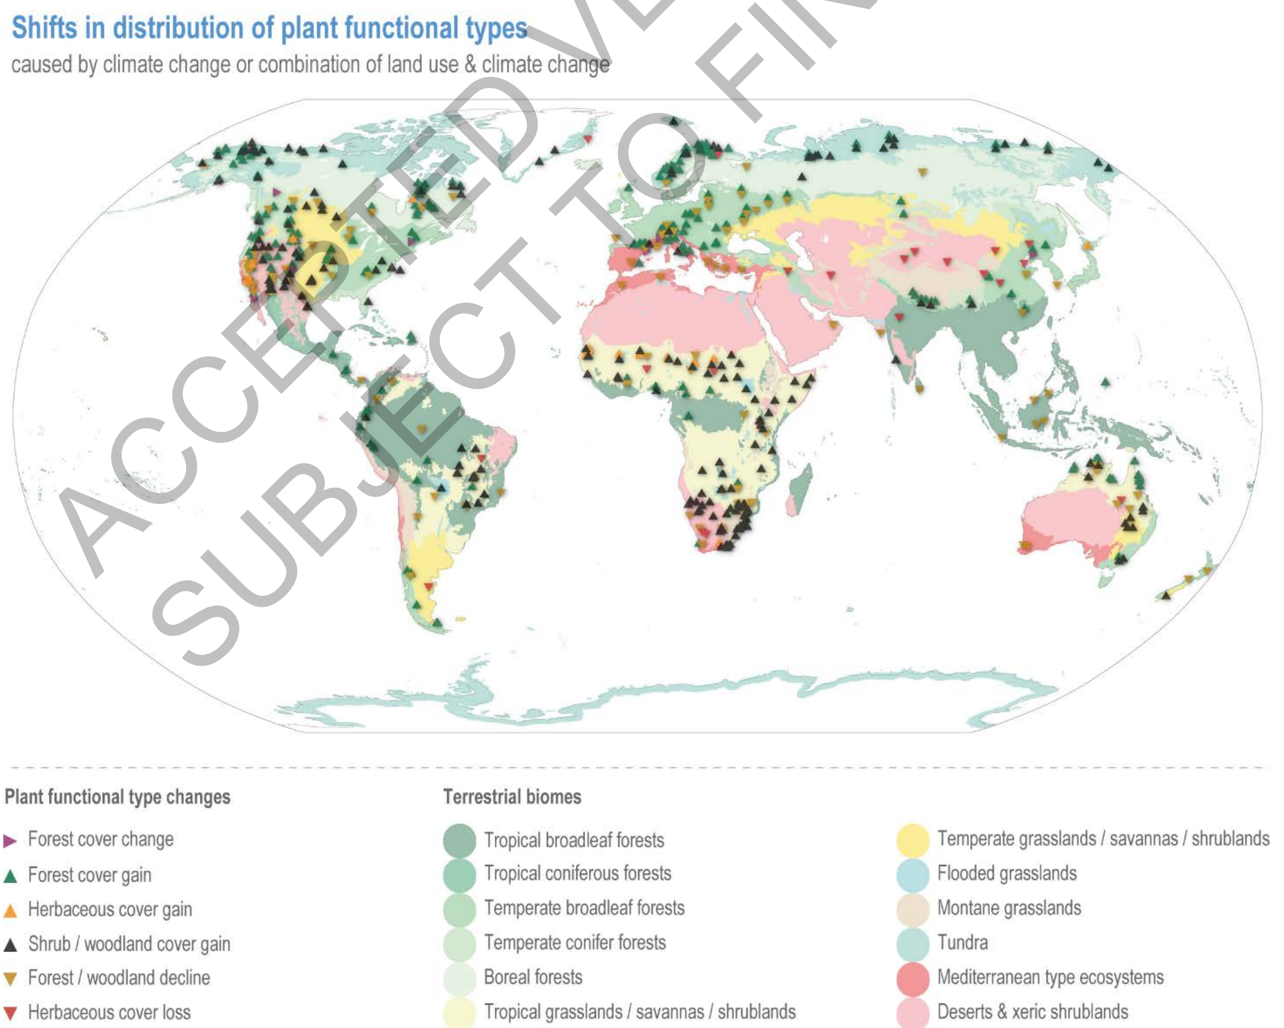

Figure Box 2.1.1: Observed changes in the distribution of plant functional types that are caused by climate change or combination of land use and climate change. Shifts in plant functional types are indicative of shift in biome function and structure

Table Box 2.1.1: Comparison of projections on biome change from the Third, Fourth and Fifth assessment report (IPCC, 2001; Fischlin et al., 2007; Settele et al., 2014) with observed changes in ecosystems as assessed in this current report (see section 2.4 and Fig Box 2.1.1). Observed changes marked in bold show good agreement with past projections, those in red show mismatch with observations and projections.

Biome	AR3	AR4	AR5	Observed trends 1990–2021
Mediterranean Type ecosystems	Increased disturbance by fire and warming will cause a loss of unique habitats	Loss of 65% of area due to warming. Increased fire frequencies will favor resprouting plants. An increase in grass dominance. Forest expansion within MTE's systems due to elevated CO_2.	Range contractions of all species	Increased in water deficit **and fire activity** (sections 2.4.3.6, *2.4.4.2*) **causing declines in diversity**, tree mortality (Fig Box 2.1.1) with resprouting trees worst affected. **Increasing dominance of grasses (often alien).** Increasing dominance of deciduous over evergreen species (Fig Box 2.1.1).
Tundra	Tree and shrub encroachment into tundra.	Increased woody plant growth due to longer and warmer growing seasons and replacement of dwarf tundra by shrub tundra Poleward expansion of tundra into polar desert and encroachment of coniferous trees into tundra	Continued woody expansion in tundra regions with reduced surface albedo due to less snow and more woody cover	**Increase in woody shrub cover in tundra and expansion of boreal forest into tundra**. (Fig Box 2.1.1, 2.4.3.4)
Boreal forest	Reduced productivity due to weather related disturbances (e.g. increase fire risk). Deciduous broadleaf tree encroachment into boreal forest	Extensive boreal tree spread into tundra. Boreal forest dieback within boreal zone and contraction of boreal forest at southern ecotone with continental grasslands		**Expansion into Tundra and upslope tree line advance** (Section 2.4.3.8 and Fig Box 2.1.1). **Increased mortality due to drought, fire, beetle infestations** (Sections 2.4.3.8, 2.4.42.1, 2.4.4.3.1)
Tropical forest	Increasing CO_2 concentration would increase net primary productivity	Increases in forest productivity and biomass through increased CO_2 with localised decreases in the Amazon. Shift in forest species composition. Expansion of forest area into mesic savanna.	Shift in the climate envelope of moist tropical forests but forests are less likely to undergo major retractions or expansions than suggested in AR4	**Expansion of tropical forest into savannas in Africa, Asia, South America** (Section 2.4.3.7, Fig Box 2.1.1) **Forest biomass increases (though slowing). (**Section 2.4.4.4) Forest degradation from drought, warming x fire and shorter residence time of trees. (Section 2.4.3.7) **Shift in species composition** towards species with more arid adapted trait (Section 2.4.3.7)
Temperate forest	Forest decline and increased mortality	Increase in tree mortality from drought related declines. A general increase of deciduous at the expense of evergreen vegetation is predicted at all latitudes		Map indicates a shift towards deciduous species in W N America (Fig Box 2.1.1) **Tree death due to interactions with drought x pest outbreaks x fire** (2.4.3.8, 2.4.42.1., 2.4.4.3.1)

Grasslands and savannas	Increasing CO_2 concentration will increase net primary productivity	Increased tree dominance in savannas and grasslands (from elevated CO_2). With C3 plants benefiting more than C4 plants	Rising CO_2 will increase the likelihood woodier states (but the transition will vary in different environments)	**Greening and encroachment across tropical and temperate savannas in Africa, Asia, Australia and N America** (Section 2.4.3.5) **Expansion of trees into grasslands and advancement of tree lines** Signs of increased C4 grass productivity in drought conditions. Increased C3 grass productivity (Section 2.4.3.5).
Desert/ arid shrublands		An increase in desert vegetation productivity was projected in southern Africa, the Sahel, central Australia, the Arabian Peninsula and parts of central Asia due to a positive impact of rising atmospheric CO_2.		**Greening** (increased LAI, woody cover) and increased herbaceous production is occurring at desert grassland interfaces (Chapter – Cross-Chapter Paper 3).

Assessment: There is a high agreement between observations and projections of tree death in temperate and boreal forests, with current projections (AR6) indicating this trend will continue (Section 2.5.4). Forest death is most widely recorded in central Europe and Westerns North America (Fig Box 2.1.1). There is also very high agreement between observations and projections of woody encroachment in savannas, grasslands and tundra, with projections also indicating that this trend is likely to continue (Section 2.5.4). Observations of desert greening show good agreement with earlier projections. Patterns of desertification are also occurring although the geographical match between projections and observations shows moderate agreement, likely due to the strong role of land use in this process. Projections of tropical forest expansion into mesic savannas and boreal forest expansion into tundra also shows agreement with observations.

Projections on the future of Mediterranean shrublands, deserts, xeric shrublands and temperate grassy systems are limited making assessment of this relationship less clear. It is also unclear, due to limited observations, how widespread a shift from deciduous forest species to evergreen forest species is. Some observations suggest this is occurring although it is not clear how widespread this change is and if the geographical pattern is as projected.

[END BOX 2.1 HERE]

2.5.3 Risk Assessment of Ecosystems and Related Services

2.5.3.1 Risks in Protected Areas

National parks and other protected areas, which, in June 2021, covered 15.7% of global terrestrial area (UNEP-WCMC, 2021), conserve higher biodiversity than adjacent unprotected areas (Gray et al., 2016), and protect one-fifth of global vegetation carbon stocks and one-tenth of global soil carbon stocks (Section 2.4.4.4). This section assesses climate change specifically in protected areas. Even though it is in a part of the chapter on projected risks, this section includes both observed exposure and projected risks to gather the chapter information on protected areas in one place.

2.5.3.1.1 Observed exposure of protected areas

Deforestation, agricultural expansion, overgrazing, and urbanisation exposed to intense human pressure one-third of global protected area (6 million km^2) in 2009, a 6% increase from 1993 (Venter et al., 2016; Jones et al., 2018). The observed change in exposure to climate change has not yet been quantified for protected areas globally but research has analysed spatial patterns and magnitudes of observed changes for the 360 000 km^2

system of U.S. national parks (Gonzalez et al., 2018), including the first national park in the world. From 1895 to 2010, mean annual temperature of the U.S. national park area increased at a rate of 1 ± 0.2ºC century^{-1}, double the rate of the U.S. as a whole, and precipitation decreased on 12% of the national park area, compared with 4% for the U.S. as a whole, due to a high fraction of U.S. national park area in the Arctic, at high elevations, and the arid Southwestern USA. (Gonzalez et al., 2018). In addition, analyses of weather station measurements in and near six South African National Parks found that maximum temperature increased at a rate of 0.024 ± 0.003ºC y^{-1} from 1960 to 2010 (Van Wilgen et al., 2016). While a substantial fraction of global protected area has been exposed to observed human land cover change, the global exposure to observed climate change is unquantified.

2.5.3.1.2 Projected risks in protected areas

Under a climate change scenario of ~3.5ºC temperature increase by 2070, current climate could disappear from individual protected areas that comprise half of global protected area and novel climates (climate conditions that are currently not present within an individual protected area) could expose half of global protected area (Hoffmann et al., 2019b). A lower emissions scenario of ~1.5ºC could reduce the climate disappearance to 40% and the exposure to novel climates to 41% (Hoffmann et al., 2019b). Models project the highest projected exposure in subtropical projected areas (Hoffmann and Beierkuhnlein, 2020). Projected disappearance of current climate conditions from protected areas is most extensive in Africa, Oceania, and North and South America (Elsen et al., 2020).

Projections indicate higher exposure to novel climates of tropical rainforests, shrublands, and grasslands, temperate conifer forests and grasslands, and tundra (Hoffmann et al., 2019b; Elsen et al., 2020). A climate change scenario of ~3.5ºC temperature increase by 2100 could expose 32% of protected area in humid tropical forests, 1.6 million km^2 in 2000, to climate that would be novel to humid tropical forest protected areas, while climate currently present in humid tropical forest protected areas could disappear from 0.6 million km^2, 12% of current total area by 2050 (Tabor et al., 2018). High deforestation and climate change combined could expose 2% of the humid tropical forest protected area (Tabor et al., 2018). Regional analyses under RCP8.5 also project substantial disappearance of current climate from protected areas in Bolivia, Chile, and Peru (Fuentes-Castillo et al., 2020), Canada, Mexico, and the U.S. (Batllori et al., 2017; Holsinger et al., 2019), China (Zomer et al., 2015), Europe (Nila et al., 2019), and Indonesia (Scriven et al., 2015). Projected climate change could expose an extensive part of global protected area to disappearing and novel climate conditions (*high confidence*) (Cross-Chapter Paper 1).

Continued climate change increases risks to individual species and vegetation types in protected areas. Under a climate change scenario of 4ºC temperature increase by 2100, suitable climate for two species of baobab trees (*Adansonia perrieri, A. suarezensis*) in Madagascar could shift entirely out of the protected areas network (Vieilledent et al., 2013). Other species and vegetation types at risk of partial disappearance of suitable climate from protected areas include Atlantic Forest amphibians in Brazil (Lemes et al., 2014), birds in Finland (Virkkala et al., 2013), birds and trees in Canada and Mexico (Stralberg et al., 2020), bog woodlands in Germany (Steinacker et al., 2019), butterflies and mammals in Egypt (Leach et al., 2013), and tropical dry forests in Mexico (Prieto-Torres et al., 2016). Projected disappearance of suitable climate conditions from protected areas increase risks to the survival of species and vegetation types of conservation concern in tropical, temperate, and boreal ecosystems (*high confidence*) (Cross-Chapter Paper 1).

Protected rivers, lakes, and other freshwater protected areas require inter-catchment connectivity to maintain species and population movements (Bush et al., 2014a; Hermoso et al., 2016; Thieme et al., 2016), but dams and other barriers interrupt connectivity (Grill et al., 2019). Climate change could also reduce freshwater connectivity (Section 2.3.3.3). Globally, over two-thirds of river reaches (by length) lack protected areas in their upstream catchments and nine-tenths of river reaches (by length) do not achieve full integrated protection (Abell et al., 2017).

Terrestrial and freshwater protected areas can also serve as climate change refugia, locations where suitable conditions may persist for the species into the future (e.g. Section 2.6.5.6). In Canada, Mexico, and the U.S., only a fraction of protected area is located in potential climate change refugia under a 4ºC temperature increase, estimated at 4% (Michalak et al., 2018) to 7% (Batllori et al., 2017). Potential refugia from biome shifts due to climate change under temperature increases of 1.8-3.4ºC cover <1% of the U.S. national park area (Gonzalez et al., 2010b), a fraction that reduces to near zero when climate change is combined with habitat fragmentation due to land use change (Eigenbrod et al., 2015). Protected areas in boreal ecosystems could serve as refugia for species shifting north in Canada (Berteaux et al., 2018) and Finland (Lehikoinen et al., 2019). Invasive species, habitat loss, and other disturbances in protected areas could be lower than in unprotected areas across Europe (Gallardo et al., 2017) and specifically in Spain (Regos et al., 2016) and in Sri Lanka (Kariyawasam et al., 2020). Protected areas conserve refugia from climate change under a temperature increase of 4ºC, important for biodiversity conservation but limited to <10% of current protected area (*medium confidence*).

2.5.3.2 Risks to Ecosystems and Services from Wildfire

2.5.3.2.1 Future projections of wildfire globally

Continued climate change under high emissions scenarios that increase global temperature ~4ºC by 2100 could increase global burned area 50% (Knorr et al., 2016b) to 70% (Kloster and Lasslop, 2017) and global mean fire frequency ~30% (Gonzalez et al., 2010b), with increases on one-third (Gonzalez et al., 2010b) to two-thirds (Moritz et al., 2012) of global land and decreases on one-fifth (Gonzalez et al., 2010b; Moritz et al., 2012). Lower emissions that would limit the global temperature increase to <2ºC would reduce projected increases of global burned area to 30% (Lange et al., 2020) to 35% (Kloster and Lasslop, 2017) and projected increases of fire frequency to ~20% (Gonzalez et al., 2010b; Huang et al., 2015). Continued climate change could further lengthen fire weather seasons (IPCC AR6 WGI Chapter 12). Models that combine projected climate change with potential agricultural expansion project decreases in total burned area (Huang et al., 2015; Knorr et al., 2016b; Park et al., 2021). The area of projected increases in burned area and fire frequency due solely to continued climate change is higher for the world as a whole than the area of projected decreases (*medium evidence, medium agreement*).

Increased wildfire due to continued climate change increases risks of tree mortality (Sections 2.5.2.6, 2.5.2.7, 2.5.3.2), biome shifts (Section 2.5.2.2), and carbon emissions (Sections 2.5.2.10, 2.5.3.4). Wildfire and biome shifts under projected climate change of 4º C above the pre-industrial period, combined with international trade and transport, cause high risks of invasive species across one-sixth of global area, including extensive high-biodiversity regions (Early et al., 2016).

Wildfire risks to people include death and destruction of homes, respiratory illnesses from smoke (Ford et al., 2018; Machado-Silva et al., 2020), post-fire flooding from areas exposed by vegetation loss, and degraded water quality through increases in sediment flows (Dahm et al., 2015) and chemical precursors of carcinogenic trihalomethanes when water is later chlorinated for drinking (Section 2.5.3.7; Uzun et al., 2020) . Under RCP8.5 and shared socio-economic pathway SSP3 (high population growth, slow urbanisation), the number of people living in fire-prone areas could increase by three-quarters, to 720 million people in 2100, in a projected global population of 12.4 billion people (Knorr et al., 2016b). Lower emissions under RCP4.5 could reduce the number of people at risk by 70 million people. In these projections, human population growth increases human exposure to wildfires more than increase in burned area (Knorr et al., 2016c). A global temperature increase <2ºC could increase global population exposure to wildfire by ~30% (Lange et al., 2020). Increased wildfire under continued climate change increases probabilities of human exposure to fire and risks to public health (*medium evidence, high agreement*).

2.5.3.2.2 Future projections of wildfire in high-risk areas

Regions identified at high risk of increased burned area, fire frequency, or fire weather by multiple global analyses include: Amazon (Gonzalez et al., 2010b; Huang et al., 2015; Knorr et al., 2016c; Burton et al., 2018; Abatzoglou et al., 2019), Mediterranean Europe (Gonzalez et al., 2010b; Burton et al., 2018; Abatzoglou et al., 2019), Arctic tundra (Moritz et al., 2012; Flannigan et al., 2013), western Australia (Gonzalez et al., 2010b; Burton et al., 2018; Abatzoglou et al., 2019), western United States (Gonzalez et al., 2010b; Moritz et al., 2012; Knorr et al., 2016c). Higher-resolution spatial projections indicate high risks of increased wildfire in the Amazon, Australia, boreal ecosystems, Mediterranean Europe, and the United States under climate change (*medium evidence, medium agreement*).

In the Amazon, climate change under RCP8.5, combined with high deforestation, could double the area of high fire probability (Fonseca et al., 2019), double burned area by 2050 (Brando et al., 2020) increase burned area 400–2800% by 2100 (Le Page et al., 2017), and increase fire intensity 90% (De Faria et al., 2017). Lower greenhouse gas emissions (RCP4.5) and reduced deforestation could reduce fire risk to a one-fifth increase in the area of high fire probability (Fonseca et al., 2019) and a 100–500% increase in burned area by 2100 (Le Page et al., 2017). Moreover, increased fire, deforestation, and drought, acting through vegetation-atmosphere feedbacks, increase risks of extensive forest dieback and potential biome shifts of up to half of Amazon rainforest to grassland, a tipping point that could release an amount of carbon that would substantially increase global emissions (Oyama and Nobre, 2003; Sampaio et al., 2007; Lenton et al., 2008; Nepstad et al., 2008; Malhi et al., 2009; Settele et al., 2014; Lyra et al., 2016; Zemp et al., 2017a; Zemp et al., 2017b; Brando et al., 2020). Continued climate change, combined with deforestation, increases risks of wildfire and extensive forest dieback in the Amazon rainforest (*robust evidence, high agreement*).

In Australia, climate change under RCP8.5 increases risks of pyroconvective fire by 20 to 40 days in rangelands of Western Australia, South Australia, and the Northern Territory (Dowdy et al., 2019). Pyroconvective fire conditions could reach more frequently into the more populated areas of New South Wales, particularly at the start of austral summer (Di Virgilio et al., 2019). General circulation models do not agree, however, on projected areas of fire increase in New South Wales (Clarke and Evans, 2019). Increases in heat and potential increases in wildfire threaten the existence of temperature montane rainforest in Tasmania, Australia (Mariani et al., 2019).

In Mediterranean Europe, climate change of 3ºC could double or triple burned area, while keeping the temperature increase to 1.5ºC could limit burned area increase to 40–50% (Turco et al., 2018). Under RCP8.5, the frequency of heat-induced fire weather could increase 30% (Ruffault et al., 2020). Severe fire followed by drought could cause biome shifts of forest to non-forest (Batllori et al., 2019) and tree mortality >50% (Dupire et al., 2019).

In Arctic tundra, boreal forests, northern peatlands, including permafrost areas, climate change under scenarios of 4ºC temperature increase could triple burned area in Canada (Boulanger et al., 2014), double the number of fires in Finland (Lehtonen et al., 2016), increase lightning-driven burned area 30 to 250% (Veraverbeke et al., 2017; Chen et al., 2021a), push half of the area of tundra and boreal forest in Alaska above the burning threshold temperature, and double burned area in Alaska (Young et al., 2017a). Thawing of Arctic permafrost from a projected temperature of 4ºC and resulting wildfire could release 11-200 Gt carbon that could substantially exacerbate climate change (Section 2.5.2.9).

In the United States, climate change under RCP8.5 could increase burned area 60−80% by 2049 (Buotte et al., 2019) and the number of fires with an area >50 km^2 by 300–400% by 2070 (Barbero et al., 2015). In montane forests in the U.S., climate change under RCP8.5 increases the risk of fire-facilitated conversion of ~7% of forest to non-forest by 2050 (Parks et al., 2019). In California, climate change under a scenario of 4ºC temperature increase could double fire frequency in some areas (Mann et al., 2016), but emissions reductions that limit the temperature increase to ~2ºC could keep fire frequency from increasing (Westerling et al., 2011). Carbon dioxide fertilisation and increased temperature under climate change could increase invasive grasses and wildfire in desert ecosystems of the Southwestern United States, where wildfire has historically been absent or infrequent, and increase mortality of the sparse tree cover (Horn and St. Clair, 2017; Klinger and Brooks, 2017; Syphard et al., 2017; Moloney et al., 2019; Sweet et al., 2019).

In summary, under a high emissions scenario that increases global temperature 4ºC by 2100, climate change could increase global burned area 50–70% and global mean fire frequency ~30% with increases on one-third to two-thirds of global land and decreases on one-fifth of global land (*medium confidence*). Lower emissions that would limit the global temperature increase to <2ºC would reduce projected increases of burned area to ~35% and projected increases of fire frequency to ~20% (*medium confidence*). Increased wildfire, combined with erosion due to deforestation, could degrade water supplies (*high confidence*). For ecosystems with historically low fire frequencies, a projected 4ºC global temperature increases risks of fire, contributing to potential tree mortality and conversion of over half of Amazon rainforest to grassland and thawing of Arctic permafrost that could release 11–200 Gt carbon that could substantially exacerbate climate change (*medium confidence*).

2.5.3.3 Risks to Ecosystems and Services from Tree Mortality

Under continued climate change, increased temperature, aridity, drought, wildfire (Section 2.5.3.2), and insect infestations (Section 2.4.4.3.3) will tend to increase tree mortality across wide parts of the world (McDowell et al., 2020). Boreal and temperate forest loss to fire, wind, and bark beetles could cause more negative than positive effects for most ecosystem services, including carbon storage to regulate climate change (Sections 2.4.4.3, 2.5.2.6, 2.5.2.7, 2.5.3.4), water supply for people (Section 2.5.3.6.1), timber production (Chapter 5), and hazard protection (Thom and Seidl, 2016). In addition, deforestation in tropical and temperate forests can increase local temperatures 0.3° to 2ºC (Hesslerová et al., 2018; Lejeune et al., 2018; Zeppetello et al., 2020) and this effect can extend up to 50 km (Cohn et al., 2019).

In Amazon rainforests, the relatively lower buffering capacity for plant moisture during drought increases the risk of tree mortality and, combined with increased heat from climate change and fire from deforestation, the possibility of a tipping point of extensive forest dieback and a biome shift to grassland (Oyama and Nobre, 2003; Sampaio et al., 2007; Lenton et al., 2008; Nepstad et al., 2008; Malhi et al., 2009; Salazar and Nobre, 2010; Settele et al., 2014; Lyra et al., 2016; Zemp et al., 2017b; Brando et al., 2020). This could occur at a 4-5ºC temperature increase above the pre-industrial period (Salazar and Nobre, 2010). Under RCP8.5, half of Amazon tropical evergreen forest could shift to grassland through drought-induced tree mortality and wildfire, but lower emissions (RCP4.5) could limit the loss to ~5% (Lyra et al., 2016). Precipitation declines from reduced evapotranspiration inputs after forest loss could cause additional Amazon forest loss of one-quarter to one-third (Zemp et al., 2017a). Similarly, in Guinean tropical deciduous forest in Africa, climate change under RCP8.5 could increase mortality 700% by 2100 or 400% under lower emissions (RCP4.5; Claeys et al., 2019). These projections indicate risks of climate change-induced tree mortality reducing tropical forest areas in Africa and South America up to half under a 4ºC increase above the pre-industrial period, but a lower projection of a 2ºC increase could limit the projected increases in tree mortality (*robust evidence, high agreement*).

Temperate and boreal forests possess greater diversity of physiological traits related to plant hydraulics, so they are more buffered against drought than tropical forests (Anderegg et al., 2018). Nevertheless, in temperate forests, drought-induced tree mortality under RCP8.5 could cause the loss of half of northern hemisphere conifer forest area by 2100 (McDowell et al., 2016). In the western United States, one-tenth of forest area is highly vulnerable to drought-induced mortality under RCP8.5 by 2050 (Buotte et al., 2019). In California, increased evapotranspiration in Sierra Nevada conifer forests increases the potential fraction of the area at risk of tree mortality 15–20% per degree Celsius (Goulden and Bales, 2019). In Alaska, fire-induced tree mortality from climate change under RCP8.5 could reduce the extent of spruce forest (*Picea sp.*) 8–44% by 2100 (Pastick et al., 2017). Under RCP8.5, tree mortality from drought, wildfire, and bark beetles could reduce timber productivity of boreal forests in Canada by 2100 below current levels (Boucher et al., 2018; Chaste et al., 2019; Brecka et al., 2020). In Tasmania, projected increases in wildfire (Fox-Hughes et al., 2014) increase risks of mortality in mesic vegetation (Harris et al., 2018b) and threaten ~~the~~ disappearance of the long-lived endemic pencil pine (*Athrotaxis cupressoides*) (Holz et al., 2015; Worth et al., 2016) and temperate montane rainforest (Mariani et al., 2019). These projections indicate risks of climate change-induced tree mortality reducing some temperate forest areas by half under emissions scenarios of 2.5-4ºC above the pre-industrial period (*medium evidence, high agreement*).

2.5.3.4 Risk to Terrestrial Ecosystem Carbon Stocks

Globally, increasing atmospheric CO_2 enhances the terrestrial sink but temperature increases constrain it, reflecting biological process understanding, highlighted in previous IPCC reports (*high confidence*). Analyses of atmospheric inversion model output and spatial climate data indicate a sensitivity of net ecosystem productivity to CO_2 fertilisation of 3.1 ± 0.1 to 8.1 ± 0.3 Gt per 100 ppm CO_2 (~1°C increase) and a sensitivity to temperature of -0.5 ± 0.2, to -1.1 ± 0.1 Gt per degree Celsius (Fernandez-Martinez et al., 2019). The future of the global land carbon sink (Section 2.4.4.4) nevertheless remains highly uncertain because (i) of regionally complex interactions of climate change and changes in atmospheric CO_2 with vegetation, soil and aquatic processes, (ii) episodic events such as heat-waves or droughts (and related impacts through mortality, wildfire or insects, pests and diseases, (Section 2.5.5.2, 2.5.5.3) so far are only incompletely captured in carbon cycle models, and (iii) legacy effects from historic land-use change and environmental changes are incompletely captured but likely to decline in future, and (iv) lateral carbon transport processes such as export of inland waters or erosion are incompletely understood and modelled (AR6 WGI Chapter 5; Pugh et al., 2019a; Friedlingstein et al., 2020; Krause et al., 2020). Enhanced carbon losses from terrestrial systems further limit the available carbon budget for global warming staying below 1.5ºC (Rogelj et al., 2018). Analyses of satellite remote sensing and ground-based observations has indicated that between 1982 and 2015 the CO_2 fertilisation effect has already declined, implying a negative climate system feedback (Wang et al., 2020c). Peatlands, permafrost regions and tropical ecosystems are particularly vulnerable due to their large carbon stocks in combination with over-proportional warming, increases in heatwaves and droughts and/or a complex interplay of climate change and increasing atmospheric CO_2 (Section 2.5.2.8, 2.5.2.9, 2.5.3.2).

Model projections suggest under all warming scenarios a reduction of permafrost extent and potentially large carbon losses (AR6 WGI Chapter 5). Already a mean temperature increase of 2ºC could reduce the total permafrost area extent by ca 5-20% by 2100 (Comyn-Platt et al., 2018; Yokohata et al., 2020). Associated CO_2 losses of order of 15 up to nearly 70 GtC by 2100 have been projected across a number of modelling studies (Schneider von Deimling et al., 2015; Comyn-Platt et al., 2018; Yokohata et al., 2020). Limiting the global temperature increase to 1.5ºC, compared to 2ºC could reduce projected permafrost CO_2 losses by 2100 by (median) 24.2 GtC (calculated for 3m depth (Comyn-Platt et al., 2018). Losses are possibly underestimated in those studies that consider only upper permafrost layers. Likewise, the actual committed carbon loss may well be larger (e.g., eventually a loss of ca. 40% of today's permafrost area extent if climate is stabilised at 2ºC above pre-industrial levels) due to the long time-scale of warming in deep permafrost layers (Chadburn et al., 2017). It is unknown at which level of global warming abrupt permafrost collapse estimated to enhance CO_2 emission by 40% in 2300 in a high emissions scenario, compared to gradual thaw emissions (Turetsky et al., 2020) would have to be considered an important additional risk. Large uncertainties arise also from interactions with changes in surface hydrology and/or northward migrating woody vegetation as climate warms, which could dampen or even reverse projected net carbon losses in some regions (McGuire et al., 2018a; Mekonnen et al., 2018; Pugh et al., 2018) so overall there is *low confidence* on how carbon-permafrost interactions will affect future carbon cycle and climate, although net carbon losses and thus positive (amplifying feedbacks) are *likely* (Sections 2.5.2.10, 2.5.3.5; Shukla et al., 2019). See also AR6 WGI (Chapter 5) for discussion of impacts of higher emission and warming scenarios.

Peatland carbon is estimated as ca. 550–1000 GtC in northern latitudes (many of these peatlands would be found in permafrost regions) (Turetsky et al., 2015; Nichols and Peteet, 2019) and > 100 GtC in tropical regions (Turetsky et al., 2015; Dargie et al., 2017). Both for northern mid- and high-latitude and for tropical peatlands a shift from contemporary CO_2 sinks to sources were simulated in high warming scenarios (Wang et al., 2018a; Qiu et al., 2020). Due to the lack of large-scale modelling studies, the confidence on climate change impacts on peat carbon uptake and emissions is low. The largest risk to tropical peatlands is expected to arise from drainage and conversion to forestry or agriculture, outpacing impacts of climate change (Page and Baird, 2016; Leifeld et al., 2019; Cooper et al., 2020) although the magnitude of possible carbon losses are uncertain and depend strongly on socio-economic scenarios. (Sections 2.4.3.8, 2.4.4.2; 2.4.4.4.2, 2.5.2.8)

For tropical and sub-tropical regions the interplay of atmospheric CO_2 with precipitation and temperature becomes of particular importance for future carbon uptake, since in warm and dry environments, elevated CO_2 fosters plants with C3 photosynthesis and enhances their water use efficiency relative to C4 species (Moncrieff et al., 2014a; Midgley and Bond, 2015; Knorr et al., 2016a). As a consequence, enhanced woody cover is expected to occur in future especially in mesic savannas, while in xeric savannas an increase in woody cover would occur in regions with enhanced precipitation (Criado et al., 2020). Even though semi-arid regions have dominated the recent decades' global trend in land CO_2 uptake (Ahlström et al., 2015), so far most studies that investigated future climate change impacts on savanna ecosystems have concentrated on changes in areal extent (2.5.2.5), rather than on carbon cycling, with *medium confidence* on increasing woody:grass ratios (Moncrieff et al., 2014a; Midgley and Bond, 2015; Moncrieff et al., 2016; Criado et al., 2020). Increases in woody vegetation in what is now grass-dominated would possibly come with a carbon benefit, for instance a broad range of future climate and CO_2 changes were found to enhance vegetation C storage in Australian savannas (Scheiter et al., 2015). Results from a number of field experiments indicate however, that impacts on total ecosystem carbon storage may be smaller, due to a loss in belowground carbon (Coetsee et al., 2013; Wigley et al., 2020). Nunez et al., 2021) critique existing incentives to promote invasion of non-native trees into treeless areas as a means of carbon sequestration, raising doubts about the effects on fire, albedo, biodiversity and water yield (see Box 2.2).

Substantial climate-change driven impacts on tropical tree cover and vegetation type are projected in all studies, irrespective of whether or not the degree amounts to a forest "dieback" (Sections 2.4.3.6, 2.4.4.3; 2.5.2.6, 2.5.3.3; AR6 WGI Chapter 5) (Davies-Barnard et al., 2015; Wu et al., 2016a; Zemp et al., 2017a). Accordingly, models also suggest a continuation of tropical forests acting as carbon sinks (Huntingford et al., 2013; Mercado et al., 2018). A recent study, combining field plot data with statistical models, (Hubau et al., 2020) indicates that in the Amazonian and possibly also in the African forest the carbon sink in aboveground biomass has already declined over the three decades to 2015. This trend is distinct in the Amazon, whereas data from Africa suggest a possible decline after 2010. the authors estimate the vegetation carbon sink in 2030-2040 to decline to zero (-0.5–0-46) Pg C a^{-1} in the Amazon and 0.26 (0.04–0.47, a loss of 14% compared to present) Pg C a^{-1} in Africa. Their results suggest that CO_2 fertilisation is over time outweighed by impacts of higher temperatures and drought, enhancing tree mortality and diminishing growth. The degree of thermal resilience of tropical forest still remains uncertain, however (Sullivan et al., 2020).

The lack of simulation studies that seek to quantify all important interacting factors (CO_2, drought and fire) for future carbon-cycling in savannas and tropical forests, and the apparent disagreement between trends projected in models compared to data-driven estimates results in *low confidence* regarding the direction or magnitude of carbon flux and pool size changes. Similar to tropical peatlands, given projected human population growth and socio-economic changes. the continued conversion of forests and savannas into agricultural or pasture systems *very likely* poses a significant risk of rapid carbon loss which will amplify climate change induced risks substantially (*high confidence*) (Sections 2.5.2.10, 2.5.3.5; Aragao et al., 2014; Searchinger et al., 2015; Aleman et al., 2016; Nobre et al., 2016).

The impacts of climate-induced altered animal composition and trophic cascades on global land ecosystem carbon cycling are as yet unquantified (Schmitz et al., 2018) even though climate change is expected to lead to shifts in consumer-resource interactions that also contribute to losses of top-predators or top herbivores (Sections 2.4.2.2, 2.5.1.3, 2.5.4; Lurgi et al., 2012; Damien and Tougeron, 2019). Cascading trophic effects triggered by top predators or the largest herbivores propagate through food webs and reverberate through to the functioning of whole ecosystems, altering notably productivity, carbon and nutrient turnover and net carbon storage (*medium confidence)* (Wilmers and Schmitz, 2016; Sobral et al., 2017; Stoner et al., 2018). Across different field experiments, the ecosystem consequences of the presence or absence of herbivores and carnivores have been found to be quantitatively as large as the effects of other environmental change drivers such as warming, enhanced CO_2, fire or variable nitrogen deposition (*medium confidence*) (Hooper et al., 2012; Smith et al., 2015). Some local and regional-scale modelling experiments have begun to explore animal impacts on vegetation dynamics and carbon and nutrient cycling (Pachzelt et al., 2015; Dangal et al., 2017; Berzaghi et al., 2019). Given that turnover rate is a chief factor that determines future land ecosystem carbon dynamics and hence carbon-climate feedbacks (Friend et al., 2014). To improve projections, it is imperative to better quantify the broader role of carnivores, grazers, browsers, and the way these interact in global studies of how ecosystems respond to climate change.

2.5.3.5 Feedbacks between Ecosystems and Climate

The possibility of feedbacks and interactions between climate drivers and biological systems or ecological processes was identified as a significant emerging issue in AR5, and has since also been highlighted in the CRCCL and the Special Report on 1.5ºC. It is virtually certain that land cover changes affect regional and global climate through changes to albedo, evapotranspiration and roughness (*very high confidence*) (Perugini et al., 2017). There is growing evidence that biosphere-related climate processes are being affected by climate change in combination with disturbance and land use change (*high confidence*) (Jia et al., 2019). It is virtually certain that land surface change caused by disturbances such as forest fire, hurricanes, phenological changes, insect outbreaks and deforestation affect carbon, water, and energy exchanges, thereby influencing weather and climate (*very high confidence*) (Table 2.4; Figure 2.10; Bright et al., 2013; Brovkin et al., 2013; Naudts et al., 2016; Prăvălie, 2018).

Table 2.4: Terrestrial and freshwater ecosystem feedbacks which affect the Earth's climate system dynamics, following (Prăvălie, 2018).

Perturbation	Implications for Warming/Feedback Mechanism the Earth's Climate System Dynamics
Phenological change	Increased primary productivity and plant growth with CO_2 fertilisation (Mao et al., 2016; Wang et al., 2018a); Increasing growing season length (Peñuelas et al., 2009; Barichivich et al., 2013); reduced diurnal temperature range through evapotranspiration (mid-latitudes) and albedo (high latitudes) caused by vegetation greening (Jeong et al., 2011); increased CO_2 storage in biomass (cooling) (Keenan et al., 2014); Reduced albedo in snow-covered regions as canopies become taller and darker (warming); increased evapotranspiration, a key component of the global water cycle and energy balance which influences global rainfall, temperature, and atmospheric motion (Zeng et al., 2017).
Insect outbreaks	Reduced carbon uptake and storage (warming); Increased surface albedo (cooling) (Landry et al., 2016); increased CO_2 emissions (warming); decreased leaf area index and gross primary productivity (Ghimire et al., 2015), leading to reduced evapotranspiration and increased land surface temperature (Bright et al., 2013).
Range shifts	Reduced albedo in snow-covered regions as trees expand poleward (warming) (Chae et al., 2015); enhanced permafrost thawing; expansion of insect outbreak range, increasing forest impact (Pureswaran et al., 2018); biome dependent changes in albedo and evapotranspiration regimes (Naudts et al., 2016). Reduction in snow and ice albedo in freshwater due to loss of ice (warming) (Lang et al., 2018).
Die-off and large-scale mortality events	Decreased Gross primary productivity (GPP); decline in carbon storage (warming); increased CO_2 emissions; increased solar radiation, reduced soil moisture, higher surface runoff; albedo effects (Lewis et al., 2011; Prăvălie, 2018)
Deforestation	Reduced carbon storage (warming) (Pugh et al., 2019a); increase in (regional) surface air temperature due to reduced evaporation (less cooling); increased albedo in high-latitude systems (regional radiative cooling) (Loranty et al., 2014); increased air temperature and diurnal temperature variation (Alkama and Cescatti, 2016), locally and globally (Winckler et al., 2019); reduced precipitation (Perugini et al., 2017); decreased biogenic volatile organic compounds (BVOC) and aerosol emissions (warming through direct and indirect aerosol effects; cooling associated with reduction in atmospheric methane (Jia et al., 2019)
Forest degradation	Reduced carbon storage (warming) (de Paula et al., 2015; Bustamante et al., 2016; de Andrade et al., 2017; Mitchard, 2018)
Fragmentation	Carbon losses because biomass is less developed in forest edges (Pütz et al., 2014; Chaplin-Kramer et al., 2015; Haddad et al., 2015)
Air pollution	Decreased plant productivity, transpiration and carbon sequestration in forest with lower biomass due to ozone toxicity (Sitch et al., 2007; Ainsworth et al., 2012); increased (regional) productivity due to increase in diffuse solar radiation caused by terrestrial aerosols (Xie et al., 2021)
Declining populations of megafauna	Changes to physical and chemical properties of organic matter, soils and sediments influence carbon uptake and storage (Schmitz et al., 2018); increased or decreased carbon storage biomass and carbon storage, with differences across biomes determined by floristic structure and animal size (Bello et al., 2015; Osuri et al., 2016; Peres et al., 2016; He et al., 2017; Berzaghi et al., 2018; Schmitz et al., 2018; He et al., 2019)
Fire	Increased carbon and aerosol emissions(van der Werf et al., 2017); surface warming (Liu et al., 2019b); albedo effect dependent on ecosystem and species-level traits (Rogers et al., 2015; Chen et al., 2018a) (initial albedo decrease post-fire; increased albedo where snow exposure is increased by canopy removal and species composition changes during recovery); black carbon deposition on snow and sea ice (short-term) (Randerson et al., 2006); indirect increases in carbon emissions due to soil erosion (Caon et al., 2014)
Change in forest composition	Reduced carbon storage due to decline in biomass (warming) (McIntyre et al., 2015)
Woody encroachment in non-forested ecosystems	Reduced production, increased water use, reduced albedo and altered land-atmosphere feedbacks; increased carbon storage in woody savannas (Zhou et al., 2017; Mureva et al., 2018); Uncertain feedbacks to C cycle (some suggest an increase, others a decrease)
Net Primary Productivity (NPP) shifts	Reduced albedo following high-latitude expansion of trees caused by photosynthetic enhancement of growth (cooling); increased photosynthesis and net ecosystem production (NEP) (Fernandez-Martinez et al., 2019); increased NPP in N-limited ecosystems due to increased nitrogen deposition from agriculture and combustion (Du and de Vries, 2018; Schulte-Uebbing and de Vries, 2018); Nutrient limited lakes are likely to become less productive, while nutrient rich lakes are likely to become more productive due to warming induced prolongation of stable stratification (Adrian et al., 2016; Kraemer et al., 2017).
Biogeochemical shifts	Decline in carbon storage due to nitrogen limitation in N limited systems (warming)(Reich et al., 2014; Wieder et al., 2015); increased carbon storage on land(Peñuelas et al., 2013) and in lakes (Heathcote et al., 2015; Mendonça et al., 2017); Increase in CO_2 and CH4 emissions from freshwater ecosystems due to increased eutrophication (DelSontro et al., 2018), the imbalance

between losses and gains of CO_2 by photosynthesis and respiration (metabolic theory of ecology), enhanced emissions from exposed river and lake sediments during droughts and re-wetting (Marcé et al., 2019; Keller et al., 2020), enhanced CH4 ebullition of seasonally hypoxic lakes (Aben et al., 2017; DelSontro et al., 2018; Bartosiewicz et al., 2019; Beaulieu et al., 2019; Sanches et al., 2019), increased transfer of organic carbon from land to water (particularly in permafrost areas) (Wauthy et al., 2018)

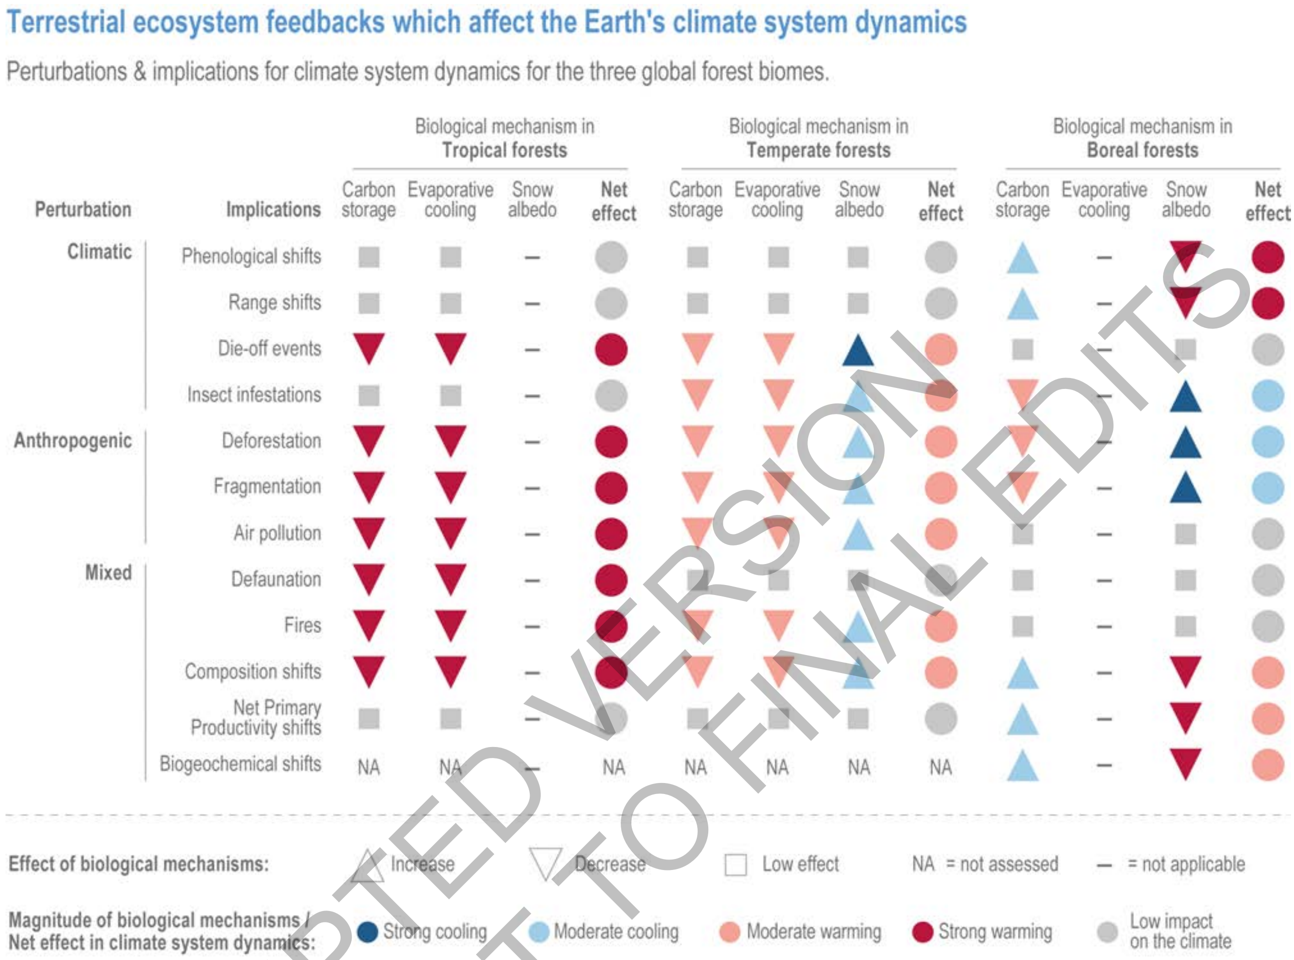

Figure 2.10: Terrestrial ecosystem feedbacks, which affect the Earth's climate system dynamics. Perturbations and implications for climate system dynamics (warming/cooling) are shown for the three global forest biomes (adapted from Figure 5, Prăvălie, 2018). The strength of the mechanism is estimated in general terms based on the magnitude of carbon storage and evaporative cooling processes that characterise each forest biome (Bonan, 2008). Carbon storage includes forest biomass, without accounting for carbon dynamics in soil, peat and underlying permafrost deposits. Implications of biogeochemical shifts were only estimated in relation to the intensification of the carbon cycle and increase in biomass at high latitudes, assuming N availability for the stoichiometric demands of forest vegetation).

Feedbacks can be positive or negative (i.e., amplify or dampen the original forcing), vary spatially and seasonally, and act over large geographic areas and long time periods (>decades), making them difficult to observe and quantify directly (AR6 WGI Chapter 5; Schimel et al., 2015). Due to the positive impacts of CO_2 on vegetation growth and ecosystem carbon storage (*high confidence*) (Sections 2.4.4.4; 2.5.5.4; AR6 WGI chapter 5), the associated climate feedback is negative (increased removal of atmospheric CO_2 and dampened warming, compared to absence of the feedback). By contrast, projected global losses of carbon in warmer climates (AR6 WGI Chapter 5) imply a positive climate feedback. Chapter 5 of WGI assesses an overall increase in land carbon uptake through the 21st century. However, the overall strength of the carbon cycle-climate feedback remains very uncertain. One of the underlying reasons may be complex interactions with ecosystem water balance and nitrogen and phosphorous availability, which are poorly constrained by observational evidence and incompletely captured in Earth System Models (AR6 WGI Chapter 5, Section 2.5.2.10; Huntzinger et al., 2017).

Land ecosystems contribute substantially to global emissions of nitrous-oxides and methane. As with CO_2, these emissions respond both directly and indirectly to atmospheric CO_2 concentration and climate change, which gives rise to potential additional biogeochemical feedbacks in the climate system. A large part of these emissions stem from land and water management, such as fertiliser application, rice production, aquaculture or animal husbandry (Jia et al., 2019). However, nearly 60% of total nitrous-oxide emissions (2007-2016) is estimated to stem from natural ecosystems, especially in the tropics (AR6 WGI Chapter 5; Tian et al., 2019), while freshwater wetlands and peatlands are estimated to contribute between 83% (top-down estimates) and 40% (bottom up estimates) of total natural CH_4 (and 31% or 20% of total methane emissions, respectively) for the period 2008-2017 (AR6 WGI Chapter 5). Median CH_4 emissions from northern latitude wetlands in 2100 were estimated to be 12.1 and 13.5 Pg C in emission scenarios leading to 1.5ºC and 2ºC warming, respectively (Comyn-Platt et al., 2018). Likewise, global warming was attributed to soil N_2O emission increases since the pre-industrial period of 0.8 (0.3–1.3) Tg N a^{-1} (Tian et al., 2020). Overall, climate feedbacks from future altered land ecosystem emissions of CH_4 or N_2O are uncertain, but expected to be small (AR6 WGI Chapter 5).

Changes in regional biodiversity are integral parts of ecosystem-climate feedback loops, including and beyond carbon-cycle processes (Figure 2.10; Table 2.4). For instance, the impacts of climate-induced altered animal composition and trophic cascades on ecosystem carbon turnover (see Sections 2.4.4.4; 2.5.3.4) could be a substantive contribution to carbon-climate feedbacks (*low confidence*). Additional surface-atmosphere feedbacks that arise from changes in vegetation cover and subsequently altered albedo, evapotranspiration or roughness (often summarised as biophysical feedbacks) can be regionally relevant and could amplify or dampen vegetation cover changes (Jia et al., 2019).

Climate-induced shifts towards forests in what is currently tundra would be expected to reduce regional albedo especially in spring but also during parts of winter when trees are snow-free (whereas tundra vegetation would be covered in snow), which amplifies warming regionally (*high confidence*) (Perugini et al., 2017; Jia et al., 2019). Trees would also enhance momentum absorption compared to low tundra vegetation thus impacting surface-atmosphere mixing of latent and sensible heat fluxes (Jia et al., 2019). Boreal forests insulate and stabilize permafrost and reduce fluctuations of ground temperature: the amplitude of variation of ground surface temperatures was 28°C in a forested site, compared to 60°C in nearby grassland (Section 2.5.2.7; Bonan, 1989; Stuenzi et al., 2021a; Stuenzi et al., 2021b). Likewise, a shift in moist tropical forests towards vegetation with drought-tolerant traits could possibly reduce evapotranspiration, increase albedo, alter heat transfer at the surface and lead to a negative feedback to precipitation (Section 2.5.2.6; Jia et al., 2019). In savannas, restoration of woody vegetation has been shown to enhance cloud formation and precipitation in response to enhanced transpiration and turbulent mixing, leading to a positive feedback on woody cover (Syktus and McAlpine, 2016). While this has not yet been systematically explored, similar feedbacks might also emerge from a CO_2-induced woody cover increase in savannas (*low confidence*) (Section 2.5.2.5).

Since biophysical feedbacks can contribute to both surface temperature warming or cooling, analyses so far suggest that, at global scale, the net impact on climate change is small (Perugini et al., 2017; Jia et al., 2019), unless these feedbacks also accelerate vegetation mortality and lead to substantive carbon losses (Zemp et al., 2017a; Lemordant and Gentine, 2019). More than one third of the Earth's land surface has at least 50% of its evapotranspiration regulated by vegetation, and in some regions between 40 and >80% of the land's evaporated water is returned to land as precipitation. Locally, both, direct human-mediated as well as climate change-mediated vegetation cover change can therefore notably affect annual average freshwater availability to human societies, especially if negative feedbacks amplify vegetation cover reduction, reduced evapotranspiration and reduced precipitation (*medium confidence*) (Keys et al., 2016; Keys and Wang-Erlandsson, 2018).

Since AR5, freshwater ecosystems (lakes, reservoirs, rivers, ponds) have been increasingly recognised as important sources of greenhouse gas emissions (CO_2, CH_4, N_2O) into the atmosphere. Key mechanisms which contribute to rising GHG emissions from freshwater ecosystems are the temperature imbalance between photosynthesis and respiration (respiration increases more than photosynthesis with rising temperature), CO_2 and CH_4 emissions from exposed sediments during droughts, increased matter transport from land to water, changes in water retention time in rivers and lakes, and temperature effects on lake stratification and anoxia, favouring CH_4 emissions.

DelSontro et al. (2018) assembled the largest global dataset to date on emission rates from lakes of CO_2, CH_4 and N_2O and found that they co-vary with lake size and trophic state. They estimated that moderate global increases in eutrophication of lakes could translate to 5–40% increases in the GHG effects in the atmosphere. Moreover, they estimated that greenhouse gas emissions from lakes and impoundments in past decades accounted for 1.25-2.30 Pg C-CO_2 yr^{-1} (DelSontro et al., 2018), thus around 20% of global burning fossil-fuel CO_2 emission (9.4 PgC-CO_2 yr^{-1} (Friedlingstein et al., 2020).

Global warming will strongly enhance freshwater CH_4 emissions through a disproportionate increase in ebullition (gas flux) by 6–20% per 1°C increase in water temperature (Aben et al., 2017). It can be expected that ongoing eutrophication enhanced by climate change-related increases in sediment nutrient release and organic carbon and nutrient loading from catchments will enhance CH_4 ebullition at a global scale (Aben et al., 2017; DelSontro et al., 2018; Bartosiewicz et al., 2019; Beaulieu et al., 2019; Sanches et al., 2019). The strongest increase in ebullition is expected in shallow waters where sediment temperatures are strongly related to atmospheric temperature (Aben et al., 2017). Given that small ponds and shallow lakes are the most abundant freshwater ecosystems globally they may become hot spots of CH_4 ebullition in the future (Aben et al., 2017). On average CH_4, CO_2, N_2O account for 75%, 23, and 2% of the total CO_2 equivalent emissions, respectively in lakes (DelSontro et al., 2018).

Further, the exposure of lake and river sediments during droughts activates decomposition of buried organic carbon. In dry river beds, mineralisation of buried organic matter is likely to increase with climate change as anoxic sediments are oxygenated downwards during drying along with pulses of microbial activity following rewetting of desiccated sediment. Conservative estimates indicate that adding emissions from exposed sediments of dry inland waters across diverse ecosystem types and climate zones to current global estimates of CO_2 emissions could result in a 6% (~0.12 Pg C y^{-1}) increase of total inland water CO_2 emission rates covering streams and rivers (334 mmol m^{-2} day^{-1}), lakes and reservoirs (320 mmol m^{-2} day^{-1}) and small ponds (148 mmol m^{-2} day^{-1}) (Marcé et al., 2019; Keller et al., 2020).

Overall, uncertainty in the quantity of carbon fluxes within freshwater ecosystems and between terrestrial and freshwater systems and subsequent emissions to the atmosphere remain very high (Raymond et al., 2013; Catalán et al., 2016; Stanley et al., 2016; Evans et al., 2017; Drake et al., 2018; Seekell et al., 2018; Sanches et al., 2019; Bodmer et al., 2020; Keller et al., 2020) (see Table 2.SM., see also Chapter 5 of WGI). Projections of carbon fluxes are e.g. challenged by the complex interaction between rising water temperature, loss of ice, changes in hydrology, ecosystem productivity, increase in extreme events, and variation in terrestrial matter transport. While we are still short in empirical data, particularly in the tropics (DelSontro et al., 2018), improvements in sensor technology (Eugster et al., 2011; Gonzalez-Valencia et al., 2014; Maeck et al., 2014; Delwiche et al., 2015) and the use of statistically robust survey designs (Beaulieu et al., 2016; Wik et al., 2016) have improved the accuracy of GHG emission rate measurements in freshwater ecosystems. Global networks such as GLEON (Global Lakes Ecological Observatory Network) increasingly allow a global view of carbon fluxes improving estimates of the contribution of freshwater ecosystems to global GHG emissions to the atmosphere.

In summary (Drake et al., 2018) aggregated contemporary estimates of CO_2 and CH_4 emissions from freshwater ecosystems with global estimates made by (Raymond et al., 2013) and arrived at an estimate of 3.9 Pg C yr^{-1}. Rivers and streams accounted for 85% of the emissions and lakes and reservoirs for 15% (Raymond et al., 2013). This trend will continue under scenarios of nutrient loading to inland waters over the next century where inland water increased CH_4 emission has an atmospheric impact of 1.7–2.6 Pg C-CO_2-eq y^{-1}, which is equivalent to 18–33% of annual CO_2 emissions from burning fossil fuels (*medium evidence, medium agreement, medium confidence*) (Beaulieu et al., 2019). For comparison, annual uptake of CO_2 in land ecosystems is estimated as 3.4 (± 0.9) PgC/yr (Friedlingstein et al., 2020). The freshwater numbers combine CO_2 and CH_4 and are thus not directly comparable. However, they are indicative for the importance to account better for freshwater systems in global carbon budgets.

2.5.3.6 Risks to Freshwater Ecosystem Services: Drinking Water, Fisheries and Hydropower

AR5 named water supply and biodiversity as freshwater ecosystem services vulnerable to climate change. We discuss risks to these and to additional services identified by model projections based both on climate-change scenarios (Schröter et al., 2005; Boithias et al., 2014; Huang et al., 2019; Jorda-Capdevila et al., 2019) and on the Common International Classification of Ecosystem Services (*high agreement, high confidence*) (CICES, 2018). Effects of floods, droughts, permafrost and glacier melting on global changes in water quality, particularly with respect to contamination with pollutants, are described in Section 4.2.6.

2.5.3.6.1 Risks to quantity and quality of drinking water

Forests and other vegetated ecosystems assist production of drinkable water by facilitating infiltration of rainfall and snowfall into the ground, where water either moves through the soil saturated zone to supply streams and other surface waters or infiltrates further to recharge groundwater aquifers (Ellison et al., 2012; Bonnesoeur et al., 2019). Globally, 4 billion people depend on forested watersheds for drinking water (Mekonnen and Hoekstra, 2016). Chapter 4 assesses the physical science of water supply, including precipitation, runoff, and hydrology, and social aspects of human water use. This section assesses ecological aspects of risks to freshwater supplies for people.

Reduction of vegetation cover following wildfires (Section 2.5.5.2) and tree mortality (Section 2.5.5.3) can reduce long-term water infiltration, increase soil erosion and flash floods, and release sediment that degrades drinking water quality. Widlfires increase impacts of extreme precipitation events due to climate change, which contribute to increased surface runoff and hence to increased risks of land erosion, landslides and flooding (Ebel et al., 2012; Robinne et al., 2020). Under current conditions, nearly half of global land area is at moderate to high risk of water scarcity due to wildfires (Robinne et al., 2018; Robinne et al., 2020). From 1984 to 2014 wildfires in the western USA affected 6-11% of stream and river length (Ball et al., 2021). Under a high emissions scenario of a 3.5ºC temperature increase post-fire erosion across the western USA could double sedimentation and degrade drinking water quality in one-third of watersheds by 2050 (Sankey et al., 2017). In Brazil, post-fire vegetation loss tends to increase runoff, reduce infiltration, and reduce groundwater recharge and flow of springs (Rodrigues et al., 2019). Runoff from wildfires can contain dissolved organic carbon precursors for the formation of carcinogenic trihalomethanes during water chlorination for drinking (Uzun et al., 2020), plus chromium, mercury, selenium, and other toxic trace metals (Burton et al., 2016; Burton et al., 2019).

Net effects of deforestation and afforestation on runoff and water supply depend on local factors, leading to conflicting evidence for effects of land cover change (Ellison et al., 2012; Chen et al., 2021b), but combinations of climate change and deforestation are projected to reduce water flows (Olivares et al., 2019). In southern Thailand, the combination of conversion of forest to rubber plantations and a one-third increase in rainfall could increase erosion and sediment load 15% (Trisurat et al., 2016). In the watershed that supplies São Paulo, Brazil, afforestation could increase water quantity and quality (Ferreira et al., 2019). In most regions with dry or Mediterranean subtropical climates, climate change reduces renewable surface water and groundwater resources significantly (Doell et al., 2015). In northeast Spain, reduced precipitation and vegetation cover under a high emissions scenario of a 3.5ºC temperature increase could reduce drinking water supplies by half by 2100 (Bangash et al., 2013).

Changes in algal biomass development and spread of cyanobacteria blooms, related to global warming, resemble those triggered by eutrophication with well-known negative effects on the services lakes provide, particularly for drinking water provision and recreation (*robust empirical evidence*, *high agreement, high confidence*) (Carvalho et al., 2013; Adrian et al., 2016; Gozlan et al., 2019).

Based on a 10% increase in precipitation, (de Wit et al., 2016) estimated increased mobilisation of organic carbon from soils to freshwaters by at least 30%, demonstrating the importance of climate wetting for the carbon cycle. Browning negatively affects the taste of drinking water and may be difficult to address (Kothawala et al., 2015; Mineau et al., 2016; Kritzberg et al., 2020). It also often reduces attractives for recreational purposes, especially swimming (Arthington and Hadwen, 2003; Keeler et al., 2015). Based on a worst-case climate scenario until 2030 (Weyhenmeyer et al., 2016) projected an increase in browning of lakes and rivers in boreal Sweden by a factor of 1.3. The chemical character of dissolved organic matter, as modified by climate change (Kellerman et al., 2014), determines its amenability to removal by water treatment (Ritson et al., 2014). Therefore, in order to provide safe and acceptable drinking water, more advanced, more expensive and more energy/resource intensive technical solutions may be required (Matilainen et al., 2010).

In summary, climate change increases risks to the integrity of watersheds and provision of safe, acceptable freshwater to people (*medium evidence, medium agreement*).

2.5.3.6.2 Risks to freshwater fisheries and biodiversity

Climate change will increase water temperatures and decrease dissolved oxygen levels (Section 2.3.1) impacting freshwater fisheries which form an important ecosystem service (Vári et al., 2021). People living in the vicinity of cold lakes will be affected by projected losses of ice. In a worst-case scenario (air temperatures increase of 8°C), 230,400 lakes and 656 million people in 50 countries will be impacted (Reid et al., 2019; Sharma et al., 2019). Winter ice fishing (Orru et al., 2014), transportation via ice roads (Prowse et al., 2011) and cultural activities (Magnuson and Lathrop, 2014) are ecosystem services at stake with ongoing loss of lake ice.

Eutrophication of central European lakes has wiped out a significant proportion of the endemic fish fauna (Vonlanthen et al., 2012), so climate-induced further eutrophication is expected to represent an additional threat to fish fauna and commercial fisheries (Ficke et al., 2007). Given that the ecological consequences of lake warming may be especially strong in the tropics (Section 2.3.1.1), ecosystem services may be most affected there. Tropical lakes support important fisheries (Lynch et al., 2016a economic; McIntyre et al., 2016) providing critical sources of nutrition to adjacent human populations. These lakes are especially prone to loss of deep-water oxygen due to warming, with adverse consequences for fisheries productivity and biodiversity (*medium evidence, medium confidence*) (Lewis Jr, 2000; Van Bocxlaer et al., 2012).

Tropical lakes tend to be hotspots of freshwater biodiversity (Vadeboncoeur et al., 2011; Brawand et al., 2014; Sterner et al., 2020); ancient tropical lakes such as Malawi, Tanganyika, Victoria, Titicaca, Towuti and Matano hold thousands of animal species found nowhere else (Vadeboncoeur et al., 2011). While biodiversity and several ecosystem services can be considered synergistic (food webs, tourism, aesthetical and spiritual value (Langhans et al., 2019), others can be considered antagonistic in case of a strong ecosystem service demand (such as water abstraction, water use, food security in terms of over-exploitation). Here the balance between biodiversity and ecosystem services is key (Langhans et al., 2019), where biodiversity can be integrated into water policy through Integrated Water Resource Management (IWRM) towards nature-based solutions (Ligtvoet et al., 2017)

2.5.3.6.3 Risks to hydro power and erosion control

River banks, riparian vegetation and macrophyte beds play important roles in erosion control through reducing current velocities, increasing sedimentation and reducing turbidity (Madsen et al., 2001). Rates of flow in rivers affect and inland navigation (Vári et al., 2021). Changing seasonality in snow-dominated basins is expected to enhance hydropower production in winter, but decrease it during summer (Doell et al., 2015). Glacier melt changes hydrological regimes, sediment transport, and biogeochemical and contaminant fluxes from rivers to oceans, profoundly influencing ecosystem services that glacier-fed rivers provide, particularly provision of water for agriculture, hydropower, and consumption (Milner et al., 2017). Loss of glacial mass and snowpack has already impacted flow rates, quantities and seasonality (Hock et al., 2019); see AR6 WGII, Chapter 4 Water). Meltwater yields from glacier ice are likely to increase in many regions during the next decades, but decrease thereafter as glaciers become smaller and smaller and finally disappear (Hock et al., 2019).

2.5.4 Key Risks to Terrestrial and Freshwater Ecosystems from Climate Change

Among numerous risks to terrestrial and freshwater ecosystems from climate change, this IPCC chapter identified five phenomena as the most fundamental risks of climate change to ecosystem integrity and the ecosystem services that support human well-being that are also quantified: species losses to ecosystems, increased wildfire, increased tree mortality, ecosystem carbon losses, and ecosystem structure change (Table 2.5, Table 2.S.4, Figure 2.11). These key risks form part of the overall assessment of key risks in Chapter 16. The IPCC Fifth Assessment Report chapter on terrestrial ecosystems (Settele et al., 2014) had also identified three of these key risks – species extinctions, tree mortality, ecosystem carbon losses – and a fourth – invasion by non-native species. This IPCC chater assesses impacts of climate change on invasive species in multiple sections with respect to different processes or systems (e.g. in Section 2.4.2.3.3), and here includes this aspect in a new broader key risk of ecosystem structure change. The IPCC Fifth Assessment Report had included wildfire as a mechanism of the ecosystem carbon loss key risk. Based on additional research and field experience with major wildfires since then, this IPCC chapter sets wildfire apart as a specific key risk to ecosystem integrity and human well-being. These different measures of risk are interconnected but approach assessment of risk to terrestrial and freshwater ecosytems from different angles, using complementary metrics.

Species are the fundamental unit of ecosystems. As species become rare, their roles in the functioning of the ecosystem diminishes, and disappears altogether if they go locally extinct *(high confidence)* (Isbell et al., 2015; Chen et al., 2018b; van der Plas, 2019; Wang et al., 2021b). Loss of species and functional groups reduces the ability of an ecosystem to provide services, and lowers its resilience to climate change *(high confidence)* (Section 2.6.7; Elmqvist et al., 2003; Cadotte et al., 2011; Harrison et al., 2014; Carlucci et al., 2020). For example, among crop systems, a key factor to succesful pollination is the phylogenetic diversity of bee species available, more than total abundances (Drossart and Gérard, 2020). Because many species have obligate interactions with, or are resources for, other species (e.g. predators and their prey, insects and their host plants, plants and their mycorrhizae symbionts), loss of one species affects risk to another species and, ultimately, ecosystem functioning (Mahoney and Bishop, 2017)

Global rates of species extinction are accelerating dramatically (Barnosky et al., 2011), with approximately 10% of species having been driven extinct by humans since the late Pleistocene, principally by over-exploitation and habitat destruction, a rate estimated to be 1000 times higher than pre-Anthropocene (natural) background extinction rates (De Vos et al., 2015). Therefore, this level—10%—of species becoming endangered (sensu IUCN) due to loss of suitable climate space (Figure 2.8b), is used here as a threshold moving risk to biodiversity from moderate to high, and twice that (20%) as the threshold from high to very high.

Key risks assessed here are interconnected. Extinction of species is an irreversible impact of climate change, has negative consequences on ecosystem integrity and functioning, and risk increases steeply with even small rises in global temperature (Section 2.5.1.3; Figure 2.6; Figure 2.7; Figure 2.8). Continued climate change substantially increases risks of carbon losses due to wildfires, tree mortality from drought and insect pest outbreaks, peatland drying, permafrost thaw, and ecosystem structure change which could exacerbate self-reinforcing feedbacks between emissions from high-carbon ecosystems and increasing global temperatures (*medium confidence*). Thawing of Arctic permafrost alone could release 11–200 Gt carbon *(medium confidence)*. Complex interactions of climate change, land use change, carbon dioxide fluxes, and vegetation changes will regulate the future carbon balance of the biosphere, processes incompletely represented in earth system models. The exact timing and magnitude of climate-biosphere feedbacks and potential tipping points of carbon loss are characterized by high ranges of the estimates, yet studies indicate increased ecosystem carbon losses could cause extreme future temperature increases (*medium confidence*) (Sections 2.5.2.7; 2.5.2.8; 2.5.2.9; 2.5.3.2; 2.5.3.3; 2.5.3.4; 2.5.3.5; Figure 2.10; Figure 2.11; Table 2.4; Table 2.5; Table 2.S.2; Table 2.S.4)

Table 2.5: Key risks to terrestrial and freshwater ecosystems from climate change. This IPCC chapter assesses these as the most fundamental risks of climate change to ecosystem integrity and the ecosystem services that support human well-being. Climate factors include the primary variables governing the risk. Non-climate factors include other phenomena that can dominate or contribute to the risk. Detection and attribution comprise cases of observed changes attributed predominantly or in part to anthropogenic climate change (Section 2.4.2, 2.4.3, 2.4.4, 2.4.5, Table 2.2, Table 2.3, Table 2.S.1). Adaptation includes options to address the risk (Section 2.6). Risk transitions (defined in Figure 2.11) indicate an approximate global mean surface temperature increase, relative to the pre-industrial period (1850-1900), to move from one level of risk to the other and confidence in the assessment. Table 2.S.4 provides details of the temperature levels for risk transitions. Both tables provides details for the key risk burning embers diagram (Figure 2.11).

Biodiversity Risk: Increasing high extinction risk (species projected loss of >50% of range) among increasing number of plant and animal species. The transition from non-detectable to moderate was based on the number of local population extinctions, major declines of sub-species and two global species extinctions and that are attributable to climate change. The transition from moderate to high is centred around 1.5°C based on a few taxa that are known from their basic biology and habitat requirements to be at risk of extinction (endangered) at 1.5°C and on the increasing number of taxa that are projected to have high extinction risk (losing >50% of their suitable climate space) affecting >10% of the species in that taxa (1000x natural background rates of extinction). The

transition to very high comes from the increasing number of taxa projected to have >20% of species at high risk of extinction. In the worst-case scenario (10th percentile of the models), some of the taxa show >50% of the species at high risk of extinction. These assessments are also weighted by role the species in the taxa play in performing ecosystem services (both to the ecosystems and to humans, e.g. pollinators, detritivores). Confidence for the moderate threshold is *high* because it is based on observed trends attributed to climate change. Confidence for future projections are is *medium* as these are based on one large study (covering more than 135,000 species) and primarily based on loss of suitable climate. Based on Sections 2.4.2, 2.5.1, 2.6.1, 2.6.6, Table 2.3, Figure 2.6, Table SM2.1 and Table SM2.2.

Climate factors	**Non-climate factors**	**Detection and attribution**	**Adaptation**	**Risk transitions (*confidence*)**
Shifts in geographic placements of climate space; loss of climate space globally; emergence of non-analogue climates, increases in extreme climate events	land use change, habitat degradation from pollution, fertilisation, invasive species	Observed D&A: many cases of population extinctions; two cases of species extinctions (2.4.2.2); species have tracked their climate niches raising confidence in SDM projections (2.4.2.1, 2.4.2.3, 2.4.2.5)	Habitat restoration, habitat creation, increased connectivity of habitats and protected areas, increase in protected areas, assisted colonisation	0.8ºC undetectable-moderate (*high confidence*) 1.58°C moderate-high (*medium confidence*) 2.07°C high-very high (*medium confidence*)

Wildfire: Increasing risk of wildfire that exceeds natural levels, damaging ecosystems, increasing illnesses and death of people, and increasing carbon emissions. Field evidence shows that anthropogenic climate change has increased the area burned by wildfire above natural levels across western North America in the period 1984–2017, increasing burned area up to 11 times in one extreme year and doubling burned area over natural levels in a 32-year period. Burned area has increased in the Amazon, the Arctic, Australia, and parts of Africa and Asia, consistent with, but not formally attributed to anthropogenic climate change. These changes have occurred at global mean surface temperature increases of 0.6-0.9ºC. Empirical and dynamic global vegetation models project increases in burned area and fire frequency above natural levels on all continents under continued climate change, emergence of an anthropogenic signal from natural variation in fire weather for a third of global area, and increases of burned area in regions where fire had been rare or absent, particularly Arctic tundra and Amazon rainforest, at global temperature increases of 1.5-2.5ºC. Models project up to a doubling of burned area globally and wildfire-induced conversion of up to half the area of Amazon rainforest to grassland at temperature increases of 3-4.5ºC. (Sections 2.4.4.2, 2.5.3.2)

Climate factors	**Non-climate factors**	**Detection and attribution**	**Adaptation**	**Risk transitions (*confidence*)**
Increase in magnitude and duration of high temperatures, decrease in precipitation, decrease in relative humidity	Deforestation, agricultural burning, peatland burning	Increased burned area in western North America above natural levels	Reduce deforestation, reduce use of fire in tropical forests, use prescribed burning and allow naturally ignited fires to burn in targeted areas to reduce fuel loads, encourage settlement in non-fire-prone areas	0.75°C undetectable-moderate (*high*) 2.0 °C moderate-high (*medium*) 4.0°C high-very high (*medium*)

Tree mortality: Tree mortality that exceeds natural levels degrades habitat for plant and animal species, increases carbon emissions, and reduces water supplies for people. Anthropogenic climate change caused three cases of drought-induced tree mortality in the period 1945–2007 in western North America, the African Sahel, and North Africa in temperate and tropical ecosystems. Pest infestations and wildfire due to climate change also caused much of the tree mortality in North America. These changes occurred at global mean surface temperature increases of 0.3–0.9ºC above the pre-industrial period. Models project increasingly extensive drought-induced tree mortality at continued temperature increases of 1–2ºC. Models project risks of mortality of up to half of forest area in different biomes at temperature increases of 2.5–4.5ºC. In Amazon rainforests, insufficient plant moisture reserves during drought increase the risk of tree mortality and, combined with increased fire from climate change and deforestation, the risk of a tipping point of massive forest dieback and a biome shift to grassland. (Sections 2.4.4.3, 2.5.2.6, 2.5.3.3, 2.5.3.5)

Climate factors	Non-climate factors	Detection and attribution	Adaptation	Risk transitions (*confidence*)
Increase in temperature, decrease in precipitation, increase in aridity, increase in frequency and severity of drought	Deforestation, land-use change	Tree mortality up to 20% in three regions in Africa and North America	Reduce deforestation, reduce habitat fragmentation, encourage natural regeneration, restore fragmented habitats	0.6°C undetectable-moderate (*high*) 1.5°C: moderate-high (*medium*) 3.0°C high-very high (*medium*)

Ecosystem carbon loss: Increasing risk of ecosystem carbon losses that could substantially raise the atmospheric carbon dioxide level. Measurements have detected emissions of carbon from boreal, temperate, and tropical ecosystems in places where increases in wildfire and tree mortality have been attributed to anthropogenic climate change, at global mean surface temperature increases of 0.6–0.9ºC above the pre-industrial period. Many factors govern the carbon balance of ecosystems, so changes have not been attributed to climate change. Tropical forests and Arctic permafrost contain the highest ecosystem stocks of aboveground and belowground carbon, respectively. Primary tropical forests currently emit more carbon to the atmosphere than they remove due to deforestation and forest degradation. Wildfires in the Arctic are contributing to permafrost thaw and soil carbon release. An emissions scenario of 2ºC increase could thaw ~15% of permafrost area and emit 20-100 Gt carbon by 2100, Under emissions scenarios of a 4ºC global temperature increase, models project possible tipping points of conversion of half of Amazon rainforest to grasslands and thawing of Arctic permafrost that could release 11–200 Gt carbon that could substantially exacerbate climate change. (Sections 2.4.3, 2.4.4.3, 2.4.4.4, 2.5.2.7–10; 2.5.3.2–5; Figure 2.9; Figure 2.10; Figure 2.11; Table 2.4; Table 2.5; Table 2.S.2; Table 2.S.3; Table 2.S.4)

Climate factors	Non-climate factors	Detection and attribution	Adaptation	Risk transitions (*confidence*)
Increase in temperature, increase in aridity, increase in frequency and severity of drought	Deforestation, road and infrastructure expansion, agricultural expansion	Losses of carbon detected in boreal, temperate, and tropical ecosystems, due to wildfire and tree mortality, not formally attributed to climate change	Reduce deforestation, especially in tropical forests, reduce road and infrastructure expansion, especially in the Arctic, reduce use of fire to clear agricultural land, increase protected areas	0.75°C undetectable-moderate (*medium*) 2°C: moderate-high (*medium*) 4°C high-very high (*low*)

Ecosystem Structure Change: Increasing risk of large-scale changes in ecosystem structure. Ecosystem structural change with most information derived for tropical forest, boreal forest, savannas, and tundra for both observations and future projections. The transition from non-detectable to moderate is based on detected changes attributable to climate change, or interactions between changing disturbance regime, climate and rising CO_2, already observed at 0.5°C above pre-industrial, with shifts initially detected in boreal forests, tundra, and tropical grassy ecosystems. Transition from moderate to high is centred around 1.5°C based on widespread global observations (at current GSAT of 1.09°C above pre-industrial) that agree with projected future impacts with at least 10% area of key ecosystems being affected (Box 2.1). Overall confidence in projections is *medium*, based on existing observations and projections giving *high* confidence of risk for several ecosystems but because data and projections are not available for all biomes, overall confidence lowers to *medium*. Transition from high to very high occurs when more than 50% of multiple ecosystems are projected to experience shifts in structure. (Sections 2.4.2.3, 2.4.3, 2.4.5, 2.5.2, Box 2.1, Figure Box 2.1.1, Table Box 2.1.1, Table 2.S.2, Table 2.S.2, Table 2.S.3, Table 2.S.5)

Climate factors	**Non-climate factors**	**Detection and attribution**	**Adaptation**	**Risk transitions (*confidence*)**
Increases in average and extreme temperatures, changes in precipitation amount and timing, increased atmospheric CO_2	Land use change, livestock grazing, deforestation, fire suppression, loss of native herbivores, food, fiber, or wood production	Individual species ranges shifts, biome shifts	Conservation of potential refugia, habitat restoration, increasing connectivity of habitats and protected areas, increase in protected areas, changes in grazing and fire management	0.5°C undetectable-moderate (*high*) 1.5°C moderate-high (*medium*) 2.5°C high-very high (*medium*)

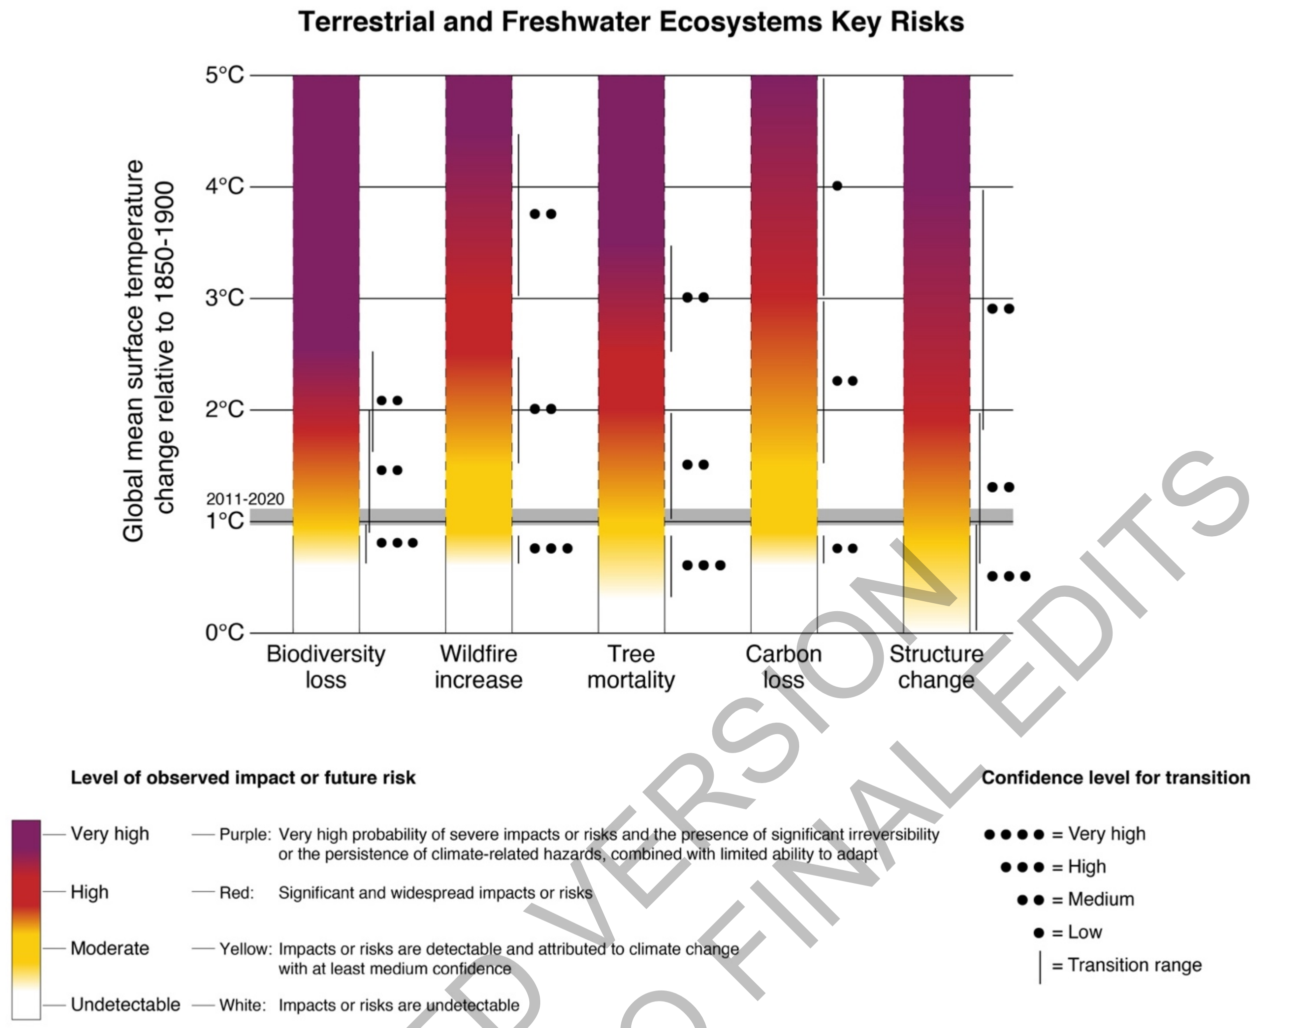

Figure 2.11: Key risks to terrestrial and freshwater ecosystems from climate change. This IPCC chapter assesses these as the most fundamental risks of climate change to ecosystem integrity and the ecosystem services that support human well-being, based on observed impacts and future risks of: (far left) Losses of animal and plant species from different ecosystems globally with resulting declines in ecosystem integrity, functioning and resilience (Section 2.4.2.1, 2.4.2.2, 2.5.1.3.3); (middle left) wildfire exceeding natural levels (Section 2.4.4.2, 2.5.3.2); (middle) tree mortality exceeding natural levels (Chapter 2.4.4.3, 2.5.3.3), (middle right) ecosystem carbon losses that could occur abruptly and substantially raise atmospheric carbon dioxide (Sections 2.4.3.6—2.4.3.9, 2.4.4.4, 2.5.2.6—2.5.2.10, 2.5.3.4, 2.5.3.5); (far right) major changes occurring in ecosystem structure (Sections 2.4.3, Box 2.1, 2.5.2, Figure 2.9, Figure Box 2.1.1, Table Box 2.1.1, Table 2.S.5). This burning embers diagram shows impacts and risks in relation to changes in global mean surface temperature, relative to the pre-industrial period (1850−1900). Risk levels reflect current levels of adaptation and do not include more interventions that could lower risk. The compound effects of climate change combined with deforestation, agricultural expansion, urbanisation, air, water, and soil pollution, and other non-climate hazards could increase risks. Tables 2.5 and 2.S.4 provide details of the key risks and temperature levels for the risk transitions.

[START FAQ2.4 HERE]

FAQ2.4: How does nature benefit human health and well-being and how does climate change affect this?

Human health and well-being are highly dependent on the "health" of nature. Nature provides material and economic services that are essential for human health and productive livelihoods, but studies also show that being in "direct contact with natural environments" has direct positive effects on well-being, health and socio-cognitive abilities. Therefore, the loss of species and biodiversity under climate change will reduce natural space, decrease biodiversity and in turn, decrease human-well-being and health worldwide.

Human health and well-being are highly dependent on the "health" of nature. Biodiversity – the variety of genes, species, communities and ecosystems – provides services that are essential for human health and productive livelihoods, such as breathable air, drinkable water, productive oceans and fertile soils for growing food and fuels. Natural ecosystems also help store carbon and regulate climate, floods, disease, pollution and water quality. The loss of species, leading to reduced biodiversity, has direct and measurable negative effects on all of these essential services, and therefore, on humankind. A recent demonstration of this is the decline of pollinator species, with potential negative effects on crop pollination, a fundamental ecosystem function crucial for agriculture. The loss of wild relatives of the domesticated varieties humans rely on for agriculture reduces the genetic variability that may be needed to support the adaptation of crops to future environmental and social challenges.

The number of species that can be lost before negative impacts occur is not known and is likely to differ in different systems. However, in general, more diverse systems are more resilient to disturbances and able to recover from extreme events more quickly. Biodiversity loss means there are fewer connections within an ecosystem. A simpler food web with fewer interactions means less redundancy in the system, reducing the stability and ability of plants and animal communities to recover from disturbances and extreme weather events such as floods and drought.

In addition to "material" and economic services such as eco-tourism, nature also provides cultural services such as recreation, spirituality and well-being. Specifically, being in "direct contact with natural environments" (versus urban environment) has a high positive and causal impact on human well-being (e.g. mood, happiness), psychological and physical health (energy, vitality, heart rate, depression) and socio-cognitive abilities (attention, memory, hyperactivity, altruism, cooperation). Therefore, the loss of species and biodiversity under climate change and urbanisation will reduce natural space, decrease biodiversity and in turn, decrease human-well-being and health worldwide.

Finally, the extent to which humans consider themselves as part of the natural world – known as human-nature connectedness – has been demonstrated to be closely associated with human health and well-being. Individuals who are more connected to nature are not only happier and healthier but also tend to engage more in pro-nature behaviours, making the enhancement of human-nature connectedness worldwide a valuable win-win solution for humans and nature to face environmental challenges.

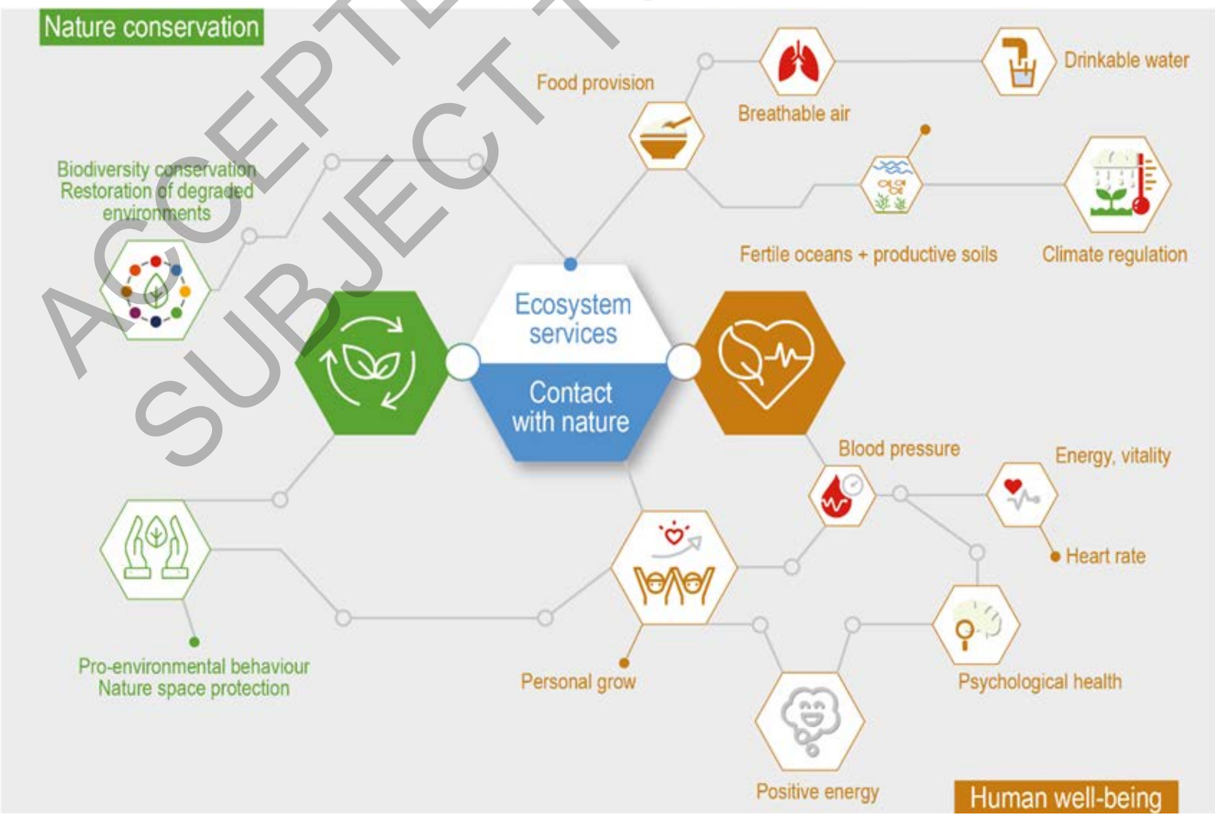

Figure FAQ2.4.1: Positive relationship between human health and well-being and nature conservation. Nature provides essential services to humans including material and economic services (i.e. ecosystem services) as well as cultural, experiential and recreational services, which, in turn enhance human psychological and physical health, and well-being. People who are more connected to nature are not only happier and healthier but are also more likely to engage in pro-nature behaviours, making the enhancement of human-nature connectedness worldwide a valuable win-win solution for humans and nature to face environmental challenges.

[END FAQ2.4 HERE]

2.6 Climate Change Adaptation for Terrestrial and Freshwater Ecosystems

Adaptation to reduce vulnerability of ecosystems and their services to climate change has been addressed in previous IPCC Reports, with AR4 and AR5 recognising both autonomous adaptation and human assisted adaptation to protect natural species and ecosystems. In AR5, Ecosystem-based Adaptation (EbA), adaptation for people, based on better protection, restoration and management of the natural environment, was identified as an area of emerging opportunity, with a dedicated Cross Chapter Box on the topic. In the SRCCL report, conservation, EbA and related concepts were integrated throughout the report; SR1.5 also noted the role of EbA. Since the last assessment report the scientific literature has expanded considerably, with growing interest in the concept of Nature-based Solutions (NbS). This section assesses this new literature and its implications for the implementation of climate change adaptation.

Previous sections of this chapter have set out the vulnerability of natural and semi-natural ecosystems to climate change and the risks this poses both to biodiversity and ecosystem services (also sometimes described as 'Nature's Contributions to People'). Natural systems respond to climatic and other environmental changes in variety of ways. Individual organisms can respond through growth, movement and developmental processes. Species and populations genetically adapt to changing conditions and evolve over successive generations. Geomorphological features, such as the path of watercourses, can also change naturally in response to climate change. However, there is a limit to which these natural processes can maintain biodiversity and the benefits people derive from nature, partly because of intrinsic limits, but also because of the pressures that people exert on the natural environment. Most of this section therefore focuses on human interventions to build the resilience of ecosystems, enable species to survive or to adjust management to climate change. Vulnerability is in many cases exacerbated by the degraded state of many ecosystems as a result of human exploitation and land use change, leading to fragmentation of habitats, loss of species and impaired ecosystem function. This interaction between climate change and environmental degradation means that protecting ecosystems in a natural or near-natural state will be an important pre-requisite for maintaining resilience and give many species the best chance of persisting in a changed climate (Belote et al., 2017; Arneth et al., 2020; Ferrier et al., 2020; França et al., 2020). Protection from degradation, deforestation and exploitation is also essential to maintain critical ecosystem services, including carbon storage and sequestration and water supply (Dinerstein et al., 2020; Pörtner, 2021).

It is worth briefly considering some key concepts that are relevant to adaptation in ecosystems. Adaptation for biodiversity and ecosystems can encompass both managing change and building resilience. We use the definition of 'resilience' set out Chapter 1: 'the capacity of social, economic and environmental systems to cope with a hazardous event or trend or disturbance, responding or reorganising in ways that maintain their essential function, identity and structure while also maintaining the capacity for adaptation, learning and transformation', It includes the concept of 'resistance', which is used in some ecological literature to distinguish systems which a resistant to change from those that recover quickly from change. We consider both interventions designed primarily to protect biodiversity and those intended to reduce the risks of climate change to people.

A variety of terms are used to describe using environmental management reduce the impacts of climate change on people in ways that also benefit biodiversity in the scientific literature, particularly Ecosystem based Adaptation (EbA) and Nature-based Solutions (NbS) (see also Section 1.4). EbA is the use of biodiversity and ecosystem services as part of an overall adaptation strategy to help people to adapt to climate change (CBD, 2009). EbA aims to maintain and increase the resilience and reduce the vulnerability of ecosystems and people in the face of the adverse effects of climate change (Vignola et al., 2009). NbS is a broader term which is not restricted to climate change and is also often used to refer to climate change mitigation; it has been defined by the International Union for the Conservation of Nature (IUCN) as 'Actions to protect, sustainably manage and restore natural or modified ecosystems that address societal challenges effectively and adaptively, simultaneously providing human well-being and biodiversity benefits' (Cohen-Shacham et al., 2016). This widely accepted definition excludes actions, which use the natural environment to solve human problems but do not provide benefits for biodiversity and is closely linked to the concept of the Ecosystem Approach. NbS is not a universally accepted term but it is increasingly used in the scientific literature. It is a concept which recognises the importance of biodiversity in ecosystem service provision and offers the opportunity to address climate change and loss of biodiversity together in an efficient integrated way (Chong, 2014; Seddon et al., 2020a; Ortiz et al., 2021). Given the focus of this chapter is on adaptation we primary use the term EbA as it is more specific, but we do so understanding that it can be regarded as a subset of NbS. The wider concept of NbS for climate change adaptation and mitigation is covered in a Cross-Chapter Box on the topic (see Cross-Chapter Box NATURAL this Chapter).

Whilst we distinguish between adaptation for biodiversity and EbA, it is important to recognise that the two are linked in that if ecosystems themselves are not resilient to climate change, they will not be able to provide adaptation benefits for people. The case for resourcing biodiversity conservation and building the resilience of ecosystems is also strengthened when there are direct benefits for people in addition to the more general benefits of biodiversity.

Ecosystems are specifically included in the adaptation goals set out in the Paris Agreement and are addressed in most national adaptation plans (Seddon et al., 2020b). There is also now a large number of adaptation programmes and plans for local governments and governmental and non-governmental conservation organisations. Adaptation for and by ecosystems needs to be understood and developed in the wider contexts of conservation, Climate Resilient Development and Sustainable Development: there is significant potential synergies, but also conflicts between different objectives, which require an integrated approach (covered further in 2.6.7).

2.6.1 Limits to Autonomous (Natural) Adaptation

Natural ecosystems often have a high degree of resilience and can to some extent adjust to change. Species can adjust through evolutionary adaptation, distribution change, behavioural change, developmental plasticity and ecophysiological adjustment. There are, however, limits to autonomous adaptation, because of intrinsic limitations, the rate at which the climate is changing and the degraded state of many ecosystems.

None of the evolutionary changes either documented or theorised would enable a species to survive and reproduce in climate spaces that it does not already inhabit. Evolutionary responses are *very unlikely* to prevent species extinctions in the case of that species losing its climate space entirely on a regional or global scale (Parmesan and Hanley, 2015). At highest risk are the world's most cold-adapted species (whose habitats are restricted to polar and high mountaintop areas). Examples include the polar bear (Regehr et al., 2016), "sky-island" plants in the tropics (Kidane et al., 2019), mountain-top amphibians in Spain (Enriquez-Urzelai et al., 2019), mountain-top lichens in the Appalachians (USA) (Allen and Lendemer, 2016), and silverswords in Hawaii (Krushelnycky et al., 2013). However, there is potential for using evolutionary changes to enhance the adaptive capacity of target species, as is being done in the Great Barrier reef by translocating symbionts and corals that have survived recent intense heat-induced bleaching events into areas that have had large die-off (Rinkevich, 2019). Multiple studies assessed when and how evolution might be able to help wild species adapt to climate change (Ratnam et al., 2011; Sgro et al., 2011).

Some of the reasons cited in the literature as limits to autonomous adaptation are:

1) Genetic changes in populations require many generations and for many species operate on longer time scales than those, on which the climate is currently changing.

2) Many species are moving to higher latitudes as the climate warms, but not all are keeping pace with changes in suitable climate space (Valladares et al., 2014; Mason et al., 2015). Such climate debt indicates an inability for non-genetic autonomous adaptation (e.g. evidence-limited ability for plastic responses, such as stemming from dispersal limitations, or behavioural restrictions, or physiological constraints).

3) Some species have low capacity for dispersal, which, combined with increased fragmentation of habitats, creates barriers to range shifts to match climate warming. Studies have shown that changes in distribution of species and composition of communities are limited by the presence of intensively managed agricultural land fragmenting natural habitats (Oliver et al., 2017).

There are a variety of mechanisms which promote the resilience of ecosystems through persistence, recovery, and reorganisation (Falk et al., 2019). Changes in the balance of different plant species within a community can maintain the persistence of the community itself, maintaining its value as a habitat for other species and providing ecosystem services (add reference?). In some cases there are negative feedback mechanisms between biological and physical processes, for example in peatlands, lowered water tables resulting from drier conditions can lead to reduced permeability of peat, increasing rates of water loss (Page and Baird, 2016). There are limits to this resilience and the concept of tipping points beyond which ecosystems change state and returning to the original state has been subject of much recent research (van Nes et al., 2016). There is clear evidence that the degradation of ecosystems has reduced their resilience and restoration can help to reduce risks to biodiversity and ecosystem services, discussed below (see Section 2.6.2, 2.6.3). However, as rates of climate change increase, the limits of this approach will start to be reached and losses, including some with potentially catastrophic consequences, cannot be prevented; this is discussed further in Section 2.6.6.

2.6.2 Adaptation for Biodiversity Conservation

A variety of approaches have been identified as potential adaptation measures which people can take to reduce the risks of climate change to biodiversity. (Heller and Zavaleta, 2009) (quoted in AR5) identified 113 categories of recommendation for adaptation from a survey of 112 papers and reports. Since this time the literature has greatly expanded, with thousands of relevant publications. Whilst there is increasing interest in adaptation for biodiversity conservation and a wide range of plans and strategies, there is less evidence of these plans being implemented. Since AR5 a number of studies, predominantly from Europe and North America, have investigated the extent to which adaptation has been integrated into conservation planning and is being implemented at site and regional scale (Macgregor and van Dijk, 2014; Delach et al., 2019; Prober et al., 2019; Clifford et al., 2020; Barr et al., 2021; Duffield et al., 2021). A common pattern in these studies is that vulnerability has been assessed and potential adaptation actions identified, but implementation has been limited beyond actions to improve ecological condition, which may increase resilience at a local scale.

To date most scientific literature on adaptation to reduce risk to biodiversity from climate change has been based on ecological theory rather than observations or practical experience. A recent review (Prober et al., 2019) concluded that out of 473 papers on adaptation, only 16% presented new empirical evidence and very few assessed the effectiveness of actual adaptation actions. It is also the case that relatively little research is focussed on local-scale management interventions rather than larger scale strategies (Ledee et al., 2021), although there are some exceptions (Duffield et al., 2021).

Although direct assessments of the effectiveness of adaptation actions are rare, since AR5 there has been an increasing number of empirical analyses of how different land use and management influences the vulnerability of species and habitats. As climate change often interacts with other factors including ecosystem degradation and fragmentation (Oliver et al., 2015a), actions to address these other interacting factors is expected to build resilience to climate change. Table 2.6 summarises evidence that supports the main categories of proposed adaptation measures. We have taken an inclusive approach and included studies that address extreme weather events such as droughts, which may be exacerbated by climate change as well as long-term changes in climate variables. We have not distinguished between studies in which climate change adaptation was an explicit focus and those in which lessons for adaptation can be learnt from studies conducted for other reasons but inform the assessment of the impacts of actions identified as potential adaptation measures.

Table 2.6: Evidence to support proposed climate change adaptation measures for biodiversity. Highlights that adaptation for biodiversity is a broad concept, encompassing a wide range of actions. It includes targeted interventions to change the microclimate for particular species (for example by shading); through to changing national conservation objectives to take account of changing distributions of species and communities. It includes targeted actions addressing

both climate change and protection and restoration of ecosystems, with multiple additional benefits including reducing vulnerability to climate change. Most of the studies are not direct tests of the impacts of adaptation actions, which, as noted above, is an important evidence gap. There is also a major limitation in that reported studies are predominantly from Europe, North America and Australasia, with little research in other regions.

Proposed Adaptation Measures for Biodiversity	Confidence Assessment	Comment	Selected References
Protect large areas of natural and semi-natural habitat	*Robust evidence, high agreement*	Considerable evidence that intact systems provide better quality and quantity of ecosystem services; that larger intact areas provide better ecosystem services; that species' extinction risk with disturbances, including climate change, are reduced by having large, connected populations; that more biodiverse systems provide higher levels of ecosystem services and are more resilient to climate change than degraded systems that have lost species	Dinerstein et al. (2019); Woodley et al. (2019); Brooks et al. (2020); Zhao et al. (2020); Sala et al. (2021); Pimm et al. (2018); Hannah et al. (2020); Luther et al. (2020)
Increase connectivity in terrestrial habitats – corridors, stepping stones	*Medium evidence, Medium agreement*	Good evidence that some species move more quickly in more connected landscapes. However, not all species do and some species that benefit are invasive / pest / disease species and there is limited empirical evidence showing connectivity has reduced climate change impacts on species to date.	Keeley et al. (2018); Stralberg et al. (2019); von Holle et al. (2020)
Increase connectivity in river networks	*Limited evidence, High agreement*	Connectivity is needed to maintain species and population movements, but river reaches and catchments lack integrated protection.	Hermoso et al. (2016); Thieme et al. (2016); Abell et al. (2017); Brooks et al. (2018)
Increase habitat patch size site and expand protected areas	*Limited evidence High agreement*	Generally increase resilience because of functioning natural processes, large species populations and refugial areas	Eigenbrod et al. (2015); Oliver et al. (2015a)
Increase replication and representation of protected areas	*Limited evidence, High agreement*	Various benefits inferred, including, wider range of climatic and other conditions, less risk of extreme events affecting many rather than few areas. More sites available for colonisation by range expanding species and better conditions to maintain species in situ under range contraction.	Mawdsley et al. (2009); Thomas et al. (2012a); Virkkala et al. (2014); Gillingham et al. (2015); Pavón-Jordán et al. (2020b)
Protect microclimatic refugia	*Medium evidence, High agreement*	Locally cool areas can be identified and there is evidence species can survive better in such areas.	Haslem et al. (2015); Suggitt et al. (2015); Isaak et al. (2016); Morelli et al. (2016); Merriam et al. (2017); Bramer et al. (2018); Suggitt et al. (2018); Massimino et al. (2020)
Creating shade to lower temperatures for vulnerable species	*Limited evidence, High agreement*	Creating shade has been used as an adaptation strategy, for example by watercourses but improvements in species survival under warming conditions have yet to be demonstrated.	Broadmeadow et al. (2011); Lagarde et al. (2012); Patino-Martinez et al. (2012); Thomas et al. (2016)
Restoring hydrological processes of wetlands, rivers and catchments, including by raising water tables and restoring original channels of watercourses,	*Medium evidence, High agreement*	Wetland restoration is well established as a conservation measure in some countries. Can reduce vulnerability to drought with climate change but evidence to demonstrate effectiveness as an adaptation measure is limited and requires long-term monitoring of a range of sites. Little restoration of degraded tropical peatlands to date	Carroll et al. (2011); Hossack et al. (2013); Dokulil (2016); Timpane-Padgham et al. (2017); Moomaw et al. (2018)
Restoration of natural vegetation dynamics	*Medium evidence,*	Includes reintroduction of native herbivores and reversing woody encroachment of	Coffman et al. (2014); Valkó et al. (2014);

	Medium agreement	savannas. Benefits for biodiversity are well established in a wide range of different regions	Batáry et al. (2015); Smit et al. (2016); Stevens et al. (2016); Hempson et al. (2017); Bakker and Svenning (2018); Cromsigt et al. (2018); Fulbright et al. (2018); Olofsson and Post (2018)
Reduce non-climatic stressors to increase resilience of ecosystems	*Limited evidence, Medium agreement*	As a general principal climate change is recognised as a 'threat multiplier' but specific details are often unclear	Oliver et al. (2017); Pearce-Higgins et al. (2019)
Assisted translocation and migration of species	*Limited evidence, Medium agreement*	Assisted translocation has been commonly suggested as an adaptation measure, but there have been very few examples of this being trialed. Translocations have been carried out for other reasons and lessons for climate change adaptation have been inferred	Willis et al. (2009); Brooker et al. (2018); Skikne et al. (2020)
Intensive management for specific species	*Medium Evidence, Medium Agreement*	A variety of approaches including manipulating microclimate and competition between species to improve chances of survival under climate change.	Angerbjörn et al. (2013); Greenwood et al. (2016); Pearce-Higgins et al. (2019)
Ex-situ conservation (seedbanks/genetic stores, etc.)	Not possible to assess at present time	Seed banks have been established but long-term effectiveness could only be evaluated at a later point.	Christmas et al. (2016)
Adjusting conservation strategies and site objectives to reflect changing species distributions and habitat characteristics	*Robust evidence, High Agreement*	Conservation management will need to take account of changes that cannot be prevented, for example in the distribution of species and composition of communities, in order to protect and manage biodiversity as effectively as possible in a changing climate.	Stein et al. (2013); Rannow et al. (2014); Oliver et al. (2016); Stralberg et al. (2019); Duffield et al. (2021)
Softening the matrix of unsuitable habitats between patches to increase permeability for species movement in response to climate change	*Limited evidence*	Potential for agri-environment schemes to do this in hostile farmed landscapes.	Donald and Evans (2006); Stouffer et al. (2011)

Many climate adaptation actions for biodiversity operate at the landscape scale (von Holle et al., 2020). The total area of habitat, how fragmented it is, the size of habitat patches and the connectivity between them are interlinked properties at this scale. A growing number of studies have investigated how these properties affect species ability to persist *in situ* and colonise new areas. Overall, larger areas of semi-natural habitat are associated with increased resilience to ongoing climate change and extreme events and the capacity to colonise new areas (Haslem et al., 2015; Oliver et al., 2017; Papanikolaou et al., 2017). Larger habitat patches can support larger populations, which are more likely to maintain themselves and recover from periods of adverse conditions. A large patch size has been found to increase resilience of some populations of species to extreme events such as droughts (Oliver et al., 2015b). They are also more likely to provide a range of different resources and microclimate conditions, which may increase chances of species persistence under climate change. A larger area of habitat may also enables greater connectivity between patches and increases the chances of species colonising new areas as they track climate change. (Oliver et al., 2015b)Protecting and restoring natural processes is a general principle for maintain and building resilience to climate change for biodiversity (Timpane-Padgham et al., 2017). One element of this is ensuring naturally functioning hydrology for wetlands and river systems (Table 6), which is particularly important in a context of changing rainfall patterns and increased evapo-transpiration. An important development in approaches to conservation over recent decades has been the concept of re-wilding (Schulte To Bühne et al., 2021); this encompasses a number of elements of restoring natural processes, including the reintroduction of top predators, larger conservation areas and less prescriptive outcomes than much previous conservation. There are elements of re-wilding which may well contribute to building resilience to climate change but it will be increasingly important to factor climate change adaptation into the planning of rewilding schemes (Carroll and Noss, 2021).

The most consistently cited climate change adaptation measure for species is increasing connectivity to facilitate colonisation of new areas. This reflects the fact that many species' habitats are highly fragmented in areas with more intensive land management, which prevents them naturally changing their range to track changing climatic conditions. Advances and innovations in modelling techniques can support decision making on connectivity (Littlefield et al., 2019). There is evidence from empirical as well as modelling studies that species can disperse more effectively in better connected areas in terrestrial habitats (Keeley et al., 2018). The issues are different in more natural landscapes—species may still be threatened in intrinsically isolated habitats, such as mountain top, but connectivity cannot be created in the same way. Evidence suggests that increased connectivity will only benefit a subset of species, probably those which are intermediate habitat specialists that are able to disperse (Pearce-Higgins et al., 2014). Generalists do not require corridors or stepping stones whilst many corridors or stepping stones will not be of sufficient quality to be used by the most habitat specialists. There should also be a caveat to the general principle that increasing connectivity is a benefit for climate change adaptation. It can increase the spread of invasive, pest and disease-causing species into newly suitable regions. In some places isolated refugia may better allow vulnerable species and biological communities to survive.

There are many different approaches to increasing connectivity, ranging from increasing overall area of suitable habitat through to 'corridors' and 'stepping stones', with different strategies likely to be more effective for different species and circumstances (Keeley et al., 2018). Connectivity can also be important in increasing resilience of populations to extreme climatic events (Newson et al., 2014; Oliver et al., 2015b). Within freshwater environments, connectivity of watercourses is essential. Fluvial corridors are necessary to ensure migrating fish population survival, even without climate change; with climate change, connectivity becomes crucial for relatively cold-adapted organisms to migrate upstream to colder areas. Connectivity is also important for the larvae of benthic invertebrates to be able to drift downstream and hence to disperse (Brooks et al., 2018); for adult benthic invertebrates, riparian and terrestrial habitat features can potentially affect dispersal. Connectivity within river and wetland systems for some species can also mediated by more mobile animal species such as fish and birds (Martín-Vélez et al., 2020) Which factors are the most important in either promoting their colonisation of new sites or persisting *in situ* will differ between species and locations. Some general principle have been recognised and can guide conservation policy and practice (England and RSPB, 2020; Stralberg et al., 2020) but this will often require additional investigation and planning based on understanding individual the niche of specific species.

Managed, translocation by moving species from areas where the climate is becoming unsuitable to places where there persistence under climate change is more likely has been discussed as an adaptation option for many years. So far there have been very few examples of this and it is likely to be a last resort in most cases as in many cases it requires a large investment of resources, the outcome is uncertain and there may be adverse impacts on receiving sites. Nevertheless there are cases where it may be a be a viable option (Stralberg et al., 2019). This is discussed in more detail as a case study in section 2.6.5.1.

The evidence that species can persist in microclimatic refugia where suitable conditions for them are maintained locally (for example, because of variations in topography) has increased in recent years. This has opened up the potential to include refugia in conservation plans and strategies to facilitate local survival of species (Jones et al., 2016; Morelli et al., 2016; Morelli et al., 2020). For example, in targeting management actions (Sweet et al., 2019) aimed at supporting populations of species and is likely to become an important aspect of climate change adaptation for biodiversity conservation in future. It is also possible to manipulate microclimate for example by creating shelters for birds' nests (see case study of African Penguins 2.6.5.5) (Patino-Martinez et al., 2012). One specific approach of this sort is planting or retention of trees and wooded corridors to shade water courses (see also case study 2.6.4.5 below; Thomas et al., 2016). In the latter case, riparian shading can also possibly help to reduce phytoplankton and benthic diatom growth in smaller streams and rivers (Halliday et al., 2016).

Refugia often refer to locally places in a landscape, such as on shaded slopes or high elevations, but they can also include places where water supply may continue during dry periods (Morelli et al., 2016) Monitoring can reveal which streams, wetlands, springs, and other aquatic resources retain suitable discharges, water quality, wetland area, and ecological integrity, especially during dry years (Cartwright et al., 2020). Measures to conserve drought refugia may include protecting springs and other groundwater-fed systems from groundwater extraction, contamination, salinisation, surface-water diversion, channelisation of streams, livestock trampling, recreation and invasive species, as well as effects from surrounding landscape disturbances (Cartwright et al., 2020; Krawchuk et al., 2020). Restoration of degraded aquatic ecosystems can include removal of flow-diversion infrastructure, exclusion of livestock, reduction of other human impacts, geomorphic restructuring, invasive species removal, and planting of native riparian vegetation.

In fire prone areas, fire suppression and management is a key element of protecting refugia (Section 2.6.5.8 below). In ecosystems in which a natural fire regime has been suppressed restoration practices such as prescribed fires, thinning trees, and allowing some wildfires where it benefits the ecosystem can be introduced to reduce increasing risks from severe wildfires (Meigs et al., 2020).

Protected areas—areas of land set aside for species and habitat protection with legal protection from development or exploitation—have been a cornerstone of nature conservation for many years. Their effectiveness under a changing climate has been the subject of debate and investigation. There is now a large body of evidence demonstrating that colonisations by range shifting species are more likely to occur on protected sites compared to non-protected sites for a wide range of taxa (e.g. Thomas et al., 2012b; Gillingham et al., 2015), including across continents (Pavón-Jordán et al., 2020a). This is probably because by protecting large areas of natural and semi-natural habitats they provide suitable places for colonising species (Hiley et al., 2013) which may not be available in the surrounding landscape. Although the evidence for protected areas being associated with reduced extinctions is weaker, the finding in Gillingham et al. (2015) that protected sites were associated with reduced extinction rates at low latitudes and elevations is strongly suggestive that they can help species' persistence in the face of climate change.

It is intrinsically difficult to assess the effectiveness of climate change adaptation measures, the benefit of which will be realised in years and decades ahead (Morecroft, 2019, Measuring success). Nevertheless, taking account of the wide range of evidence reported above, including theory, modelling and observations of climate change impacts in contrasting circumstances, it is possible to make an overarching assessment that appropriate adaptation measures can reduce the vulnerability of many aspects of biodiversity to climate change (*robust evidence, high agreement*). It is also however clear that to be most effective and avoid unintended consequences, measures need to be carefully implemented taking account of specific local circumstances *(robust evidence, high agreement)* and include the management of inevitable changes (*robust evidence, high agreement*). It is also clear that whilst there are now many plans and strategies for adapting biodiversity conservation to climate change, many have yet to be implemented fully (*medium evidence, high agreement*).

2.6.3 Nature-based Solutions: Ecosystem-based Adaptation

Ecosystem-based Adaptation is an increasingly important element of Nature-based Solutions (see 2.6 above). A study published in 2020 found that out of 162 Intended Nationally Determined Contributions (covering 189 countries) submitted to the United Nations Framework Convention on Climate Change, as commitments to action under the Paris Agreement, 109 indicated 'ecosystem-orientated visions' for adaptation, although only 23 use the term 'Ecosystem-based Adaptation' (Seddon et al., 2020b).

EbA includes a range of different approaches. Examples include restoring coastal and river systems to reduce flood risk and improve water quality and the creation of natural areas within urban areas to reduce temperatures through shading and evaporative cooling. EbA is closely linked with a variety of other concepts such as ecosystem services, natural capital and Disaster Risk Reduction (DRR). EbA was becoming a well-recognised concept at the time of AR5 but implementation was still at an early stage in many cases. Since then pilot studies have been assessed and EbA projects have been initiated around the world. The evidence base continues to grow (Table 2.7) and this has led to increasing confidence in approaches which have been shown to work leading to further expansion in some countries (Table 2.7). However, this is not uniform and there is relatively little synthesis across disciplines and regions (Seddon et al., 2020a). Chausson et al. (2020) used a systematic mapping methodology to characterise 386 published studies. They found that interventions in natural or semi-natural ecosystems ameliorated adverse climate change impacts in 66% of cases, with fewer trade-offs than for more artificial systems such as plantation forest. However, the evidence base has substantial gaps. Most of the evidence has been collected in the Global North and there is a lack of robust, site-specific investigations of the effectiveness of interventions compared to alternatives and of more holistic appraisals accounting for broader social and ecological outcomes.

Table 2.7: Examples of key Ecosystem- based Adaptation measures with assessments of confidence. Note only adaptation related services are shown – many measures also provide a range of other benefits to people. All also provide benefits for biodiversity.

Ecosystem Based Adaptation Measures	Confidence Assessment	Ecosystem Services for climate change adaptation	Climate Change Impact addressed	Social Benefits from adaptation	Relevant Ecosystems and contexts	Selected References
Natural Flood risk management in river systems –restoring natural river courses (removing canalisation), restoring and protecting wetlands and riparian vegetation	*Medium evidence Medium agreement*	Flood regulation; sediment retention; water storage; water purification	Increased rainfall intensity	Reduction of flood damage Increased water security (quality and supply)	Multiple	Iacob et al. (2014); Meli et al. (2014); Burgess-Gamble et al. (2017); Dadson et al. (2017); Rowiński et al. (2018)
Shade rivers and streams by restoration of riparian vegetation or trees.	*Medium evidence High agreement*	Provision of fish stocks	Warmer water temperatures	Food security income benefits	Multiple	Broadmeadow et al. (2011); Isaak et al. (2015); Williams et al. (2015b); Thomas et al. (2016)
Managed realignment of coastlines; re-establishing and protecting coastal habitats including mangroves, salt marsh,	*Robust evidence High agreement*	Coastal storm and flood protection Coastal erosion control Salt water intrusion prevention	Rising sea level Increasing storm energy	Protection of life, property and livelihoods Water security	Coastal	Høye et al. (2013); Spalding et al. (2014); Narayan et al. (2016); Morris et al. (2018); Chowdhury et al. (2019); Powell et al. (2019)
Agroforestry and other agro-ecological/conservation agricultural practices on agricultural land	*Medium evidence Medium agreement*	Local climate regulation; soil conservation; soil nutrient regulation; water conservation; pest control; food provisioning	High temperature or changing temperature regimes Changing precipitation regimes	Food security income benefits	Multiple	Vignola et al. (2015); Torralba et al. (2016); Paul et al. (2017); Blaser et al. (2018); Nesper et al. (2019); Verburg et al. (2019); Aguilera et al. (2020); Tamburini et al. (2020)
Restore and maintain urban and peri-urban green space – trees, parks, local nature reserves, created wetlands	*Robust evidence High agreement*	Local climate regulation Flood regulation Water purification Water storage	Higher temperatures and heatwaves Increased rainfall intensity or	Cooler microclimate Reduced flood damage, water security	Urban areas	Norton et al. (2015); Liquete et al. (2016); Liu (2016); Bowler et al. (2017); Aram et al. (2019);

		Erosion control	reduced rainfall intensity			Stefanakis (2019); Ziter et al. (2019)
Ecological restoration for fire risk reduction through restoration of natural vegetation and herbivory and by re-instating natural fire regimes	*Medium evidence High agreement*	Regulation of wildfires	Mega-fires from increases in drought and heat	Reduce deaths and infrastructure damage from fires	Fire-adapted ecosystems	Waldram et al. (2008); Stephens et al. (2010); van Mantgem et al. (2016); Boisramé et al. (2017); Johnson et al. (2018); Parisien et al. (2020a); Parisien et al. (2020b); Stephens et al. (2020)
Invasive non-native aquatic plant control to improve water security	*Robust evidence High agreement*	Water provision	Increasing droughts	water security	Water scarce regions prone to an increase in droughts	van Wilgen and Wannenburgh (2016)
Woody plant control (of encroaching biomass) in open grassy ecosystems to restore and maintain grassy vegetation (see 2.4.3.5)	*Medium evidence Medium agreement*	Fodder biomass production	Elevated CO_2 increasing tree growth/ increases in rainfall promoting tree growth	income through bush clearing, fuelwood supplies, restore grazing	Savanna and grasslands	Haussmann et al. (2016)
Rangeland rehabilitation and management such as through livestock enclosures, appropriate grazing management, re-introducing native grassland species	*Medium evidence Medium agreement*	Fodder biomass production; soil erosion control; soil formation; nutrient cycling; water retention	Changing precipitation and temperature regimes including prolonged dry seasons and increased drought frequency	Food security Water security, income benefits	Rangelands	Descheemaeker et al. (2010); Wairore et al. (2016); Kimiti et al. (2017)
Sustainable forestry of biodiverse managed forests, maintaining forest cover and protecting soils	*Medium evidence Medium agreement*	Timber production	Increased frequency and severity of storms Higher temperatures Changing precipitation regimes (more intensive wet and dry periods) Increased incidents of wildfire, pest, and disease outbreaks	Livelihood and income benefits	Boreal, temperate, subtropical, tropical forests	Gyenge et al. (2011); Barsoum et al. (2016); Jactel et al. (2017); Cabon et al. (2018)

Watershed reforestation and conservation for hydrological services	*Medium evidence Medium agreement*	Flood control; erosion control; water provisioning; water purification	Changing precipitation regimes	Food security; Water security; Flood Protection	Boreal, temperate, subtropical, tropical forests	Filoso et al. (2017); Bonnesoeur et al. (2019)
Multifunctional forest management and conservation to provide climate resilient sources of food and livelihoods and protect water sources	*Medium evidence Medium agreement*	Timber and non-timber forest production; fuel wood production; water provisioning; water purification	Multiple	Food security; Water security; income benefits	Boreal, temperate, subtropical, tropical forests	Lunga and Musarurwa (2016); Strauch et al. (2016); Adhikari et al. (2018)
Slope revegetation for landslide prevention and erosion control	*Robust evidence High agreement*	Soil retention; slope stabilisation	Increased rain frequency	Reduced landslide damage; prevention of loss of life	Montane and other steep sloped regions	Fox et al. (2011a); Krautzer et al. (2011); Leal Filho et al. (2013); Bedelian and Ogutu (2017); Getzner et al. (2017); de Jesús Arce-Mojica et al. (2019)

Restoring coasts, rivers and wetlands to reduce flood risk have probably seen the largest investment in EbA and it is becoming an increasingly accepted approach in some places (e.g. case studies in Sections 2.6.5.2, 2.6.5.7) although significant social, economic and technical barriers remain (Wells et al., 2020; Bark et al., 2021; Hagedoorn et al., 2021). Natural flood management encompasses a wide range of techniques in river systems and at the coast and have been used in varied locations around the world. In tropical and sub-tropical areas, the restoration of mangroves to reduce the risk of coastal flooding is widely advocated, evidence-based approach (for example (Høye et al., 2013; Sierra-Correa and Kintz, 2015; Powell et al., 2019)). In temperate regions salt marsh is a similarly important habitat (Spalding et al., 2014). Both provide buffering against rising sea levels and storm surges. Managed realignment of the coast, by creating new habitats can lead to a loss of terrestrial and freshwater ecosystems, but it can protect them and the services they provide by reducing the risks of catastrophic failure from hard-engineered sea defences. In river systems (Iacob et al., 2014) management of both catchments and the channel itself is important: restoring natural meanders in canalised water courses and allowing the build-up of woody debris can slow flows rates; restoring upstream wetlands or creating them in urban and peri-urban situations can store water during flood events if they are in the right place in a catchment (Acreman and Holden, 2013; Ameli and Creed, 2019; Wu et al., 2020). There is less data on the potential for natural flood management in tropical compared to temperate catchments, however (Ogden et al., 2013) showed that flooding was reduced from a secondary forested catchment compared to those which were pasture or a mosaic of forest, pasture and subsistence agriculture. EbA approaches to reduce flooding can be applied within urban areas, as well as in rural catchments, as in Durban (Section 2.6.5.7), although its effectiveness will depend on its being implemented at a sufficient scale and in the right locations (Hobbie and Grimm, 2020; Costa et al., 2021). which may in turn provide protection to downstream urban communities.

Protecting and restoring natural river systems, natural vegetation cover within catchments and integrating agro-ecological techniques into agricultural systems can also help to maintain and manage water supplies for human use, under climate change, including during drought periods, by storing water in catchments and improving water quality (Taffarello et al., 2018; Agol et al., 2021; Khaniya et al., 2021) (Lara et al., 2021) showed that replacing a non-native *Eucalyptus* plantation in Chile with native forest caused base flow increased by 28% to 87% during the restoration period compared to pre-treatment, and found it remained during periods with low summer precipitation

EbA can operate at a range of different scales, from local to catchment to region. At the local scale, there is a variety of circumstances in which microclimates can be managed and local temperatures lowered by the presence of vegetation (Table 2.7), and these EbA techniques are now being used more widely. In both urban and agricultural situations, shade trees are a traditional technique, which can be applied to contemporary climate change adaptation. Shading of water courses can lower temperatures, as reported in Section 2.6.2, above, which can allow species to survive locally, as well as supporting diversity it can help to maintain are important fisheries, including of Salmonid fish (O'Briain et al., 2020). Within cities, green spaces, including parks, local nature reserves and green roofs and walls can also provide cooling as a result of evapo-transpiration (Bowler et al., 2010a; Aram et al., 2019; Hobbie and Grimm, 2020), although this may be reduced in drought conditions.

Wildfire is an increasing risk for people as well as to ecosystems, in many parts of the world. As discussed in Section 2.4.4.2, this is the result not just of climate change but also past management practices, including fire suppression. Better fire management including reinstating more natural fire regimes can reduce risks.

EbA is usually a place-specific approach and a number of studies have documented how attempts to implement it without an understanding of local circumstances and full engagement of local communities have been unsuccessful (Nalau et al., 2018). Since AR5, a number of studies have considered the factors that are important for environment adaptation programmes and projects (UNFCCC, 2015; Nalau et al., 2018; Duncan et al., 2020; Network and ENCA, 2020; Townsend et al., 2020). Considering these sources, others described above and the case studies presented, in 2.6.5, a number of requirements for effective implementation of EbA can be identified, including the following:

- Targeting of the right EbA measure in the right location
- Decision-making at the appropriate level of governance with participation from all affected communities
- Integration of Local Knowledge and Indigenous Knowledge & capacity into decision-making and management of project
- Involvement of government and non-government stakeholders
- Full integration of EbA with other policy areas, including agriculture, water resources and natural resource protection
- Protection and if possible improvement of incomes of local people.
- Effective institutional support to manage finances and implementation of projects and programmes.
- Time -many EbA interventions take time to establish e.g. trees to grow, wetlands recover
- Monitoring of intended outcomes and other impacts and communication of results

Whilst it is essential to develop place-specific EbA measures, with full engagement of local communities, it is worth noting that new opportunities may emerge that would not have been possible in the past. As the climate changes, novel ecosystems may emerge with no present day analogue which have the potential to provide different adaptation benefits and societies may be more willing to adopt transformative approaches (Colloff et al., 2017; Lavorel et al., 2020).

Increasingly it is essential to integrate adaptation and the protection of biodiversity with land based climate change mitigation initiatives; this is discussed in more detail in Cross-Chapter Box NATURAL, this Chapter. The new IUCN standard (IUCN, 2020, Global standard) offers a basis for assessing whether actions are true Nature-based Solutions and take account of the wider factors necessary for success.

Whilst policy interest is growing and there is an increasing deployment of EbA there is still a long way to go in delivering it full potential (Huq and Stubbings, 2015) and significant institutional and cultural barriers remain(Huq et al., 2017; Nalau et al., 2018). Nevertheless it is increasingly clear that EbA can offer a portfolio of effective measures to reduce risks from climate change to people at the same time as benefiting biodiversity (*robust evidence, high agreement*), providing they are deployed with careful planning in a way that is appropriate local ecological and societal contexts (*robust evidence, high agreement*).

2.6.4 Adaptation for Increased Risk of Disease

Low-probability events can be very high impact (for example, the transmission of the SARS-CoV-2 from wild animals to humans). A robust disease risk reduction policy would include utilizing a One Biosecurity approach (Hulme, 2020) with actions to reduce disease risk across multiple sectors and from a variety of anthropogenic drivers, including climate change, even if there is high uncertainty in projected risk (see Cross-Chapter Boxes: ILLNESS, COVID, DEEP). Kraemer et al. (2019) found that vector importation was a key risk factor and focus should be on preventing invasive species introductions. Further, many neglected tropical diseases (NTDs) are also VBDs, and the UN SDG of good health and well-being explicitly calls for increased control and intervention with a focus on emergency preparedness and response (Stensgaard et al., 2019a). Online tools are being developed to warn conservation biologists when species of conservation concern are at greater risk of disease outbreaks due to environmental changes (e.g., for Hawaiian Honeycreepers and avian malaria (Berio Fortini et al., 2020) and for coral diseases (Caldwell et al., 2016)). Forecasting models to warn of human disease outbreaks like malaria and dengue are also now available, with findings that multiple model ensemble forecasts outperform individual models (Lowe et al., 2013; Lowe et al., 2014; Lowe et al., 2018; Zhai et al., 2018; Johansson et al., 2019; Tompkins et al., 2019; Muñoz et al., 2020; Colón-González et al., 2021; Petrova et al., 2021). Improving vector-borne disease and NTD public health responses will require multi-disciplinary teams capable of interpreting, analyzing, and synthesizing diverse components of complex ecosystem-based studies for effective intervention (Mills James et al., 2010; Rubin et al., 2014; Valenzuela and Aksoy, 2018), broad epidemiological and entomological surveillance (Depaquit et al., 2010; Lindgren et al., 2012; Springer et al., 2016), and community-based disease control programs that build local capacity (Andersson et al., 2015; Jones et al., 2020b).

Cross-Chapter Box ILLNESS: Infectious Diseases, Biodiversity and Climate: Serious Risks Posed by Vector- and Water-borne Diseases

Authors: Marie-Fanny Racault (United Kingdom/France, Chapter 3), Stavana E. Strutz (USA, Chapter 2), Camille Parmesan (France/United Kingdom /USA, Chapter 2), Rita Adrian (Germany, Chapter 2), Guéladio Cissé (Mauritania/Switzerland/France, Chapter 7), Sarah Cooley (USA, Chapter 3), Adugna Gemeda (Ethiopia, Chapter 9), Nathalie Jeanne Marie Hilmi (Monaco/France, Chapter 18), Salvador E. Lluch-Cota (Mexico, Chapter 5), Gretta Pecl (Australia, Chapter 11), David Schoeman (Australia, Chapter 3), Jan C. Semenza (Italy, Chapter 7), Maria Cristina Tirado (USA/Spain, Chapter 7), Gautam Hirak Talukdar (India, Chapter 2), Yongyut Trisurat (Thailand, Chapter 2), Meghnath Dhimal (Nepal, CA), Luis E. Escobar (Guatemala/Columbia/USA, CA), Erin Mordecai (USA, CA), A. Townsend Peterson (USA, CA), Joacim Rocklöv (Sweden, CA), Marina Romanello (United Kingdom, CA)

Climate change is altering the life cycles of many pathogenic organisms and changing the risk of vector- and water-borne infectious diseases transmission to humans (high confidence). Re-arrangement and emergence of some diseases are already observed in temperate-zone and high-elevation areas, and coastal areas (medium to high confidence). Shifts in the geographic and seasonal range suitability of pathogens and vectors are related to climatic-impact drivers (warming, extreme events, precipitation, humidity) (high to very high confidence), but there are substantial non-climatic drivers (land use change, wildlife exploitation, habitat degradation, public health and socio-economic conditions) that affects the attribution of the overall impacts on prevalence or severity of some vector- and water-borne infectious diseases over recent decades (high confidence). Adaptation options that involve sustained and rapid surveillance systems, and the preservation and restoration of natural habitats, with their associated higher levels of biodiversity, both marine and terrestrial, will be key to reducing risk of epidemics and large-scale disease transmissions (medium confidence).

Since AR5, further evidence is showing that climate-related changes in the geographic and seasonal range suitability of pathogens and vectors and in the prevalence or new emergence of vector- and water-borne infectious diseases have continued across many regions worldwide and are sustained over decadal time scales (*medium to high confidence*) (WGII Sections 2.4.2.5, 3.5.5.3, 7.2, 7.3, 9.10.1.2.1; Harvell et al., 2009; Garrett et al., 2013; Burge et al., 2014; Guzman and Harris, 2015; Baker-Austin et al., 2018; Watts et al., 2019; Semenza, 2020; Watts et al., 2021) . Ecosystem-mediated infectious diseases at risk of increase from climate change include water-borne diseases associated with pathogenic *Vibrio* species (e.g., those causing cholera and vibriosis), and harmful algal blooms (e.g., ciguatera-fish poisoning) (SROCC 5.4.2.1.1, Box 5.4, AR6 WGII 3.5, Table 3.S.3, 5.12; Baker-Austin et al., 2013; Levy, 2015; Trtanj et al., 2016; Ebi Kristie et al., 2017; Mantzouki et al., 2018; Nichols et al., 2018), and vector-borne diseases associated with arthropods (e.g., malaria, dengue, chikungunya, Zika virus, West Nile virus, and Lyme disease), helminths (e.g., schistosomiasis) and zoonotic diseases associated with cattle and wildlife (e.g., leptospirosis) (*medium to high confidence*) (Sections 2.4.2.7, 3.5, 7.2, 7.3, 9.10.1.1.1, 13.7.1.2, 14.4.6, Cross-Chapter Box COVID in Chapter 7; Table Cross-Chapter Box ILLNESS.1; SR1.5 3.4.7.1; Ebi et al., 2021) .

The attribution of observed changes in disease incidence partly or fully to climatic-impact drivers remains challenging because of the difficulty of accurately capturing the contributions of multiple, interacting, and often nonlinear underlying responses of host, pathogen, and vector, which can be influenced further by non-climate stressors and the long history of anthropogenic disturbance. Disease emergence in new areas requires independent drivers to coincide (i.e., increasing climate suitability for pathogen or vector survival and competence/capacity, and introduction of the pathogen via mobility of human populations). Further, the extent to which changes in ecosystem-mediated diseases impact human health is highly dependent upon local socio-economic status, sanitation, medical systems, and practices (Section 2.4.2.5; Figure FAQ2.3.1; Gething et al., 2010; Lindgren et al., 2012; Mordecai et al., 2013; Liu-Helmersson et al., 2014; Bhatt et al., 2015; Morin et al., 2015; Ryan et al., 2015; Wesolowski et al., 2015; Stanaway et al., 2016; Yamana et al., 2016; Mordecai et al., 2017; Tesla et al., 2018; Ryan et al., 2019; Shah et al., 2019; Iwamura et al., 2020; Mordecai et al., 2020; Colón-González et al., 2021; Ryan et al., 2021).Thus, the links between climate change, ecosystem change, health and adaptation need to be considered concurrently (AR6 WGII 2.4, 3.5.3, 7.2, 7.3, 4.3.3, 6.2.2.3, Table 2.S.1).

Table Cross-Chapter Box ILLNESS.1: Observed climate change impacts on cholera, dengue, and malaria. 1) Cholera: Endemicity based on Ali et al., 2015. Changes (2003-2018) in suitability for coastal *Vibrio cholerae* estimated from model observations driven by sea-surface temperature (SST) and chlorophyll-a (CHL) concentration (Escobar et al., 2015; Watts et al., 2019). Vulnerabilities based on Sigudu et al., 2015, Agtini et al., 2005, and Sack et al., 2003. 2) Dengue: Endemicity based on Guzmen et al., 2015. 3) Malaria: Endemicity based on Phillips et al. 2017, and WHO Global Malaria Programme. Impacts of climate change on diseases and their vectors are most evident at the margins of current distributions. However, climate change is difficult to implicate in areas with extensive existing transmission and vector/pathogen abundance, and in particular is difficult to separate from concurrent directional trends in disease control, changes in land use, water access, socioeconomic and public health conditions. As a result, while many studies indicate increasing climate suitability of some areas for cholera, dengue, and malaria, the degree to which these changes can be attributed to climate change remains challenging. For these cases, confidence statements of *low, medium*, or *high* reflect confidence that variation in the disease and/or vector/pathogen is associated with variation in climate drivers, rather than with directional climate change *per se*. Acronyms: ONI (Oceanic Niño Index), Tmin (minimum temperature), SPI (Standardised Precipitation Index), LST Land-surface temperature. Full references for this table can be seen in supplemental table 6 (see Table 2.S.6).

	Cholera	Dengue	Malaria
Africa			
Endemicity	Endemic	Endemic in sub-Saharan Africa but not S South Africa	Endemic
Climate drivers	Disease incidence: NE Africa, Central Africa & Madagascar: Rainfall (*medium confidence*) SE Africa: Rainfall, LST, SST, Plankton (*medium to high confidence*) ES Africa: SST, CHL (*low* confidence due to *limited evidence*) W Africa: Rainfall (floods), LST, SST (*medium to high confidence*)		W Africa: Temp (*medium to high confidence)* E Africa: Temp *medium to high confidence)*
Change and Confidence	Area of coastline suitable for outbreak: N&W Africa: Increase (*low to medium confidence)* C & E Africa: No change (*low to medium confidence)* S Africa: Decrease (*low to medium confidence)*	Potentially expanding *(low confidence)* Dengue and *Ae. aegypti* present but underdetected in climatically suitable areas.	E Africa: Upward shift and increase in malaria & *Anopheles* spp. in highland areas *(medium to high confidence)* Widespread decreases due to malaria control *(medium confidence)* and warming climate *(low confidence)*

Vulnerabilities	ES Africa: women of all ages more affected than men by outbreaks		
Asia			
Endemicity	Endemic	Endemic in S Asia, SE Asia, and E Asia	Endemic in S Asia, SE Asia, Partially endemic in E Asia
Climate drivers	Disease incidence: E Asia: SST, CHL, Sea Level (medium to high confidence) S Asia: SST, CHL, LST, Rainfall(floods) (high to very high conficende)	S Asia: Rainfall, Temp, Humidity *(medium confidence)* SE Asia: Rainfall, Temp *medium confidence)* E Asia: Rainfall, Temp, Typhoons *(low confidence)*	S Asia: Rainfall, Temp *(*medium to high confidence*)* SE Asia: Rainfall, Temp *(medium confidence)*
Change and Confidence	Area of coastline suitable for outbreak: Increase (*low to medium confidence*)	SE Asia: Increase (*low confidence)* S Asia: Increase (*medium confidence)* E Asia: Increase (*low confidence)*	S Asia: Increase *(medium confidence)*
Vulnerabilities	SE Asia: infants (<9 years) with highest incidences of cholera S Asia: older children and young adults (16-20 years old) more frequently reported with cholera than non-cholera diarrhoea		
Australasia			
Endemicity	Not endemic	Partially endemic in N Australia	Not endemic
Climate drivers	No evidence for disease incidence	Rainfall, Temp *(low confidence)*	
Change and Confidence	Area of coastline suitable for outbreak: No change (*low to medium confidence*)	Increase in sporadic outbreaks due to climate change (*low confidence)*	No change
Central America			
Endemicity	Not endemic	Endemic	Partially endemic
Climate drivers	No evidence for disease incidence	ONI, SST, Tmin, Temp, Rainfall, Drought (*low confidence)*	
Change and Confidence	Areas of coastline suitable for outbreak: Decrease (*low to medium confidence)*	Increasing due to climate (*low confidence)* Upward expansion of *Ae. aegypti (low confidence)*	Overall decrease not linked to climate change. Focal increases due to human activities.
South America			
Endemicity	Epidemic	Endemic in all regions except S South America	Endemic
Climate drivers	Abundance of coastal *V. cholerae*: NW South America: SST, Plankton (*low to medium confidence*)	Temp, Prec, Drought	N South America: Temp (*low confidence)* N SE South America: Tmax, Tmin, humidity *(low confidence)*
Change and Confidence	Area of coastline suitable for outbreak: No change (*low to medium confidence*)	Increasing due to urbanization and decreased vector control programmes, not strongly linked to climate	Higher elevation regions: Increase (*low confidence)*
Europe			
Endemicity	Not endemic	S Europe: focal outbreaks	Not endemic
Climate drivers	No evidence for disease incidence Abundance of coastal *V. cholerae*: N Europe: SST, Plankton (medium confidence)		
Change and Confidence	Area of coastline suitable for outbreak: Increase (*low to medium confidence*)	Mediterranean regions of S Europe: Outbreaks *(low confidence)*	No change
North America			
Endemicity	Not endemic	Partially endemic in S North America	Not endemic
Climate drivers	Area of coastline suitable for outbreak: Increase (*low to medium confidence*)	Winter minT *(Low)*	

Change and Confidence	No evidence for disease incidence Abundance of coastal *V. cholerae*: EN America: SST (*Low* due to *limited evidence*)	Declining	No change
Small Islands			
Endemicity	Epidemic	Endemic in many small islands in the Tropics	Endemic in many small islands in the Tropics
Climate drivers	Disease incidence: Caribbean: SST, LST, Rainfall (low to medium confidence)	Caribbean: SPI, Tmin *(low confidence)*	
Change and Confidence	Area of coastline suitable for outbreak: Caribbean & Pacific Small Island: Decrease (low to medium confidence)	Increasing (*low confidence)*	Decrease in Caribbean not linked to climate

Observed and projected changes

In aquatic systems, at least 30 human pathogens with water infection-routes (freshwater and marine) are affected by climate change (Section 3.5.3 Table SM3.G; Nichols et al., 2018) . Warming, acidification, hypoxia, sea-level rise, and increases in extreme weather and climate events (*e.g.* marine heatwaves, storm surges, flooding, and drought), which are projected to intensify in the 21st century (*high confidence*) (AR6 WGI SPM B2.2, B.3.2), are driving species' geographic range shifts and global rearrangements in the location and extent of areas with suitable conditions for many harmful pathogens, including viruses, bacteria, algae, protozoa, and, helminths (*high confidence*) (Sections 2.3, 2.4.2.7, 3.5.5.3, SROCC 5.4.2.1.1, Box 5.4; Trtanj et al., 2016; Ebi Kristie et al., 2017; Manning and Nobles, 2017; Pecl et al., 2017; Mantzouki et al., 2018; Nichols et al., 2018; Bindoff et al., 2019; Kubickova et al., 2019; Watts et al., 2019; Watts et al., 2020; Watts et al., 2021).

Incidence of cholera and *Vibrio*-related disease outbreaks has been shown to originate primarily in coastal regions, and then spread inland via human transportation. Our understanding of impacts of climate drivers on the dynamics of *Vibrio*-related infections have been strengthened through improved observations from long-term monitoring programs (e.g., (Vezzulli et al., 2016)), and statistical modelling supported by large-scale and high-resolution satellite observations of climate drivers (*high confidence*) (e.g., Baker-Austin et al., 2013; Escobar et al., 2015; Jutla et al., 2015; Martinez et al., 2017; Semenza et al., 2017; Racault et al., 2019; Campbell et al., 2020).

The coastal area suitable for *V. cholerae* (the causative agent for cholera) has increased by 9.9% globally compared to a 2000s baseline (Escobar et al., 2015; Watts et al., 2019). The poleward expansion of the distribution of *Vibrio* spp. has increased the risk of vibriosis outbreaks in northern latitudes. Specifically, the coastal area suitable for *Vibrio* infections in the past 5 years has increased by 50.6% compared with a 1980s baseline at latitudes of 40–70°N; in the Baltic region, the highest-risk season has been extended by 6.5 weeks over the same periods (Watts et al., 2021). Already, studies have noted greater numbers of *Vibrio*-related human infections, and most notably disease outbreaks linked to extreme weather events such as heat waves in temperate regions such as Northern Europe (Baker-Austin et al., 2013; Baker-Austin et al., 2017; Baker-Austin et al., 2018) (*high confidence*). By the end of the 21^{st} century, under RCP6.0, the number of months of risk of *Vibrio* illness is projected to increase in Chesapeake Bay by 10.4±2.4%, with largest increases during May and September, which are the months of strong recreational and occupational use, compared to a 1985-2000 baseline (Jacobs et al., 2015; Davis et al., 2019a). In the Gulf of Alaska, the coastal area suitable for *Vibrio* spp. is projected to increase on average by 58%±17.2% in summer under RCP6.0 by the 2090s, compared to a 1971-2000 baseline (*low to medium confidence*) (Jacobs et al., 2015).

On land, increased global connectivity and mobility, unsustainable exploitation of wild areas and species, land conversion (agricultural expansion, intensification of farming, deforestation, infrastructure development), together with climate-change-driven range shifts of species and human migration (Cross-Chapter Box MOVING PLATE in Chapter 5), have modified interfaces between people and natural systems (IPBES, 2018a). Climate-driven increase in temperature, frequency and intensity of extreme events, and changes in precipitation and relative humidity, have provided opportunities for re-arrangements of disease geography and seasonality, and emergence into new areas (*high confidence*) (Section 2.4.2.7). In particular, malaria has expanded into higher elevations in recent decades and although climate change attribute remains challenging (Hay et al., 2002; Pascual et al., 2006; Alonso et al., 2011; Campbell et al., 2019c), evidence that the elevational distribution of malaria has tracked warmer temperatures is compelling for some regions (Siraj et al., 2014). Models based on both empirical relationships between temperature and the *Anopheles* mosquito and *Plasmodium* parasite traits that drive transmission (Mordecai et al., 2013; Yamana Teresa and Eltahir Elfatih, 2013; Johnson et al., 2015) and existing mosquito distributions (Peterson, 2009) predict that warming will increase the risk of malaria in highland East Africa and Southern Africa, while decreasing the risk in some lowland areas of Africa, as temperatures exceed the thermal optimum and upper thermal limit for transmission (Peterson, 2009; Yamana Teresa and Eltahir Elfatih, 2013; Ryan et al., 2015; Watts et al., 2021).

In contrast to malaria, dengue has expanded globally since 1990, particularly in Latin America and the Caribbean, South Asia, and sub-Saharan Africa (Stanaway et al., 2016). While urbanization, changes in vector control, and human mobility play roles in this expansion (Gubler, 2002; Åström et al., 2012; Wesolowski et al., 2015), the physiological suitability of temperatures for dengue transmission is also expected to have increased as climates have warmed (Colón-González et al., 2013; Liu-Helmersson et al., 2014; Mordecai et al., 2017; Rocklöv and Tozan, 2019). Models predict that dengue transmission risk will expand across many tropical, subtropical, and seasonal temperate environments with future warming (Åström et al., 2012; Colón-González et al., 2013; Ryan et al., 2019; Iwamura et al., 2020; Watts et al., 2021)).

Adaptation options

During the 21st century, public health adaptation measures (Figure Cross-Chapter Box ILLNESS.2) have been put in place in attempts to control or eradicate a variety of infectious diseases by improving surveillance and early detection systems; constraining pathogen, vector, and/or reservoir host distributions and abundances; reducing likelihood of transmission to humans; and improving treatment and vaccination programs and strategies (*medium to robust evidence, medium to high agreement*) (Chinain et al., 2014; Adrian et al., 2016; Friedman et al., 2017; Konrad et al., 2017; Semenza et al., 2017; Borbor-Córdova et al., 2018; Rocklöv and Dubrow, 2020). In addition, effective management and treatment of domestic and wastewater effluent, through better infrastructure and preservation of aquatic systems acting as natural water purifiers, have been key to securing the integrity of the surrounding water bodies, such as groundwater, reservoirs and lakes, and agricultural watersheds, as well as protecting public health (*high confidence*) (Okeyo et al., 2018; Guerrero-Latorre et al., 2020; Kitajima et al., 2020; Sunkari et al., 2021). The preservation and restoration of natural ecosystems, with their associated higher levels of biodiversity, have been reported as significant buffers against epidemics and large-scale pathogen transmission (*medium confidence*) (Johnson and Thieltges, 2010; Ostfeld and Keesing, 2017; Keesing and Ostfeld, 2021). Further, the timely allocation of financial resources and sufficient political will in support of a "One Health" scientific research approach, recognising the health of humans, animals and ecosystems as interconnected (Rubin et al., 2014; Whitmee et al., 2015; Zinsstag et al., 2018), holds potential for improving surveillance and prevention strategies that may help to reduce the risks of further spread, and new emergence of pathogens and vectors (*medium confidence*) (Destoumieux-Garzón et al., 2018; Hockings et al., 2020; Volpato et al., 2020; Hopkins et al., 2021; Services and Ecosystem, 2021).

Adaptation measures to reduce risks of ecosystem-mediated diseases under climate change

Type	Description of adaptation options			Climate impact	Confidence
Warning systems	Early surveillance in wildlife & humans	Seasonal & dynamic forecasts of disease outbreaks; detailed risk mapping	Early Warning systems targeted locally		+++
Diagnostic abilities	Technology & trained personnel to permit rapid diagnosis and awareness of cases	Reporting in near-real time, for efficient response & resources mobilization for mitigation	Rapid response to disease emergence events, with public health and medical resources		+++
Capacity building	Training health & environmental officials to respond to new disease emergent risks	Awareness of local populations of the health risks from pathogens & vectors	Robust healthcare systems with good facilities, access & epidemic protocols		++
Public policy	Policy-making and international cooperation within a One Health framework	Large-scale public health programs for diseases/vectors eradication	Herd-immunity level vaccination for pathogens with few host species		++
Financing	Green recovery funds to tackling biodiversity loss & climate change	National funds for nature-based projects for forest conservation, water services	Funds to provide jobs for tribal groups in plantation work, forest & water management		+
Technology	Non-insecticide-based controls of vectors	Other control alternatives (avoiding use of antibiotics & chemical drugs)	Genetic surveillance & control of disease vectors & pathogens		++
Management	Planning aligned with climate targets	Long-term observing & monitoring systems	Environmental regulations & sustainable agriculture, livestock & fisheries farming practice		++
Infrastructure	Urban forests & green spaces, standing water removal	Drinking water access, sewage & drainage maintenance	Better homes keeping mosquitoes out of habited-indoor areas		+++
Nature-based solutions	Natural habitats restoration, reforestation	Reducing habitats fragmentation & limiting human proximity to risky environments	Ecosystem-based management to regulate pathogens & vectors population		++
Practice change	Diets diversification, more resilient food systems	Reduction of wildlife trade	Alternatives to reduce reliance on bushmeat and usage of wild animals		++
Co-benefits from mitigation	Reducing local emission from energy systems	Clean transport systems	Better access to food, water & energy		++

Figure Cross-Capter Box ILLNESS.1: Adaptation measures to reduce risks of climate change impact on water- and vector-borne diseases. Impacts are identified at three levels: 1) impact on pathogen, host/vector distributions and abundance; 2) impact on pathogen-host transmission cycle occurrence and efficiency; and 3) impact on likelihood of transmission to humans. Adaptation typology is based on (Biagini et al., 2014; Pecl et al., 2019). For each type of adaptation, examples are provided with their level of evidence and agreement.

[END CROSS-CHAPTER BOX ILLNESS HERE]

2.6.5 Adaptation in Practice: Case Studies and Lessons Learned

Adaptation plans for biodiversity and EbA have been adopted in many places and different scales but it is difficult to get a systematic overview of adaptation in practice. We have therefore reviewed a series of contrasting case studies to illustrate the some key issues. There is a pressing need for more thorough monitoring and evaluation of adaptation to assess effectiveness. Climate change adaptation is conceptually difficult to measure but it is possible to test which techniques work in reducing vulnerability and monitor their deployment (Morecroft et al., 2019).

Adaptation can take place at a range of scales with specific projects nested within overarching national strategies. Small scale projects can be adaptation focused, but in larger scale adaptation is often integrated with wider objectives. Within an urban or peri-urban context, the benefits of natural and semi-natural areas for health and well- help to justify support for EbA. Economic wellbeing is also an important factor in many cases, whether as, in Durban (Section 2.6.5.7), by providing new job opportunities or, in the Andes (Section 2.6.5.4) by supporting long-established agricultural practice. Action on the ground often depends on factors at a range of scales, for example, a local plan, a national strategy and international funding. Within Durban, partnership between local communities, local authorities and the academic community were essential, together with an international context. Nevertheless, there are examples of communities using traditional or local knowledge to adapt to changing circumstances, with little or no external input, (Section 2.6.5.4). They are, however, limited in their scope to adapt by factors beyond their direct control.

Specific interventions to protect species from climate change, such as the case of South African penguins(Section 2.6.5.5) and the Tasmanian Wilderness World Heritage Area (Section 2.6.5.8), are rare. However, in countries where nature reserves are actively managed or where ecosystem restoration projects are progressing, local practitioners may use local knowledge to adapt to weather conditions and their associated effects (fire or water shortage for example). This is good practice, but it may not be sufficiently to address likely future changes in climate (Duffield et al., 2021). Training and resources to support conservation practitioners are becoming available to help address this. Examples include the Climate Change Adaptation Manual in England (Section 2.6.5.2), and The Alliance for Freshwater Life (https://allianceforfreshwaterlife.org), that provide expertise for the sustainable management of freshwater biodiversity (Darwall et al., 2018).

Adaptation is widely recognised as important for national conservation policy and is being considered in a variety of countries (Section 2.6.5.2, 2.6.5.3). Adaptation in this strategic context includes decisions about the selection and objectives for protected areas, for example identifying places which can act as refugia. It can also mean recognising where protected areas remains important but will support a changing range of species and ecosystems. This is important for directing resources effectively and ensuring that site management remains appropriate. There are however often major uncertainties and the extent to which there will be a need for more radical measures will depend on success in reducing greenhouse gas emissions globally. A global rise of 1.5–2°C would require relatively incremental adjustments to conservation management in many parts of the world, but a 3–4°C rise would require radical, transformational changes to maintain many species and ecosystem services (Morecroft et al., 2012).

Whilst adaptation strategies for conservation are relatively common, at least at an outline level, implementation is slow in most places. This may partly reflect lack of resources for conservation in many parts of the world; however, another barrier is that people often value protected sites in their present form. Actions, which might jeopardise this, are inevitably a last resort. Initiatives to engage wider communities in discussions are likely to be essential in gaining support for such changing approaches.

EbA and adaptation for biodiversity are intrinsically linked and the largest scale interventions for adaptation in ecosystem have tended to bring together both elements. For example adaptation to reduce flood risk by habitat creation and using natural processes, (Section 2.6.5.2, Cross-Chapter Box SLR in Chapter 3), such as by re-naturalising straightened river systems or creating wetlands for water storage, offers the potential to meet multiple objectivesand has increased overall funding available for ecosystem restoration.

2.6.5.1 Case study: Assisted Colonisation / Managed Relocation in Practice

Scale: Global
Issue: Helping species move to track shifting climate space

Managed relocation (assisted migration, assisted colonisation) is the movement of species, populations, or genotypes to places outside the areas of their historical distributions (Hoegh-Guldberg et al., 2008) and may be an option where they are not able to disperse and colonise naturally. It requires careful consideration of scientific, ethical, economic and legal issues between the object of relocation and the receiving ecosystem (Hoegh-Guldberg et al., 2008; Richardson et al., 2009; Schwartz et al., 2012).

Individual cases show that assisted migration can be successful. Anich & Ward (2017) extended the geographic breeding range of a rare bird, Kirtland's warbler, *Setophaga kirtlandii*, by 225km by using song playbacks to attract migrating individuals. Wadgymar (2015) successfully transplanted an annual legume, *Chamaecrista fasciculata,* to sites beyond its current poleward range limit, while Liu (2012) found that all but one of 20 orchid species survived when transplanted to higher elevations than their current range limits. After introducing two British butterfly species to sites ~65 and ~35 km beyond their poleward range margins, Willis (2009) observed that both introduced populations grew, expanded their ranges and survived for at least 8 years.

Butterflies have been favoured subjects for assisted migration in response to regional climate warming, since they are easy to move and their range dynamics have been extensively studied. The Chequered Skipper butterfly, *Carterocephalus palaemon,* became locally extinct in England in the 1970's, in an area not close to either the species' poleward or equatorial range limits. Nonetheless, Maes (2019) consider climate a crucial parameter for re-introduction, using SDMs both for choosing the source population in Belgium and introduction site.

Success of assisted migration for conservation purposes has been variable. Bellis (2019), identified 56 successes and 33 failures among 107 translocations of insects that had been undertaken explicitly for conservation purposes. They concluded failure was most strongly associated with low numbers of individuals released. Another potential source of failure is local adaptation: there is *good evidence* that adaptive differences among potential source populations can be important. For example, the transplants of *C. fasciculata* were more successful when sourced from the most poleward existing sites, while individuals from more equatorial habitats performed poorly even when artificially warmed (Wadgymar et al., 2015).

2.6.5.2 Case study: Adaptation for conservation and Natural Flood Management in England, United Kingdom

Scale: National
Issue: National approach to adaptation in the natural environment

Climate change threats to biodiversity in England include range retraction of cold adapted species and effects of more frequent extreme weather events such as droughts. These threats are exacerbated by land use and management: with habitats fragmented, land often drained and rivers straightened. There are also risks to people, which are exacerbated by environmental factors, including flooding and over-heating in urban areas. A National Adaptation Programme, provides a broad policy framework for England and includes a chapter on the natural environment. There are also adaptation plans produced by public bodies such as Natural England, the conservation agency and the Environment Agency, with a wide range of responsibilities including flood defence. The principles of climate change adaptation are well established in the UK conservation community and resources are available. Natural England has published a Climate Change Adaptation Manual jointly with the Royal Society for the Protection of Birds–a major conservation NGO (England and RSPB, 2020) and spatial mapping tool for climate change vulnerability (Taylor et al., 2014).

(Duffield et al., 2021) found that awareness of the need for adaptation was common amongst nature reserve managers and that they were implementing actions that might building resilience to climate change, such as restoring ecosystem processes and reducing fragmentation. . There is a recognition that it will be necessary to change management objectives of protected sites to adjust to changing circumstances but there was little implementation of such changes (Duffield et al., 2021). The main examples of managing change, was at the coast where rising sea level is causing transitions from terrestrial and freshwater systems to coastal and marine ones.

A range of EbA approaches are starting to contribute to adaptation in England but the best developed is Natural Flood Management (NFM): restoring natural processes and natural habitats to reduce flood risk (Wingfield et al., 2019). Over the last decade, a series of NFM projects have been established in local areas. The Environment Agency collated the evidence base on NFM (Burgess-Gamble et al., 2017) and was able to draw on 65 case studies (Ngai et al., 2017), covering river and floodplain management, woodland management, run-off management and coast and estuary management.

NFM includes a broad range of techniques, some of which, deliver real benefits for biodiversity and allow natural ecological process to re-establish. Others, such as creating 'woody debris dams' – barriers artificially constructed from tree trunks and branches in water courses to slow flow of water –will have fewer benefits, although they may benefit some species. Dadson et al. (2017) concluded that 'the hazard associated with small floods in small catchments may be significantly reduced' by natural flood management techniques.

However, they noted that the most extreme flood events may overwhelm any risk management measures and failed to find clear evidence of NFM in reducing flood risk downstream in large catchments.

There remain challenges in deploying NFM at larger scales, partly reflecting the time necessary to demonstrate the effectiveness of pilot studies and build confidence and building stakeholder support is important (Huq et al., 2017). There are now a number of examples of where collaborative initiatives between local communities, land owners and government agencies have been successful in establishing effective NFM schemes (Short et al., 2019).

2.6.5.3 Case Study: Protected Areas Planning in Response to Climate Change in Thailand

Scale: National
Issue: Protected area network planning

Many countries in the Association of South East Asian Nations (ASEAN) are expanding protected area networks to meet the Aichi target 11 of at least 17% of terrestrial area protected and it is important to take the effects of climate change into account. Existing protected areas in Thailand cover approximately 21% of the land area, and it is one of the few tropical countries that passes the Aichi Target 11. Most protected areas in Thailand were established on an ad hoc basis to protect remaining forest cover, and as a result do not represent diverse habitats and their associated species (Chutipong et al., 2014; Tantipisanuh, 2016) and may not be resilient to the interacting impacts of future land use and climate change (Klorvuttimontara et al., 2011; Trisurat, 2018).

Recent research conducted in northern Thailand indicated that the existing protected areas (31% of the region area) cannot secure viability of many medium- size and large mammals. Most species climate space would substantially shift, bringing a risk of extinction. The model results based on the spatial distribution model and network flow determined there was a need for expansion areas of 5,200 km^2 or 3% of the region to substantially minimise the high-risk level and increase the average coping capacity of the protection of suitable habitats from 82% as the current plan to 90%. These results were adopted by the Thailand's Department of National Parks, Wildlife and Plant Conservation and included in the National Wildlife Administration and Conservation Plan (2021-2031).

2.6.5.4 Case Study: Effects of Climate Change on Tropical High Andean Social Ecological Systems

Scale: Regional
Issue: Complex ramifications of glacial retreat on vegetation, animals, herders and urban populations

Accelerated warming is shrinking tropical glaciers at rates unseen since the middle of the Little Ice Age (Rabatel et al., 2013; Zemp et al., 2015). Climate-driven upward migration of species associated with warming and glacier retreat has modified species distribution and richness, and community composition along the Andes altitudinal gradient (Seimon et al., 2017; Carilla et al., 2018; Zimmer et al., 2018; Moret et al., 2019). Climate-driven glacier retreat alters hydrological regimes, impacting Andean pastoralists directly (López-i-Gelats et al., 2016; Postigo, 2020; Thompson et al., 2021), and water provisioning to lowland regions (Vuille et al., 2018; Hock et al., 2019; Orlove et al., 2019; Rasul and Molden, 2019). Drying wetlands has modified alpine plant communities, which are relevant to storing carbon, regulating water, and providing food for local livestock, leading to negative impacts on herders' livelihoods (Dangles et al., 2017; Polk et al., 2017; Postigo, 2020) and differently affecting the wild vicuña and the domesticated alpaca and llama. Vicuña (*Vicugna vicugna*) and alpaca (*Vicugna pacos)* wool are important income sources for indigenous communities and Llama (*Lama glama*) is the main source of meat. Vicuña is adjusting its feeding behaviour and spatial distribution as vegetation migrates upwards (Reider and Schmidt, 2020), causing them to roam outside protected areas and become vulnerable to illegal poaching.

Andean herders have responded to drying of grasslands by increasing livestock mobility, accessing new grazing areas through kinship and leases, creating and expanding wetlands through building long irrigation canals (of several km), limiting allocation of wetlands to new households, and sometimes cultivating grasses (Postigo, 2013; López-i-Gelats et al., 2015; Postigo, 2020). These adaptive responses to regional climate change are enabled by deeply-embedded indigenous institutions that have traditionally governed Andean pastoralists, but have become severely compromised by national socio-economic pressures (Valdivia et al., 2010; Postigo, 2019; Postigo, 2020). For instance, water quality, access and control by local pastoralists has declined due to new mining concessions in headwaters of Andean watersheds (Bebbington and Bury, 2009) and diversion of water to lowland coastal desert for agricultural irrigation (Mark et al., 2017).

Glacier mass and runoff in the tropics are projected to reduce >70% and >10%, respectively, by 2100 under RCP 2.6, RCP 4.5 and RCP 8.5 (Huss and Hock, 2018; Hock et al., 2019). In Peru, montane ice-field melt-water provides 80% of the water resources for the arid coast where half the population lives (Thompson et al., 2021). Increasing variability of precipitation has compromised rain-fed agriculture and power generation, particularly in the dry season, exacerbating pressures for new water sources (Bradley et al., 2006; Bury et al., 2013; Buytaert et al., 2017). Thus, there is risk of increasing conflicts between climate change adaptation to benefit high Andean human and natural communities and adaptation to maintain water provisioning for lowland agricultural and urban areas.

2.6.5.5 Case Study: Helping African Penguins Adapt to Climate Change

Scale: Regional / local
Issue: Adaptation for a threatened species

The African penguin, *Spheniscus demersus,* is the only resident penguin species on mainland Africa and breeds in a handful of colonies in South Africa and Namibia. In 2017, penguins in Cape Town's Boulders Beach colony attracted almost one million visitors, providing 885 jobs and $18.9m revenue (Van Zyl and Kinghorn, 2018).Ninety-six percent of the population has been lost since 1900, with a 77% decline in the last two decades (Sherley et al., 2018) and by 2019 only 17,700 pairs remained (Sherley et al., 2020). The species is listed as Endangered on the IUCN Red List (IUCN, 2018) and if this trajectory persists the African penguin will become functionally extinct in the near future (Sherley et al., 2018).

Historically, hunting, egg and guano collection were the species' main threats, but three aspects of climate change now predominate. Firstly, a several-hundred-kilometre eastward shift in distributions of their main prey species, anchovies and sardines, has reduced food availability (Roy et al., 2007; Crawford et al., 2011). While adult penguins typically forage up to 400 km from their colonies, they are restricted to a ~20 km radius from their colonies during breeding months (Ludynia et al., 2012; Pichegru et al., 2012). The resulting food shortage at this critical time is compounded by competition with commercial fisheries and environmental fluctuations (Crawford et al., 2011; Pichegru et al., 2012; Sherley et al., 2018). This has impacted adults' survival and their ability to raise high-quality offspring (Crawford et al., 2006; Crawford et al., 2011; Sherley et al., 2013; Sherley et al., 2014).

Increasing heat wave frequency and intensity recorded in recent decades presents a second threat (van Wilgen and Wannenburgh, 2016; Van Wilgen et al., 2016; Mbokodo et al., 2020). Nests were historically built in insulated guano burrows, but are now frequently sited on open ground (Kemper et al., 2007; Pichegru et al., 2012; Sherley et al., 2012). High temperatures frequently expose the birds to severe heat stress, causing adults to abandon nests and resulting in mortality of eggs and chicks (Frost et al., 1976; Shannon and Crawford, 1999; Pichegru et al., 2012).Intensifying storm surges and greater wave heights can cause nest flooding (Randall et al., 1986; de Villiers, 2002).

The African penguin's survival in the wild is dependent on the success of adaptation action. Increasing access to food resources is a management priority (IUCN, 2018). One approach is to reduce fishing pressure immediately around breeding colonies. An experiment excluding fishing around colonies since 2008 has demonstrated positive effects (Pichegru et al., 2010; Pichegru et al., 2012; Sherley et al., 2015; Sherley et al., 2018; Campbell et al., 2019b). A second approach is to establish breeding colonies closer to their prey. An ongoing translocation initiative aims to entice birds eastwards to recolonise an extinct breeding colony and potentially to establish a new one (Schwitzer et al., 2013; Sherley et al., 2014; International, 2018). Penguin "look-alikes" or decoys, constructed from rubber and concrete, have been placed at the extinct colony site and, along with call play-backs, give the illusion of an established penguin colony (Morris and Hagen, 2018). This approach has not yet proven successful.

To promote on-site adaptation to heat extremes and flooding, initiatives are underway to provide cooler nesting sites that also provide storm protection and are sufficiently above the high water level (Extinction, 2018; International, 2018). Artificial nest boxes of various designs and constructed from a range of materials have been explored in combination with use of natural vegetation. Some designs have proven successful, increasing breeding success (Kemper et al., 2007; Sherley et al., 2012), but the same designs have had less success at other locations (Pichegru, 2013; Lei et al., 2014).

Hand-rearing and releasing African penguin chicks, including from eggs, has long proven valuable because moulting parents, being shore-bound, are unable to feed late-hatching chicks. Since 2006, over 7,000-orphaned chicks have been released into the wild as part of the Chick Bolstering Project with a success rate of 77% (Schwitzer et al., 2013; Sherley et al., 2014; Klusener et al., 2018; SANCCOB, 2018). A new project at Boulders Beach aims to use real-time weather station data, within-nest temperatures and known thresholds of penguin heat stress as triggers for implementing a Heat Wave Response Plan. Drawing on well-established chick-rearing facilities and a large body of expertise, this includes removing heat-stressed eggs and birds, hand rearing and/or rehabilitation and release. It is hoped that such birds may be released at the proposed new colony site.

2.6.5.6 Case study: Conserving Climate Change Refugia for the Joshua tree in Joshua Tree National Park, California, United States of America

Scale: Local
Issue: Possible extirpation of a plant species from a national park

Joshua Tree National Park conserves 3200 km2 of Mojave and Sonoran Desert ecosystems. The climate of the national park is arid, with a 1971-2000 average summer temperature of 27.3ºC ± 0.7ºC and average annual precipitation of 170 ± 80 mm y^{-1} (Gonzalez et al., 2018). From 1895 to 2017, average annual temperature increased at a significant ($p < 0.0001$) rate of 1.5 ± 0.1ºC $century^{-1}$ and average annual precipitation decreased at a significant ($p = 0.0174$) rate of -32 ± 12% $century^{-1}$ (Gonzalez et al., 2018). Anthropogenic climate change accounts for half the magnitude of a 2000–2020 drought in the Southwestern USA, the most severe since the 1500s (Williams et al., 2020).

The national park was established to protect ecosystems and cultural features unique to the region, particularly the Joshua tree (*Yucca brevifolia*), a tall, tree-like yucca that provides habitat for birds and other small animals and holds cultural significance. The national park protects the southernmost populations of the Joshua tree. Paleobiological data from packrat (*Neotoma spp.*) middens and fossil dung of the extinct Shasta ground sloth (*Nothrotheriops shastensis*) show that Joshua trees grew 13 000–22 000 thousand years before present a across a wider range, extending as far as 300 km south into what is now México (Holmgren et al., 2010; Cole et al., 2011). A major retraction of the range began ~11 700 thousand years before present, coinciding with a warming in the region of 4ºC, caused by Milankovitch cycles, that marked the end of the Pleistocene and beginning of the Holocene (Cole et al., 2011), suggesting a sensitivity of Joshua trees of 300 km latitude per 4ºC.

Under an emissions scenario that could increase park temperatures over 4ºC by 2100, suitable climate for the Joshua tree could shift north and the species become extirpated from the park (Sweet et al., 2019). Plant mortality would increase from drought stress and wildfires, which have been rare or absent in the Mojave, but which invasive grasses have and may continue to fuel (Brooks and Matchett, 2006; DeFalco et al., 2010; Abatzoglou and Kolden, 2011; Hegeman et al., 2014).

The national park had been trying to conserve the species wherever in the park it was found. The future risk of extirpation prompted them to adapt conservation to focus on protecting potential refugia, where suitable conditions may persist for the species into the future (Barrows et al., 2020). The national park used spatial analyses of suitable climate to identify potential refugia under all emissions scenarios except for the highest (Barrows and Murphy-Mariscal, 2012; Sweet et al., 2019). The park prioritises the refugia for removal of invasive grasses and fire control (Barrows et al., 2020)and works to restore refugia that have burned in fires, using native plants, including nursery-grown Joshua tree seedlings. The park and its partners are monitoring plant species composition and abundance in the refugia for early warning of any changes (Barrows et al., 2014).

2.6.5.7 Case Study: Ecosystem based Adaptation in Durban, South Africa

Scale: Local
Issue: Ecosystem based adaptation (EbA) in a city and surrounding area

Durban was an early pioneer of EbA in a city context, establishing a Municipal Climate Protection Programme (MCPP) in 2004 (Roberts et al., 2012). The City, situated in a global biodiversity hotspot (Bank, 2016), has a rapidly growing population (approximately 3.5 million) and is highly fragmented (Roberts et al., 2013). High levels of development, particularly in peri-urban areas, have encroached into natural habitats (Bank, 2016). Degradation of the natural resource base in this way has direct economic and financial costs, is threatening the City's long-term sustainability, and is exacerbated by climate change (Bank, 2016; Municipality, 2020). The impacts of climate change are anticipated to increase unless appropriate mitigation and adaptation interventions are prioritised (Municipality, 2020). High rates of poverty, unemployment and health problems have pushed Durban to explore a climate change adaptation work stream within its MCPP (Roberts et al., 2013; Roberts et al., 2020b).

A single approach to adaptation is likely to be insufficient (Archer et al., 2014), and community-based adaptation should be integrated as part of a package of tools applied at the city level. Durban's climate change adaptation work stream is composed of three separate components: municipal adaptation (adaptation activities linked to the key functions of local government); community-based adaptation (focused on improving the adaptive capacity of local communities); and a series of urban management interventions (addressing specific challenges such as the urban heat island, increased storm water runoff, water conservation and sea level rise) (Roberts et al., 2013).

Lessons learnt from Duban's experience include the importance of meaningful partnerships, long-term financial commitments (Douwes et al., 2015) and significant political and administrative will (Roberts et al., 2012; Roberts et al., 2020b). Securing these requires strong leadership (Douwes et al., 2015), including from local champions (Archer et al., 2014), even if EbA is considered cost-effective (Roberts et al., 2012). Natural habitat restoration projects are seen as an ideal tool, as they combine mitigation outcomes with increased adaptation capacity that not only reduces vulnerability of ecosystems and communities (Douwes et al., 2016), but creates economic opportunities. These include direct job creation (Diederichs and Roberts, 2016; Douwes and Buthelezi, 2016) with various spinoffs such as better education for schoolchildren (Douwes et al., 2015). Indirect benefits, include better water quality and reduced flooding, are generated as a result of improved ecosystem service delivery (Douwes and Buthelezi, 2016). In areas that are already developed, opportunities for green roof infrastructure can yield reductions in roof storm water run-off (by approximately 60 ml/m^2/minute during a rainfall event), slow release of water over time, and reduced temperatures on roof surfaces (Roberts et al., 2012).

2.6.5.8 Case Study: Protecting Gondwanan refugia against fire in Tasmania, Australia

Scale: Local
Issue: Protection of rare endemic species

The Tasmanian Wilderness World Heritage Area (TWWHA) has a high concentration of 'paleo-endemic' plant species restricted to cool, wet climates and fire free environments, but recent wildfires have burnt substantial stands, which are unlikely to recover (Harris et al., 2018b, Bowman et al., 2021, The 2016 Tasmanian). The fires led to government inquiries and a fire-fighting review, which have suggested changes to management as that climate change will make such fires more likely in the future (Council, 2016; Press, 2016; Council, 2019).

The majority of the TWWHA is managed as a Wilderness Zone, where management is currently carried out in a manner that allows natural processes to predominate. The exclusion of fire from stands of fire-sensitive trees such as the Pencil pine, *Athrotaxis cupressoides,* is part of this management strategy, possible in the past due to the moisture differential and lower flammability of these areas. However, in recent years, the threat posed by extensive and repeated wildfires, and an increasing awareness that fire risk is likely to increase (Fox-Hughes et al., 2014; Love et al., 2017; Love et al., 2019) have meant that more direct management intervention has been implemented. There has been a realisation that a "hands off" approach to managing the threat will not be sufficient to protect the paleo-endemics. Not only is fire-fighting difficult in the remote wilderness area, but limited resources mean that fire managers must prioritise where fires will be fought when many fires are threatening towns and lives across the state simultaneously.

After wildfires in 2016 caused extensive damage (Bowman et al., 2020a), significant effort and resources were spent trying to protect the remaining stands of Pencil pine during the 2019 fires, using new approaches including the strategic application of long-term fire retardant and the installation of kilometres of sprinkler lines (Council, 2019). These approaches are thought to have been effective at halting the fire and protecting the high value vegetation in some situations. Impact reports are currently being finalised to quantify the extent of fire-sensitive vegetation communities that have been affected. However, there is concern that these interventions may have adverse effects on the values of the TWWHA if applied widely, so while research is ongoing, these will only be applied in strategic areas (e.g., fire retardant is not being applied to some areas).

The TWWHA Management Plan (2016) emphasises Aboriginal fire management as an important value of the area, along with their knowledge of plants, animals, marine resources, minerals (ochre and rock sources), and their connection with the area as a living and dynamic landscape. Fire management planning aims to protect important sites from fire and ensure that management does not impact Aboriginal cultural values (DPIPWE, 2016). Increasingly, there is an acknowledgment that the cessation of traditional fire uses has led to changes in vegetation and calls to incorporate Aboriginal burning knowledge into fire management of the TWWHA.

2.6.5.9 Case Study: Bhojtal Lake, Bhopal, India

Scale: Local
Issue: Protection of water resources and biodiversity

The city of Bhopal, the capital of Madhya Pradesh state in central India, is dependent on Bhojtal, a large man-made lake bordering the city, for its water supply (Everard et al., 2020). It is also an important conservation site with wetlands protected under the Ramsar convention and diverse flora and fauna (WWF, 2006). Bhojtal also provides a wide range of other benefits to people, including tourism, recreation, navigation, and subsistence and commercial fisheries, supporting the livelihoods of many families (Verma, 2001).

Climate change in Bhopal may pose ecological and socio-economic stresses due to changes in rainfall and weather patterns (Anonymous, 2019), exacerbated by a series of problems such as wastewater discharge, illegal digging of bore wells and unsustainable water extraction/exploitation (Everard et al., 2020). Ecosystem service provision at Bhojtal was assessed using the Rapid Assessment of Wetland Ecosystem Services (RAWES) approach, including water quality analysis from the lake. Information on the geology, hydrology and catchment ecology of the lake was collected and a Baseline Biodiversity Assessment was conducted.

The Lake Bhopal Conservation and Management Project (JICA, 2007) was developed with the following actions:

1. Desilting and dredging; deepening and widening of spill channel; prevention of pollution (sewerage scheme); management of shoreline and fringe area; improvement and management of water quality

2. Soil and water conservation measures using vegetative and engineering structures particularly at upper ridges of watersheds; construction of small check dams or percolation tanks for recharge purposes in areas marked for 'drainage line recharge measures'.

3. Afforestation initiatives.

Implementation of these measures with the help of local communities improved the lake's health. Nature-based solutions are more resilient adaptation measures towards climate change. Restoration not only reduced water stress but also provides multiple societal benefits in the urban area (Kabisch et al., 2016).

2.6.5.10 Case Study: Addressing Vulnerability of Peat Swamp Forests in South East Asia (SEA)

Scale: Regional
Issue: Protecting peatland biodiversity, carbon and ecosystem services from climate change and land degradation

SEA peatlands have undergone extensive logging, drainage and land-use conversion that have caused habitat loss for endemic species, i.e., orangutan (*Pongo* spp) (Gregory et al., 2012; Struebig et al., 2015). Prolonged droughts associated with El Niño (Section 4.4.3.2) compound the effects of drainage, leading to large recurrent fires (Langner and Siegert, 2009; Gaveau et al., 2014; Putra et al., 2019). Under RCP 8.5, it is projected that by the end of the century, the annual rainfall will significantly decrease (30%) over SEA, and the number of consecutive dry days will significantly increase (60%) over Indonesia and Malaysia (Supari et al., 2020). Peat degradation and losses to fire result in large GHG emissions (Miettinen et al., 2016) as well as haze pollution that is a trans-boundary problem in the region (Heil et al., 2007).

Improving resilience to fire and climate change in SEA peatlands through restoration is extremely difficult and presents many challenges. The Indonesian government has tasked the Badan Restorasi Gambut (Peatland Restoration Agency) to restore peatlands (Darusman et al., 2021; Giesen, 2021). Other local initiatives exist, such as fire management programmes and restoration projects (Puspitaloka et al., 2020). Since 2016, the Government of Indonesia has rewetted ~380,000 hectares of degraded peatlands mainly through canal blocking and flooding, but less than 2000 hectares were successfully restored to native plant species common to peat swamp forests (Giesen, 2021).Replanting native trees has had relatively low success (Lampela et al., 2017) because they have a low tolerance to prolonged inundation and a lack of fire adaptation strategies (Page et al., 2009; Roucoux et al., 2013; Dohong et al., 2018; Cole et al., 2019; Luom, 2020; Giesen, 2021). Barriers to successful management are complex, and include the disparity in timeframes between ecological restoration and political/socioeconomic needs (Harrison et al., 2020) and an over-focus on fire-fighting rather than fire prevention (Mishra et al., 2021a). Early protection of peat forests has been highlighted as a more effective management strategy than restoration, not only in insular SEA but also in areas like Papua New Guinea, which may be targeted for expansion of estate crop plantations (Neuzil et al., 1997; Dennis, 1999; Anshari et al., 2001; Anshari et al., 2004; Hooijer et al., 2006 Assessment of; Heil et al., 2007; Page et al., 2009; Page et al., 2011; Posa et al., 2011; International, 2012; Miettinen et al., 2012; Biagioni et al., 2015; Miettinen et al., 2016; Rieley and Page, 2016; Adila et al., 2017; Cole et al., 2019; Vetrita and Cochrane, 2019; Harrison et al., 2020; Hoyt et al., 2020; Ruwaimana et al., 2020; Ward et al., 2020; Cole et al., 2021).

2.6.6 Limits to Adaptation Actions by People

The evidence summarised above (Sections 2.6.2 - 2.6.4) shows that by restoring ecosystems it is possible to increase their resilience to climate change, including the resilience of the populations of species they support and of human communities. However, changes to healthy ecosystems and biodiversity are already happening as described in this chapter *(robust evidence, high agreement)* and further changes are inevitable even under low greenhouse gas emissions scenarios (*robust evidence, high agreement*). Planning to manage the consequences of inevitable changes and prioritise investments in conservation actions where they have best chance of succeeding (e.g. Section 2.6.4.6) will be an increasingly necessary component of adaptation (*robust evidence, high agreement*) (Table 2.6).

It is possible to help species survive by active interventions such as translocation but as described above (Section 2.6.4.1) it is not a straightforward process, is not suitable for all species and is resource intensive. Modifying local microclimate or hydrological conditions can work for some species (Sections 2.6.2, 2.6.4.5), but is likely to be less effective at higher levels of climate change. It will also be less successful for larger species and more mobile ones. The microclimate of a tree is much more closely coupled with wider atmospheric conditions than that of a small plant or animal in the boundary layer and mobile species such birds and large mammals range over large areas rather than being confined to discrete locations where conditions can be manipulated. There is potential for using evolutionary changes to enhance the adaptive capacity for target species, such as is being done in the Great Barrier reef by translocating symbionts and corals that have survived recent intense heat-induced bleaching events into areas that have had large die-off.

However, known limitations to genetic adaptation preclude species-level adaptation to climates beyond their ecological and evolutionary history (Sections 2.2.4.6; 2.6.1). All of these interventionist approaches are constrained by requiring significant financial resources and expertise, they also require a high level of understanding of individual species autecology, which can take years to acquire, even if resources were available. Ex situ conservation (for example in seed banks may be the only option to conserve some species, especially as levels of warming increase and this will not be feasible for all.

While the science of restoration has generated many successes, some habitats are very difficult to restore, making certain decisions effectively irreversible. For example, *Acacia nilotica* was introduced into Indonesia in the 1850s for gum arabic with planting expanded for fire breaks in the 1960s. This tree became invasive and has already replaced >50% of savanna habitat in Baluran National Park, with complete replacement expected in the near future. This shift from savanna to Acacia forest is causing large declines in native species, including the charismatic wild banteng, *Bos javanicus* and wild dog (dhole, *Cuon alpinus)*, (Caesariantika et al., 2011; Padmanaba et al., 2017; Zahra et al., 2020). Multiple approaches to controlling the spread of this Acacia have been ineffective, highlighting the difficulty of reversing the decision to plant this tree (Zahra et al., 2020). Another example is the difficulties in restoring tropical peat forests of South East Asia (Section 6.5.10).

EbA when implemented well can reduce risks to people but there are limits, for example, an extreme flood event may exceed the capacity of natural catchments to hold water or slow its flow (Dadson et al., 2017), urban shade trees and green space can make a few degrees difference to temperatures experienced by people but that may not be enough in the hottest conditions.

In general adaptation measures can substantially reduce the adverse impacts of 1-2°C of global temperature rise, but beyond this losses will increase (IPCC, 2018b), including species extinctions and changes, such as major biome shifts which are cannot be reversed on human timescales. Some adaptation measures will also become less effective at higher temperatures. Whilst adaptation is essential to reduce risks, it cannot be regarded as a substitute for effective climate change mitigation (*robust evidence, high agreement*).

2.6.7 Climate Resilient Development

Climate Resilient Development (CRD) is the subject of Chapter 18. This section briefly assesses some of the fundamental issues for CRD relating to ecosystems; an overview of the importance of specific ecosystem services for CRD is presented in Box 18.7 in Chapter 18. A large body of evidence has demonstrated the extent to which human life, well-being and economies are dependent on healthy ecosystems and the range of threats they are under (*high confidence*) (IPBES, 2019; Dasgupta, 2021; Pörtner et al., 2021). An analysis of 64 studies found a strong positive synergy among eight critical regulating services of healthy ecosystems, including climate regulation, water provisioning, pest and disease control and adjacent crop pollination (Lee and Lautenbach, 2016). Health of ecosystems is, in turn, reliant upon maintenance of natural levels of species' richness and functional diversity (*high confidence*) (Lavorel et al., 2020) (see Section 2.5.4). A meta-analysis of 74 studies documented the mechanism for increased ecosystem stability was increased asynchrony among species, that itself was a product of higher species diversity (Xu, 2021, consistently positive effect). Responding to these threats requires the protection and restoration of natural and semi-natural ecosystems, together with sustainable management of other areas.

The Convention on Biological Diversity set the Aichi 2020 target of 17% of each country to be protected for biodiversity. Analyses suggest that 30% or even 50% of land and sea needs to be protected or restored to confer adequate protection for species and ecosystem services (*high confidence*) (Pimm et al., 2018; Dinerstein et al., 2019) (Woodley et al., 2019; Brooks et al., 2020; Hannah et al., 2020; Luther et al., 2020; Zhao et al., 2020; Sala et al., 2021). Hannah (2020) estimated that limiting warming to 2°C and protecting 30% of high biodiversity regions (Africa, Asia and Latin America) reduced risk of species' extinctions in half (*medium confidence*). Placement of protected areas is as important as total area (Pimm et al., 2018), and quality of protection (strictness and enforcement) is as important as the official land designation (Shah et al., 2021). Pimm et al. (Pimm et al., 2018) found that many small protected areas are successful because they are in areas of very high biodiversity containing species of small ranges size, while many large regions identified as wild often are of low biodiversity value, though they may have high mitigation value (e.g. high Arctic tundra). Finally, a global meta-analysis of 89 restoration projects, biodiversity increased by 44% and ecosystem services by 25% after restoration, but values remained lower than in intact reference systems (Benayas José et al., 2009).

There is also increasing evidence, reported in this chapter, that the loss and degradation of natural and semi-natural habitats exacerbates the impacts of climate change and climatic extreme events on biodiversity and ecosystem services (*high confidence*); example references include: (Ogden et al., 2013; Eigenbrod et al., 2015; Struebig et al., 2015; Stevens et al., 2016; Oliver et al., 2017; McAlpine et al., 2018; Taffarello et al., 2018; Lehikoinen et al., 2019; Birk et al., 2020; Chapman et al., 2020; Agol et al., 2021; Khaniya et al., 2021; Lara et al., 2021; Lehikoinen et al., 2021). Considering these two sets of evidence together, it is clear that climate change adaptation and ecosystem degradation both need to be addressed if either is to be tackled successfully (*robust evidence, high agreement*) as a number of recent publications have concluded (Haddad et al., 2015; Hannah et al., 2020; Arneth et al., 2021; Pörtner, 2021). Taking this combined body of evidence together, this assessment is that the protection and restoration of natural and semi-natural ecosystems are key adaptation measures (*robust evidence, high agreement*) (Section 2.5.4).

Large scale protection and restoration of ecosystems can also make a significant contribution to climate change mitigation (Dinerstein et al., 2020; Roberts et al., 2020a; Soto-Navarro et al., 2020). Globally, there is a 38% overlap between areas of high carbon storage and high intact biodiversity (mainly in the peatland tropical forests of Asia, Western Amazon and the high Arctic), but only 12% of that is protected (*high confidence*) (Soto-Navarro et al., 2020). Peatlands are particularly important carbon stores but are threatened human disturbance, land use change (Leifeld et al., 2019) and fire (Turetsky et al., 2015). Restoration of peatlands is not only an efficient nature climate solution in terms of GHG (Nugent et al., 2019), but it may also increase ecosystem resilience (Glenk et al., 2021). Global restoration efforts are ongoing to target degraded temperate peatlands in the American and Europe (Chimner et al., 2017), as a result of their importance for climate change mitigation being recognised (Paustian et al., 2016; Bossio et al., 2020; Humpenöder et al., 2020; Drever et al., 2021; Tanneberger et al., 2021). It has been estimated that the global GHG saving potential of peatland restoration is similar to the most optimistic sequestration potential from all agricultural soils (Leifeld and Menichetti, 2018). However the pressure on peatlands from human activity remains high in many parts of the world (Humpenöder et al., 2020; Tanneberger et al., 2021). Currently, the rapid destruction of tropical peatlands overshadows any current restoration efforts in temperate peatlands or any potential carbon gain from natural high-latitude peatlands (Roucoux et al., 2017; Wijedasa et al., 2017; Leifeld et al., 2019). (Sections 2.4.3.8, 2.4.4.4.2, 2.4.4.4.4, 2.5.2.8, 2.5.3.4)

Recent studies have highlighted the importance of ensuring that ecosystem protection is not implemented in a way which disadvantages those who live in or depend on the most intact ecosystems (Mehrabi et al., 2018; Schleicher et al., 2019) or risk food security. The actual area of land to be protected and the balance between sustainable use and protection will need careful planning and targeting to where it can have most benefit (Pimm et al., 2018); it will also be important to ensure that protection measures are effective in preventing damage (Shah et al., 2021).

At a local level, EbA can often provide a wide range of additional benefits for sustainable development in both rural and urban areas (Wilbanks, 2003; Nelson et al., 2007; Cohen-Shacham et al., 2016; Hobbie and Grimm, 2020; Martín et al., 2020). A number of the case studies above, such as those in Durban and at Bhojtal Lake illustrate this (2.6.5). A key element of Climate Resilient Development is ensuring that actions taken to mitigate climate change do not compromise adaptation, biodiversity and human needs. This depends on choosing appropriate actions for different locations (Box 2.2, Cross-Chapter Box NATURAL this Chapter). A particularly notable case of this is woodland creation as described in Box 2.2: re-afforestation of previously forested areas can provide multiple benefits (Lee et al., 2018; Lee et al., 2020) including for climate change mitigation, adaptation and biodiversity. However planting trees where they would not naturally grow can create multiple problems include the loss of native biodiversity and disruption of hydrology (Box 2.2). It is also the case that protection of existing natural forest ecosystems is the highest priority for reducing greenhouse gas emissions (Moomaw et al., 2019) and restoration may not always be practical (see Section 2.6.4.10). (Sections 2.4.3.6, 2.4.3.7, 2.4.4.3, 2.4.4.4, 2.5.2.6, 2.5.2.7, 2.5.3.3, Box 2.2, Cross-Chapter Box NATURAL this Chapter)

In some cases actions supported by international donors and presented as addressing climate change adaptation and mitigation in the natural environment can have damaging consequences for people and nature as well as failing to deliver adaptation and mitigation. One example of this was presented by (Work et al., 2019) who reviewed three climate change mitigation and adaptation projects in Cambodia: an irrigation project, a protected-area forest management project, and a reforestation project. In each case they found evidence of local communities rights being violated, maladaptation and destruction of biodiverse habitats. They concluded that the potential for maladaptation and adverse social and environmental impacts had been ignored by international donors as well as national authorities and that there was a need for much strict accountability mechanisms. Moyo et al. (Moyo et al., 2021), using case studies from South Africa, documented higher success of ecosystem restoration projects when they embraced broader SDGs, particularly enhancement of people's livelihoods. Better assessment of the impacts of adaptation and mitigation measures on people and ecosystems, before they are implemented, will be increasingly necessary to avoid unintended and damaging consequences as their deployment is scaled up (Larsen, 2014; Enríquez-de-Salamanca et al., 2017; Pour et al., 2017). This applies to ostensibly nature-based approaches as well as more engineering-based ones.

Another aspect of the benefits to people from ecosystems that needs to be taken into account in Climate Resilient Development is increasingly strong evidence of the benefits of natural environments for human health and well-being beyond the provision of basic necessities, such as food and water (Bratman et al., 2019; Marselle et al., 2021). Meta-analyses of 162 studies across 51,738 people documented that individuals with high levels of contact with nature through their lives felt significantly happier, healthier and more satisfied with their lives, and engage in more pro-nature behaviours, than those with little or no contact with nature *(high confidence)* (Capaldi et al., 2014; Mackay and Schmitt, 2019; Pritchard et al., 2020; Whitburn et al., 2020). Meta-analyses of manipulative human trials across 65 studies document a significant increase in positive feelings and attitudes, and declines in negative feelings, after experimental treatments involving nature *(medium confidence)* (Bowler et al., 2010b; McMahan and Estes, 2015; Soga et al., 2017). Within the context of CRD improving *the extent to which humans see themselves as part of the natural world* – known as human-nature connectedness (HNC) – by increasing access to natural areas, particularly within urban areas, can provide additional health, cultural and recreation benefits of NbS as well as increasing public engagement and support *(robust evidence, high agreement)* (Wilbanks, 2003; Nelson et al., 2007; Bowler et al., 2010b; Capaldi et al., 2014; McMahan and Estes, 2015; Cohen-Shacham et al., 2016; Soga et al., 2017; Mackay and Schmitt, 2019; Work et al., 2019; Hobbie and Grimm, 2020; Pritchard et al., 2020; Whitburn et al., 2020).

Cross-Chapter Box NATURAL: Nature-Based Solutions for Climate Change Mitigation and Adaptation

Authors: Camille Parmesan (Chapter 2), Gusti Anshari (Chapter 2, CCP7), Polly Buotte (Chapter 4), Donovan Campbell (Chapter 15), Edwin Castellanos (Chapter 12), Annette Cowie (WGIII Chapter 12), Marta Rivera Ferre (Chapter 8), Patrick Gonzalez (Chapter 2, CCP3), Elena López Gunn (ch4), Rebecca Harris (ch2, CCP3), Jeff Hicke (Chapter 14), Rachel Bezner Kerr (Chapter 5), Rodel Lasco (Chapter 5), Robert Lempert (Chapter 1), Brendan Mackey (Chapter 11), Paulina Martinetto (Chapter 3), Robert Matthews (WGIII, Chapter 3), Timon McPhearson (Chapter 6), Mike Morecroft (Chapter 2, CCP5), Aditi Mukherji (Chapter 4), Gert-Jan Nabuurs (WGIII Chapter 7), Henry Neufeldt (Chapter 5), Roque Pedace (WGIII Chapter 3), Julio Postigo (Chapter 12), Jeff Price (Chapter 2, CCP1), Juan Pulhin (Chapter 10), Joeri Rogelj (WGI Chapter 5), Daniela Schmidt (Chapter 13), Dave Schoeman (Chapter 3), Pramod Kumar Singh (Chapter 18), Pete Smith (WGIII Chapter 12), Nicola Stevens (Chapter 2, CCP3), Stavana E. Strutz (ch2), Raman Sukumar (Chapter 1), Gautam Talukdar (Chapter 2, CCP1), Maria Cristina Tirado (Chapter 7), Chapter ris Trisos (Chapter 9)

Nature-based Solutions provide adaptation and mitigation benefits for climate change as well as contributing to other sustainable development goals (high confidence). Effective nature-based climate mitigation stems from inclusive decision-making and adaptive management pathways that deliver climate-resilient systems serving multiple sustainable development goals. Robust decision-making adjusts management pathways as systems are impacted by on-going climate change. Poorly conceived and designed nature-based mitigation efforts have the potential for multiple negative impacts, including

competing for land and water with other sectors, reducing human well-being and failing to provide mitigation that is sustainable in the long-term (high confidence).

The concept of Nature-based Solutions (NbS) is broad and debated but has become prominent in both the scientific literature and policy since AR5, including earlier concepts, including Ecosystem based Adaptation (EbA). The key point is that these are actions benefiting both people and biodiversity (IUCN 2020; WGII Glossary). In the context of climate change, NbS provide adaptation and mitigation benefits for climate change in ways that support wild species and habitats, often contributing to other sustainable development goals *(robust evidence, high agreement)* (Keesstra et al., 2018; Lavorel et al., 2020; Malhi et al., 2020) (Griscom et al., 2017; Hoegh-Guldberg et al., 2019; IPCC, 2019a; Lewis et al., 2019; Seddon et al., 2020b)(AR6 WGIII Chapter 12, see Sections 2.2, 2.5.4, 2.6.3, 2.6.5, 2.6.7). Well-designed and implemented NbS mitigation schemes can increase carbon uptake or reduce greenhouse gases emissions at the same time as protecting or restoring biodiversity and incorporating elements of food provisioning (Mehrabi et al., 2018). A variety of measures can be part of NbS, ranging from the protection of natural terrestrial, freshwater and marine ecosystems, the restoration of degraded ones (this Cross-Chapter Box; Section 13.3), to more sustainable management of naturally regenerating ecosystems used for food, fibre and energy production (Figure Cross-Chapter Box NATURAL 1, Chapter 5, Cross-Working Group Box BIOECONOMY in Chapter 5). Agroecological practices mitigate and adapt to climate change and can promote native biodiversity (*high confidence*) (Sinclair et al., 2019; Snapp et al., 2021).

The role of restoration in NbS

Where natural ecosystems have been degraded or destroyed, re-establishing them and restoring natural processes can be a key action for adaptation and mitigation, and the science of restoration is well-established (de los Santos et al., 2019; Duarte et al., 2020) (Section 13.4.1). Such restoration activities need to adapt to on-going climate change risks for the landscape and ocean scape and the species composition of biological communities. Indeed, climate-change impacts may overwhelm attempts at restoration/conservation of previous or existing ecosystems, particularly when the ecosystem is already near its tipping point, as are tropical coral reefs (Bates et al., 2019; Bruno et al., 2019).

Lands (e.g.forests) and oceans (e.g. fisheries) managed for products using sustainable practices (whether applied by private, state, or indigenous peoples) can also be carbon- and biodiversity-rich, and so effective NbS (Paneque-Gálvez et al., 2018; Soto-Navarro et al., 2020). Indigenous people and private forest owners manage, use or occupy at least one-quarter of global land area, over one-third of which overlaps with protected areas, thus combining both protection and production (Jepsen et al., 2015; Garnett et al., 2018; IPBES, 2019; Santopuoli et al., 2019).

Protection/restoration of natural systems, including reducing non-climate stressors, and sustainable management of semi-natural areas emerge as necessary actions for adaptation to minimise extinctions of species, reaching tipping points that cause regime shifts in natural systems, loss of whole ecosystems, and their associated benefits for humans (Scheffer et al., 2001; Folke et al., 2005; Luther et al., 2020) (Chapters 2 and 3, AR6 WGIII Chapter 7). Such measures are critical for conservation of biodiversity and the provision of ecosystem goods and services in the face of projected climate change (Duarte et al., 2020). Supporting local livelihoods and providing benefits to indigenous, local communities and millions of private landowners, together with their active engagement in decision-making, is critical to ensuring support for NbS and its successfully delivery *(high confidence)* (Chapter 05; Figure Cross-Chapter Box NATURAL 1; Ceddia et al., 2015; Blackman et al., 2017; Nabuurs et al., 2017; Smith et al., 2019a; Smith et al., 2019b; Jones et al., 2020a; McElwee et al., 2020; Cao et al., 2021).

Forests

Intact natural forest ecosystems are major stores of carbon and support large numbers of species that cannot survive in degraded habitats *(very high confidence)*. Extensive areas of natural forest ecosystems remain in tropical, boreal and (to a lesser extent) temperate biomes regions, but in many regions, they are managed (sustainably and unsustainably) or have been degraded or cleared. Deforestation and degradation continue to be a source of global greenhouse gas emissions *(very high confidence)* (Friedlingstein et al., 2019). Protecting existing natural forests and sustainable management of semi natural forests providing goods and services is a highly effective NbS (Bauhus et al., 2009) *(high confidence).* Natural forests and sustainably managed diverse forests play important roles for climate change mitigation and adaptation while providing many other ecosystem goods and services *(very high confidence)* (Bradshaw and Warkentin, 2015; Favero et al., 2020; Mackey et al., 2020). Contributions to climate change mitigation are estimated at medians of 5-7 Gt CO_2/y (Roe et al., 2019). Forests influence the water cycle at local, regional and global scales (Creed and van Noordwijk, 2018) reducing surface runoff, increasing infiltration to groundwater and improving water quality (Bruijnzeel, 2004; Zhou et al., 2015a; Ellison et al., 2017; Alvarez-Garreton et al., 2019). Recent evidence shows that downwind precipitation is also influenced by evapo-transpiration from forests (Keys et al., 2016; Ellison et al., 2017). Protecting existing natural forest and sustainably managing production forests, in a holistic manner, can optimise the provision of the many functions forests fulfil for owners, conservation, mitigation and for society as a whole (Bauhus et al., 2009; Nabuurs et al., 2013).

Reforestation of formerly forested land can help to protect and recover biodiversity and can be one of the most practical and cost effective ways of sequestering and storing carbon *(high confidence)* (Nabuurs et al., 2017; Hoegh-Guldberg et al., 2018b; Paneque-Gálvez et al., 2018; Smith et al., 2018; Cook-Patton et al., 2020; Cowie et al., 2021; Drever et al., 2021). This can be achieved through planting or by allowing natural colonisation by tree and shrub species. The most effective method to employ depends upon local circumstances (such as the presence of remnant forest cover) or socio-cultural and management objectives. Reforestation with climate-resilient native or geographically near species restores biodiversity at the same time as sequestering large amounts of carbon (Lewis et al., 2019; Rozendaal et al., 2019). It can also restore hydrological processes, improving water supply and quality (Ellison et al., 2017) and reducing risks of soil erosion and floods *(high confidence)* (Locatelli et al., 2015).

Climate change may mean that in any given location, different species will be able to survive and become dominant, and restoring the former composition of forests may not be possible (Sections 2.4; 2.5). Severe disturbances such as insect/pathogen outbreaks, wildfires, and droughts, which are an increasing risk, can cause widespread tree mortality resulting in sequestered forest carbon being returned to the atmosphere (Anderegg et al., 2020; Senf and Seidl, 2021) thus suggesting we need to adapt (Sections 2.4, 2.5, 13.3 14.4.1, Box 14.1). Adaptation measures, such as increasing the diversity of forest stands through ecological restoration rather than monoculture plantations can help to reduce these risks (*confidence*). When plantations are established without effective landscape planning and meaningful engagement including free prior and informed consent, they can present risks to biodiversity and the rights, well-being and livelihoods of Indigenous and local communities, as well as being less climate-resilient than natural forests *(very high confidence)* (Section 5.6; Corbera et al., 2017; Mori et al., 2021).

Afforesting areas such as savannahs and many temperate peatlands, which would not naturally be forested, damages biodiversity and increase vulnerability to climate change *(high confidence)* so is not a Nature-based Solution and can exacerbate greenhouse gas emissions (Sections 2.4.3.5, 2.5.2.5, Box 2.2 this Chapter). Remote sensing based assessments of suitability for tree planting can over-estimate potential, due to failure to adequately distinguish between degraded forest and naturally open areas (Bastin et al., 2019; Veldman et al., 2019; Bastin et al., 2020; Sullivan et al., 2020).

Peatlands

Peatlands are naturally high-carbon ecosystems, which have built up over millennia. Draining, cutting and burning peat lead to oxidation and the release of CO_2 (*very high confidence*). Rewetting by blocking drainage, preventing cutting and burning can reverse this process on temperate peatlands (*medium confidence*) although can take many years (Bonn et al., 2016). Trees are naturally found on many tropical peatlands and restoration can involve removing non-native species such as oil palm and re-establishing natural forest. However, peatland tropical forest is difficult to fully restore, and native pond fish, that are vital as a local food, often do not return. Protection of intact peat forests, rather than attempting to restore cleared forest, is by far the more effective pathway both in terms of cost, CO_2 mitigation, and protection of food sources (Kreft and Jetz, 2007). Naturally treeless temperate and boreal peatlands have in some cases been drained to enable trees to be planted, which leads to CO_2 emissions, and restoration requires removal of trees as well as re-blocking drainage. *(high confidence*) (Sections 2.4.3.8; 2.5.4.8; 2.6.5.10).

Blue Carbon

Blue Carbon ecosystems (mangroves, saltmarshes and seagrass meadows; see glossary) often have high rates of carbon accumulation and sequestration (Section 3.5.5.5; Macreadie et al., 2019). However, quantification of their overall mitigation value is difficult due to variable production of CH_4 and N_2O (Adams et al., 2012; Rosentreter et al., 2018; MacLean et al., 2019b), uncertainties regarding the provenance of carbon accumulated (Macreadie et al., 2019), and the release of CO_2 by biogenic carbonate formation in seagrass ecosystems (Saderne et al., 2019). Therefore, blue carbon strategies, referring to climate change mitigation and adaptation actions based on conservation and restoration of blue carbon ecosystems, can be effective NbS, with evidence of recovery in carbon stocks following restoration, although their global or regional carbon sequestration potential and net mitigation potential may be limited *(medium confidence)* (Sections 3.6.3.1.6; 13.4.3, AR6 WGI 5.6.2.2.2; Duarte et al., 2020). They can also significantly attenuate wave energy, raise the seafloor thus counteracting sea level rise effects, and buffer storm surges and flooding erosion *(high confidence)* (Sections 13.2.2; 13.10.2). Additionally, they provide a suite of cultural (for example, tourism, livelihood and well-being for native and local communities), provision (e.g. mangrove woods, edible fish and shellfish) and regulation (e.g. nutrient cycling) services *(high confidence)* (Section 3.5.5.5). These services have motivated the implementation of management and conservation strategies of these ecosystems (Sections 3.6.3.1.6; 13.4.2). Blue carbon strategies are relatively new, with many of them experimental and small scale; therefore there is *limited evidence* of their long-term effectiveness. There is also limited information on the potential emission of other GHGs from restored blue carbon ecosystems, although reconnecting hydrological flow in mangroves and saltmarsh restoration are effective interventions to reduce CH_4 and CO_2 (*limited evidence, medium agreement*) (Kroeger et al., 2017; Al-Haj and Fulweiler, 2020).

Urban NbS

Nature-based Solutions can be a key part of urban climate adaptation efforts. Direct human adaptation benefit may stem from the cooling effects of urban forests and green spaces (parks and green roofs), from coastal wetlands and mangroves reducing storm surge and flooding, and from sustainable drainage systems designed to reduce surface flooding from extreme rainfall, as well as general benefits to human health and well-being *(high confidence)* (Sections 2.2; 2.6; Chapter 6; Frantzeskaki et al., 2019; Keeler et al., 2019) (Kowarik, 2011). Not all green schemes are considered "Nature Based Solutions" if they do not benefit biodiversity, but carefully designed urban greening can be effective NbS. Careful planning also helps limit negative equity consequences, benefiting wealthy neighbourhoods more than poor (Geneletti et al., 2016; Pasimeni et al., 2019; Grafakos et al., 2020). Effective planning should also consider what is appropriate for the climate and conditions of each city. For example, some trees emit volatiles (e.g. isoprene) that, in the presence of certain atmospheric pollutants, can increase surface ozone that in turn can cause human respiratory problems (Kreft and Jetz, 2007). Wetlands restoration close to human settlements needs to be paired with mosquito control to prevent negative impacts on human health and well-being (Stewart-Sinclair et al., 2020), but has been shown to provide better filtration and toxicity reduction with lower environmental impact than other forms of waste-water treatment (Vymazal et al., 2021), including "green roofs" and "green walls" (Chapter 06; Addo-Bankas et al., 2021).

Agroecological Farming

Agroecological farming (AF) is a holistic approach that incorporates ecologic and socio-economic principles. It strives to enhance biodiversity, soil health and synergies between agroecosystem components, reduce reliance on synthetic inputs (e.g., pesticides), builds on Indigenous knowledge and local knowledge, and fosters social equity (e.g., supporting fair, local markets (HLPE, 2019; Wezel et al., 2020). AF practices include intercropping, mobility of livestock grazing across landscapes, organic agriculture, integration of livestock, fish and cropping, cover crops and agroforestry. (Sections 5.14; FAQ 12.5, 13.5.)

Agroforestry, cover crops and other practices that increase vegetation cover and enhance soil organic matter, carefully management and varying by agroecosystem, mitigate climate change (*high confidence*) (Zomer et al., 2016; Aryal et al., 2019; Nadège et al., 2019). Global meta-analyses demonstrate agroforestry storing 20 -33% more soil carbon than conventional agriculture (De Stefano and Jacobson, 2018; Shi et al., 2018) and reducing the spread of fire (Sections 5.6, 13.5.2, 7.4.3, Box 7.7). Minimising synthetic inputs such as N-based fertilisers reduces emissions (Gerber et al., 2016). Cover crops can reduce N_2O emissions and increase soil organic carbon (Abdalla et al., 2019). Conservation farming (no-till with residue retention and crop rotation) increases soil organic carbon particularly in arid regions (Sun et al., 2020). Silvo-pastoral systems (pastures with trees), and other practices that increase vegetation cover and enhance soil organic matter increase sequestered carbon in vegetation and soils (Zomer et al., 2016; Aryal et al., 2019; Nadège et al., 2019; Ryan et al. 2019). Agroecologically improved cropland and grazing land management have significant mitigation potential, estimated at 2.8- 4.1 $GtCO_2e$ per year (Smith et al., 2020). (Sectiond 5.10, 5.14, Box 5.10, Cross Working-Group Box BIOECONOMY in Chapter 5; WGIII 7.4.3; Box 7.7).

AF enhances adaptation to climate change, including resilience to extreme events. Building organic matter improves soil water-holding capacity and buffers against drought; increased perenniality and high levels of ground cover reduce soil erosion during storms; agroforestry shelters stock and crops in heat waves; landscape complexity and agrobiodiversity increase resilience to disease and pests and stabilise livestock production and restoration of oyster reefs provides thermal refugia and storm surge protection (Allred et al., 2014; Henry et al., 2018; Kremen and Merenlender, 2018; Beillouin et al. 2019; ; Kuyah et al. 2019; Gilby et al., 2020; Niether et al. 2020; Richard et al. 2020; Howie and Bishop, 2021; Snapp et al. 2021) (;) . Livestock mobility enables adjusting to increased climatic variability while maintaining pastoral systems' productivity (Turner and Schlecht, 2019; Scoones, 2020). Thus, adoption of agroecology principles and practices will be highly beneficial to maintaining healthy, productive food systems under climate change (*high confidence*) (Sections 5.4.4; 13.5.2; FAQ 12.4).

AF practices such as hedgerows and polycultures maintain habitat and connectivity for biodiversity and support ecosystem functioning under climate stress compared to conventional agriculture (*high confidence*), Section 5.4.4.4; Buechley et al., 2015; Kremen and Merenlender, 2018; Albrecht et al., 2020). Increasing farm biodiversity benefits pollination, pest control, nutrient cycling, water regulation and soil fertility (Snapp et al. 2021; Beillouin et al. 2019; Tamburini et al. 2020). Biodiverse agroforestry systems increase ecosystem services and biodiversity benefits compared to simple agroforestry and conventional agriculture (*high confidence);* up to 45% more biodiversity and 65% more ecosystem services compared to conventional timber, crop or livestock production in the Brazilian Atlantic Forest (Santos et al., 2019), including for birds (M. Greenler and Ebersole, 2015; Karp et al., 2019), local tree species (Braga et al., 2019) and fewer invasive exotic plants species (Cordeiro et al., 2018). AF includes conservation of semi-natural woodlands, which can conserve bird predators of insect pests (Gonthier et al., 2019). Organic production increases insect species richness and abundance in and around the farm, including essential pollinators (Sections 5.10, 12.6; Kennedy et al., 2013; Haggar et al., 2015; Lichtenberg et al., 2017).

AF significantly improves food security and nutrition by increasing access to healthy, diverse diets and rising incomes for food producers, through increased biodiversity of crops, animals, and landscapes (*high confidence)* (Garibaldi et al., 2016; D'Annolfo et al., 2017; Isbell et al., 2017; Dainese et al., 2019; Bezner Kerr et al. 2021). Livestock mobility improves the site-specific matching of animals' needs with food availability (Damonte et al., 2019; Mijiddorj et al., 2020; Postigo, 2021), and can generate a form of rewilding that restores lost ecosystem functioning (Gordon et al., 2021). Conservation of crop wild relatives in situ supports genetic diversity in crops for the range of future climate scenarios (Redden et al., 2015).

System-level agroecological transitions require policy support for farmer experimentation and knowledge exchange, community-based participatory methodologies and market and policy measures e.g. public procurement, local and regional market support, regulation or payments for environmental services (HLPE 2019; Snapp et al. 2021; Mier y Teran et al. 2018). Scientific consensus about the food security and environmental implications of agroecological transitions at a global scale is lacking. Yields in agroforestry and organic can be lower than high-input agricultural systems, but conversely, AF can boost productivity and profit, varying by timeframe, socio-economic, political and ecosystem context (*medium confidence)* (Section 5.14; Muller et al., 2017; LaCanne, 2018; Barbieri et al., 2019; Rosa-Schleich et al. 2019; Smith et al., 2019b; Smith et al., 2020). ;. Such contrasting results and the limited investment in agroecological research to date make paramount assessing the global and regional impacts of agroecological transitions on food production, ecosystems and economy (Section 5.14; DeLonge et al., 2016; Muller et al., 2017; Barbieri et al., 2019).

Conclusions

Nature–based Solutions provide adaptation and mitigation benefits for climate change as well as contributing to other sustainable development goals *(high confidence)*. NbS avoid further emissions and promote CO_2 removal using approaches that yield long-lasting mitigation benefits and avoid negative outcomes for other sustainable development goals. Poorly conceived and designed mitigation efforts have the potential for multiple negative impacts: (1) They can have cascading negative effects on long-term mitigation by promoting short term sequestration over existing long-term accumulated carbon stocks, (2) They can be detrimental to biodiversity, undermining conservation adaptation, and (3) They can erode other ecosystem services important for human health and well-being *(high confidence)*. Conversely, well-designed and implemented mitigation efforts have the potential to provide co-benefits in terms of climate-change adaptation, as well as multiple goods and services, including conservation of biodiversity, clean and abundant water resources, flood mitigation, sustainable livelihoods, food and fibre security, and human health and well-being *(high confidence)*. A key aspect to such 'smart' climate mitigation is implementation of inclusive and adaptive management pathways (Section 1.4.2). These entail acceptance of the inherent uncertainty in projections of future climate change, especially at a regional or local level, and using decision making processes that keep open as many options as possible, for as long as possible, with periodic re-evaluation to aid in choosing pathways forward even as systems are being impacted by on-going climate change (Figure Cross-Chapter Box NATURAL 1; Cross-Chapter Box DEEP in Chapter 17; Section 1.4.2).

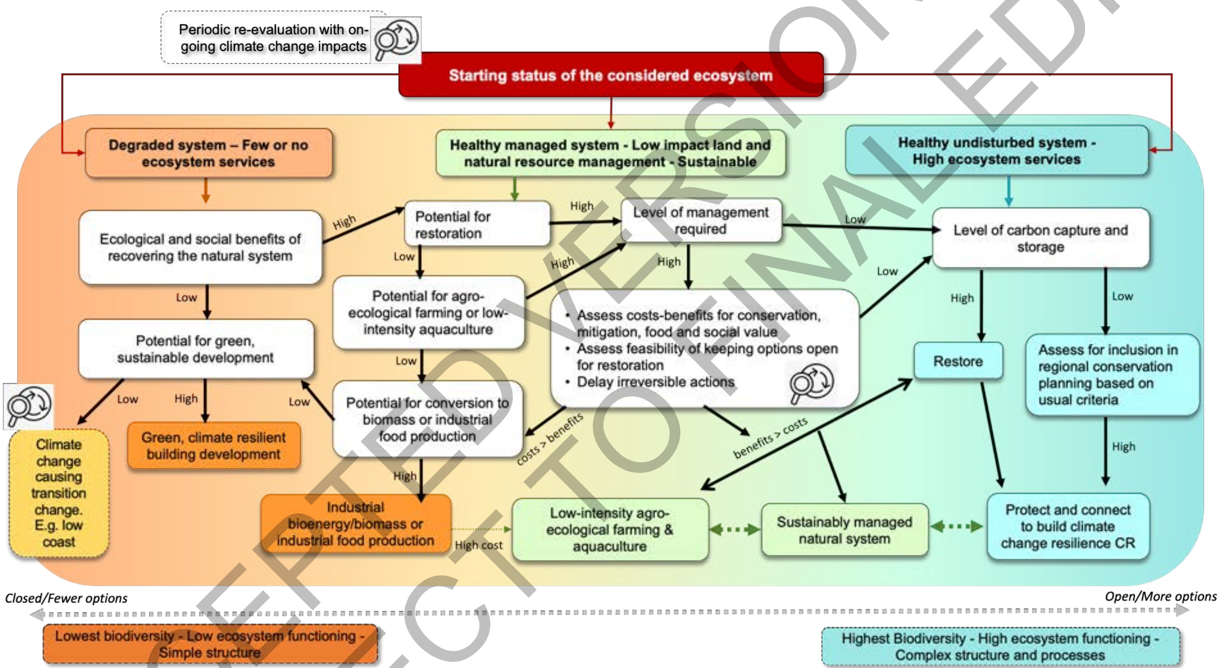

Figure Cross-Chapter Box NATURAL.1: Decision-making framework to co-maximise adaptation and mitigation benefits from natural systems. Decision-making pathways are designed to add robustness in the face of uncertainties in future climate change and its impacts. Emphasis is on keeping open as many options as possible, for as long as possible, with periodic re-evaluation to aid in choosing pathways forward even as systems are being impacted by on-going climate change

Table Cross-Chapter Box NATURAL.1: Assessment of benefits and tradeoffs between mitigation and strategies for both biodiversity and human adaptation to future climate change. Best practices highlight approaches that lead to maximal positive synergies between mitigation and adaptation; worst practices are those most likely to lead to negative tradeoffs for adaptation. Many best practices have additional societal benefits beyond adaptation, such as food provisioning, recreation and improved water quality. Mitigation Potential (Mit. Pot.) and Restoration Potential (Rest. Pot.) are considered.

System	Mit. Pot.	Rest. Pot.	Best practices and adaptation benefits	Worst practices and negative adaptation tradeoffs	Additional societal benefits	References
Forests						

Boreal Forests	Medium	Medium	Maintain or restore species and structural diversity, reduce fire risk, spatially separate wood production, and sustainably intensify management in some regions	Very large scale clear cuts, aiming for one or few tree species, although boreal is characterised by few tree species and a natural fire risk	Providing goods and services, improved air quality, improved hydrology, jobs	Drever et al. (2021)
Temperate forests	Very high	High	Maintain or restore natural species and structural diversity, leading to more biodiverse and resilient system	Planting large scale non-native monocultures which would lead to loss of biodiversity and poor climate change resilience	Providing goods and services, jobs, improved hydrology and biodiversity	Sections 2.4.3; 2.5; Box 2.2 ; Nabuurs et al. (2017); Roe et al. (2019); Favero et al. (2020)
Tropical wet forests	High	Moderate	Maintain or restore natural species and structural diversity, high biodiversity, more resilient to climate change	Planting non-native monocultures, loss of biodiversity, poor climate change resilience, soil erosion	Indiginous foods, medicines and other forest products, including sustainable selective logging	Section 2.4.3 Edwards et al. (2014)
Tropical dry forests	High	Moderate	Integrated landscape management	Planting non-native monocultures, Loss of biodiversity, poor climate change resilience, soil erosion		Foli et al. (2018)
Tropical peatland forests	Very high	Low	Integrated landscape management	Cutting native rainforest and planting palm oil for biodiesel results in very high carbon emissions from exposed peat soils	Forest pond fish are major food for local communities	Section 2.4.3; 2.5; Smith et al. (2019b)
Blue Carbon						AR6 WGI 5.6.2.2.2
Mangroves	Moderate	High	Conservation, restoration of hydrological flows, revegetation with native plants, livelihoods diversification, landscape planning for landward and upstream migration	Potential NH4 emissions	Improved fisheries and biodiversity, coastal protection against SLR and storm surges, recreation and cultural benefits	Sections 3.4.2.5; 3.5.5.5; 3.6.3.1 ; Macreadie et al. (2019); Duarte et al. (2020); Sasmito et al. (2020)
Saltmarshes	Moderate	High	Conservation, reduce nutrient loads, restoration of hydrological flows and sediment delivery, revegetation with native plants, landscape planning for landward and upstream migration	Potential NH4 emissions	Improved fisheries and biodiversity, protection against SLR and storm surges, recreational and cultural benefits	Sections 3.4.2.5; 3.5.5.5; 3.6.3.1 ; Macreadie et al. (2019); Duarte et al. (2020)
Seagrasses	Moderate	High	Conservation; restoration; improve water quality and reduce local stressors (reduction of industrial sewage, anchoring and trawling regulation)	Potential NH4 emissions	Improved fisheries and biodiversity; protection from shoreline erosion; recreational benefits	Section 3.4.2.5; 3.5.5.5; 3.6.3.1 ; de los Santos et al. (2019); Macreadie et al. (2019); Duarte et al. (2020)
Urban Ecosystems						
Urban forests	Moderate to High*	Moderate	Integrated landscape management. Species richness (including exotics) can be high	monoculture of an exotic tree lowers resilience and reduces biodiversity	Recreation & aesthetics; stormwater absorption benefits;	WGII Chapter 06

					heat mitigation, air quality improvements	
Urban wetlands	Moderate*	Moderate	Integrated landscape management.		Recreation & aesthetics; stormwater absorption; heat mitigation; coastal flood protection	WGII Chapter 06
Urban grasslands	Moderate*	Moderate	Integrated landscape management	fertilized commercial grass monocultures often require irrigation and are less resilient to droughts than native, mixed grasses and forbs	Recreation & aesthetics; stormwater absorption; heat mitigation	WGII Chapter 06
Open grasslands & savanna						
Boreal & Temperate Peatlands	High	Moderate	Blocking drainage channels; Raise water level to natural condition; remove planted trees; revegetation of bare peat; No burns; Increases biodiversity resilience; Reduce flood risk	Inappropriate hydrological restoration, e.g., flood surface depth greater than natural depth leading to methane emissions	Improved water quality in some conditions.	Sections 2.4.3; 2.5 ; Bonn et al. (2016); Nugent (2019); Taillardat et al. (2020)
Tropical savannas and grasslands (including rangelands)	Moderate	High	Control of feral herbivores; Reintroduce indigenous burns; reintroduce native Herbivores, controlled grazing; strategic design of water-holes; Community-based natural resource management, grass reseeding, clearing of invasive and encroaching woody plants	Afforestation,over-grazing/stocking; No burns; inappropriate placement and design of watering points. All leads to loss of biodiversity, and resilience; soil erosion; water insecurity	Improved grazing potential for livestock and dairy production, sustainable wildlife harvests, Increased water security, income from eco-tourism, medicanal plants, fuel wood. Enhanced food security.	Sections 2.4.3; 2.5; Box 2.1 ; Stafford et al. (2017); Moura et al. (2019); Shackelford et al. (2021); Stringer et al. (2021); Wilsey (2021)
Temperate Grasslands and rangelands	Moderate to High	Moderate to High	Integrated landscape management; sustainable grazing; Community-based natural resource management; Native grassland species more resistant to drought than introduced species	Monoculture of introduced species; over-fertilising with chemical or organic amendments; Failure to manage human-wildlife clashes; Failure to distribute income equitably; inadequate enabling policy to facilitate integrated landscape management	Sustainable harvest of wildlife, livestock and dairy production, wild fruits, medicinal plants, construction material, fuelwood; income from ecotourism	Sections 2.4.3; 2.5, Box 2.1; Farai, (2017); Baker et al. (2018); Homewood et al. (2020) Wilsey (2021)
Agroecologial farming and aquaculture	High	High (context specific)	Biodiverse systems at landscape scale; participatory adaptation to context; Short value chains; Farmer incentives; Biodiversity synergies; reduced climate risk	Poorly chosen species, practices and amendments can lead to low yields; Simplified agroforestry systems or industrial scale organic agriculture lacks holistic system-wide approach. Over-fertilising with organic amendments	Food security, human health, livelihoods, socio-cultural benefits e.g. culturally-appropriate foods.	Sections 5.4, 5.10, 5.12, 5.14 ; Coulibaly et al. (2017); HLPE (2019); Quandt et al. (2019); Sinclair et al. (2019); Smith et al. (2019b); Muchane et al. (2020); Reppin et al. (2020)

[END CROSS-CHAPTER BOX NbS-NATURAL HERE]

[INSERT FAQ2.5 HERE]

FAQ2.5: How can we reduce the risk of climate change to people by protecting and managing nature better?

Damage to our natural environment can increase the risk climate change poses to people. Protecting and restoring nature can be a way to adapt to climate change, with benefits for both humans and biodiversity. Examples include reducing flood risk by restoring catchments and coastal habitats, the cooling effects of natural vegetation and shade from trees and reducing the risk of extreme wildfires by better managing of natural fires.

Protecting and restoring natural environments, such as forests and wetlands can reduce the risks climate change poses to people, as well as supporting biodiversity, storing carbon and providing many other benefits for human health and wellbeing. Climate change is bringing an increasing number of threats to people, including flooding, droughts, wildfire, heat waves and rising sea levels. These threats can however be reduced or aggravated, depending on how land, sea and freshwater are managed or protected. There is now clear evidence that 'Nature-based Solutions' (NbS) can reduce the risks that climate change presents to people. This is sometimes called 'Ecosystem-based Adaptation (EbA) and includes::

- *Natural flood management*: As warm air holds more water, and in some places, because of changing seasonal rainfall patterns, we are seeing more heavy downpours in many parts of the world. This can create serious flooding problems, with loss of life, homes and livelihoods. The risk of flooding is higher where natural vegetation has been removed, wetlands drained or channels straightened. In these circumstances, water flows quicker and the risk of flood defenses being breached is increased. Restoring the natural hydrology of upstream catchments, including by restoring vegetation, creating wetlands and re-naturalising watercourse channels and reinstating connections with the flood plain can reduce this risk. In a natural catchment with trees or other vegetation, water flows slowly overland and much of it soaks into the soil. When the water reaches a watercourse, it moves slowly down the channel, both because of the longer distance it travels when the channel bends and because vegetation and fallen trees slow the flow. Wetlands, ponds and lakes can also hold water back and slowly release it into river systems.

- *Restoring natural coastal defences:* Rising sea levels as a result of climate change, mean that coasts are eroding at a fast rate and storm surges are more likely to cause damaging coastal flooding. Natural coastal vegetation, such as saltmarsh and mangrove swamps can, in the right places, stabilise the shoreline and act as a buffer, absorbing the force of waves. On a natural coast, the shoreline will move inland and as sea level rises, the coastal vegetation will gradually move inland with it. This contrasts with hard coastal defences such as sea walls and banks, which can be overwhelmed and fail. In many places however, coastal habitats have been cleared and where there are hard sea defences behind the coastal zone, the vegetation disappears as the coast erodes rather than moving inland. This is often referred to as 'coastal squeeze' as the vegetation is squeezed between the sea and the sea wall. Restoring coastal habitats and removing hard sea defences, can help reduce the risks of catastrophic flooding.

- *Providing local cooling:* Climate change is bringing higher temperatures globally, which can result in heatwaves affecting people's health, comfort and agriculture. In cities, this can be a particular problem for health as temperatures are typically higher than in the countryside. Trees give shade, which people, in both rural and urban areas, have long used to provide cool places for themselves and for crops such as coffee and livestock. Planting trees in the right place can be a valuable, low-cost Natural-based Solution to reduce the effects of increasing heat, including in reducing water temperatures in streams and rivers, which can help to maintain fisheries. Trees and other vegetation also have a cooling effect as a result of water being lost from their leaves through evaporation and transpiration (loss of water through pores in the leaves, known as stomata). Natural areas, parks, gardens in urban areas can help reduce air temperatures by up to a few degrees.

- *Restoring natural fire regimes:* Some natural ecosystems are adapted to burning, such as savannas and boreal forests. Where fire has been suppressed or non-native species of trees planted in more open habitats, there is a risk that potential fuel accumulates, which can result in larger and hotter fires. Solutions can include restoring natural fire regimes and removing non-native species to decrease people and ecosystems' vulnerability to the exacerbated fire risk climate change is bringing through higher temperatures and in some places changing rainfall patterns.

Nature-based Solutions, including protecting and restoring mangroves, forests and peatlands, also play an important part in reducing greenhouse gas emissions and taking carbon dioxide out of the atmosphere. They can also help people in a wide range of other ways, including through providing food, materials and providing opportunities for recreation. There is increasing evidence that spending time in natural surroundings is good for physical and mental health.

It is important that the right adaptation actions are carried out in the right place and that local communities play an active part in making decisions about their local environment if Nature-based Solutions are to be effective. When they are not part of the process, conflicts can emerge and benefits can be lost.

Whilst Nature-based Solutions help us to adapt to climate change and reduce the amount of greenhouse gases in the atmosphere, it is important to note that there are limits to what they can do. To provide a safe environment for both people and nature, it will be essential to radically reduce greenhouse gas emissions, especially from fossil-fuel burning in the near future.

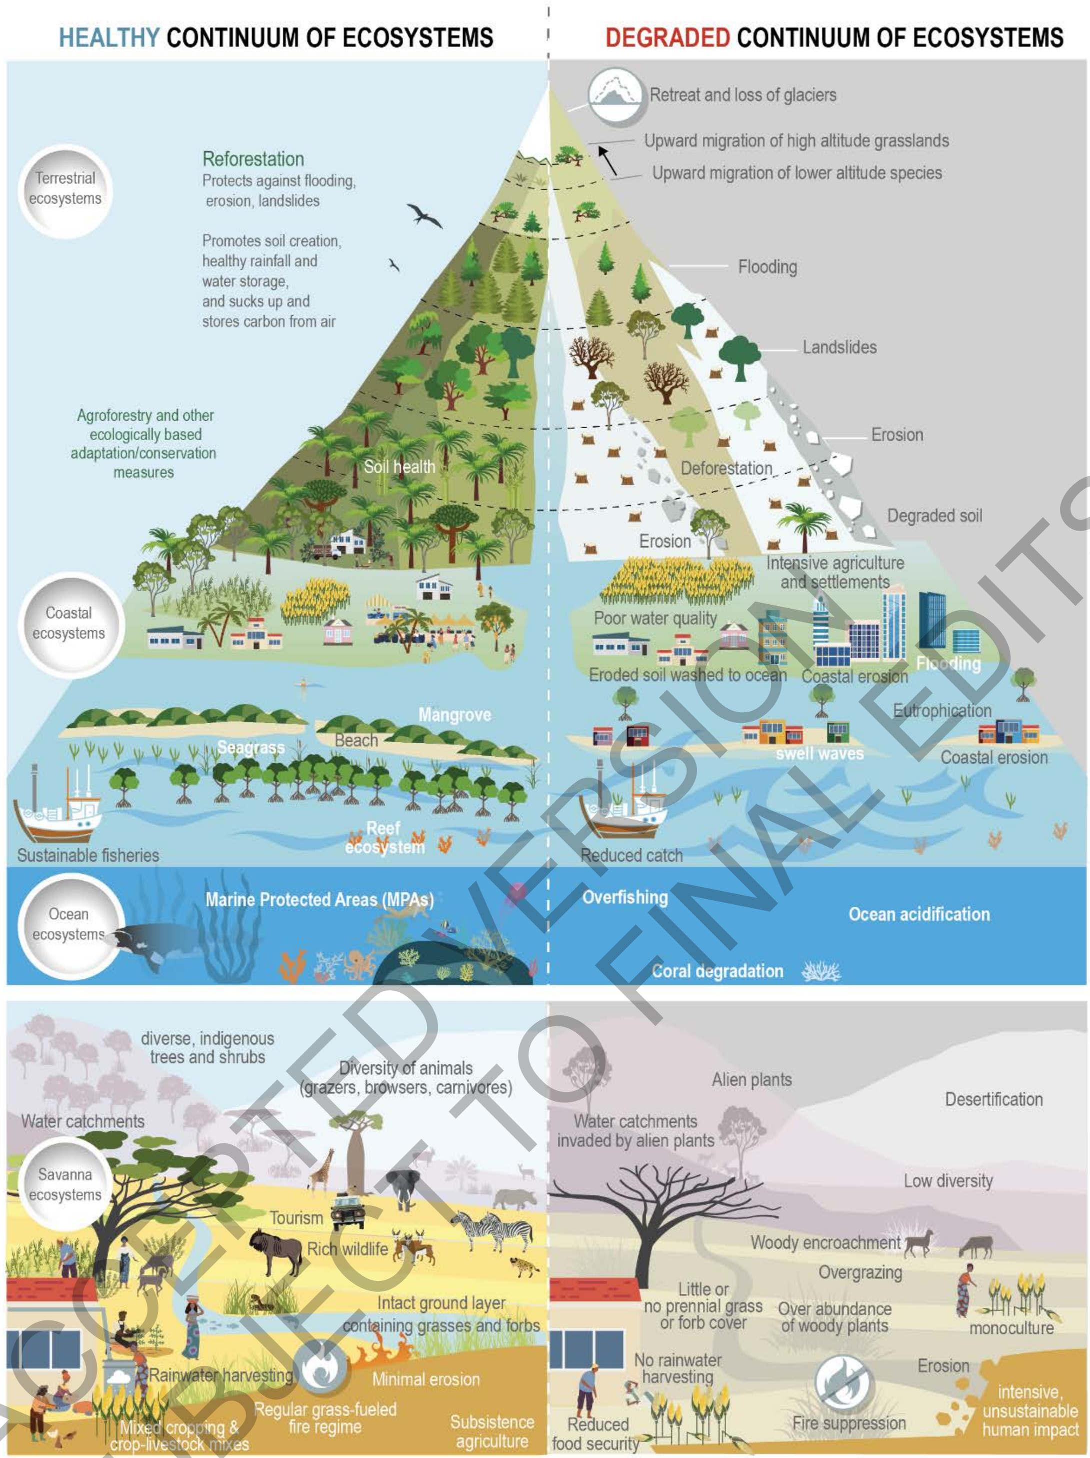

Figure FAQ2.5.1: Different Nature-based Solutions strategies.

[END FAQ2.5 HERE]

2.6.8 Feasibility of Adaptation Options

IPCC (2018a) defined feasibility as "the degree to which climate goals and response options are considered possible and/or desirable" (IPCC 2018) and set out an approach to assessing feasibility of pathways to limit global temperature rise to 1.5 °C. (Singh et al., 2020) have developed this approach for adaptation, recognising 6 different dimensions of feasibility: economic, technological, institutional, socio-cultural, environmental / ecological and geophysical (Table 2.9). Feasibility is considered more fully in other chapters of this report, including Cross-Chapter Box FEASIB in Chapter 18. Adaptation for biodiversity conservation and EbA encompasses a large range of approaches and techniques (Sections 2.6.2, 2.6.3) and will vary in different contexts globally, as illustrated by the range of case studies (Section 2.6.5). It is important to take account of specific regional and local circumstances as well as the type of adaptation action that envisaged before making a feasibility assessment. It is also important to note that what is a feasible adaptation response may change with the level of warming experienced – some techniques will be become less effective at higher levels of warming. With global temperature rises of less than 2°C, in many cases it will be realistic to build resilience and maintain species and ecosystems *in situ*, but at higher levels of warming, this will become increasingly difficult and managing inevitable change, including the consequences of loss and damage will be important (Prober et al., 2019). Similarly to be effective at higher levels of warming may require the adaptation of EbA approaches themselves (Calliari et al., 2019; Martín et al., 2021; Ossola and Lin, 2021). We have therefore not attempted a global scale assessment of the feasibility of adaptation options, but rather present some key cross cutting considerations in assessing feasibility for adaptation for and through ecosystems.

Many of the necessary techniques for climate change adaptation for biodiversity and EbA have been demonstrated and shown to provide a wide range of additional benefits. This does however depend on deploying the right techniques in the right place (Box 2.2) and the engagement of local communities (see Section 2.6.6). There is also a challenge where there is high demand for land for other purposes, especially for agriculture and urban developments. Table 2.8 summarise the main feasibility considerations, drawing on previous sections. An assessment of constraints on EbA by Nalau et al. (2018) addressed similar issues.

Table 2.8: Considerations in assessing feasibility of ecosystem restoration for climate change adaptation, following Singh et al. (2020)

Feasibility characteristics	Feasibility indicators	Factors relevant to ecosystem restoration
Economic	Micro-economic viability Macro-economic viability Socio-economic vulnerability reduction potential Employment & productivity enhancement potential	Costs are highly variable, depending on techniques and whether land purchase is required. Costs will depend on local rates for labour and materials. Economic benefits to local communities where employment is created and where loss from extreme events are avoided. (Section 2.6.4; De Groot et al., 2013)
Technological	Technical resource availability Risks mitigation potential (stranded Assets, unforeseen Impacts)	Techniques are available for restoration of most ecosystems (Sections 2.6.2; 2.6.3) although it can be very difficult to achieve in some circumstances and take a long time, e.g. the restoration of peat swamp forests (Section 2.6.5.10). Successful implementation may also require skills which are in short supply and training may be required.
Institutional	Political acceptability Legal, Regulatory feasibility Institutional capacity & Administrative feasibility Transparency & accountability potential	This will vary according to local factors. It should however be noted that EbA and adaptation for conservation has been implemented in wide range of different countries, including ones (see case studies in Section 2.6.5). In many cases EbA can meet multiple policy objectives but fall between different decision makers responsibilities.
Socio-cultural	Social co-benefits (Health, education) Socio-Cultural acceptability Social & Regional Inclusiveness Benefits for gender equity Intergenerational equity	Multiple benefits to local communities are possible but full engagement and/or leadership of affected members of communities has been shown to be critical. Local Knowledge and Indigenous Knowledge can provide important insights. (Section 2.6.6)
	Ecological capacity	

Environmental/ ecological	Adaptive capacity/potential	It is important to assess the benefits for ecosystems in relation to other potential options. In particular for some EbA approaches, it may be possible to achieve a range of different outcomes for biodiversity.
Geophysical	Physical Feasibility Land use change enhancement potential Hazard risk reduction potential	Appropriate measures need to be designed to take account of local geophysical conditions, for example catchment characteristics which define where some habitats can occur. This is also critical for ensuring the effectiveness of EbA in reducing natural hazards.

A key element of economic feasibility is the cost of adaptation options. Costs of adaptation vary greatly depending on the actions taken, the location, the methods used, the need for ongoing maintenance and whether land purchase is necessary. At its simplest adaptation may be a matter of taking account of actual or potential climate change impacts in the course of conservation planning and have little or no additional cost. For example, if a species of conservation concern colonises or starts to use a new area as a result of climate change (for example, migrant waterfowl shifting the locations where they overwinter (Pavón-Jordán et al., 2020b), protection or habitat management may be re-directed there. At the other extreme large scale restoration can incur significant costs, for example between 1993 and 2015, the EU-LIFE nature programme invested 167.6M € in 80 projects, which aim to restore over 913 km^2 of peatland habitats in Western European countries (Andersen et al., 2017). This is equivalent to less than 2% of the remaining peatland area, much of which has been affected to at least some extent by human pressures and restoring the total areas will cost considerably more. De Groot et al. (2013) analysed 94 restoration projects globally and found costs varied by several orders of magnitude but terrestrial and freshwater ecosystems mostly in the range of 100–10,000 USD per ha. They did however estimate that the majority of these projects provided net benefits and should be considered as high yield investments. Some methods can however be much cheaper than others even in the same type of ecosystems in the same Country: estimated cost of restoring forest cover in Brazil varied between a mean of 49 USD using natural regeneration compared to a mean of 2041 USD per hectare using planting (Brancalion et al., 2019). In assessing costs it is also important to take account of the benefits delivered by different options, both in economic terms and other wider benefits.

The 'technological' dimension of feasibility in the context of ecosystems can be regarded as the range of techniques available and the capacity to implement them. As described in Sections 2.6.2 and 2.6.3, above, a wide range of techniques have been developed and are starting to be implemented. There is good evidence to support adaptation for biodiversity and EbA in general terms and in many cases adaptation draws on techniques for habitat creation and restoration which have been develop to mee other objectives. However, feasibility needs to be assessed alongside likely effectiveness: a feasible but ineffective scheme is of no value and the evaluation of success for specific interventions remains poorly developed (Morecroft et al., 2019). It is often therefore important to proceed with the use of pilot studies and good monitoring and evaluation of outcomes to build confidence before wider deployment of approaches. A linked technical area is the availability of specialist skills and knowledge to implement adaptation which can vary considerably according to the type of adaptation measure.

Institutional dimensions are dealt with more fully in other chapters, but in the specific context of the natural environment, it is notable that EbA is relevant to a wide range of organisations and policy objectives, in addition to environmental departments, NGOs and agencies, which conservation has traditionally been delivered by. Upscaling implementation is likely to be dependent on this wider range of interests. There can however be problems in that appropriate geographies for decision making on ecosystems (such as a catchment) may not directly map onto governance arrangements

Socio-cultural factors are important in adaptation of the natural environment, in reviewing constraints on EbA Nalau et al. (2018) found that risk perceptions and cultural preferences for particular types of management approaches were frequently identified in studies.

In the IPCC feasibility assessment framework, one integral dimension is 'Environmental / ecological'. In this respect adaptation by and for ecosystems should perform well and this may be a reason to prefer EbA to other approaches when there is an alternative. It should however be noted that sometimes apparently environmentally positive approaches such as forest creation can be done in ways which are damaging (Section 2.6.7 and Box 2.2) and impacts need to be critically assessed for local circumstances.

Geophysical dimensions are important for ecosystems as they have typically shaped which ecosystems can occur where and feasibility will depend on implementing adaptation options in places where they are appropriate. Paleoecological studies can help inform potential options (Wingard et al., 2017)

[START BOX 2.2 HERE]

Box 2.2: Risks of Maladaptive Mitigation

To hold global temperature rise to well below 2°C and pursue efforts to limit it to 1.5°C as required by the Paris Agreement requires major changes in land use and management. There are many opportunities for Nature-based Solutions, which can provide climate change mitigation and adaptation in ways, which protect and restore biodiversity and provide a wide range of benefits to people (Cross Chapter Box NATURAL this Chapter). There are also new technologies and approaches to develop the bioeconomy in ways, which provide many benefits (Cross-Working Group Box BIOECONOMY in Chapter 5). Nevertheless, renewable energy is a large and essential element of the climate change mitigation and there are adverse impacts on biodiversity associated with some renewable energy, including wind and solar technologies (Rehbein et al., 2020) However, of the most serious emerging conflicts are between land-based approaches to mitigation and the protection of biodiversity, particularly as a result of afforestation strategies and potentially large areas devoted to bioenergy, including bioenergy with carbon capture and storage (BECCS). It is important to recognise the impacts of climate change mitigation at the same time as assessing the direct impacts of climate change and ensure that adaptation and mitigation are joined up.

BECCS is an integral part of all widely accepted pathways to holding global temperature rise to 1.5°C (IPCC, 2018b). This requires large areas of land which can conflict with the need to produce food and protect biodiversity (Smith et al., 2018). One study that examined the combined impacts of climate change and land use change for bioenergy and found severe impacts on species were likely if bioenergy were a major component of climate change mitigation strategies (Hof et al., 2018). A study on the potential impacts of bioenergy production and climate change on European birds found that land conversion for biodiversity to meet a 2°C target would have greater impacts on species range loss than a global temperature increase of 4°C, if bioenergy were the only mitigation option (Meller et al., 2015). To avoid the worst impacts of BECCS, it will need to be carefully targeted, according to context and local conditions (and other mitigation strategies prioritised so its use can be minimised IPCC, 2019, Special Report on Land; Ohashi, 2019, Biodiversity can benefit).

Reforestation of formerly forested areas can bring multiple benefits, but planting trees in places where they do not naturally grow can have serious environmental impacts, including potentially exacerbating the effects of climate change. Savannas, are at amongst those that are at risk from afforestation programmes. Savannas are grass dominated, high diversity ecosystems with endemic species adapted to high light environments, herbivory and fire (Staver et al., 2011; Murphy et al., 2016). Interactions between climate change, elevated CO_2 and the disruption of natural disturbance regimes have led to widespread woody plant encroachment (Stevens et al., 2016) causing a fundamental shift in ecosystem structure and function with loss of grass, reduced fire frequency (Archibald et al., 2009) and streamflow (Honda and Durigan, 2016). Afforestation exacerbates this degradation (Bremer and Farley, 2010; Veldman et al., 2015; Abreu et al., 2017). Global-scale analyses aimed at identifying degraded forest areas suitable for afforestation (Veldman et al., 2019) cannot reliably separate grassy ecosystems with sparse tree cover from degraded forests and local knowledge is essential to ensure tree planting is targeted where it can most benefit and avoid harm. Figure Box 2.2.1 indicates where these issues are most likely to arise.

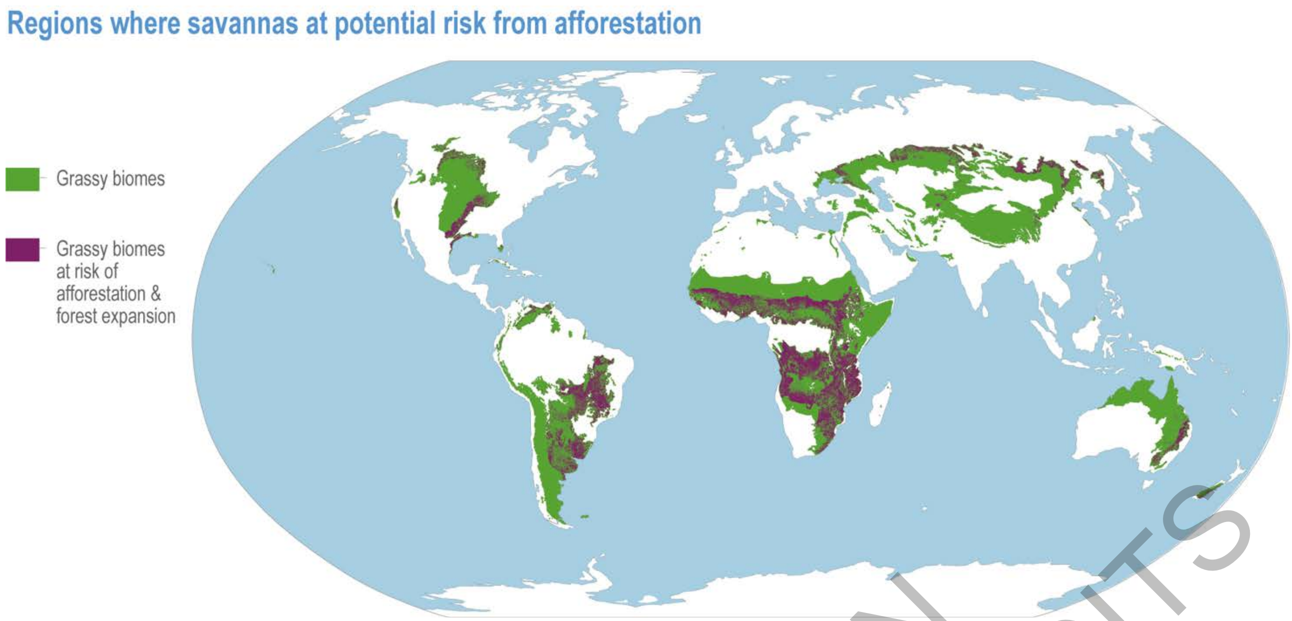

Figure Box 2.2.1: Regions where savannas at potential risk from afforestation. Based on (Veldman et al., 2015)

A similar issue can occur in naturally treeless peatlands which can be afforested if they are drained, but this leads to the loss of distinctive peatland species and communities as well as high greenhouse gas emissions (Wilson et al., 2014). Mitigation benefits of growing timber are reduced or become negative in these conditions by CO_2 emissions from the oxidation of the drained peat - they can be a net sources rather than a sinks (Simola et al., 2012; Crump, 2017; Goldstein et al., 2020).

[END BOX 2.2 HERE]

[START FAQ2.6 HERE]

FAQ2.6: Can tree planting tackle climate change?

Restoring and preventing further loss of native forests is essential for combating climate change. Planting trees in historically unforested areas (grasslands, shrublands, savannas, some peatlands) can reduce biodiversity and increase the risks of damage from climate change. It is therefore essential to target tree planting to the appropriate locations and use appropriate species. Restoring and protecting forests reduces human vulnerability to climate change, reduces air pollution, stores carbon and builds natural systems resilience.

Like all living plants, trees remove carbon dioxide from the atmosphere through the process of photosynthesis. In trees, this carbon uptake is relatively long-term, since much of it is stored in the trees' woody stems and roots. Therefore, tree planting can be a valuable contribution to reducing climate change. Besides capturing carbon, planting trees can reduce some negative impacts of climate change by providing shade and cooling. It can also help prevent erosion and reduce flood risk by slowing water flow. Restoring forest in degraded areas supports biodiversity and can provide benefits to people, ranging from timber to food and recreation.

There are some areas where replacing lost trees is useful. These include forest that has been recently cut down, and where reforestation is usually practical. However, it is very important to identify correctly areas of forest that are degraded or have definitely been deforested. Reforesting places, especially where existing native forest patches occur, brings benefits both in sucking up carbon from the atmosphere and helping us adapt to climate change. Plantations of a non-native species, although offering economic benefits, do not usually provide the same range of positive impacts and generally have lower biodiversity and carbon uptake and storage.

Reforestation options include the natural regeneration of the forest, assisted restoration, enrichment planting, native tree plantations, commercial plantations and directed tree planting can occur in agroforestry systems and urban areas. Reforestation with native species, usually contributes to a wide range of sustainability goals, including biodiversity recovery, improved water filtration and groundwater recharge. It can reduce the risks of soil erosion and flood risk. In cities, planting trees can support climate change adaptation by reducing the heat of the area and can promote a wide range of social benefits such as providing shade and benefiting outdoor recreation. Urban trees can also lower energy costs by reducing demand for conventional sources of cooling like air-conditioning, especially during peak-demand periods. It is therefore important to recognise that there are a wide range of different planting and forest management strategies. The choice will depend on the objectives and the location.

Not everywhere is suitable for tree planting. It is particularly problematic in native non-forested ecosystems. These natural ecosystems are not deforested and degraded but are instead naturally occurring non-forested ecosystems. These areas vary from being open grasslands to densely wooded savannas and shrublands. Here restoring the natural ecosystems instead of afforesting them will better contribute to increasing carbon storage and increasing the areas resilience. It is important to remember, just because a tree can grow somewhere, it does not mean that it should. These systems are very important in their own right, storing carbon in soils, supporting a rich biodiversity and providing people with important ecosystem services such as grazing. Planting trees in these areas destroys the ecosystem and threatens the biodiversity, which is adapted to these environments. They can also impact on ecosystem services such as forage for livestock, on which many people rely.

Many of these open areas also occur in low rainfall areas. Planting trees there uses a lot of water, can cause reductions in stream flow and groundwater. Many of these locations also burn regularly and planting trees threatens both the establishing trees but can also increase the intensity of the fires from that of a grass-fuelled fire to that of a woody-fuelled fire. Swapping grassy ecosystems for forests may contribute to warming, as forests absorb more incoming radiation (warmth) than grasslands. Aside from the negative impacts to adaptation, it is also questionable just how much carbon can be sequestered in these landscapes asplanting trees in grassy ecosystems can reduce carbon gains. Furthermore, a high belowground carbon store prevents carbon loss to fire in these fire-prone environments.

Another example is with peatlands. Peats store an incredible amount of carbon within them and are therefore important in maintaining and restoring to reduce atmospheric carbon. However, the restoration actions depend on what type of peatland it is and where it is located. Many temperate and boreal peatlands are naturally treeless. Here planting trees is often only possible following drainage, but draining and planting (especially with non-native species) destroys native biodiversity and releases greenhouse gases. Yet many peatlands, especially in the tropics, are naturally forested and restoring these peatlands requires re-wetting and restoring natural tree cover (see Figure FAQ2.2.1) which will increase carbon storage.

There are actions we can do instead of planting trees in non-forested ecosystems, and these include:

- Address the causes of deforestation, forest degradation and widespread ecosystem loss;
- Reduce carbon emissions from fossil fuels;
- Focus on ecosystem restoration over tree planting. For example, in restoring tropical grassy ecosystems, we can look at actions that cut down trees, enhance grass regrowth, and restore natural fire regimes. We have then a much better chance of both enhancing carbon capture and reducing some of the harmful effects of climate change.

In between the two extremes of where planting trees is highly suitable and areas where it is not, it is important to remember that the context matters and decisions to (re)forest should look beyond simply the act of planting trees. We can consider **what the ecological, social and economic goals are of tree planting**. It is then important to verify the local context and then decide **what restoration action will be most effective**. It is also very important to conserve forests before worrying about reforesting.

Figure FAQ2.6.1: Some places are more appropriate for tree planting than others and caution needs to be applied when planting in different biomes with some biomes being more suitable than others. This figure highlights some basic biome specific guidelines when planting in natural and semi-natural vegetation.

[END FAQ2.6 HERE]

2.7 Reducing Scientific Uncertainties to Inform Policy and Management Decisions

Research since the IPCC Fifth Assessment Report (Settele et al., 2014) has increased understanding of climate change impacts and vulnerability in ecosystems. Evidence gaps remain and geographic coverage of research is uneven. This section assesses gaps in ecosystem science where research is necessary for environmental policies and natural resource management, including under the UN Framework Convention on Climate Change and the Convention on Biological Diversity.

2.7.1 Observed impacts

Detection and attribution efforts have yet to give robust assessments of the roles of climate change in wildfires, tree mortality and human infectious diseases. Only one fire impact – the increase of the area burned by wildfire in western North America in the period 1984–2017 (Section 2.4.4.2.1) and just a few cases of tree mortality (Section 2.4.4.3) have been formally attributed to anthropogenic climate change. Global changes in soil and freshwater ecosystem carbon over time remain uncertainties in global carbon stocks and changes (Section 2.4.4.4); due to physical inabilities to conduct repeat monitoring and the lack of remote sensing to scale up point measurements, no global methods can yet produce repeating spatial estimates of soil carbon stock changes.

Despite the growing understanding of the importance of ecosystem services this assessment found limited research on observed impacts of climate change on ecosystem services for 14 of 18 ecosystem services (Table 2.1)

2.7.2 Projected risks

A challenge for future projections that continues from previous IPCC reports is accurately characterising and quantifying interactions among climate change and other factors causing ecological change, including deforestation, agricultural expansion, urbanisation, and air and water pollution. Interactions can be particularly complex for invasive species, pests and pathogens, and human infectious diseases. Modelling of risks at the species level requires comprehensive databases of physiological, life-history, and functional traits relevant to ecosystem resilience to climate change. Taxa that particularly lack this basis for model projections include fungi and bacteria. For numerous plant and animal species, research on genotypic and phenotypic diversity as a source of ecosystem resilience would inform projections of risk.

Soil plays a vital role in ecosystem function, is the habitat of a large number of species and is a large carbon store which is currently a major source of greenhouse gas emissions, it is therefore a priority for climate change research (Hashimoto et al., 2015). Major uncertainties remain in our understanding of soil functions. Earth System Models (ESMs) predict soil respiration to increase with rising temperature (Friedlingstein et al., 2014). However, there is evidence of acclimation post-increase (Carey et al., 2016) as the opposite response of decrease in respiration with warming (Li et al., 2013; Reynolds et al., 2015). Long-term, large scale field observations combined with a better conceptual understanding of factors governing soil process responses to climate change is needed. A better understanding of plant water relations is also necessary, including the response of plant transpiration to increased CO_2, climate warming and changes in soil moisture and groundwater elevation.

2.7.3 Adaptation and Climate Resilient Development

There are significant evidence gaps in developing adaptation, both for biodiversity conservation and EbA. In particular, whilst many adaptation measures have been proposed and implementation is starting, there are very few evaluations of success in the scientific literature (Morecroft et al., 2019; Prober et al., 2019). As detailed in Section 2.6.2, there is a strong literature on conceptual approaches to climate change adaptation for biodiversity, but very little empirical testing of which approaches actual work best. Going forward it is important put in place good monitoring and evaluation of adaptation strategies. For EbA, there are good examples of measuring changes in response to new adaptation measures, but these remain relatively rare globally.

Human factors which promote or hinder adaptation are important as well as the technical issues. There are few studies incorporating climate change and ecosystem services in integrated decision making, and even fewer aimed to identify solutions robust to uncertainty (Runting et al., 2017).
Over the last decades, losses from natural disasters including those from events related to extreme weather have strongly increased (Mechler and Bouwer, 2015). There is a need for better assessment of global adaptation costs, funding and investment (Micale et al., 2018). Potential synergies between international finance for disaster risk management and adaptation have not yet been fully realised. Research has almost exclusively focused on normalising losses for changes in exposure, yet not for vulnerability, a major gap given the dynamic nature of vulnerability (Mechler and Bouwer, 2015).

Large Tables

Table 2.2: Global Fingerprints of Climate Change Impacts across Wild Species. Updated from (Parmesan and Hanley, 2015). For each dataset, a response for an individual species or functional group was classified as (1) no response (no significant change in the measured trait over time), (2) if a significant change was found, the response was classified as either consistent or not consistent with expectations from local or regional climate trends. Percentages are approximate and estimated for the studies as a whole. Individual analyses within the studies may differ. The specific metrics of climate change analysed for associations with biological change vary somewhat across studies, but most use changes in local or regional temperatures (e.g. mean monthly T or mean annual T), with some using precipitation metrics (e.g. total annual rainfall). For example, a consistent response would be poleward range shifts in areas that are warming. Probability (P) of getting the observed ratio of consistent: not consistent responses by chance was <10-13 for (Parmesan and Yohe, 2003; Root et al., 2003; Root et al., 2005; Poloczanska et al., 2013) and was <0.001 for Rosenzweig 2008 (source=publication) (Parmesan and Yohe, 2003; Root et al., 2003; Root et al., 2005; Rosenzweig et al., 2008; Poloczanska et al., 2013). Test were all binomial tests against p=0.5, performed by Parmesan.

Study	N: total numbers of species, functional groups or studies	Species in given system: Terrestrial (T) Marine (M) Freshwater (F)	Types of change	Changes documented	Geographical region	Study allows for attribution to climate change
2.2a Observed Phenological changes						
Parmesan and Yohe (2003)	677 species	461 plants, 168 birds, 35 insects, 9 amphibians, 2 fish	spring phenology	Overall: 9% delay; 27% no trend; 62% advance Mean change 2.3 days per decade advance	global	yes
Menzel et al. (2006)	agricultural crops, fruit trees, wild plants	T	spring and fall phenology	From 1971-2000 48% responding as expected; spring advance 2.5 days per decade; Mean fall delay = 0.2 days per decade fruit ripening 2.4 days per decade advance; farmer's activities 0.4 days per decade advance	Europe	yes
Parmesan (2007)	200 species		spring phenology	Overall advance 2.8 days per decade 20 changes delay, 153 advance, 8 no change; Significantly more advance at higher latitudes	global	yes
Rosenzweig et al. (2008)	55 studies (~100-200 species)	1T: 65% 1M: 13% 1F: 22%	various	90% of changes consistent with local/regional climate change	global	yes
Thackeray et al. (2010)	726 taxa	M,T&F; birds, moths, aphids, terrestrial plants, marine & FW phytoplankton	spring phenology	83.5 % of "trends" were advances; mean overall advance 3.9 days per decade. Terrestrial plants 93% advancing, mean 5.8 days per decade; FW plants 62% advancing, mean 2.3 days per decade secondary consumers advanced less than primary consumers & producers	UK	no
While and Uller (2014)	59 populations, 17 studies	amphibia	phenology	35% statistically significant change; mean advance 6.1±1.65 days per decade; range 17.5 days delay to 41.9 days advance; 65% (n=47 populations) found	global	no

				significant relationship between breeding phenology and temperature; higher latitudes advanced more.		
Gill et al. (2015)	64 studies	T: 100% trees	delay of autumn senescence	Delay averaged 0.33 days yr^{-1} and 1.20 days per degree warming; more delay at low latitudes across N-hemisphere; High latitude species driven more by photoperiod than low latitude species	global	no
Ficetola and Maiorano (2016)	n= 66 studies of temperature effects; 15 of precipitation	T/F 100% (amphibians)	phenology and abundances	Population dynamics driven by precipitation while breeding phenology driven by temperature	global	no
Halupka and Halupka (2017)	28 spp multi- brooded, 27 spp single-brooded, some spp. several pops	T 100% (birds)	phenology: Length of breeding season	Shows differences in sign of response between single & multi-broods & migrant vs resident; Season extended by 4 days per decade for multi-brooded, shortened by 2 days per decade for single-brooded; Multi: 26 species; 15 of 34 pops sig extended, none sig reduced	northern hemisphere	yes
Kharouba et al. (2018)	88 species in 54 pair-wise interactions	Not given	T: changes in relative phenologies of consumers and their resources	Asynchrony between consumer and resource has increased in some cases and decreased in others, with no significant trend; the prediction that asynchronies should be increasing in general is not supported.	global	no
Cohen et al. (2018)	127 studies	T 100% (animals)	phenological trends	81% of 127 studies of animals show phenological change in direction of earlier spring. Some studies were multi-species. Mean advance since 1950: 2.88 days per decade	Europe North America Australia Japan	no
Keogan et al. (2018)	145 populations, 209 time series	seabirds - terrestrial breeding sites	phenological trends	No change in breeding dates between 1952 and 2015	global	yes
Radchuk et al. (2019)	4835 studies, 1413 species	non-aquatic animals	phenological trends	Greatest phenological advancements in amphibians, followed by insects and birds in that order	global but most in N hemisphere	no
Piao et al. (2019)	Review	plants	spring and autumn phenologies	Rate of advance slowing down across northern hemisphere and reversed in parts of western N America in response to regional cooling since 1980s	Global	no
Menzel et al. (2020)	53 species in Germany, 37 in Austria, 21 in Switzerland (includes overlaps)	plants	spring and autumn phenologies	Long time series 1951–2018. Autumn leaf colouring: mean delay 0.36 days per decade. Spring phenology (leaf infolding) mean advance 0.24 days per decade. Summer phenology (fruit ripening)	Europe	yes

				mean advance 0.26 days per decade. Growing season length mean increase 0.26 days yr^{-1} but farming season length decreased by 0.02 days yr^{-1}		
2.2b. Observed Changes in distributions, abundances and local population extinctions						
Parmesan and Yohe (2003)	920 species	T: 85.2% M: 13.5% F: 1.3%	Distibutions and abundances	50% of species (n=460/920) showed changes in distribution or abundances consistent with local or regional climate change	global	yes
Root et al. (2003)	n=926 species	T: 94% M: 5.4% F: 0.6%	Distibutions and abundances	52 % of species (n=483/926) showed changes in distribution or abundances consistent with local or regional climate change	global	yes
Rosenzweig et al. (2008)	n=18 studies	T: 65% M: 13% F: 22%	Distibutions and abundances	90% of studies showed changes in distribution or abundances consistent with local or regional climate change	global	yes
Pöyry et al. (2009)	48 species	T, butterflies	range shifts	From 1992-2004 37 ranges shifted poleward; 9 shifted equatorial; 2 no change. Non-threatened species expanded poleward by 84.5 km, threatened species showed no significant change (-2.1 km)	Finland	yes
Tingley et al. (2009)	53 species	T, birds	elevational range shifts	Resurvery (2003—2008) of historical elevational transects (1911—1929). 90.6% of species track their climate niche (temperature and/or precipitation) with regional climate change. Lower elevation species (mean range centroid = 916m) tracked only precipitation; high elevation species (mean range centroid = 1,944m) tracked only temperature; Species that tracked both T and P had mid-elevation range centroids (1,374—1,841)	California	yes
Chen et al. (2011)	24 taxonomic group x region combinations for latitude, 31 for elevation	T >264 M>10 F >34	range shifts: elevation and latitude	Mean upward elevation shift 11.0 m per decade Poleward shift 16.9 km per decade	pseudo-global	no
Grewe et al. (2013)	90 species	dragonflies	shifts of northern range boundaries	48 poleward shifts; 26 equatorial; 16 no change from 1988 to2006	Europe	no

				southern lentic (standing water) species expanded 116 km polewards; southern lotic (running water) & all northern species stable.		
Mason et al. (2015)	21 animal groups, 1573 species	T: Birds, Lepidoptera F: Odonates	range shifts in 3 time periods	Northward shifts 23 km per decade (1966–1975) and 18 km per decade(1986–1995), with significant differences among taxa in rates of change	UK	yes
Gibson-Reinemer and Rahel (2015)	13 studies, 273 species: plants birds mammals marine inverts	T M	Range shifts in 2 or 3 areas for each species. shift measured as change of limit OR centroid	50% shifts of cold limit inconsistent with each other in within species despite similar warming. Percent species showing inconsistent shifts (including stable vs directional or different directions) = 47% plants,; 54% birds; 46% marine invert; 60% mammals. Large difference in magnitude of range shifts when in same direction (mean difference 8.8x);	global	no
Ficetola and Maiorano (2016)	n= 66 studies temperature effects; 15 precipitation	T/F 100% (amphibians)	phenology and abundances	Population dynamics driven by precipitation, breeding phenology driven by temperature	global	no
Scheffers et al. (2016)	n= 94 ecological processes	all	all possible types and levels of ecological change	82% of ecological processes affected by climate change	global	no
Wiens (2016)	976 species	all	population extinction rates near warm latitudinal and elevational range limits	47% of species suffered climate-related local extinctions: fish 59%; insects 56%; birds 44%; plants 39%; amphibians 37%; mammals 35%	global	yes
Bowler et al. (2017)	1,167 populations, 22 communities	T: 48% M: 61% F: 35%	abundance; population trends	Terrestrial species with warm temperature preference performed better than cool preferers; Freshwater and marine species: no effect of temperature preference on performance. 47% of species with significant abundance changes: 61%M, 48%T, 35% FW	Europe	yes
Pacifici et al. (2017)	873 mammals; 1272 birds	T 100% (birds and mammals)	multiple: range change, abundance, reproductive rate, survival, body mass	Estimated negative impacts (range contraction, reduced reproductive rates, or other measures of fitness estimates) for IUCN threatened species based on actual observed change in more common, related species. 47% threatened mammals and 23% birds	global for bird; mammals N America	unclear - complex methods

				negatively impacted by climate change in part of their ranges		
MacLean and Beissinger (2017)	21studies 26 assemblages of taxonomically related species	plants and animals	Range shifts in latitude and altitude related to species' traits: dispersal, body size, habitat, diet specialization & historic range limit.	High latitude/altitude range boundaries shifted less than lower laatitude/altitude boundaries. Author explanation is that habitat limits being reached (eg mountain top). Magnitudes of shifts positively related to dispersal traits and habitat breadth.	global	no
Ralston et al. (2017)	46 species	birds	Shifts in climate niche breadth, filling of climate space and overall abundance.	Species increasing in abundance were also increasing breeding climate niche breadth and niche filling. Declining species were opposite: niche breadths narrowing and greater climate debt.	north America	no
Rumpf et al. (2019)	1,026 species	terrestrial plants, invertebrates, vertebrates	Comparison of rates of range limit shift at leading & trailing elevational edges.	No difference in mean rate of shift of leading and trailing edges; elevational range sizes not changing systematically. Greater lags in regions with faster warming.	global	no
Freeman et al. (2018)	975 species, 32 elevational gradients	terrestrial plants, endotherms, ectotherms	Comparison of rates of range limit shift at leading & trailing elevational edges.	Mean change at warm limit 92±455 m per °C; cool limit 131±465 m per °C; (± SD, not significantly different from each other. Available area and range sizes decreased for mountaintop species.	global	no
Anderegg et al. (2019b)	meta-analysis 50 studies >100 species	T: 100% woody plants	mortality at dry range edges	100 indiv. species + a community of 828 species mortality at range edges due to drought was 33% greater than for core populations	apparently global	yes; drought not warming
Román-Palacios and Wiens (2020)	10 studies, 538 species, 581 sites	terrestrial plants and animals	analysis for drivers of population extinctions at warm range edges	44% of species had suffered local population extinctions near warm range limits. In temperate regions sites with local extinction had greater increases in maixmum temperature than those without (0.456°C vs. 0.153°C, $P < 0.001$, $n = 505$ sites) and smaller increases in mean temperatures (0.412°C vs 1.231°C, $P < 0.001$). In tropical regions, range edges with local extinction also had greater increases in maximum temperatures (0.316°C vs 0.061°C $P < 0.001$, $n = 76$) but changes	global	yes

				in mean temperatures were similar between edges with and without extinctions (0.415°C vs 0.406°C, P = 0.9		

Chapter 3: Oceans and Coastal Ecosystems and their Services

Table of Contents

Executive Summary

Ocean and coastal ecosystems support life on Earth and many aspects of human well-being. Covering two-thirds of the planet, the ocean hosts vast biodiversity and modulates the global climate system by regulating cycles of heat, water, and elements including carbon. Marine systems are central to many cultures, and they also provide food, minerals, energy and employment to people. Since previous assessments[1], new laboratory studies, field observations and process studies, a wider range of model simulations, Indigenous Knowledge, and local knowledge provide increasing evidence on the impacts of climate change on ocean and coastal systems, how human communities are experiencing these impacts, and the potential solutions for ecological and human adaptation.

Observations: vulnerabilities and impacts

Anthropogenic climate change has exposed ocean and coastal ecosystems to conditions that are unprecedented over millennia (*high confidence*[2]), and this has greatly impacted life in the ocean and along its coasts (*very high confidence*). Fundamental changes in the physical and chemical characteristics of the ocean acting individually and together are changing the timing of seasonal activities (*very high confidence*), distribution (*very high confidence*), and abundance (*very high confidence*) of oceanic and coastal organisms, from microbes to mammals and from individuals to ecosystems, in every region. Evidence of these changes is apparent from multi-decadal observations, laboratory studies and mesocosms, as well as meta-analyses of published data. Geographic range shifts of marine species generally follow the pace and direction of climate warming (*high confidence*): surface warming since the 1950s has shifted marine taxa and communities poleward at an average (mean ± *very likely* range) of 59.2 ± 15.5 km per decade (*high confidence*), with substantial variation in responses among taxa and regions. Seasonal events occur 4.3 ± 1.8 to 7.5 ± 1.5 days earlier per decade among planktonic organisms (*very high confidence*) and on average 3 ± 2.1 days earlier per decade for fish (*very high confidence*). Warming, acidification and deoxygenation are altering ecological communities by increasing the spread of physiologically sub-optimal conditions for many marine fish and invertebrates (*medium confidence*). These and other responses have subsequently driven habitat loss (*very high confidence*), population declines (*high confidence*), increased risks of species extirpations and extinctions (*medium confidence*) and rearrangement of marine food webs (*medium* to *high confidence*, depending on ecosystem). {3.2, 3.3, 3.3.2, 3.3.3, 3.3.3.2, 3.4.2.1, 3.4.2.3–3.4.2.8, 3.4.2.10, 3.4.3.1, 3.4.3.2, 3.4.3.3, Box 3.2}

Marine heatwaves lasting weeks to several months are exposing species and ecosystems to environmental conditions beyond their tolerance and acclimation limits (*very high confidence*). WGI AR6 concluded that marine heatwaves are more frequent (*high confidence*), more intense and longer (*medium confidence*) since the 1980s, and since at least 2006, *very likely*[3] attributable to anthropogenic climate change. Open-ocean, coastal and shelf-sea ecosystems, including coral reefs, rocky shores, kelp forests, seagrasses, mangroves, the Arctic Ocean and semi-enclosed seas, have recently undergone mass mortalities from marine heatwaves (*very high confidence*). Marine heatwaves, including well-documented events along the west coast of North America (2013–2016) and east coast of Australia (2015–2016, 2016–2017 and 2020), drive abrupt shifts in community composition that may persist for years (*very high confidence*), with associated biodiversity loss (*very high confidence*), collapse of regional fisheries and

[1] Previous IPCC assessments include the IPCC Fifth Assessment Report (AR5) (IPCC, 2013; IPCC, 2014c; IPCC, 2014b; IPCC, 2014d), the Special Report on Global Warming of 1.5°C (SR1.5) (IPCC, 2018), the Special Report on Ocean and Cryosphere in a Changing Climate (SROCC) (IPCC, 2019b) and the IPCC Sixth Assessment Report Working Group I (WGI AR6).

[2] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

[3] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: virtually certain 99–100% probability, very likely 90–100%, likely 66–100%, about as likely as not 33– 66%, unlikely 0–33%, very unlikely 0–10%, exceptionally unlikely 0–1%. Additional terms (extremely likely: 95– 100%, more likely than not >50–100%, and extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*.

aquaculture (*high confidence*) and reduced capacity of habitat-forming species to protect shorelines (*high confidence*). {WGI AR6 Chapter 9, 3.2.2.1, 3.4.2.1–3.4.2.5, 3.4.2.7, 3.4.2.10, 3.4.2.3, 3.4.3.3.3, 3.5.3}

At local to regional scales, climate change worsens the impacts on marine life of non-climate anthropogenic drivers, such as habitat degradation, marine pollution, overfishing and overharvesting, nutrient enrichment, and introduction of non-indigenous species (*very high confidence*). Although impacts of multiple climate and non-climate drivers can be beneficial or neutral to marine life, most are detrimental (*high confidence*). Warming exacerbates coastal eutrophication and associated hypoxia, causing 'dead zones' (*very high confidence*), which drive severe impacts on coastal and shelf-sea ecosystems (*very high confidence*), including mass mortalities, habitat reduction and fisheries disruptions (*medium confidence*). Overfishing exacerbates effects of multiple climate-impact drivers on predators at the top of the marine food chain (*medium confidence*). Urbanization and associated changes in freshwater and sediment dynamics increase the vulnerability of coastal ecosystems like sandy beaches, saltmarshes and mangrove forests to sea-level rise and changes in wave energy (*very high confidence*). Although these non-climate drivers confound attribution of impacts to climate change, adaptive, inclusive, and evidence-based management reduces the cumulative pressure on ocean and coastal ecosystems, which will decrease their vulnerability to climate change (*high confidence*). {3.3, 3.3.3, 3.4.2.4–3.4.2.8, 3.4.3.4, 3.5.3, 3.6.2, Cross-Chapter Box SLR in Chapter 3}

Climate-driven impacts on ocean and coastal environments have caused measurable changes in specific industries, economic losses, emotional harm, and altered cultural and recreational activities around the world (*high confidence*). Climate-driven movement of fish stocks is causing commercial, small-scale, artisanal, and recreational fishing activities to shift poleward and diversify harvests (*high confidence*). Climate change is increasing the geographic spread and risk of marine-borne pathogens like *Vibrio* sp. (*very high confidence*), which endanger human health and decrease provisioning and cultural ecosystem services (*high confidence*). Interacting climatic impact-drivers and non-climate drivers are enhancing movement and bioaccumulation of toxins and contaminants into marine food webs (*medium evidence, high agreement*), and increasing salinity of coastal waters, aquifers, and soils (*very high confidence*), which endangers human health (*very high confidence*). Combined climatic impact-drivers and non-climate drivers also expose densely populated coastal zones to flooding (*high confidence*) and decrease physical protection of people, property, and culturally important sites (*very high confidence*). {3.4.2.10, 3.5.3, 3.5.5, 3.5.5.3, 3.5.6, Cross-Chapter Box SLR in Chapter 3}

Projections: vulnerabilities, risks, and impacts

Ocean conditions are projected to continue diverging from a pre-industrial state (*virtually certain*), with the magnitude of warming, acidification, deoxygenation, sea-level rise and other climatic impact-drivers depending on the emission scenario (*very high confidence*), and to increase risk of regional extirpations and global extinctions of marine species (*medium confidence*). Marine species richness near the equator and in the Arctic is projected to continue declining, even with less than 2°C warming by the end of the century (*medium confidence*). In the deep ocean, all global warming levels will cause faster movements of temperature niches by 2100 than those that have driven extensive reorganisation of marine biodiversity at the ocean surface over the past 50 years (*medium confidence*). "At warming levels beyond 2°C by 2100, risks of extirpation, extinction and ecosystem collapse escalate rapidly (*high confidence*)." Paleorecords indicate that at extreme global warming levels (>5.2°C), mass extinction of marine species may occur (*medium confidence*). {Box 3.2, 3.2.2.1, 3.4.2.5, 3.4.2.10, 3.4.3.3, Cross-Chapter Box PALEO in Chapter 1}

Climate impacts on ocean and coastal ecosystems will be exacerbated by increases in intensity, reoccurrence and duration of marine heatwaves (*high confidence*), in some cases, leading to species extirpation, habitat collapse or surpassing ecological tipping points (*very high confidence*). Some habitat-forming coastal ecosystems including many coral reefs, kelp forests and seagrass meadows, will undergo irreversible phase shifts due to marine heatwaves with global warming levels >1.5°C and are at high risk this century even in <1.5°C scenarios that include periods of temperature overshoot beyond 1.5°C (*high confidence*). Under SSP1-2.6, coral reefs are at risk of widespread decline, loss of structural integrity and transitioning to net erosion by mid-century due to increasing intensity and frequency of marine heatwaves (*very high confidence*). Due to these impacts, the rate of sea-level rise is *very likely* to exceed that of reef growth by 2050, absent adaptation. Other coastal ecosystems, including kelp forests, mangroves and seagrasses, are vulnerable to phase shifts towards alternate states as marine heatwaves intensify (*high confidence*). Loss of kelp forests are expected to be greatest at the low-latitude warm edge of species' ranges (*high confidence*). {3.4.2.1, 3.4.2.3, 3.4.2.5, 3.4.4}

Escalating impacts of climate change on marine life will further alter biomass of marine animals (*medium confidence*), the timing of seasonal ecological events (*medium confidence*) and the geographic ranges of coastal and ocean taxa (*medium confidence*), disrupting life cycles (*medium confidence*), food webs (*medium confidence*) and ecological connectivity throughout the water column (*medium confidence*). Multiple lines of evidence suggest that climate-change responses are *very likely* to amplify up marine food webs over large regions of the ocean. Modest projected declines in global phytoplankton biomass translate into larger declines of total animal biomass (by 2080–2099 relative to 1995–2014) ranging from (mean ± *very likely* range) –5.7% ± 4.1% to –15.5% ± 8.5% under SSP1-2.6 and SSP5-8.5, respectively (*medium confidence*). Projected declines in upper-ocean nutrient concentrations, *likely* associated with increases in stratification, will reduce carbon export flux to the mesopelagic and deep-sea ecosystems (*medium confidence*). This will lead to a decline in the biomass of abyssal meio- and macrofauna (by 2081–2100 relative to 1995–2014) by –9.8% and –13.0% under SSP1-2.6 and SSP5-8.5, respectively (*limited evidence*). By 2100, 18.8% ± 19.0% to 38.9% ± 9.4% of the ocean will *very likely* undergo a change of more than 20 days (advances and delays) in the start of the phytoplankton growth period under SSP1-2.6 and SSP5-8.5, respectively (*low confidence*). This altered timing increases the risk of temporal mismatches between plankton blooms and fish spawning seasons (*medium* to *high confidence*) and increases the risk of fish recruitment failure for species with restricted spawning locations, especially in mid-to-high latitudes of the northern hemisphere (*low confidence*). Projected range shifts among marine species (*medium confidence*) suggest extirpations and strongly decreasing tropical biodiversity. At higher latitudes, range expansions will drive increased homogenisation of biodiversity. The projected loss of biodiversity ultimately threatens marine ecosystem resilience (*medium* to *high confidence*), with subsequent effects on service provisioning (*medium* to *high confidence*). {3.2.2.3, 3.4.2.10, 3.4.3.1–3.4.3.5, 3.5, WGI AR6 Section 2.3.4.2.3}

Risks from sea-level rise for coastal ecosystems and people are *very likely* to increase tenfold well before 2100 without adaptation and mitigation action as agreed by Parties to the Paris Agreement (*very high confidence*). Sea-level rise under emission scenarios that do not limit warming to 1.5°C will increase the risk of coastal erosion and submergence of coastal land (*high confidence*), loss of coastal habitat and ecosystems (*high confidence*) and worsen salinisation of groundwater (*high confidence*), compromising coastal ecosystems and livelihoods (*high confidence*). Under SSP1-2.6, most coral reefs (*very high confidence*), mangroves (*likely*, *medium confidence*) and saltmarshes (*likely*, *medium confidence*) will be unable to keep up with sea-level rise by 2050, with ecological impacts escalating rapidly beyond 2050, especially for scenarios coupling high emissions with aggressive coastal development (*very high confidence*). Resultant decreases in natural shoreline protection will place increasing numbers of people at risk (*very high confidence*). The ability to adapt to current coastal impacts, cope with future coastal risks, and prevent further acceleration of sea-level rise beyond 2050 depends on immediate implementation of mitigation and adaptation actions (*very high confidence*). {3.4.2.1, 3.4.2.4, 3.4.2.5, 3.4.2.6, 3.5.5.3, Cross-Chapter Box SLR in Chapter 3}

Climate change will alter many ecosystem services provided by marine systems (*high confidence*), but impacts to human communities will depend on people's overall vulnerability, which is strongly influenced by local context and development pathways (*very high confidence*). Catch composition and diversity of regional fisheries will change (*high confidence*), and fishers who are able to move, diversify, and leverage technology to sustain harvests decrease their own vulnerability (*medium confidence*). Management that eliminates overfishing facilitates successful future adaptation of fisheries to climate change (*very high confidence*). Marine-dependent communities, including Indigenous Peoples and local peoples, will be at increased risk of losing cultural heritage and traditional seafood-sourced nutrition (*medium confidence*). Without adaptation, seafood-dependent people face increased risk of exposure to toxins, pathogens, and contaminants (*high confidence*), and coastal communities face increasing risk from salinisation of groundwater and soil (*high confidence*). Early-warning systems and public education about environmental change, developed and implemented within the local and cultural context, can decrease those risks (*high confidence*). Coastal development and management informed by sea-level rise projections will reduce the number of people and amount of property at risk (*high confidence*), but historical coastal development and policies impede change (*high confidence*). Current financial flows are globally uneven and overall insufficient to meet the projected costs of climate impacts on coastal and marine socio-ecological systems (*very high confidence*). Inclusive governance that accommodates geographically shifting marine life; financially supports needed human transformations; provides effective public education; and incorporates scientific evidence, Indigenous knowledge, and local knowledge to manage resources sustainably shows greatest promise for decreasing human vulnerability to all of these projected changes in ocean and coastal ecosystem services (*very high confidence*). {3.5.3, 3.5.5, 3.5.6, 3.6.3, Box 3.4, Cross-Chapter Box ILLNESS in Chapter 2, Cross-Chapter Box SLR in Chapter 3}

Solutions, trade-offs, residual risk, decisions and governance

Humans are already adapting to climate-driven changes in marine systems, and while further adaptations are required even under low-emission scenarios (*high confidence*), transformative adaptation will be essential under high-emission scenarios (*high confidence*). Low-emission scenarios permit a wider array of feasible, effective and low-risk nature-based adaptation options (e.g., restoration, revegetation, conservation, early-warning systems for extreme events, and public education) (*high confidence*). Under high-emission scenarios, adaptation options (e.g., hard infrastructure for coastal protection, assisted migration or evolution, livelihood diversification, migration and relocation of people) are more uncertain and require transformative governance changes (*high confidence*). Transformative climate adaptation will reinvent institutions to overcome obstacles arising from historical precedents, reducing current barriers to climate adaptation in cultural, financial, and governance sectors (*high confidence*). Without transformation, global inequities will *likely* increase between regions (*high confidence*) and conflicts between jurisdictions may emerge and escalate. {3.5, 3.5.2, 3.5.5.3, 3.6, 3.6.2.1, 3.6.3.1, 3.6.3.2, 3.6.3.3, 3.6.4.1, 3.6.4.2, 3.6.5, Cross-Chapter Box SLR in Chapter 3, Cross-Chapter Box ILLNESS in Chapter 2}

Available adaptation options are unable to offset climate-change impacts on marine ecosystems and the services they provide (*high confidence*). Adaptation solutions implemented at appropriate scales, when combined with ambitious and urgent mitigation measures, can meaningfully reduce impacts (*high confidence*). Increasing evidence from implemented adaptations indicates that multi-level governance, early-warning systems for climate-associated marine hazards, seasonal and dynamic forecasts, habitat restoration, ecosystem-based management, climate-adaptive management, and sustainable harvesting tend to be both feasible and effective (*high confidence*). Marine protected areas, as currently implemented, do not confer resilience against warming and heatwaves (*medium confidence*) and are not expected to provide substantial protection against climate impacts past 2050 (*high confidence*). However, marine protected areas can contribute substantially to adaptation and mitigation if they are designed to address climate change, strategically implemented, and well governed (*high confidence*). Habitat restoration limits climate-change related loss of ecosystem services, including biodiversity, coastal protection, recreational use and tourism (*medium confidence*), provides mitigation benefits on local to regional scales (e.g., via carbon-storing 'blue carbon' ecosystems) (*high confidence*), and may safeguard fish stock production in a warmer climate (*limited evidence*). Ambitious and swift global mitigation offers more adaptation options and pathways to sustain ecosystems and their services (*high confidence*). {3.4.2, 3.4.3.3, 3.5, 3.5.2, 3.5.3, 3.5.5.4, 3.5.5.5, 3.6.2.1, 3.6.2.2, 3.6.2.3, 3.6.3.1, 3.6.3.2, 3.6.3.3, 3.6.5, Figure 3.24, Figure 3.25}

Nature-based solutions for adaptation of ocean and coastal ecosystems can achieve multiple benefits when well-designed and implemented (*high confidence*), but their effectiveness declines without ambitious and urgent mitigation (*high confidence*). Nature-based solutions such as ecosystem-based management, climate-smart conservation approaches (i.e., climate-adaptive fisheries and conservation) and coastal habitat restoration can be cost-effective and generate social, economic and cultural co-benefits, while contributing to the conservation of marine biodiversity and reducing cumulative anthropogenic drivers (*high confidence*). The effectiveness of nature-based solutions declines with warming; conservation and restoration will alone be insufficient to protect coral reefs beyond 2030 (*high confidence*) and to protect mangroves beyond the 2040s (*high confidence*). The multi-dimensionality of climate change impacts and their interactions with other anthropogenic stressors calls for integrated approaches that identify trade-offs and synergies across sectors and scales in space and time to build resilience of ocean and coastal ecosystems and the services they deliver (*high confidence*). {3.4.2, 3.5.2, 3.5.3, 3.5.5.3, 3.5.5.4, 3.5.5.5, 3.6.2.2, 3.6.3.2, 3.6.5, Figure 3.25, Table SM3.6}

Ocean-focused adaptations, especially those that employ nature-based solutions, address existing inequalities, and incorporate just and inclusive decision-making and implementation processes, support the UN Sustainable Development Goals (SDGs) (*high confidence*). There are predominantly positive synergies between adaptation options for Life Below Water (SDG14), Climate Action (SDG13), and social, economic and governance SDGs (SDG1–12, 16–17) (*high confidence*), but the ability of ocean adaptation to contribute to the Sustainable Development Goals is constrained by the degree of mitigation action (*high confidence*). Furthermore, existing inequalities and entrenched practices limit effective and just responses to climate change in coastal communities (*high confidence*). Momentum is growing towards transformative international and regional governance that will support comprehensive, equitable ocean and coastal adaptation while also achieving SDG14 (*robust evidence*), without compromising achievement of other SDGs. {3.6.4.0, 3.6.4.2, 3.6.4.3, Figure 3.26}.

3.1 Point of Departure

The ocean contains approximately 97% of Earth's water within a system of interconnected basins that cover 71% of its surface. Coastal systems mostly extend seaward from the high-water mark, or just beyond, to the edge of the continental shelf and include shores of soft sediments, rocky shores and reefs, embayments, estuaries, deltas and shelf systems. Oceanic systems comprise waters beyond the shelf edge, from ~200 m to nearly 11,000 m deep (Stewart and Jamieson, 2019), with an average depth of approximately 3700 m. The epipelagic zone, or upper 200 m of the ocean, is illuminated by sufficient sunlight to sustain photosynthesis that supports the rich marine food web. Below the epipelagic zone lies the barely-lit mesopelagic zone (200–1000 m), the perpetually dark bathypelagic zone (depth >1000 m) and the deep seafloor (benthic ecosystems at depths > 200 m), which spans rocky and sedimentary habitats on seamounts, mid-ocean ridges and canyons, abyssal plains and sedimented margins. Semi-enclosed seas (SES) include both coastal and oceanic systems.

The ocean sustains life on Earth by providing essential resources and modulating planetary flows of energy and materials. Together, harvests from the ocean and inland waters provide more than 20% of dietary animal protein for more than 3.3 billion people worldwide and livelihoods for about 60 million people (FAO, 2020b). The global ocean is centrally involved in sequestering anthropogenic atmospheric CO_2 and recycling many elements, and it regulates the global climate system by redistributing heat and water (WGI AR6 Chapter 9, Fox-Kemper et al., 2021). The ocean also provides a wealth of aesthetic and cultural resources (Barbier et al., 2011), contains vast biodiversity (Appeltans et al., 2012), supports more animal biomass than on land (Bar-On et al., 2018), and produces at least half the world's photosynthetic oxygen (Field et al., 1998). Ecosystem services (Annex II: Glossary) delivered by ocean and coastal ecosystems support humanity by protecting coastlines, providing nutrition and economic opportunities (Figure 3.1, Selig et al., 2019), and providing many intangible benefits. Even though ecosystem services and biodiversity underpin human well-being and support climate mitigation and adaptation (Pörtner et al., 2021b), there are also ethical arguments for preserving biodiversity and ecosystem functions regardless of the beneficiary (e.g., Taylor et al., 2020). This chapter assesses the impact of climate change on the full spectrum of ocean and coastal ecosystems, on their services and on related human activities, and it assesses marine-related opportunities within both ecological and social systems to adapt to climate change.

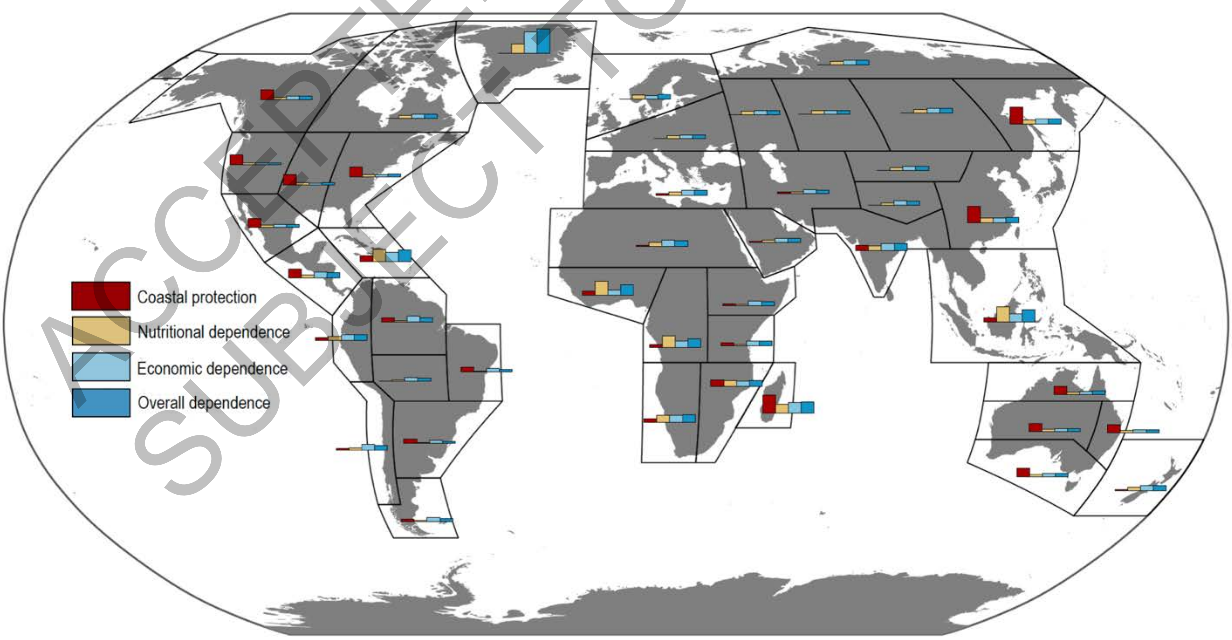

Figure 3.1: Estimated relative human dependence on marine ecosystems for coastal protection, nutrition, fisheries economic benefits and overall. Each bar represents an index value that semi-quantitatively integrates the magnitude, vulnerability to loss and substitutability of the benefit. Indices synthesize information on people's consumption of marine protein and nutritional status, gross domestic product, fishing revenues, unemployment, education, governance and coastal characteristics. Overall dependence is the mean of the three index values after standardization from 0–1 (Details are found in Table 1 and supplementary material of Selig et al. (2019)). This index does not include the

economic benefits from tourism or other ocean industries, and data limitations prevented including artisanal or recreational fisheries or the protective impact of saltmarshes (Selig et al., 2019). Values for reference regions established in the WGI AR6 Atlas (Gutiérrez et al., 2021) were computed as area-weighted means from original country-level data.

Previous IPCC Assessment Reports (IPCC, 2014c; IPCC, 2014b; IPCC, 2018; IPCC, 2019b) have expressed growing confidence in the detection of climate-change impacts in the ocean and their attribution to anthropogenic greenhouse gas emissions. Heat and CO_2 taken up by the ocean (*high* to *very high confidence*) (IPCC, 2021b) directly affect marine systems, and the resultant "climatic impact-drivers" (CIDs, e.g., ocean temperature and heatwaves, sea level, dissolved oxygen levels, acidification, Annex II: Glossary, WGI Figure SPM.9, IPCC, 2021b) also influence ocean and coastal systems (Section 3.2, Cross-Chapter Box SLR in Chapter 3, Cross-Chapter Box EXTREMES in Chapter 2, Figure SM3.1), from individual biophysical processes to dependent human activities. Several marine outcomes of CIDs are themselves drivers of ecological change (e.g., climate velocities, stratification, sea ice changes). This chapter updates and extends the assessment of SROCC (IPCC, 2019b) and WGI AR6 by assessing the ecosystem effects of the CIDs in WGI AR6 Figure SPM.9 (IPCC, 2021b) and their biologically relevant marine outcomes (detailed in Section 3.2), which are referred to collectively hereafter as "climate-impact drivers[4]".

[4] We henceforth use the term "climate-impact drivers" in reference to all drivers of ecological change that are related directly to climate change (CIDs, IPCC, 2021a) as well as those that emerge in response to CIDs.

Detrimental human impacts on ocean and coastal ecosystems are not only caused by climate. Other anthropogenic activities are increasingly affecting the physical, chemical, and biological conditions of the ocean (Doney, 2010; Halpern et al., 2019), and these "non-climate drivers[5]" also alter marine ecosystems and their services. Fishing and other extractive activities are major non-climate drivers in many ocean and coastal systems (Steneck and Pauly, 2019). Many activities, such as coastal development, shoreline hardening and habitat destruction, physically alter marine spaces (Suchley and Alvarez-Filip, 2018; Ducrotoy et al., 2019; Leo et al., 2019; Newton et al., 2020; Raw et al., 2020). Other human activities decrease water quality by overloading coastal water with terrestrial nutrients (eutrophication) and by releasing runoff containing chemical, biological and physical pollutants, toxins, and pathogens (Jambeck et al., 2015; Luek et al., 2017; Breitburg et al., 2018; Froelich and Daines, 2020) Some human activities disturb marine organisms by generating excess noise and light (Davies et al., 2014; Duarte et al., 2021), while others decrease natural light penetration into the ocean (Wollschläger et al., 2021). Several anthropogenic activities alter processes that span the land-sea interface by changing coastal hydrology or causing coastal subsidence (Michael et al., 2017; Phlips et al., 2020; Bagheri-Gavkosh et al., 2021). Atmospheric pollutants can harm marine systems or unbalance natural marine processes (Doney et al., 2007; Hagens et al., 2014; Lamborg et al., 2014; Ito et al., 2016). Organisms frequently experience non-climate drivers simultaneously with climate-impact drivers (Section 3.4), and feedbacks may exist between climate-impact drivers and non-climate drivers that enhance the effects of climate change (Rocha et al., 2015; Ortiz et al., 2018; Wolff et al., 2018; Cabral et al., 2019; Bowler et al., 2020; Gissi et al., 2021). SROCC assessed with *high confidence* that reduction of pollution and other stressors, along with protection, restoration, and precautionary management, supports ocean and coastal ecosystems and their services (IPCC, 2019b). This chapter examines the combined influence of climate-impact drivers and primary non-climate drivers on many ecosystems assessed.

Detecting changes and attributing them to specific drivers have been especially difficult in ocean and coastal ecosystems because drivers, responses and scales (temporal, spatial, organizational) often overlap and interact (IPCC, 2014c; IPCC, 2014b; Abram et al., 2019; Gissi et al., 2021). In addition, some marine systems have short, heterogeneous, or geographically biased observational records, which exacerbate the interpretation challenge (Beaulieu et al., 2013; Christian, 2014; Huggel et al., 2016; Benway et al., 2019). It is even more challenging to detect and attribute climate impacts on marine-dependent human systems, where culture, governance and society also strongly influence observed outcomes. To assess climate-driven change in natural and social systems robustly, IPCC reports rely on multiple lines of evidence, and the available types of evidence differ depending on the system under study (Section 1.3.2.1, Cross-Working Group Box ATTRIB). Lines of evidence used for ocean and coastal ecosystems for this and previous assessments include observed phenomena, laboratory and field experiments, long-term monitoring, empirical and dynamical model analyses, Indigenous knowledge (IK) and local knowledge (LK), and paleorecords (IPCC, 2014c; IPCC, 2014b; IPCC, 2019b). The growing body of climate research for ocean and coastal ecosystems and their services increasingly provides multiple independent lines of evidence whose conclusions support each other, raising the overall confidence in detection and attribution of impacts over time (Section 1.3.2.1, Cross-Working Group Box ATTRIB in Chapter 3).

[START FAQ3.1 HERE]

FAQ3.1: How do we know which changes to marine ecosystems are specifically caused by climate change?

To attribute changes in marine ecosystems to human-induced climate change, scientists use paleorecords (reconstructing the links between climate, evolutionary and ecological changes in the geological past), contemporary observations (assessing current climate and ecological responses in the field and through experiments) and models. We refer to these as multiple lines of evidence, meaning that the evidence comes from diverse approaches, as described below.

[5] We henceforth use the term "non-climate drivers" in reference to drivers of ecological change that are not caused by climate change.

Emissions of greenhouse gases like carbon dioxide from human activity cause ocean warming, acidification, oxygen loss, and other physical and chemical changes that are affecting marine ecosystems around the world. At the same time, natural climate variability and direct human impacts, such as overfishing and pollution, also affect marine ecosystems locally, regionally and globally. These climate and non-climate impact drivers counteract each other, add up or multiply to produce smaller or larger changes than expected from individual drivers. Attribution of changes in marine ecosystems requires evaluating the often-interacting roles of natural climate variability, non-climate drivers, and human-induced climate change. To do this work, scientists use

- paleorecords: reconstructing the links between climate and evolutionary and ecological changes of the past
- contemporary observations: assessing current climate and ecological responses,
- manipulation experiments: measuring responses of organisms and ecosystems to different climate conditions
- models: testing whether we understand how organisms and ecosystems are impacted by different stressors, and quantifying the relative importance of different stressors.

Paleorecords can be used to trace the correlation between past changes in climate and marine life. Paleoclimate is reconstructed from the chemical composition of shells and teeth or from sediments and ice cores. Changes to sea life signalled by changing biodiversity, extinction or distributional shifts are reconstructed from fossils. Using large datasets, we can infer the effects of climate change on sea life over relatively long timescales – usually hundreds to millions of years. The advantage of paleorecords is that they provide insights into how climate change affects life from organisms to ecosystems, without the complicating influence of direct human impacts. A key drawback is that the paleo and modern worlds do not have fully comparable paleoclimate regimes, dominant marine species, and rates of climate change. Nevertheless, the paleorecord can be used to derive fundamental rules by which organisms, ecosystems, environments and regions are typically most affected by climate change. For example, the paleorecord shows that coral reefs repeatedly underwent declines during past warming events, supporting the inference that corals may not be able to adapt to current climate warming.

Contemporary observations over recent decades allow scientists to relate the status of marine species and ecosystems to changes in climate or other factors. For example, scientists compile large datasets to determine whether species usually associated with warm water are appearing in traditionally cool-water areas that are rapidly warming. A similar pattern observed in multiple regions and over several decades (i.e., longer than timescales of natural variability) provides confidence that climate change is altering community structure. This evidence is weighed against findings from other approaches, such as manipulation experiments, to provide a robust picture of climate change impacts in the modern ocean.

In manipulation experiments, scientists expose organisms or communities of organisms to multiple stressors, for example, elevated CO_2, high temperature, or both, based on values drawn from future climate projections. Such experiments will involve multiple treatments (i.e., different aquarium tanks) in which organisms are exposed to different combinations of the stressors. This approach enables scientists to understand the effects of individual stressors as well as their interactions to explore physiological thresholds of marine organisms and communities. The scale of manipulation experiments can range from small tabletop tanks to large installations or natural ocean experiments involving tens of thousands of litres of water.

Ecological effects of climate change are also explored within models developed from fundamental scientific principles and observations. Using these numerical representations of marine ecosystems, scientists can explore how different levels of climate change and non-climate stressors influence species and ecosystems at scales not possible with experiments. Models are commonly used to simulate the ecological response to climate change over recent decades and centuries. Convergence between the model results and the observations suggests that our understanding of the key processes is sufficient to attribute the observed ecological changes to climate change, and to use the models to project future ecological changes. Differences between model results and observations indicate gaps in knowledge to be filled in order to better detect and attribute the impacts of climate change on marine life.

Using peer-reviewed research spanning the full range of scientific approaches (paleorecords, observations, experiments and models), we can assess the level of confidence in the impact of climate change on observed modifications in marine ecosystems. We refer to this as multiple lines of evidence, meaning that the evidence comes from the diverse approaches described above. This allows policy-makers and managers to address the specific actions needed to reduce climate change and other impacts.

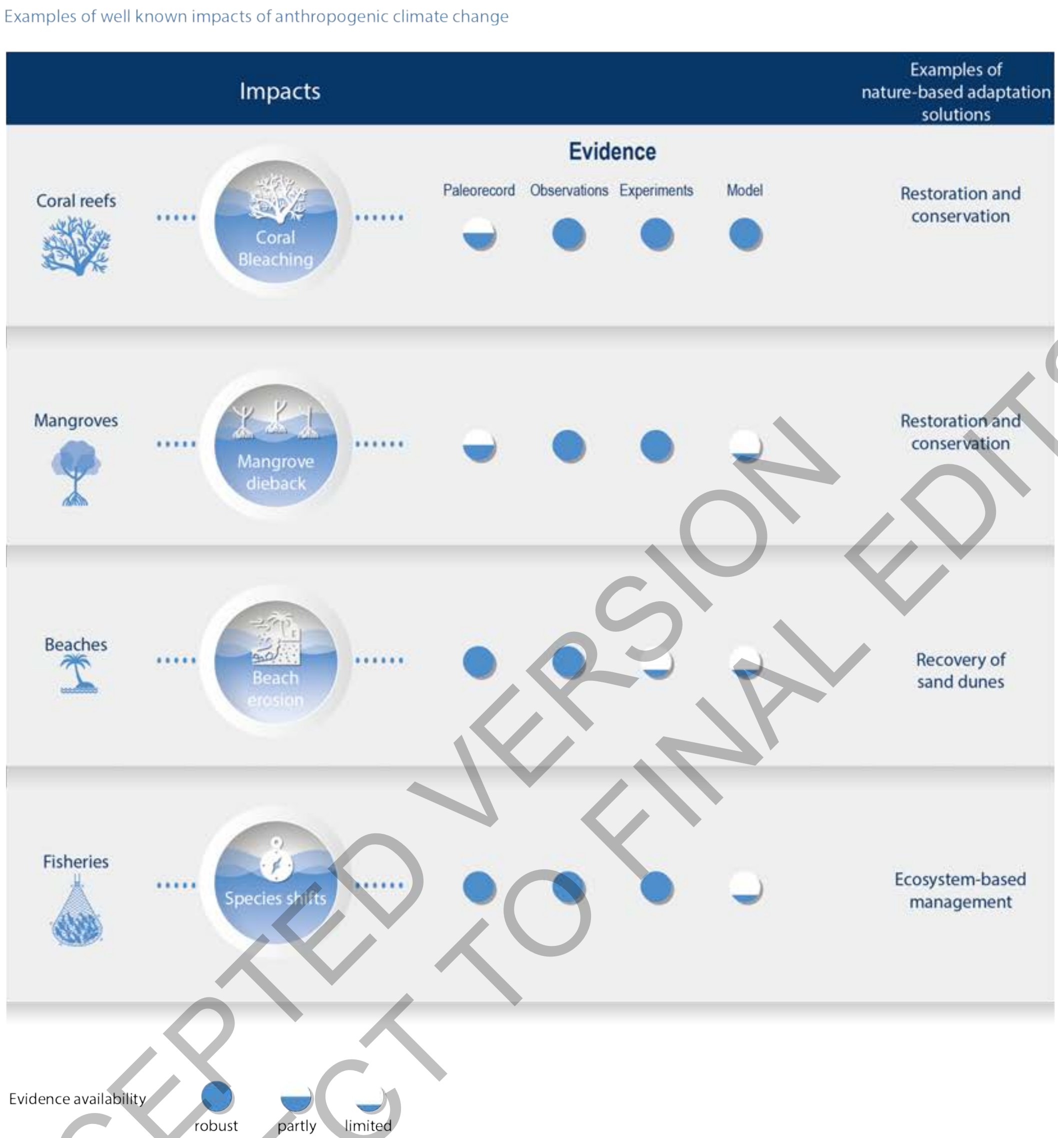

Figure FAQ3.1: Examples of well-known impacts of anthropogenic climate change and associated nature-based adaptation. To attribute changes in marine ecosystems to anthropogenic climate change, scientists use multiple lines of evidence including paleorecords, contemporary observations, manipulation experiments and models.

[END FAQ3.1 HERE]

Natural adaptation to climate change in ocean and coastal systems includes an array of responses taking place at scales from cells to ecosystems. Previous IPCC assessments have established that many marine species "have shifted their geographic ranges, seasonal activities, migration patterns, abundances and species interactions in response to climate change," (*high confidence*) (IPCC, 2014c; IPCC, 2014b), which has had global impacts on species composition, abundance and biomass, and on ecosystem structure and function (*medium confidence*) (IPCC, 2019b). Warming and acidification have affected coastal ecosystems in concert with non-climate drivers (*high confidence*), which have affected habitat area, biodiversity, ecosystem function and services (*high confidence*) (IPCC, 2019b). Confidence has grown in these assessments over time as observational datasets have lengthened and other lines of evidence have corroborated observations. AR5 and SROCC assessed how physiological sensitivity to climate-impact drivers is the underlying cause of most marine organisms' vulnerability to climate (*high confidence*) (Pörtner et al., 2014; Bindoff et al., 2019). Since those assessments, more evidence supports the empirical physiological models of tolerance and plasticity (Sections 3.3.2, 3.3.4) and of interactions among multiple (climate and non-climate) drivers at individual to ecosystem scales (Sections 3.3.3, 3.4.5). New experimental evidence about evolutionary adaptation (Section 3.3.4) bolsters previous assessments that adaptation options to climate change are limited for eukaryotic organisms. Tools such as ecosystem models can now constrain probable ecosystem states (Sections 3.3.4–3.3.5 and 3.4). Observations have increased understanding of how extreme events affect individuals, populations and ecosystems, helping refine understanding of both ecological tolerance to climate impacts and ecological transformations (Section 3.4).

Human adaptation to climate impacts on ocean and coastal systems spans a variety of actions that change human activity to maintain marine ecosystem services. After AR5 concluded that coastal adaptation could reduce the effects of climate impacts on coastal human communities (*high agreement*, *limited evidence*) (Wong et al., 2014), SROCC confirmed that mostly risk-reducing ocean and coastal adaptation responses were underway (Bindoff et al., 2019). However, overlapping climate-impact and non-climate drivers confound implementation and assessment of the success of marine adaptation, revealing the complexity of attempting to maintain marine ecosystems and services through adaptation. SROCC assessed with *high confidence* that while the benefits of many locally implemented adaptations exceed their disadvantages, others are marginally effective and have large disadvantages, and overall, adaptation has a limited ability to reduce the probable risks from climate change, being at best a temporary solution (Bindoff et al., 2019). SROCC also concluded that a portfolio of many different types of adaptation actions, effective and inclusive governance, and mitigation must be combined for successful adaptation (Bindoff et al., 2019). The portfolio of adaptation measures has now been defined (Section 3.6.2), and individual and combined adaptation solutions have been implemented in several marine sectors (Section 3.6.3). Delays in marine adaptation have been partly attributed to the complexity of ocean governance (Section 3.6.4, Cross-Chapter Box 3 and Figure CB3.1 in Abram et al., 2019) and to the low priority accorded the ocean in international development goals (Nash et al., 2020), but in recent years the ocean is being increasingly incorporated in international climate policy and multilateral environmental agreements (Section 3.6.4).

This chapter assesses the current understanding of climate-impact drivers, ecological vulnerability and adaptability, risks to coastal and ocean ecosystems, and human vulnerability and adaptation to resulting changes in ocean benefits, now and in the future (Figure 3.2). It starts by assessing the biologically relevant outcomes of anthropogenic climate-impact drivers (Section 3.2). Next, it sets out the mechanisms that determine the responses of ocean and coastal organisms to individual and combined drivers from the genetic to the ecosystem level (Section 3.3). This supports a detailed assessment of the observed and projected responses of coastal and ocean ecosystems to these hazards, placing them in context using the paleo-record (Section 3.4). These observed and projected impacts are used to quantify consequent risks to delivery of ecosystem services and the socioeconomic sectors that depend on them, with attention to the vulnerability, resilience and adaptive capacity of social-ecological systems (Section 3.5). The chapter concludes by assessing the state of adaptation and governance actions available to address these emerging threats while also advancing human development (Section 3.6). Abbreviations used repeatedly in the chapter are defined in Table 3.1.

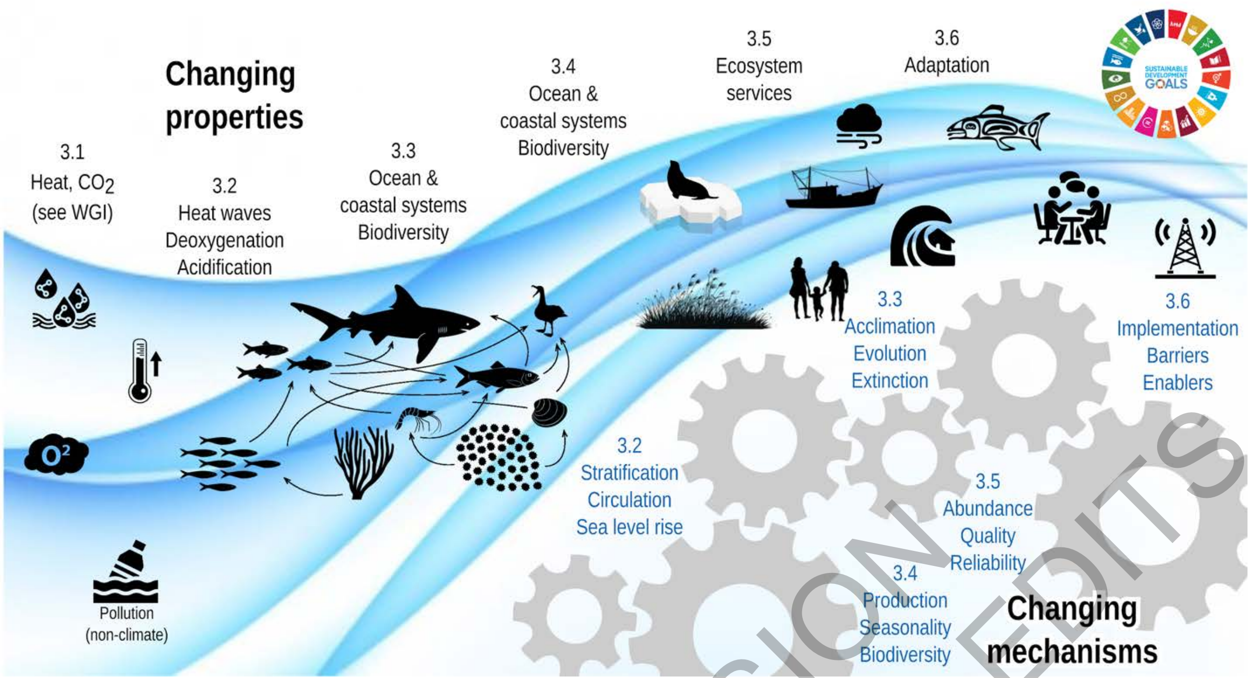

Figure 3.2: WGII AR6 Chapter 3 concept map. This chapter assesses how climate changes both the properties (top of wave, Sections 3.1–3.6) and the mechanisms (below wave, Sections 3.2–3.6) that influence the ocean and coastal social-ecological system. The Sustainable Development Goals (top right) represent ideal outcomes and achievement of equitable, healthy and sustainable ocean and coastal social-ecological systems.

Table 3.1: List of abbreviations frequently used in this chapter, with brief definitions for many of the abbreviations used.

Abbreviation	Definition
ABNJ	Areas beyond national jurisdiction. The water column beyond the exclusive economic zone called the high seas and the seabed beyond the limits of the continental shelf established in conformity with United Nations Convention on the Law of the Sea.
AMOC	Atlantic meridional overturning circulation (WGI AR6 Glossary, IPCC, 2021a).
AR5	The IPCC Fifth Assessment Report (IPCC, 2013; IPCC, 2014c; IPCC, 2014b; IPCC, 2014d).
CBD	Convention on Biological Diversity. An international legal instrument that has been ratified by 196 nations to conserve biological diversity, sustainably use its components and share its benefits fairly and equitably.
CE	Common era.
CID	Climatic Impact-Driver (WGI AR6 Glossary, IPCC, 2021a).
CMIP5, CMIP6	The Coupled Model Intercomparison Project, Phase 5 or 6 (WGI AR6 Glossary, IPCC, 2021a).
EbA	Ecosystem-based adaptation. The use of ecosystem management activities to increase the resilience and reduce the vulnerability of people and ecosystems to climate change.
EBUS	Eastern boundary upwelling system (WGI AR6 Glossary, IPCC, 2021a).
EBUE/EUS	Eastern boundary upwelling systems/equatorial upwelling systems. EBUEs are marine ecosystems in EBUS. EUSs

	are located on the equator, mostly on the eastern side of major ocean basins, where trade winds drive upwelling.
EEZ	Exclusive economic zone. The area from the coast to 200 nautical miles (370 km) off the coast, where a nation exercises its sovereign rights and exclusive management authority.
ESM	Earth-system model. A coupled atmosphere–ocean general circulation model (AOGCM, WGI AR6 Glossary, IPCC, 2021a) in which a representation of the carbon cycle is included, allowing for interactive calculation of atmospheric CO_2 or compatible emissions.
Fish-MIP	The Fisheries and Marine Ecosystem Model Intercomparison Project. Fish-MIP is a component of the Inter-Sectoral Impact Model Intercomparison Project (ISIMIP) that explores the long-term impacts of climate change on fisheries and marine ecosystems using scenarios from CMIP models.
GMSL/GMSLR	Global mean sea level/global mean sea-level rise (Sea-level change, WGI AR6 Glossary, IPCC, 2021a).
HAB	Harmful algal bloom. A HAB is an algal bloom composed of phytoplankton known to naturally produce bio-toxins that are harmful to the resident population, as well as humans.
ICZM	Integrated coastal zone management. ICZM is a dynamic, multidisciplinary and iterative process to promote sustainable management of coastal zones (European Environmental Agency).
IK and LK	Indigenous knowledge and Local knowledge (SROCC Glossary, IPCC, 2019a).
MHW	Marine heatwaves (WGI AR6 Glossary, IPCC, 2021a).
MPA	Marine protected area. MPA is an area-based management approach, commonly intended to conserve, preserve, or restore biodiversity and habitat, protect species, or manage resources (especially fisheries).
NbS	Nature-based Solution. Actions to protect, sustainably manage and restore natural or modified ecosystems that address societal challenges effectively and adaptively, simultaneously providing human well-being and biodiversity benefits (IUCN, 2016).
NDC	Nationally determined contribution by Parties to the Paris Agreement.
NPP	Net primary production. The difference between how much CO_2 vegetation takes in during photosynthesis (gross primary production) minus how much CO_2 the plants release during respiration.
OECM	Other effective area-based conservation measures. OECM is a conservation designation for areas that are achieving the effective *in situ* conservation of biodiversity outside of protected areas.
OMZ	Oxygen minimum zone (WGI AR6 Glossary, IPCC, 2021a).
pCO_2	Partial pressure of carbon dioxide. For seawater, pCO_2 is used to measure the amount of carbon dioxide dissolved in seawater.
pH	Potential of hydrogen (WGI AR6 Glossary, IPCC, 2021a).
POC	Particulate organic carbon. POC is a fraction of total organic carbon operationally defined as that which does

	not pass through a filter pore size that typically ranges in size from 0.053–2 mm.
SDG	Sustainable Development Goals. The 17 global goals for development for all countries established by the United Nations through a participatory process and elaborated in the 2030 Agenda for Sustainable Development.
SES	Semi-enclosed sea. SES means a gulf, basin or sea surrounded by land and connected to another sea by a narrow outlet.
SIDS	Small Island Developing States (WGI AR6 Glossary, IPCC, 2021a).
SLR/RSLR/RSL	Sea-level rise/Relative rea-level rise/Relative Sea Level (Sea-level change, WGI AR6 Glossary, IPCC, 2021a).
SR15	The IPCC Special Report on 1.5 Degrees C (IPCC, 2018).
SROCC	The IPCC Special Report on the Ocean and Cryosphere (IPCC, 2019b).
SSP/RCP	Shared socio-economic pathways/Representative concentration pathways (Pathways, IPCC, 2021a).
SST	Sea-surface temperature (WGI AR6 Glossary, IPCC, 2021a).
$\Omega_{aragonite}$	Saturation state of seawater with respect to the calcium carbonate mineral aragonite, used as a proxy measurement for ocean acidification.

3.2 Observed Trends and Projections of Climatic Impact-Drivers in the Global Ocean

3.2.1 Introduction

Climate change exposes ocean and coastal ecosystems to changing environmental conditions, including ocean warming, SLR, acidification, deoxygenation and other climatic-impact drivers, which have distinct regional and temporal characteristics (Gruber, 2011; IPCC, 2018). This section aims to build on the WGI AR6 assessment (Table 3.2) to provide an ecosystem-oriented framing of climatic impact-drivers. Updating SROCC, projected trends assessed here are based on a new range of scenarios (Shared Socio-Economic Pathways, SSPs), as used in the Coupled Model Intercomparison Project Phase 6 (CMIP6, Section 1.2.2).

Table 3.2: Overview of the main global ocean Climatic Impact-Drivers and their observed and projected trends from WGI AR6, with corresponding confidence levels and links to WGI chapters, where these trends are assessed in detail.

Climatic-Impact Drivers (Hazards)	Observed trends over the historical period	WGI Section	Projected trends over the 21st century	WGI Section
Ocean Temperature				
Ocean Warming	At the ocean surface, temperature has on average increased by 0.88 [0.68–1.01] °C from 1850–1900 to 2011–2020.	2.3.3.1, 9.2.1 (Fox-Kemper et al., 2021; Gulev et al., 2021)	Ocean warming will continue over the 21st century (*virtually certain*), and with the rate of global ocean warming starting to be scenario-dependent from about the mid-21st century (*medium confidence*).	9.2.1 (Fox-Kemper et al., 2021)
Marine Heatwaves (MHW)	MHW have become more frequent (*high confidence*), more intense, and longer (*medium confidence*) over the 20th century.	Box 9.2 (Fox-Kemper et al., 2021)	MHW will become 4 [2–9, *likely* range] times more frequent in 2081–2100 compared to 1995–2014 under SSP1-2.6, and 8 [3–15, *likely* range] times more frequent under SSP5-8.5.	Box 9.2 (Fox-Kemper et al., 2021)
Climate Velocities	Not assessed in WGI.		Not assessed in WGI.	
Sea-Level				

Global Mean Sea Level (GMSL)	Since 1901, GMSL has risen by 0.20 [0.15–0.25] m, and the rate of rise is accelerating.	2.3.3, 9.6.1 (Fox-Kemper et al., 2021; Gulev et al., 2021)	There will be continued rise in GMSL through the 21st century under all assessed SSPs (*virtually certain*).	4.3.2.2, 9.6.3 (Fox-Kemper et al., 2021; Lee et al., 2021)
Extreme Sea Levels	Relative sea-level rise is driving a global increase in the frequency of extreme sea levels (*high confidence*).	9.6.4 (Fox-Kemper et al., 2021)	Rising mean relative sea level will continue to drive an increase in the frequency of extreme sea levels (*high confidence*).	9.6.4 (Fox-Kemper et al., 2021)
Ocean circulation				
Ocean Stratification	The upper ocean has become more stably stratified since at least 1970 (*virtually certain*).	9.2.1.3 (Fox-Kemper et al., 2021)	Upper-ocean stratification will continue to increase throughout the 21st century (*virtually certain*).	9.2.1.3 (Fox-Kemper et al., 2021)
Eastern Boundary Upwelling Systems	Only the California current system has experienced some large-scale upwelling-favourable wind intensification since the 1980s (*medium confidence*).	9.2.5 (Fox-Kemper et al., 2021)	Eastern boundary upwelling systems will change, with a dipole spatial pattern within each system of reduction at low latitude and enhancement at high latitude (*high confidence*).	9.2.5 (Fox-Kemper et al., 2021)
Atlantic Overturning Circulation (AMOC)	For the 20th century, there is *low confidence* in reconstructed and modelled AMOC changes.	2.3.3.4, 9.2.3 (Fox-Kemper et al., 2021; Gulev et al., 2021)	The AMOC will decline over the 21st century (*high confidence*, but *low confidence* for quantitative projections).	4.3.2.3, 9.2.3 (Fox-Kemper et al., 2021; Lee et al., 2021)
Sea-Ice				
Arctic Sea-Ice Changes	Current Arctic sea-ice coverage levels are the lowest since at least 1850 for both annual mean and late-summer values (*high confidence*).	2.3.2.1, 9.3.1 (Fox-Kemper et al., 2021; Gulev et al., 2021)	The Arctic will become practically ice-free in September by the end of the 21st century under SSP2-4.5, SSP3-7.0, and SSP5-8.5 (*high confidence*)	4.3.2.1, 9.3.1 (Fox-Kemper et al., 2021; Lee et al., 2021)
Antarctic Sea Ice Changes	There is no global significant trend in Antarctic sea-ice area from 1979 to 2020 (*high confidence*).	2.3.2.1, 9.3.2 (Fox-Kemper et al., 2021; Gulev et al., 2021)	There is *low confidence* in model simulations of future Antarctic sea ice.	9.3.2 (Fox-Kemper et al., 2021)
Ocean Chemistry				
Changes in Salinity	The large-scale, near-surface salinity contrasts have intensified since at least 1950 (*virtually certain*).	2.3.3.2, 9.2.2.2 (Fox-Kemper et al., 2021; Gulev et al., 2021)	Fresh ocean regions will continue to get fresher and salty ocean regions will continue to get saltier in the 21st century (*medium confidence*).	9.2.2.2 (Fox-Kemper et al., 2021)
Ocean Acidification	Ocean surface pH has declined globally over the past four decades (*virtually certain*).	2.3.3.5, 5.3.2.2 (Canadell et al., 2021; Gulev et al., 2021)	Ocean surface pH will continue to decrease through the 21st century, except for the lower-emission scenarios SSP1-1.9 and SSP1-2.6, (*high confidence*).	4.3.2.5, 4.5.2.2, 5.3.4.1 (Lee et al., 2021) (Canadell et al., 2021)
Ocean Deoxygenation	Deoxygenation has occurred in most open ocean regions since the mid 20th (*high confidence*).	2.3.3.6, 5.3.3.2 (Canadell et al., 2021; Gulev et al., 2021)	Subsurface oxygen content is projected to transition to historically unprecedented condition with decline over the 21st century (*medium confidence*).	5.3.3.2 (Canadell et al., 2021)
Changes in Nutrient Concentrations	Not assessed in WGI.		Not assessed in WGI.	

3.2.2 Physical Changes

3.2.2.1 Ocean Warming, Climate Velocities and Marine Heatwaves

Global mean SST has increased since the beginning of the 20th century by 0.88°C (*very likely* range: 0.68–1.01°C), and it is *virtually certain* that the global ocean has warmed since at least 1971 (WGI AR6 Section 9.2, Fox-Kemper et al., 2021). A key characteristic of ocean temperature change relevant for ecosystems is climate velocity, a measure of the speed and direction at which isotherms move under climate change (Burrows et al., 2011), which gives the rate at which species must migrate to maintain constant climate conditions. It has been shown to be a useful and simple predictor of species distribution shifts in marine ecosystems (Chen et al., 2011; Pinsky et al., 2013; Lenoir et al., 2020). Median climate velocity in the surface ocean has been 21.7 km per decade since 1960, with higher values in the Arctic/sub-Arctic and within 15° of the Equator (Figure 3.3, Burrows et al., 2011). While climate velocity has been slower in the mesopelagic layer (200–1000 m) than in the epipelagic layer (0–200 m) over the last 50 years, it has been shown to be faster in the bathypelagic (1000–4000 m) and abyssopelagic (>4000 m) layers (Figure 3.4, Brito-Morales et al., 2020), suggesting that deep-ocean species could be as exposed to effects of warming as species in the surface ocean (Brito-Morales et al., 2020).

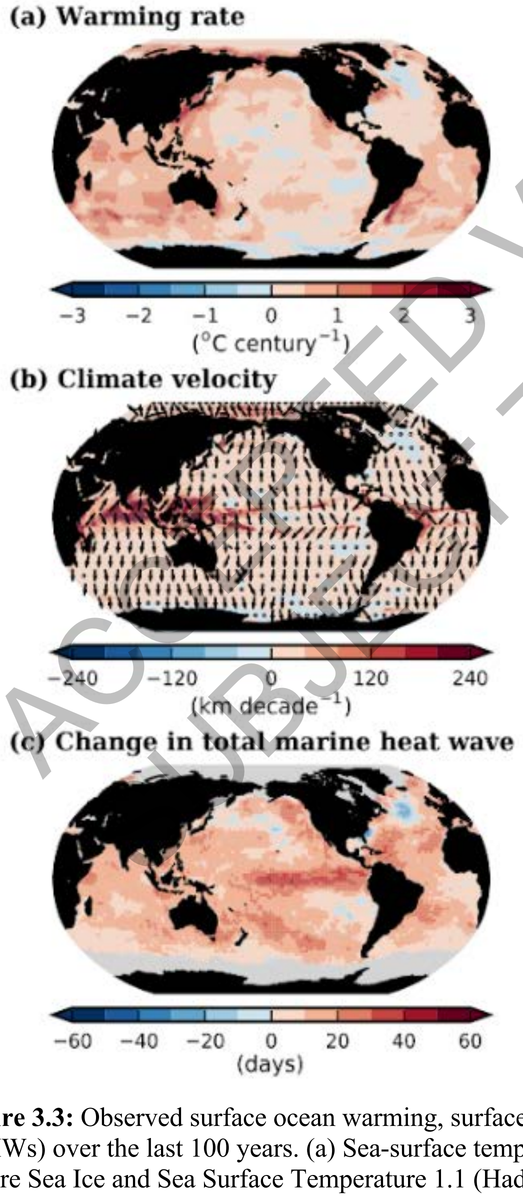

Figure 3.3: Observed surface ocean warming, surface climate velocity and reconstructed changes in marine heatwaves (MHWs) over the last 100 years. (a) Sea-surface temperature trend (°C per century) over 1925–2016 from Hadley Centre Sea Ice and Sea Surface Temperature 1.1 (HadISST1.1), (b) surface climate velocity (km per decade) over

1925–2016 computed from HadISST1.1, and (c) change in total MHW days for the surface ocean from 1925–1954 to 1987–2016 based on monthly proxies, from Oliver et al. (2018).

Marine heatwaves (MHW) are periods of extreme seawater temperature relative to the long-term mean seasonal cycle, that persist for days to months, and that may carry severe consequences for marine ecosystems and their services (WGI AR6 Box 9.2, Hobday et al., 2016a; Smale et al., 2019; Fox-Kemper et al., 2021). MHW have become more frequent over the 20th century (*high confidence*), approximately doubling in frequency (*high confidence*) and becoming more intense and longer since the 1980s (*medium confidence*) (WGI AR6 Box 9.2, Fox-Kemper et al., 2021). These trends in MHW are explained by an increase in ocean mean temperatures (Oliver et al., 2018), and human influence has *very likely* contributed to 84–90% of them since at least 2006 (WGI AR6 Box 9.2, Fox-Kemper et al., 2021). The probability of occurrence (as well as duration and intensity) of the largest and most impactful MHWs that have occurred in the past 30 years has increased more than 20-fold due to anthropogenic climate change (Laufkötter et al., 2020).

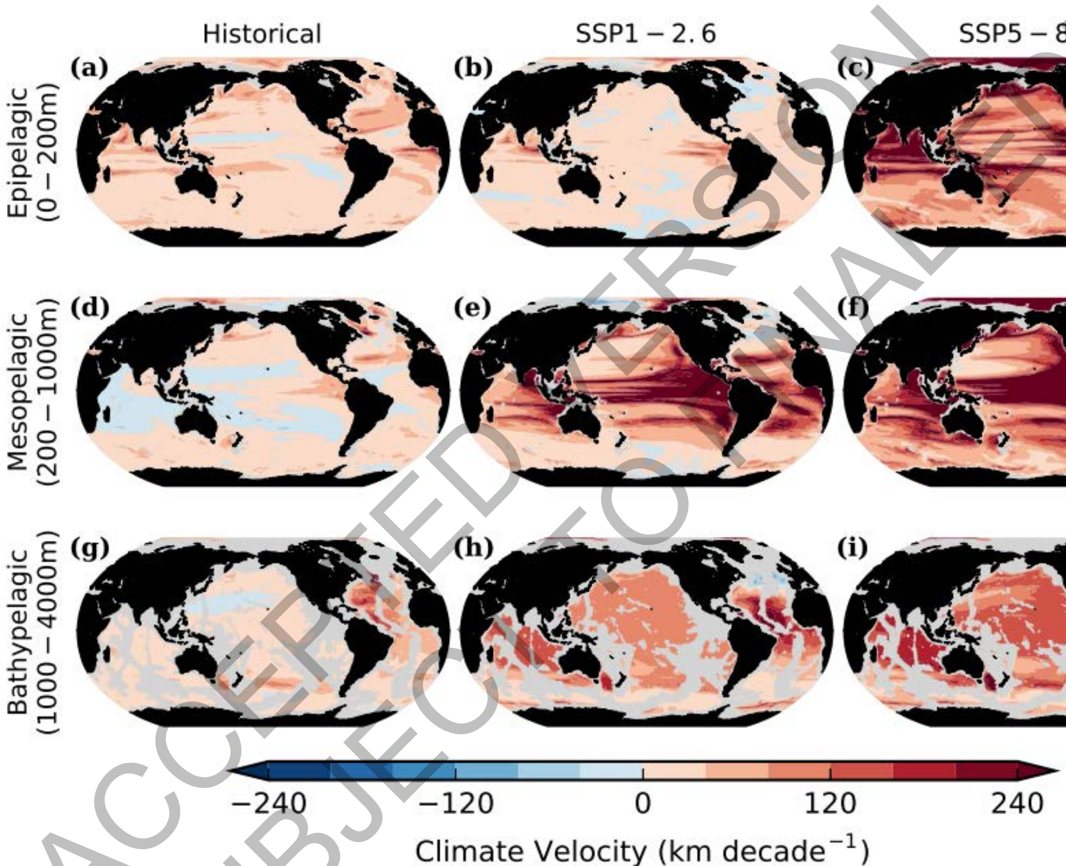

Figure 3.4: Historical and projected climate velocity. Climate velocities (in km per decade) for the (a,d,g) historical period (1965–2014), and for the last 50 years of the 21st century (2051–2100) under (b,e,h) SSP1-2.6 and (c,f,i) SSP5-8.5. Shown are the epipelagic (0–200 m), mesopelagic (200–1000 m) and bathypelagic (1000–4000 m) domains. Updated figure from Brito-Morales et al. (2020), with Coupled Model Intercomparison Project 6 models used in Kwiatkowski et al. (2020).

Ocean warming will continue over the 21st century (*virtually certain*), and with the rate of global ocean warming starting to be scenario-dependent from about the mid-21st century (*medium confidence*). At the ocean surface, it is *virtually certain* that SST will continue to increase throughout the 21st century, with increasing hazards to many marine ecosystems (WGI AR6 Box 9.2, Fox-Kemper et al., 2021). The future global mean SST increase projected by CMIP6 models for the period 1995–2014 to 2081–2100 is 0.86°C (*very likely* range: 0.43–1.47°C) under SSP1-2.6, 1.51 °C (1.02–2.19°C) under SSP2-4.5, 2.19°C (1.56–3.30°C) under SSP3-7.0, and 2.89°C (2.01–4.07°C) under SSP5-8.5 (WGI AR6 Section 9.2.1, Fox-Kemper et al., 2021). Stronger surface warming occurs in parts of the tropics, in the North Pacific, and in the Arctic

Ocean, where SST increases by >4°C in 2080–2099 under SSP5-8.5 (Kwiatkowski et al., 2020). The CMIP6 climate models also project ocean warming at the seafloor, with the magnitude of projected changes being less than that of surface waters but having larger uncertainties (Kwiatkowski et al., 2020). The projected end-of-the-century warming in CMIP6 as reported here is greater than assessed with Coupled Model Intercomparison Project 5 (CMIP5) models in AR5 and in SROCC for similar radiative forcing scenarios (Figure 3.5, Kwiatkowski et al., 2020), because of greater climate sensitivity in the CMIP6 model ensemble than in CMIP5 (WGI AR6 Chapter 4, Forster et al., 2020; Lee et al., 2021).

MHWs will continue to increase in frequency, with a *likely* global increase of 2–9 times in 2081–2100 compared to 1995–2014 under SSP1-2.6, and 3–15 times under SSP5-8.5, with the largest increases in tropical and Arctic oceans (WGI AR6 Box 9.2, Frölicher et al., 2018; Fox-Kemper et al., 2021).

3.2.2.2 Sea-Level Rise and Extreme Sea Levels

Global mean sea-level (GMSL, see also Cross-Chapter Box SLR in Chapter 3) has risen by about 0.20 m since 1901 and continues to accelerate (WGI AR6 Section 2.3.3.3, Church and White, 2011; Jevrejeva et al., 2014; Hay et al., 2015; Kopp et al., 2016; Dangendorf et al., 2017; Cazenave et al., 2018; Kemp et al., 2018; Ablain et al., 2019; Gulev et al., 2021).

Most coastal ecosystems (mangroves, sea grasses, saltmarshes, shallow coral reefs, rocky shores and sandy beaches) are affected by changes in relative sea-level (RSL, the change in the mean sea level relative to the land, Section 3.4.2). Regional rates of RSL rise differ from the global mean due to a range of factors, including local subsidence driven by anthropogenic activities such as groundwater and hydrocarbon extraction (WGI AR6 Box 9.1, Fox-Kemper et al., 2021). In many deltaic regions, anthropogenic subsidence is currently the dominant driver of RSL rise (WGI AR6 Section 9.6.3.2, Tessler et al., 2018; Fox-Kemper et al., 2021). RSL rise is driving a global increase in the frequency of extreme sea levels (*high confidence*) (WGI AR6 Section 9.6.4.1, Fox-Kemper et al., 2021).

GMSL rise through the middle of the 21st century exhibits limited dependence on emissions scenario; between 1995–2014 and 2050, GMSL is *likely* to rise by 0.15–0.23 m under SSP1-1.9 and 0.20–0.30 m under SSP5-8.5 (WGI AR6 Section 9.6.3, Fox-Kemper et al., 2021). Beyond 2050, GMSL and RSL projections are increasingly sensitive to the differences among emission scenarios. Considering only processes in which there is at least *medium confidence* (thermal expansion, land water storage, land ice surface mass balance, and some ice sheet dynamic processes), GMSL between 1995–2014 and 2100 is *likely* to rise by 0.28–0.55 m under SSP1-1.9, 0.33–0.61 m under SSP1-2.6, 0.44–0.76 m under SSP2-4.5, 0.55–0.90 m under SSP3-7.0, and 0.63–1.02 m under SSP5-8.5 (Figure 3.5). Under high-emission scenarios, ice-sheet processes in which there is *low confidence* and *deep uncertainty* might contribute more than one additional metre to GMSL rise by 2100 (WGI AR6 Chapter 9, Fox-Kemper et al., 2021).

Rising mean RSL will continue to drive an increase in the frequency of extreme sea levels (*high confidence*). The expected frequency of the current one-in-100-year extreme sea level is projected to increase by a median of 20–30 times across tide-gauge sites by 2050, regardless of emission scenario (*medium confidence*). In addition, extreme-sea-level frequency may be affected by changes in tropical cyclone climatology (*low confidence*), wave climatology (*low confidence*), and tides (*high confidence*) associated with climate change and sea-level change (WGI AR6 Section 9.6.4.2, Fox-Kemper et al., 2021).

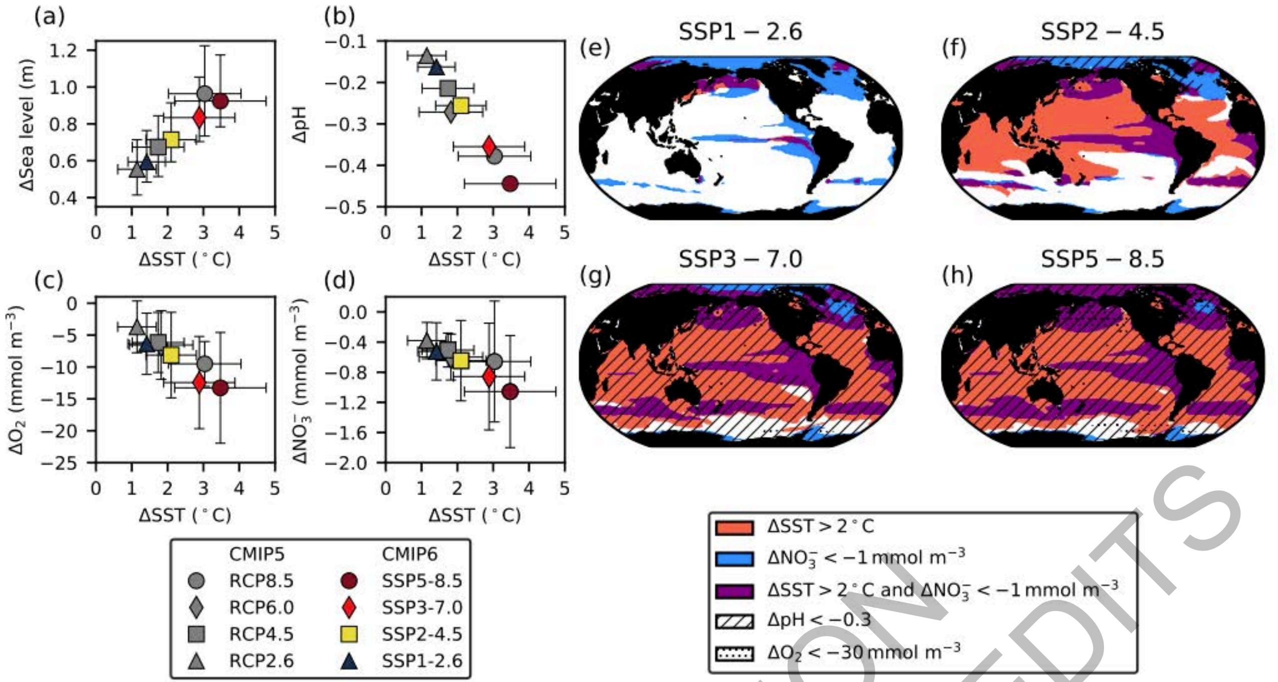

Figure 3.5: Projected trends in climatic-impact drivers for ocean ecosystems. Panels (a,b,c,d) represent Coupled Model Intercomparison Project 5 (CMIP5) Representative Concentration Pathway (RCP) and CMIP6 Shared Socioeconomic Pathway (SSP) end-of-century changes in (a) global sea-level rise (SLR), (b) average surface pH, (c) subsurface (100–600 m) dissolved oxygen concentration and (d) euphotic-zone (0–100 m) nitrate (NO_3) concentration against anomalies in sea surface temperature. All anomalies are model-ensemble averages over 2080–2099 relative to the 1870–1899 baseline period (from Kwiatkowski et al., 2020), except for SLR, which shows model-ensemble median in 2100 relative to 1901 (from AR6 WGI Chapter 9). Error bars represent *very likely* ranges, except for SLR where they represent *likely* ranges. *Very likely* ranges for pH changes are too narrow to appear on the figure (see text). Panels (e,f,g,h) show regions where end-of-century projected CMIP6 surface warming exceeds 2°C, where surface ocean pH decline exceeds 0.3, where subsurface dissolved oxygen decline exceeds 30 mmol m^{-3} and where euphotic-zone (0–100 m) nitrate decline exceeds 1 mmol m^{-3} in (e) SSP1-2.6, (f) SSP2-4.5, (g) SSP3-7.0 and (h) SSP5-8.5. All anomalies are 2080–2099 relative to the 1870–1899 baseline period (modified from Kwiatkowski et al., 2020).

3.2.2.3 *Changes in Ocean Circulation, Stratification and Coastal Upwelling*

Ocean circulation and its variations are key to the evolution of the physical, chemical and biological properties of the ocean. Vertical mixing and upwelling are critical factors affecting the supply of nutrients to the sunlit ocean and hence the magnitude of primary productivity. Ocean currents not only transport heat, salt, carbon, and nutrients, but they also control the dispersion of many organisms and the connectivity between distant populations.

Ocean stratification is an important factor controlling biogeochemical cycles and affecting marine ecosystems. WGI AR6 Section 9.2.1.3 (Fox-Kemper et al., 2021) assessed that it is *virtually certain* that stratification in the upper 200 m of the ocean has been increasing since 1970. Recent evidence has strengthened estimates of the rate of change (Yamaguchi and Suga, 2019; Li et al., 2020a; Sallée et al., 2021), with an estimated increase of 1.0 ± 0.3% (*very likely* range) per decade over the period 1970–2018 (*high confidence*) (WGI AR6 Section 9.2.1.3, Fox-Kemper et al., 2021), higher than assessed in SROCC. It is *very likely* that stratification in the upper few hundred metres of the ocean will increase substantially in the 21st century in all ocean basins, driven by intensified surface warming and near-surface freshening at high latitudes (WGI AR6 Section 9.2.1.3, Capotondi et al., 2012; Fu et al., 2016; Bindoff et al., 2019; Kwiatkowski et al., 2020; Fox-Kemper et al., 2021).

Contrasting changes among the major eastern boundary coastal upwelling systems (EBUS) were identified in AR5 (Hoegh-Guldberg et al., 2014). While SROCC assessed with *high confidence* that three (Benguela, Peru-Humboldt, California) out of the four major EBUS have experienced upwelling-favourable wind intensification in the past 60 years (Sydeman et al., 2014; Bindoff et al., 2019), WGI AR6 revisited this assessment based on evidence showing *low agreement* between studies that have investigated trends over past decades (Varela et al., 2015). WGI AR6 assessed that only the California Current system has undergone large-scale upwelling-favourable wind intensification since the 1980s (*medium confidence*) (WGI AR6 Section 9.2.1.5, García-Reyes and Largier, 2010; Seo et al., 2012; Fox-Kemper et al., 2021).

While no consistent pattern of contemporary changes in upwelling-favourable winds emerges from observation-based studies, numerical and theoretical work projects that summertime winds near poleward boundaries of upwelling zones will intensify, while winds near equatorward boundaries will weaken (*high confidence*) (WGI AR6 Section 9.2.3.5, García-Reyes et al., 2015; Rykaczewski et al., 2015; Wang et al., 2015; Aguirre et al., 2019; Fox-Kemper et al., 2021). Nevertheless, projected future annual cumulative upwelling wind changes at most locations and seasons remain within ±10–20% of present-day values (*medium confidence*) (WGI AR6 Section 9.2.3.5, Fox-Kemper et al., 2021).

Continuous observation of the Atlantic meridional overturning circulation (AMOC) has improved the understanding of its variability (Frajka-Williams et al., 2019), but there is *low confidence* in the quantification of AMOC changes in the 20th century because of *low agreement* in quantitative reconstructed and simulated trends (WGI AR6 Sections 2.3.3, 9.2.3.1, Fox-Kemper et al., 2021; Gulev et al., 2021). Direct observational records since the mid-2000s remain too short to determine the relative contributions of internal variability, natural forcing and anthropogenic forcing to AMOC change (*high confidence*) (WGI AR6 Sections 2.3.3, 9.2.3.1, Fox-Kemper et al., 2021; Gulev et al., 2021). Over the 21st century, AMOC will *very likely* decline for all SSP scenarios, but will not involve an abrupt collapse before 2100 (WGI AR6 Sections 4.3.2, 9.2.3.1, Fox-Kemper et al., 2021; Lee et al., 2021).

3.2.2.4 Sea Ice Changes

Sea ice is a key driver of polar marine life, hosting unique ecosystems and affecting diverse marine organisms and food webs through its impact on light penetration and supplies of nutrients and organic matter (Arrigo, 2014). Since the late 1970s, Arctic sea-ice area has decreased for all months, with an estimated decrease of two million km^2 (or 25%) for summer sea-ice (averaged for August, September, October) in 2010–2019 as compared to 1979–1988 (WGI AR6 Section 9.3.1.1, Fox-Kemper et al., 2021). For Antarctic sea-ice there is no significant global trend in satellite-observed sea-ice area from 1979 to 2020 in either winter or summer, due to regionally opposing trends and large internal variability (WGI AR6 Section 9.3.2.1, Maksym, 2019; Fox-Kemper et al., 2021).

CMIP6 simulations project that the Arctic Ocean will *likely* become practically sea-ice free (area below 1 million km^2) for the first time before 2050 and in the seasonal sea-ice minimum in each of the four emission scenarios SSP1-1.9, SSP1-2.6, SSP2-4.5, and SSP5-8.5 (Figure 3.7, WGI AR6 Section 9.3.2.2, SIMIP Community, 2020; Fox-Kemper et al., 2021). Antarctic sea-ice area is also projected to decrease during the 21st century, but due to mismatches between model simulations and observations, combined with a lack of understanding of reasons for substantial inter-model spread, there is *low confidence* in model projections of future Antarctic sea-ice changes, particularly at the regional level (WGI AR6 Section 9.3.2.2, Roach et al., 2020; Fox-Kemper et al., 2021).

3.2.3 Chemical Changes

3.2.3.1 Ocean Acidification

The ocean's uptake of anthropogenic carbon affects its chemistry in a process referred to as ocean acidification, which increases the concentrations of aqueous CO_2, bicarbonate and hydrogen ions, and decreases pH, carbonate ion concentrations and calcium carbonate mineral saturation states (Doney et al., 2009). Ocean acidification affects a variety of biological processes with, for example, lower calcium carbonate saturation states reducing net calcification rates for some shell-forming organisms and higher CO_2 concentrations increasing photosynthesis for some phytoplankton and macroalgal species (Section 3.3.2).

Direct measurements of ocean acidity from ocean time series, as well as pH changes determined from other shipboard studies, show consistent decreases in ocean surface pH over the past few decades (*virtually* *certain*) (WGI AR6 Section 5.3.2.2, Takahashi et al., 2014; Bindoff et al., 2019; Sutton et al., 2019; Canadell et al., 2021).

Since the 1980s, surface ocean pH has declined by a *very likely* rate of 0.016–0.020 per decade in the subtropics and 0.002–0.026 per decade in the subpolar and polar zones (WGI AR6 Section 5.3.2.2, Canadell et al., 2021). Typically, the pH of global surface waters has decreased from 8.2 to 8.1 since the pre-industrial era (1750 CE), a trend attributable to rising atmospheric CO_2 (*virtually certain*) (Orr et al., 2005; Jiang et al., 2019).

Ocean acidification is also developing in the ocean interior (*very high confidence*) due to the transport of anthropogenic CO_2 to depth by ocean currents and mixing (WGI AR6 Section 5.3.3.1, Canadell et al., 2021). There, it leads to the shoaling of saturation horizons of aragonite and calcite (*high confidence*) (WGI AR6 Section 5.3.3.1, Canadell et al., 2021), below which dissolution of these calcium carbonate minerals is thermodynamically favoured. The calcite or aragonite saturation horizons have migrated upwards in the North Pacific (1–2 m yr–1 over 1991–2006, Feely et al., 2012) and in the Irminger Sea (10–15 m yr–1 for the aragonite saturation horizon over 1991–2016, Perez et al., 2018). In some locations of the Western Atlantic Ocean, calcite saturation depth has risen by ~300 m since the pre-industrial due to increasing concentrations of deep-ocean dissolved inorganic carbon (Sulpis et al., 2018). In the Arctic, where some coastal surface waters are already undersaturated with respect to aragonite due to the degradation of terrestrial organic matter (Mathis et al., 2015; Semiletov et al., 2016), the deep aragonite saturation horizon has shoaled on average by 270 ± 60 m during 1765–2005 (Terhaar et al., 2020).

Detection and attribution of ocean acidification in coastal environments are more difficult than in the open ocean due to larger spatial and temporal variability of carbonate chemistry (Duarte et al., 2013; Laruelle et al., 2017; Torres et al., 2021), and to the influence of other natural acidification drivers such as freshwater and high-nutrient riverine inputs (Cai et al., 2011; Laurent et al., 2017; Fennel et al., 2019; Cai et al., 2020) or anthropogenic acidification drivers (Section 3.1) like atmospherically deposited nitrogen and sulphur (Doney et al., 2007; Hagens et al., 2014). Since AR5, the observing network in coastal oceans has expanded substantially, improving understanding of both the drivers and amplitude of observed variability (Sutton et al., 2016). Recent studies indicate that two more decades of observations may be required before anthropogenic ocean acidification emerges over natural variability in some coastal sites and regions (WGI AR6 Section 5.3.5.2, Sutton et al., 2019; Turk et al., 2019; Canadell et al., 2021).

Mean open-ocean surface pH is projected to decline by 0.08 ± 0.003 (*very likely range*), 0.17 ± 0.003, 0.27 ± 0.005 and 0.37 ± 0.007 pH units in 2081–2100 relative to 1995–2014, for SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5, respectively (Figure 3.5, WGI AR6 Section 4.3.2, Kwiatkowski et al., 2020; Lee et al., 2021). Projected changes in surface pH are relatively uniform in contrast with those of other surface-ocean variables, but they are largest in the Arctic Ocean (Figure 3.6, WGI AR6 Section 5.3.4.1, Canadell et al., 2021). Similar declines in the concentration of carbonate ions are projected by Earth System Models (ESMs, Bopp et al., 2013; Gattuso et al., 2015; Kwiatkowski et al., 2020). The North Pacific, the Southern Ocean and Arctic Ocean regions will become undersaturated for calcium carbonate minerals first (Orr et al., 2005; Pörtner et al., 2014). Concurrent impacts on the seasonal amplitude of carbonate chemistry variables are anticipated (i.e., increased amplitude for pCO2 and hydrogen ions, decreased amplitude for carbonate ions, McNeil and Sasse, 2016; Kwiatkowski and Orr, 2018; Kwiatkowski et al., 2020).

Future declines in subsurface pH (Figure 3.6) will be modulated by changes in ocean overturning and water-mass subduction (Resplandy et al., 2013), and in organic matter remineralisation (Chen et al., 2017). In particular, decreases in pH will be less consistent at the seafloor than at the surface and will be linked to the transport of surface anomalies to depth. For example, >20% of the North Atlantic seafloor deeper than 500 m, including canyons and seamounts designated as marine protected areas (MPAs), will experience pH reductions >0.2 by 2100 under RCP8.5 (Gehlen et al., 2014). Changes in pH in the abyssal ocean (>3000 m deep) are greatest in the Atlantic and Arctic Oceans, with lesser impacts in the Southern and Pacific Oceans by 2100, mainly due to ventilation time scales (Sweetman et al., 2017).

3.2.3.2 Ocean Deoxygenation

Ocean deoxygenation, the loss of oxygen in the ocean, results from ocean warming, through a reduction in oxygen saturation, increased oxygen consumption, increased ocean stratification and ventilation changes (Keeling et al., 2010; IPCC, 2019a). In recent decades, anthropogenic inputs of nutrients and organic matter (Section 3.1) have increased the extent, duration, and intensity of coastal hypoxia events worldwide (Diaz and Rosenberg, 2008; Rabalais et al., 2010; Breitburg et al., 2018), while pollution-induced atmospheric deposition of soluble iron over the ocean has accelerated open-ocean deoxygenation (Ito et al., 2016). Dexoygenation and acidification often coincide because biological consumption of oxygen produces CO_2. Deoxygenation can have a range of detrimental effects on marine organisms and reduce the extent of marine habitats (Sections 3.3.2, 3.4.3.1, Vaquer-Sunyer and Duarte, 2008; Chu and Tunnicliffe, 2015).

Changes in ocean oxygen concentrations have been analysed from compilations of *in situ* data dating back to the 1960s (Helm et al., 2011; Ito et al., 2017; Schmidtko et al., 2017). SROCC concluded that a loss of oxygen had occurred in the upper 1000 m of the ocean (*medium confidence*), with a global mean decrease of 0.5–3.3% (*very likely range*) over 1970–2010 (Bindoff et al., 2019). Based on new regional assessments (Queste et al., 2018; Bronselaer et al., 2020; Cummins and Ross, 2020; Stramma et al., 2020). WGI AR6 assesses that ocean deoxygenation has occurred in most regions of the open ocean since the mid-20th century (*high confidence*), but is modified by climate variability on interannual and decadal time-scales (*medium confidence*) (WGI AR6 Sections 2.3.3.6, 5.3.3.2, Canadell et al., 2021; Gulev et al., 2021). New findings since SROCC also confirm that the volume of oxygen minimum zones (OMZs) are expanding at many locations (*high confidence*) (WGI AR6 Section 5.3.3.2, Canadell et al., 2021).

The most recent estimates of future oxygen loss in the subsurface ocean (100–600 m), using CMIP6 models, amount to –4.1 ± 4.2 (*very likely range*), –6.6 ± 5.7, –10.1 ± 6.7 and –11.2 ± 7.7% in 2081–2100 relative to 1995–2014 for SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5, respectively (Figure 3.5, Kwiatkowski et al., 2020). Based on these CMIP6 projections, WGI AR6 concludes that the oxygen content of the subsurface ocean is projected to decline to historically unprecedented conditions over the 21st century (*medium confidence*) (WGI AR6 Section 5.3.3.2, Canadell et al., 2021). These declines are greater (by 31–72%) than simulated by the CMIP5 models in their Representative Concentration Pathway (RCP) analogues, a *likely* consequence of enhanced surface warming and stratification in CMIP6 models (Figure 3.5, Kwiatkowski et al., 2020). At the regional scale and for subsurface waters, projected changes are not spatially uniform, and there is *lower agreement* among models than they show for the global mean trend (Bopp et al., 2013; Kwiatkowski et al., 2020). In particular, large uncertainties remain for these future projections of ocean deoxygenation in the subsurface tropical oceans, where the major OMZs are located (Cabré et al., 2015; Bopp et al., 2017).

3.2.3.3 Changes in Nutrient Availability

The availability of nutrients in the surface ocean often limits primary productivity, with implications for marine food webs and the biological carbon pump. Nitrogen availability tends to limit phytoplankton productivity throughout most of the low-latitude ocean, whereas dissolved iron availability limits productivity in high-nutrient, low-chlorophyll regions, such as in the main upwelling region of the Southern Ocean and the Eastern Equatorial Pacific (*high confidence*) (Moore et al., 2013; IPCC, 2019b). Phosphorus, silicon, other micronutrients such as zinc, and vitamins can also co-limit marine phytoplankton productivity in some ocean regions (Moore et al., 2013). Whereas some studies have shown coupling between climate variability and nutrient trends in specific regions, such as in the North Atlantic (Hátún et al., 2016), North Pacific (Di Lorenzo et al., 2009; Yasunaka et al., 2014) and tropical (Stramma and Schmidtko, 2021) Oceans, very few studies have been able to detect long-term changes in ocean nutrient concentrations (but see Yasunaka et al., 2016).

Future changes in nutrient concentrations have been estimated using ESMs, with future increases in stratification generally leading to decreased nutrient levels in surface waters (IPCC, 2019b). CMIP6 models project a decline in the nitrate concentration of the upper 100 m in 2080–2099 relative to 1995–2014 of –0.46 ± 0.45 (*very likely range*), –0.60 ± 0.58, –0.80 ± 0.77 and –1.00 ± 0.78 mmol m^{-3} under SSP1-2.6, SSP2-4.5 and SSP5-8.5, respectively (Figure 3.5, Kwiatkowski et al., 2020). These declines in nitrate concentration are greater than simulated by the CMIP5 models in their RCP analogues, a *likely* consequence of enhanced surface warming and stratification in CMIP6 models (Figure 3.5, Kwiatkowski et al., 2020). It is concluded that the surface ocean will encounter reduced nitrate concentrations in the 21st century (*medium confidence*).

3.2.4 Global Synthesis on Multiple Climatic Impact Drivers

In the 21st century, ocean and coastal ecosystems are projected to face conditions unprecedented over past centuries to millennia (*high confidence*) (Section 3.2, WGI AR6 Chapters 4, 9, Fox-Kemper et al., 2021; Lee et al., 2021), with increased temperatures (*virtually certain*) and frequency and severity of MHWs (*very high confidence*), stronger upper-ocean stratification (*high confidence*), continued rise in GMSL through the 21st century (*high confidence*) and increased frequency of extreme sea levels (*high confidence*), further acidification (*virtually certain*), oxygen decline (*high confidence*), and decreased surface nitrate inventories (*medium confidence*).

The rates and magnitudes of these changes largely depend on the extent of future emissions (*very high confidence*), with surface ocean warming and acidification (*very likely range*) at +3.47°C ± 1.28°C and –0.44 pH units ± 0.008 in 2080–2099 (relative to 1870–1899) for SSP5-8.5 compared to +1.42°C ± 0.53°C and –0.16 ± 0.003 for SSP1-2.6 (Figure 3.5, Kwiatkowski et al., 2020).

3.2.4.1 Compound Changes in the 21st Century

ESMs project distinct regional evolutions of the different climatic-impact drivers over the 21st century (*very high confidence*) (Figures 3.5, 3.6, 3.7, Kwiatkowski et al., 2020). Tropical and subtropical oceans are characterized by projected warming and acidification, accompanied by declining nitrate concentrations in equatorial upwelling regions. The North Atlantic is characterized by a high exposure to acidification and declining nitrate concentrations. The North Pacific is characterized by high sensitivity to compound changes, with high rates of warming, acidification, deoxygenation and nutrient depletion. In contrast, the development of compound hazards is limited in the Southern Ocean, where rates of warming and nutrient depletion are lower. The Arctic Ocean is characterized by the highest rates of acidification and warming, strong nutrient depletion, and it will *likely* become practically sea-ice free in the September mean for the first time before the year 2050 in all SSP scenarios (*high confidence*) (Figures 3.5, 3.6, 3.7, Sections 3.2.2–3.2.3).

In general, the projected changes in climatic-impact drivers are less in absolute terms in the deep-sea (mesopelagic and bathypelagic domains and deep-sea habitats) than in the surface ocean and in shallow-waters habitats (kelp ecosystems, warm-water corals) (*very high confidence*) (Figures 3.6, 3.7, Mora et al., 2013; Sweetman et al., 2017). The mesopelagic domain will be nevertheless exposed to high rates of deoxygenation (Figure 3.6) and high climate velocities (Figure 3.4, Section 3.2.2.1), as well as impacted by the shoaling of aragonite or calcite saturation horizon (Section 3.2.3.2). Significant differences in projected trends between the SSPs show that mitigation strategies will limit exposure of deep-sea ecosystems to potential warming, acidification and deoxygenation during the 21st century (*very high confidence*) (Figure 3.6, Kwiatkowski et al., 2020).

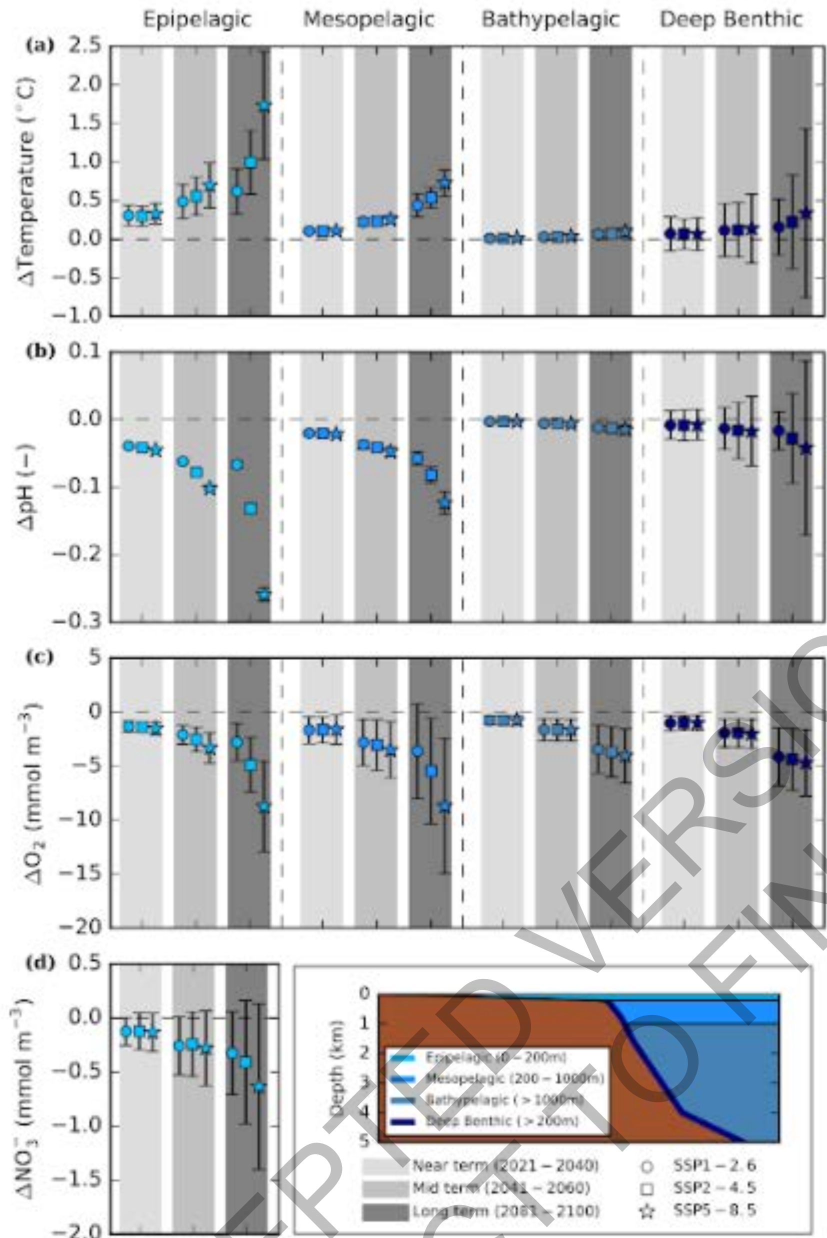

Figure 3.6: Projected trends across open-ocean systems. Projected annual and global (a) average warming, (b) acidification, (c) changes in dissolved oxygen concentrations and (d) changes in nitrate (NO_3) concentrations for four open-ocean systems, including the epipelagic (0–200 m depth), mesopelagic (200–1000 m), bathypelagic (>1000 m) domains, and deep benthic waters (>200 m). All projections are based on Coupled Model Intercomparison Project 6 models and for three Shared Socioeconomic Pathways (SSPs), SSP1-2.6, SSP2-4.5 and SSP5-8.5 (Kwiatkowski et al., 2020). Anomalies in the near-term (2020–2041), mid-term (2041–2060) and long-term (2081–2100) are all relative to 1985–2014. Error bars represent *very likely* ranges.

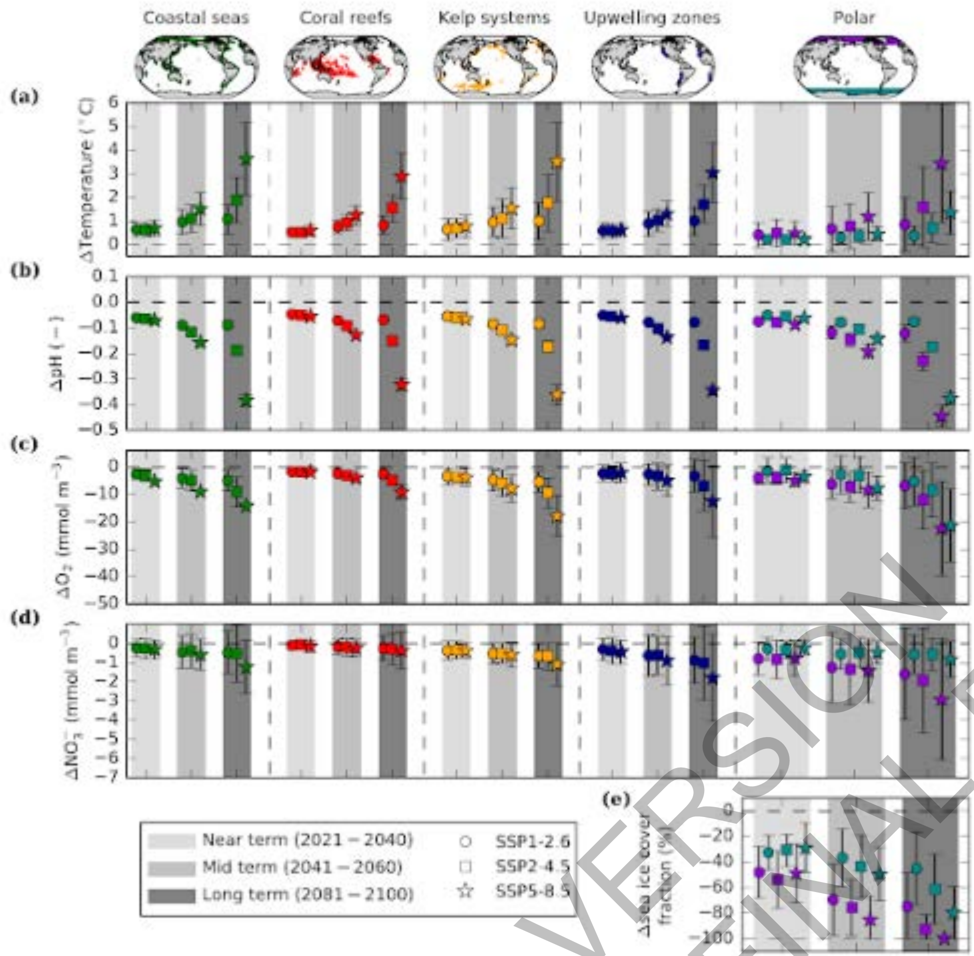

Figure 3.7: Projected trends across coastal-ocean ecosystems. Projected (a) warming, (b) acidification, (c) changes in dissolved oxygen concentrations, (d) changes in nitrate (NO_3) concentrations and (e) changes in summer sea ice cover fraction (September and north of 66°N for the Northern Polar Oceans, and March and south of 66°S for the Southern Polar Ocean) for five coastal-ocean ecosystems. All projected trends are for the surface ocean, except oxygen concentration changes that are computed for the subsurface ocean (100–600 m depth) for the upwelling ecosystems and the polar seas. All projections are based on Coupled Model Intercomparison Project 6 (CMIP6) models and for three Shared Socioeconomic Pathways (SSPs): SSP1-2.6, SSP2-4.5 and SSP5-8.5 (Kwiatkowski et al., 2020). Anomalies in the near-term (2020–2041), mid-term (2041–2060) and long-term (2081–2100) are all relative to 1985–2014. Error bars represent *very likely* ranges. Coastal seas are defined on a 1° × 1° grid when bathymetry is less than 200 m deep. Distribution of warm-water corals is from UNEP-WCMC et al. (2018). Distribution of kelp ecosystems is from OBIS (2020). Upwelling areas are defined according to Rykaczewski et al. (2015).

3.2.4.2 Time of Emergence

Anthropogenic changes in climatic impact-drivers assessed here exhibit vastly distinct times of emergence, which is the time scale over which an anthropogenic signal related to climate change is statistically detected to emerge from the background noise of natural climate for a specific region (Christensen et al., 2007; Hawkins and Sutton, 2012). SROCC concluded that for ocean properties, the time of emergence ranges from under a decade (e.g., surface ocean pH) to over a century (e.g., net primary production, see Section 3.4.3.3.4 for time of emergence of biological properties, Bindoff et al., 2019).

The literature assessed in SROCC mainly focused on surface ocean properties and gradual mean changes. Since then, the time of emergence has also been investigated for subsurface properties, ocean extreme events and particularly vulnerable regions, such as the Arctic Ocean (Hameau et al., 2019; Oliver et al., 2019; Burger et al., 2020; Landrum and Holland, 2020; Schlunegger et al., 2020), but subsequent assessments are *low confidence* due to *limited evidence*. Below the surface, changes in temperature typically emerge from internal variability prior to changes in oxygen. However in about a third of the global thermocline, deoxygenation emerges prior to warming (Hameau et al., 2019). Permanent MHW states, defined as when

SST exceeds the MHW threshold continuously over a full calendar year, will emerge during the 21st century in many parts of the surface ocean (Oliver et al., 2019). Ocean acidification extremes have already emerged from background natural internal variability during the 20th century in most of the surface ocean (Burger et al., 2020). In the Arctic, anthropogenic sea-ice changes have already emerged from the background internal variability, and anthropogenic alteration of air temperatures will emerge in the early- to mid-21st century (Landrum and Holland, 2020).

3.2.4.4 Perspectives from Paleo Data

Paleo observations are useful to assess multiple hazards of environmental change while excluding direct anthropogenic impacts (Section 3.4.3.3). Ancient intervals of rapid climate warming that occurred between 300 to 50 million years ago (Ma) were triggered by the release of greenhouse gases (*high confidence*). The sources of greenhouse gases varied but include volcanic degassing from continental flood basalts and methane hydrates stored in marine sediments and soils (Foster et al., 2018). Six extreme ancient hyperthermal events are known from the last 300 Ma, when tropical SSTs reached 1.5°C–10°C warmer than pre-industrial conditions, and with substantial impacts on ancient life (Cross-Chapter Box PALEO in Chapter 1). Warming and deoxygenation in the oceans were closely associated in hyperthermal events (*high confidence*), with anoxia reaching the photic zone and abyssal depths (Kaiho et al., 2014; Müller et al., 2017; Penn et al., 2018; Weissert, 2019), whereas ocean acidification has not been demonstrated consistently (*medium confidence*) (Hönisch et al., 2012; Penman et al., 2014; Clarkson et al., 2015; Harper et al., 2020a; Jurikova et al., 2020; Müller et al., 2020).

Greenhouse gases also contributed substantially to shaping the longer-term climate trends over the last 50 million years, although changes in continental configuration and ocean circulation as well as planetary orbital cycles were equally important (WGI AR6 Cross-Chapter Box 2.1, Westerhold et al., 2020; Gulev et al., 2021). There is little evidence for ocean acidification in the last 2.6 Ma (*low confidence*) (Hönisch et al., 2012), but ocean ventilation was highly sensitive to even modest warming such as observed in the last 10,000 years (*medium confidence*) (Jaccard and Galbraith, 2012; Lembke-Jene et al., 2018).

3.3 Linking Biological Responses to Climatic-Impact Drivers

3.3.1 Introduction

This section assesses new evidence since AR5 (Pörtner et al., 2014) and SROCC (Bindoff et al., 2019) regarding biotic responses to multiple environmental drivers. It assesses differential sensitivities among life stages within individual organisms, changing responses across scales of biological organisation and the potential for evolutionary adaptation to climate change (e.g., Przeslawski et al., 2015; Boyd et al., 2018; Reddin et al., 2020), providing examples and identifying key gaps and uncertainties that limit our ability to project the ecological impact of multiple climate-impact drivers (Figure 3.8a). The assessment includes physiological responses to single environmental drivers and their underlying mechanisms (Section 3.3.2), the characteristics of multiple drivers and organisms' responses to them (Section 3.3.3), short-term acclimation and longer-term evolutionary adaptation of populations (Section 3.3.4), and it concludes with an assessment of progress in upscaling laboratory findings to ecosystems within *in situ* settings (Figure 3.8b, Section 3.3.5).

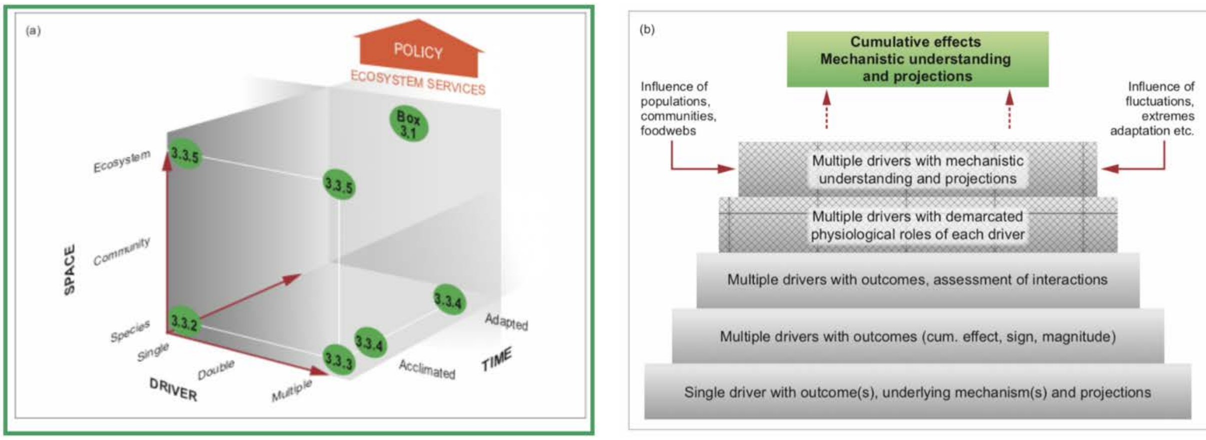

Figure 3.8: The state of knowledge regarding ecological responses to environmental drivers in experimental settings. (a) Schematic indicating where themes are discussed within Section 3.3, and how they jointly inform policy; adapted from Riebesell and Gattuso (2014). (b) The hierarchy of accumulating physiological knowledge (grey layers), from single (e.g., Pörtner et al., 2012) to multiple drivers, and from simple outcomes (e.g., Sciandra et al., 2003), interactions among drivers (e.g., Crain et al., 2008) and identification of physiological roles of drivers (e.g., Bach et al., 2015) to mechanistic understanding of drivers (e.g., Thomas et al., 2017). At present, the upper grey layer has been achieved, in full, for two drivers e.g., temperature and nutrient concentrations, with validation of dual controls on phytoplankton growth rate, Thomas et al. (2017). Hatched layers denote major advances since WGII AR5 Chapter 6 (Pörtner et al., 2014). The green layer indicates the level of understanding potentially needed to project the response of marine life subjected to multiple drivers. Red horizontal arrows indicate the influence of confounding factors on our current understanding, including population genetics, fluctuating oceanic conditions, or extreme events.

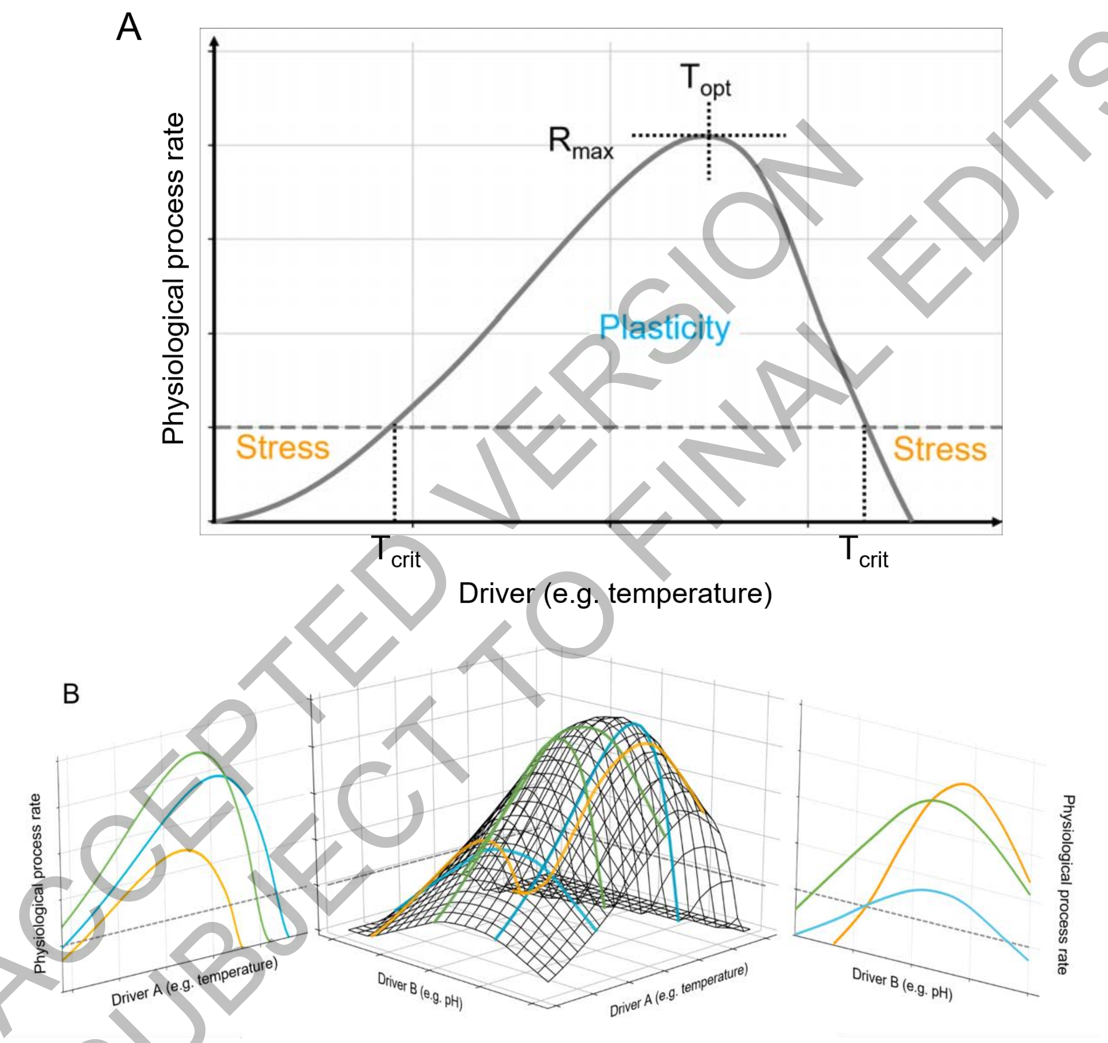
3.3.2 Responses to Single Drivers

Anthropogenic CO_2 emissions trigger a suite of changes that alter ocean temperature, pH and CO_2 concentration, oxygen concentration, and nutrient supply at global scales (Section 3.2). The response pathways of these climate-impact drivers have been investigated primarily as single variables.

Temperature affects the movement and transport of molecules and, thereby, the rates of all biochemical reactions. Thus, ongoing and projected warming (Section 3.2.2.1) that remains below an organism's physiological optimum will generally raise metabolic rates (*very high confidence*) (Pörtner et al., 2014). Beyond this optimum (T_{opt}, Figure 3.9), metabolism typically decreases sharply, finally reaching a critical threshold (T_{crit}) beyond which enzymes become thermally inactivated and cells undergo oxidative stress. Local and regional adaptation affect the heat tolerance thresholds of organisms. For example, organisms adapted to thermally-stable environments (e.g., tropical, polar, deep-sea) are often more sensitive to warming than those from thermally variable environments (e.g., estuaries) (*very high confidence*) (Section 3.4, Sunday et al., 2019; Collins et al., 2020). Heat tolerance also decreases with increasing organisational complexity (Storch et al., 2014; Pörtner and Gutt, 2016), and is lower in eggs, embryos and spawning fish than for their larval stages or adults outside the spawning season (*high confidence*) (Dahlke et al., 2020b). By altering physiological responses, projected changes in ocean warming (Section 3.2.2.1) will modify growth, migration, distribution, competition, survival and reproduction (*very high confidence*) (Messmer et al., 2017; Dahlke et al., 2018; Andrews et al., 2019; Pinsky et al., 2019; Anton et al., 2020).

Altered seawater carbonate chemistry (Section 3.2.3.1) affects specific processes to varying degrees. For example, higher CO_2 concentrations can increase photosynthesis and growth in some phytoplankton, macroalgal and seagrass species (*high confidence*) (Pörtner et al., 2014; Seifert et al., 2020; Zimmerman, 2021), while lower pH levels decrease calcification (*high confidence*) (Pörtner et al., 2014; Falkenberg et al., 2018; Doney et al., 2020; Fox et al., 2020; Reddin et al., 2020) or silicification (*low confidence*) (Petrou et al., 2019). Organisms' capacity to compensate for or resist acidification of internal fluids depends on their capacity for acid-base regulation, which differs due to organisms' wide-ranging biological complexity and adaptive abilities (*low* to *medium confidence*) (Vargas et al., 2017; Melzner et al., 2020). Detrimental impacts of acidification include decreased growth and survival, and altered development, especially in early life stages (*high confidence*) (Dahlke et al., 2018; Onitsuka et al., 2018; Hancock et al., 2020), along with lowered recruitment and altered behaviour in animals (Kroeker et al., 2013a; Wittmann and Pörtner, 2013; Clements and Hunt, 2015; Cattano et al., 2018; Esbaugh, 2018; Bednaršek et al., 2019; Reddin et al., 2020). For finfish, laboratory studies of behavioural and sensory consequences of ocean acidification showed mixed results (Rossi et al., 2018; Nagelkerken et al., 2019; Stiasny et al., 2019; Velez et al., 2019; Clark et al., 2020; Munday et al., 2020). Calcifiers are generally more sensitive to acidification (e.g., for growth and survival) than non-calcifying groups (*high confidence*) (Kroeker et al., 2013a; Wittmann and Pörtner, 2013; Clements and Hunt, 2015; Cattano et al., 2018; Bednaršek et al., 2019; Reddin et al., 2020; Seifert et al., 2020). For calcifying primary producers, including phytoplankton and coralline algae, ocean acidification has different, often opposing effects, for example, decreasing calcification while photosynthetic rates increase (*high confidence*) (Riebesell et al., 2000; Van de Waal et al., 2013; Bach et al., 2015; Cornwall et al., 2017b; Gafar et al., 2019).



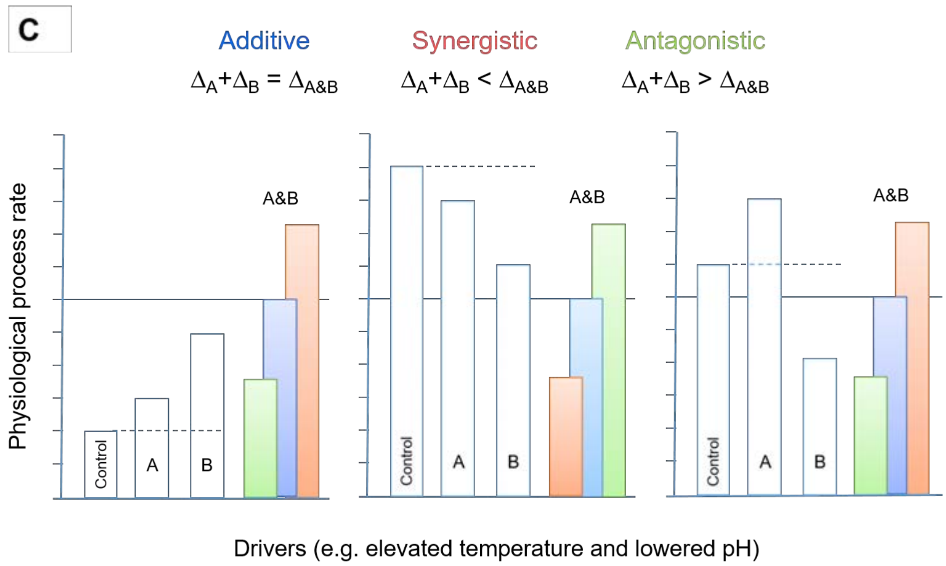


Figure 3.9: Organismal responses to single and multiple drivers. (a) The generic temperature-response curve describing physiological process rates as a nonlinear function of a particular driver (e.g., temperature) with maximum rates (R_{max}) and temperature optima (T_{opt}). The driver range that keeps physiological rates above a certain threshold represents the organism's range of phenotypic plasticity, while below that threshold, the critical temperature (T_{crit}), physiological performance is so low as to constitute stressful conditions. (b) The response curve for one driver can depend on other drivers, here exemplified for temperature and pH in the central panel. This interaction causes rates as well as optima to change with (left) pH and (right) temperature, indicated by the coloured lines. (c) Impacts of multiple drivers on processes can be (blue) additive, (red) synergistic or (green) antagonistic, that is, the cumulative effects of two (or more) drivers are equal to, larger than or smaller than the sum of their individual effects, respectively. Potential experimental outcomes affected by additive, synergistic, and antagonistic interactions are shown for scenarios where drivers (left) increase rates, (centre) decrease rates, or (right) cause opposite responses, showing how experimental outcomes can mask these mechanistic interactions. Adapted from Crain et al. (2008) and Piggott et al. (2015). For a quantitative analysis of effects of driver pairs on animals, see Figure SM3.2.

Oxygen concentrations affect aerobic and anaerobic processes, including energy metabolism and denitrification. Projected decreases in dissolved oxygen concentration (Section 3.2.3.2) will thus impact organisms and their biogeography in ways dependent upon their oxygen requirements (Deutsch et al., 2020), which are highest for large, multicellular organisms (Pörtner et al., 2014). The upper ocean generally contains high dissolved-oxygen concentrations due to air-sea exchange and photosynthesis, but in subsurface waters, deoxygenation may impair aerobic organisms in multiple ways (Oschlies et al., 2018; Galic et al., 2019; Thomas et al., 2019; Sampaio et al., 2021). Many processes contribute to lowered oxygen levels: altered ventilation and stratification; microbial respiration enhanced by nearshore eutrophication; and less oxygen solubility in warmer waters. For example, deoxygenation in highly eutrophic estuarine and coastal marine ecosystems (Section 3.4.2) can result from accelerated microbial activity, leading to acute organismal responses. Under hypoxia (oxygen concentrations ≤2 mg L–1, Limburg et al., 2020), physiological and ecological processes are impaired and communities undergo species migration, replacement and loss, transforming community composition (*very high confidence*) (Chu and Tunnicliffe, 2015; Gobler and Baumann, 2016; Sampaio et al., 2021). Hypoxia can lead to expanding OMZs which will favour specialised microbes and hypoxia-tolerant organisms (*medium confidence*) (Breitburg et al., 2018; Ramírez-Flandes et al., 2019). As respiration consumes oxygen and produces CO_2, lowered oxygen levels are often interlinked with acidification in coastal and tropical habitats (Rosa et al., 2013; Gobler and Baumann, 2016; Feely et al., 2018) and is an example of a compound hazard (Sections 3.2.4.1, 3.4.2.4).

Increased density stratification and mixed-layer shallowing, caused by warming, freshening and sea-ice decline, can alter light climate and nutrient availability within the surface mixed layer (*high confidence*) (Section 3.2.2.3). As light and nutrient levels drive photosynthesis, changes in these drivers directly affect primary producers, often in different directions (Matsumoto et al., 2014; Deppeler and Davidson, 2017). Decreased upward nutrient supply is expected to decrease primary production in the low-latitude ocean (*medium confidence*) (Section 3.4.4.2.1, Moore et al., 2018a; Kwiatkowski et al., 2019). Alternatively, higher mean underwater light levels resulting from changes in sea ice and/or mixed layer shallowing can increase primary production in high-latitude offshore regions, provided nutrient levels remain sufficiently high (*medium confidence*) (Section 3.4.4.2.1, Cross-Chapter Paper 6, Vancoppenolle et al., 2013; Deppeler and Davidson, 2017; Tedesco et al., 2019; Ardyna and Arrigo, 2020; Lannuzel et al., 2020). In some parts of the open Southern Ocean, where iron limitation largely controls primary productivity (Tagliabue et al., 2017), changes in wind fields will deepen the summer mixed-layer depth (Panassa et al., 2018), entrain more nutrients, and raise primary productivity in the future (*medium confidence*) (Cross-Chapter Paper 6, Hauck et al., 2015; Leung et al., 2015; Moore et al., 2018a; Kwiatkowski et al., 2020).

Climate-impact drivers fluctuate on time scales ranging from diurnal to annual, with potential consequences for organismal responses (Figure 3.10), but these fluctuations are commonly not incorporated experimentally. Experiments that simulate natural fluctuations in drivers, especially beyond tidal or diel cycles, can result in more detrimental impacts than those based on quasi-constant conditions (Eriander et al., 2015; Sunday et al., 2019), but can also ameliorate effects (Comeau et al., 2014; Laubenstein et al., 2020; Cabrerizo et al., 2021), confirming that the influence of environmental variability requires evaluation (Dowd et al., 2015). MHWs exacerbate the impacts of rising mean temperatures, with major ecological consequences (*very high confidence*) (Frölicher et al., 2018; IPCC, 2018; Arafeh-Dalmau et al., 2020; Laufkötter et al., 2020). Higher temperature variability decreased phytoplankton growth and calcification in *Emiliania huxleyi* relative to a stable warming regime (Wang et al., 2019b). Diel fluctuations (i.e., over 24 h) in carbonate chemistry superimposed on current and future pCO_2 levels influenced diatom species differently, depending on their habitat (Li et al., 2016). CO_2 fluctuations overlaid on changing mean values also altered phenotypic evolutionary outcomes of picoeukaryotic algae (Schaum et al., 2016). In the bivalve *Mytilus edulis*, fluctuating pH regimes exerted higher metabolic costs (Mangan et al., 2017), while salinity fluctuations might be more influential than pH fluctuations in other bivalves (Velez et al., 2016). The amplitude of diel and seasonal pH and CO_2 changes are projected to increase in the future due to lowered CO_2 seawater buffering capacity (*very high confidence*) (Section 3.2.3.1, Burger et al., 2020), which can impose additional stress on organisms.

3.3.3 Responses to Multiple Drivers

Each organism encounters a unique combination of local and climate-impact drivers, which vary in space and time. The contribution of these drivers to an organism's overall biological response, and thereby also potential risks for the organism, depends on the intensity and duration of its exposure to these drivers and associated sensitivities. Both geographical location (e.g., polar, tropical) and marine habitat (e.g., benthic, pelagic) strongly affect the combination of climate and non-climate drivers that organisms are exposed to. Non-climate drivers (Section 3.1) can dominate outcomes or amplify vulnerability to climate-impact drivers, with mostly detrimental effects such as extirpation (*very high confidence*) (Section 3.4, Boyd et al., 2018; Gissi et al., 2021), and unique feedbacks may exist between climate change and drivers like habitat loss or invasive species that further confound climate change effects (Ortiz et al., 2018; Wolff et al., 2018; Gissi et al., 2021). Individual responses are further influenced by an organism's behaviour, trophic level and life-history strategy (Figure 3.10, Przeslawski et al., 2015; Boyd et al., 2018). Evidence is increasing that some life-history stages are more sensitive to specific drivers than others (Dahlke et al., 2020b). To identify the most influential drivers for an organism requires targeting key traits (e.g., calcification, reproduction). The trophic level of the organism must also be considered, because autotrophs directly depend on light and nutrients while invertebrates are often more sensitive to changes in oxygen or altered prey, but temperature plays a key role for both groups (Figure 3.10b).

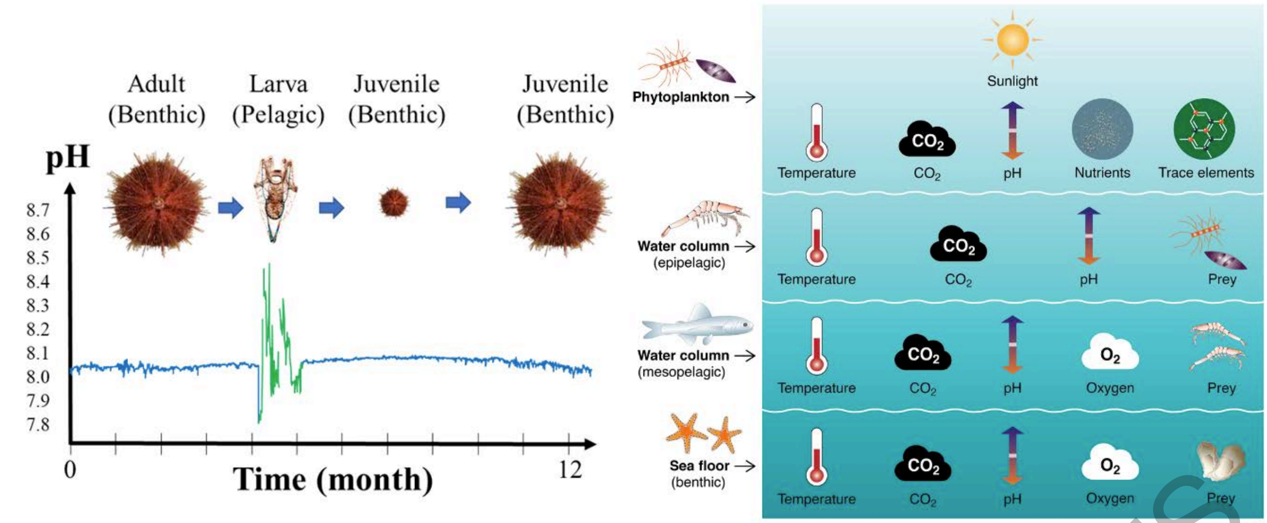

Figure 3.10: The effect of environmental drivers differs depending upon organisms' life history, and trophic strategy or habitat. (a) pH variability differs for benthic invertebrates, such as sea urchins (in blue), and their pelagic larvae (in green); pH fluctuations over the annual cycle can be much larger in the water column (due to primary production) relative to the seafloor. Variability associated with behaviour and life stage strongly defines organisms' niches and sensitivities to present and future conditions. (b) Examples of organisms that are influenced by different suites of drivers that are set jointly by their habitat (e.g., benthic versus epipelagic settings) and trophic strategy (e.g., nutrients for phytoplankton, prey characteristics for grazers).

Co-occurring environmental drivers often cause complex organismal responses (*high confidence*) (Pörtner et al., 2014). Individual drivers can have detrimental, neutral or beneficial effects, depending on the relationship between driver and physiological process (Section 3.3.2, Figure 3.9a). Multiple drivers can have interactive effects, where the response to one driver alters the sensitivity to another, and outcomes cannot be deduced from individual drivers' effects (Figure 3.9b). Impacts of multiple drivers can be additive, synergistic or antagonistic (Figure 3.9c, Crain et al., 2008; Piggott et al., 2015; Boyd et al., 2018; Bindoff et al., 2019). Well-controlled laboratory studies on multiple-driver effects have revealed insights into the mode of action of individual drivers and their interdependence (Kroeker et al., 2017; Gao et al., 2019; Reddin et al., 2020; Seifert et al., 2020; Green et al., 2021b; Sampaio et al., 2021). Understanding the outcomes of interactive drivers is important for robustly assessing risks to organisms under different climate-change scenarios.

3.3.3.1 *Effects of Multiple Drivers on Primary Producers*

Warming and rising CO_2 concentrations enhance growth and/or photosynthetic rates in many species of cyanobacteria, picoeukaryotes, coccolithophores, dinoflagellates and diatoms (*high confidence*) (Fu et al., 2007; Sett et al., 2014; Hoppe et al., 2018a; Wolf et al., 2018; Brandenburg et al., 2019), and the optimum pCO_2 for growth and/or primary production shifts upward under warming (*medium confidence*) (Sett et al., 2014; Hoppe et al., 2018a). Warming and ocean acidification appear to jointly favour the proliferation and toxicity of harmful algal bloom (HAB) species (*limited evidence, high agreement*) (Section 3.5.5.3, Bindoff et al., 2019; Brandenburg et al., 2019; Griffith et al., 2019a; Wells et al., 2020), but a 2021 analysis found no uniform global trend in HABs or their distribution over 1985–2018, once field data were adjusted for regional variations in monitoring effort (Hallegraeff et al., 2021). The predominantly detrimental impacts of ocean acidification on coccolithophores can partly be offset by warming (Seifert et al., 2020), but also be exacerbated, depending on the magnitudes of drivers (D'Amario et al., 2020). For non-calcifying macroalgae, responses are highly species-specific and often indicate synergistic interactions between warming and acidification (Kram et al., 2016; Falkenberg et al., 2018). Ocean acidification poses a large risk for coralline algae that is further amplified by warming (*medium confidence*) (Section 3.4.2.2, Cornwall et al., 2019). However, temperatures up to 5°C above ambient do not decrease calcification (Cornwall et al., 2019), and there is *limited evidence* that some species have the physiological capacity to resist acidification via pH upregulation at the calcification site (Cornwall et al., 2017a). For seagrass, warming beyond a species' thermal tolerance will limit growth and impact germination, but ocean acidification appears to increase thermal tolerance of some eelgrass species by increasing the photosynthesis-to-respiration ratio (*medium confidence*) (Egea et al., 2018; Scalpone et al., 2020; Zimmerman, 2021).

Thermal sensitivity of pelagic primary producers changes with nutrient supply (*high confidence*) (Thomas et al., 2017; Marañón et al., 2018; Fernández et al., 2020). Phosphorus limitation lowers the temperature optimum for growth of phytoplankton, making these organisms more prone to heat stress (Thomas et al., 2017; Bestion et al., 2018). This trend may hold for open-ocean phytoplankton, which are often iron-limited (*medium confidence*) (Boyd, 2019). Such temperature-nutrient interactions might be especially relevant during summer MHWs (Section 3.2.2.1, Cross-Chapter Box EXTREMES in Chapter 2, IPCC, 2018; Holbrook et al., 2019; DeCarlo et al., 2020; Hayashida et al., 2020), when primary producers are often nutrient-limited and near their thermal limits. Increasingly frequent and intense MHWs along with projected decreases in nutrient availability (Section 3.2.3.3) may push some primary producers beyond tolerance thresholds. Temperature-nutrient interactions can also alter the photosynthesis-to-respiration ratio in phytoplankton (Marañón et al., 2018). Overall, rising metabolic rates due to warming will be restricted to primary producers in high-nutrient regions (*medium confidence*) (Thomas et al., 2017; Marañón et al., 2018). For zooxanthellae-containing corals, nutrient supply from upwelling or from runoff can increase coral susceptibility to bleaching during warm-season MHWs (DeCarlo et al., 2020; Wooldridge, 2020).

The effects of ocean acidification on growth, metabolic rates or elemental composition of primary producers changes with nutrient availability and light conditions (*high confidence*) (Gao et al., 2019; Seifert et al., 2020). While interactions with nutrients are often additive in phytoplankton, diatoms revealed predominantly synergistic interactions (Seifert et al., 2020). Growth or photosynthesis of some diatom and HAB species, for instance, are stimulated by ocean acidification only if nutrients are replete (Hoppe et al., 2013; Boyd et al., 2015b; Eberlein et al., 2016; Griffith et al., 2019a). Interactions with light are more complex because relative effects of ocean acidification are larger under limiting irradiances, while saturating light levels decrease beneficial or detrimental effects on these processes (Kranz et al., 2010; Garcia et al., 2011; Rokitta and Rost, 2012; Heiden et al., 2016). For the coccolithophore *Emiliania huxleyi*, for example, the impacts of ocean acidification are less detrimental under high light availability, which could partly explain why this species is moving poleward (Winter et al., 2013; Kondrik et al., 2017; Neukermans et al., 2018), although acidification is more pronounced in polar waters (Section 3.2.3.1, Cross-Chapter Paper 6). Under excess light, however, the detrimental impacts of ocean acidification are amplified for many species (*high confidence*) (Gao et al., 2012; Li and Campbell, 2013; Zhang et al., 2015; Kottmeier et al., 2016; Gafar et al., 2019). Lowered photo-physiological capacity to cope with high-light stress and avoid photodamage (Gao et al., 2012; Li and Campbell, 2013; Hoppe et al., 2015; Kvernvik et al., 2020) is also consistent with observations that dynamic light regimes can become more stressful under ocean acidification (Jin et al., 2013; Hoppe et al., 2015). Given the expected mixed-layer shallowing in some regions (Section 3.2.2.3), the exposure to overall higher mean irradiances could shift the effects of acidification from beneficial to detrimental for some primary producers, depending on species and organismal traits (*medium confidence*) (Gao et al., 2019; Seifert et al., 2020).

Studies investigating two drivers provide most of the information on the wide range of interactive effects of drivers on phytoplankton (Gao et al., 2019; Seifert et al., 2020), although climate change alters several oceanic drivers concurrently (Section 3.2). The few experimental studies that have addressed three or more drivers (Xu et al., 2014; Boyd et al., 2015b; Brennan and Collins, 2015; Brennan et al., 2017; Hoppe et al., 2018b; Moreno-Marín et al., 2018) indicate that one or two drivers generally dominate the cumulative outcome, with others playing a subordinate role (*medium confidence*). In these studies, temperature had a disproportionately large influence, while other drivers differed in importance, depending on the type of primary producer, ecosystem characteristics and selected driver values.

3.3.3.2 Effects of Multiple Drivers on Animals

When changing CO_2 concentrations affect marine ectotherms, they typically combine additively or synergistically with warming (*medium confidence*) (e.g., Lefevre, 2016; Reddin et al., 2020; Sampaio et al., 2021), and their cumulative effects can lead to detrimental, neutral or beneficial effects (*high confidence*) (Figure 3.9a, Bennett et al., 2017; Büscher et al., 2017; Dahlke et al., 2017; Foo and Byrne, 2017; Johnson et al., 2017b; Cominassi et al., 2019). Higher ocean CO_2 influences the thermal tolerance of species adapted to extreme but stable habitats in tropical and polar regions, more than that of thermally tolerant generalists (*high confidence*) (Byrne et al., 2013; Schiffer et al., 2014; Flynn et al., 2015; Kunz et al., 2016; Pörtner et al., 2017; Kunz et al., 2018; Bindoff et al., 2019, but see) (Ern et al., 2017), especially in early life stages (Dahlke et al., 2020a). In thermal generalists from temperate and subtropical species, warming and ocean acidification generally have detrimental effects on growth and survival (e.g., Gao et al., 2020), but warming can also alleviate the detrimental effects of ocean acidification by increasing metabolic rate and/or growth (Garzke et al., 2020), provided that other conditions (e.g., thermal niche, food availability) are beneficial. For example, larval growth and survival of Australasian snapper (*Pagrus auratus*) appear to benefit from combined acidification and warming (but see Watson et al., 2018; McMahon et al., 2020), introducing major uncertainties to population modelling (Section 3.3.4, Parsons et al., 2020).

As with ocean acidification, reduced oxygen availability further alters the influence of warming on metabolic rates (*high confidence*). Acidification and hypoxia can contribute to a decrease or shift in thermal tolerance, while the magnitude of this effect depends on the duration of exposure (Tripp-Valdez et al., 2017; Cattano et al., 2018; Calderón-Liévanos et al., 2019; Schwieterman et al., 2019). Warming and hypoxia are mostly positively correlated and tolerance to both phenomena are often linked after long-term acclimation (e.g., Bouyoucos et al., 2020). Acute short-term heat shocks can impair hypoxia tolerance, for instance in intertidal fish (McArley et al., 2020). This is relevant for shallow waters, specifically for MHWs (Section 3.2.2.1, Hobday et al., 2016a; IPCC, 2018; Collins et al., 2019a). Ocean acidification can increase hypoxia tolerance in some cases, possibly by downregulating activity (Faleiro et al., 2015) and/or changing blood oxygenation (Montgomery et al., 2019). Other studies, however, reported additive negative effects of acidification and warming on hypoxia tolerance (Schwieterman et al., 2019; Götze et al., 2020), in line with the oxygen- and capacity-limited thermal tolerance (OCLTT) hypothesis presented in AR5 (Pörtner et al., 2014): warming causes increased metabolic rates and oxygen demand in ectotherms, which at some point exceed supply capacities (that also depend on environmental oxygen availability) and reduce aerobic scope. In consequence, expansion of OMZs and other regions where warming, hypoxia and acidification combine will further reduce habitat for many fish and invertebrates (*high confidence*) (Sections 3.4.3.2–3.4.3.3).

Food availability modulates, and may be more influential than, other driver responses by affecting the energetic and nutritional status of animals (Cole et al., 2016; Stiasny et al., 2019; Cominassi et al., 2020). Laboratory studies conducted under an excess of food risk underestimating the ecological effects of climate-impact drivers, because increased feeding rates may help mitigate adverse effects (Nowicki et al., 2012; Towle et al., 2015; Cominassi et al., 2020). Lowered food availability from reduced open-ocean primary production (Sections 3.2.3.3, 3.4.4.2.1) will act as an additional driver, amplifying the detrimental effects of other drivers. However, warming and higher CO_2 availability may increase primary productivity in some coastal areas (Section 3.4.4.1), ameliorating the adverse direct effects on animals (e.g., Sswat et al., 2018). Due to the few studies addressing food availability under multiple-driver scenarios (Thomsen et al., 2013; Pistevos et al., 2015; Towle et al., 2015; Ramajo et al., 2016; Brown et al., 2018a; Cominassi et al., 2020), there is *medium confidence* in its modulating effect on climate-impact driver responses.

Animal behaviour can be affected by ocean acidification, warming and hypoxia. While warming and hypoxia mostly induce avoidance behaviour, potentially leading to migration and habitat compression (Section 3.4, McCormick and Levin, 2017; Limburg et al., 2020), the effects of acidification appear more complex. Some studies reported that acidification dominates behavioural effects (Schmidt et al., 2017), although outcomes vary with experimental design and duration of exposure (*low confidence, low agreement*) (Maximino and de Brito, 2010; Munday et al., 2016; Laubenstein et al., 2018; Munday et al., 2019; Sundin et al., 2019; Clark et al., 2020; Munday et al., 2020; Williamson et al., 2021). Behaviour represents an integrated phenomenon that can be influenced both directly and indirectly by multiple drivers. For instance, increased pCO_2 can directly act on neuronal signalling pathways (e.g., Gamma-aminobutyric acid hypothesis, Nilsson et al., 2012; Thomas et al., 2020) and influence learning (Chivers et al., 2014), vision (Chung et al., 2014), and choice and escape behaviour (Watson et al., 2014; Wang et al., 2017b). There is further evidence that observed alterations in fish olfactory behaviour under ocean acidification may result from physiological and molecular changes of the olfactory epithelium, influencing olfactory receptors (Roggatz et al., 2016; Porteus et al., 2018; Velez et al., 2019; Mazurais et al., 2020). Temperature mainly drives metabolic processes and thus energetic requirements, which can indirectly influence behaviour, including increased risk-taking during feeding (Marangon et al., 2020). Ocean warming also accelerates the biochemical reactions and metabolic processes that are primarily influenced by acidification. It is therefore difficult to generalise to what extent co-occurring ocean warming ameliorates or exacerbates effects of acidification on behaviour (Laubenstein et al., 2019); outcomes depend upon species and life stage (Faleiro et al., 2015; Chan et al., 2016; Tills et al., 2016; Wang et al., 2018b; Jarrold et al., 2020), interactions between species (e.g., Paula et al., 2019) along with confounding factors including food availability and salinity (*medium confidence*) (Ferrari et al., 2015; Pistevos et al., 2015; Pimentel et al., 2016; Pistevos et al., 2017; Horwitz et al., 2020).

While hypoxia can dominate multiple-driver responses locally (Sampaio et al., 2021), warming is the fundamental physiological driver for most marine ectotherms, globally, as it directly affects their entire biochemistry and energy metabolism. Other influential drivers include ocean acidification, salinity (*high confidence*) (Lefevre, 2016; Whiteley et al., 2018; Reddin et al., 2020) or food availability/quality (*medium confidence*) (Nagelkerken and Munday, 2016; Gao et al., 2020). Fluctuating and decreasing salinity may aggravate the detrimental effects of warming and elevated CO_2, because dilution with freshwater lowers acid-base buffering capacity, resulting in lower pH and calcium carbonate saturation state (Dickinson et al., 2012; Shrivastava et al., 2019; Melzner et al., 2020).

3.3.4 Acclimation and Evolutionary Adaptation

Climate change is and will continue to be a major driver of natural selection, causing important changes in fitness-related (e.g., growth, reproduction, survival) and functional (e.g., body/cell size, morphology, physiology) traits, and in the genetic diversity of natural populations (*medium confidence*) (Pauls et al., 2013; Merilä and Hendry, 2014). Climate-change impacts will continue to be exacerbated by interactions with non-climate drivers such as habitat fragmentation or loss, pollution, or resource overexploitation, which limit the adaptive potential of populations to future conditions (Trathan et al., 2015; Gaitán-Espitia and Hobday, 2021). However the ultimate responses to complex change are conditioned by the rate and magnitude of environmental change, organisms' capacity for acclimation, the degree of local adaptation of natural populations, and populations' potential for adaptive evolution (Figure 3.11, Pespeni et al., 2013; Calosi et al., 2017; Vargas et al., 2017). These controlling factors are mainly determined by local environmental conditions encountered by populations across their geographical distribution (Boyd et al., 2016). In highly fluctuating environments (e.g., upwelling regions, coastal zones), multiple drivers can change and interact across temporal and spatial scales, generating geographical mosaics of tolerances and sensitivities to environmental and climate change in marine organisms (*medium confidence*) (Pespeni et al., 2013; Boyd et al., 2016; Vargas et al., 2017; Li et al., 2018a). A further challenge for marine life lies in its ability to cope with extreme events such as MHWs (Cross-Chapter Box EXTREMES in Chapter 2). The interplay between the abruptness, intensity, duration, magnitude and reoccurrence of extreme events may alter or prevent evolutionary responses (e.g., adaptation) to climate change and the potential for acclimation to extreme conditions such as MHWs (Cheung and Frölicher, 2020; Coleman et al., 2020a; Gurgel et al., 2020; Gruber et al., 2021).

Some studies have documented higher phenotypic plasticity and tolerance to ocean warming and acidification in marine invertebrates (Dam, 2013; Kelly et al., 2013; Pespeni et al., 2013; Gaitán-Espitia et al., 2017a; Vargas et al., 2017; Li et al., 2018a), seaweeds (Noisette et al., 2013; Padilla-Gamiño et al., 2016; Machado Monteiro et al., 2019), and fish (*medium confidence*) (Sandoval-Castillo et al., 2020; Enbody et al., 2021) living in coastal zones characterised by strong temporal fluctuations in temperature, pH, pCO_2, light and nutrients. For these populations, strong directional selection with intense and highly fluctuating conditions may have favoured local adaptation and increased tolerance to environmental stress (*low confidence, low evidence*) (Hong and Shurin, 2015; Gaitán-Espitia et al., 2017b; Li et al., 2018a).

Other mechanisms acting within and across generations can influence selection and inter-population tolerances to environmental and climate-impact drivers. For instance, transgenerational effects and/or developmental acclimation, both so-called "carry-over effects" (where the early-life environment affects the expression of traits in later life stages or generations), can influence within- and cross-generational changes in the tolerances of marine organisms (*medium confidence*) to ocean warming (Balogh and Byrne, 2020) and acidification (Parker et al., 2012). Over longer time scales, increasing tolerance to these drivers may be mediated by mechanisms such as transgenerational plasticity (Murray et al., 2014), leading to locally-adapted genotypes, as seen in bivalves (Thomsen et al., 2017), annelids (Rodríguez-Romero et al., 2016; Thibault et al., 2020), corals (Putnam et al., 2020), and coralline algae (Cornwall et al., 2020). However, transgenerational plasticity is species-specific (Byrne et al., 2020; Thibault et al., 2020) and, depending on the rate and magnitude of environmental change, it may either be insufficient for evolutionary rescue

(Morgan et al., 2020) or could induce maladaptive responses (i.e., reduced fitness) in marine organisms exposed to multiple drivers (*medium confidence, low evidence*) (Figure 3.11, Griffith and Gobler, 2017; Parker et al., 2017; Byrne et al., 2020).

Acclimation to environmental pressures and climate change via phenotypic plasticity (Section 3.3.3, Collins et al., 2020) enables species to undergo niche shifts, such that their present-day climatic niche is altered to incorporate new or shifted conditions (Fox et al., 2019). Although plasticity provides an adaptive mechanism, it is *unlikely* to provide a long-term solution for species undergoing sustained directional environmental change (e.g., global warming) (*medium confidence*) (Fox et al., 2019; Gaitán-Espitia and Hobday, 2021). Beyond the limits for plastic responses (Figure 3.9, DeWitt et al., 1998; Valladares et al., 2007), genetic adjustments are required to persist in a changing world (Figure 3.11, Fox et al., 2019). The ability of species and populations to undergo these adjustments (i.e., adaptive evolution) depends on extrinsic factors including the rate and magnitude of environmental change (important determinants of the strength and form of selection, Hoffmann and Sgrò, 2011; Munday et al., 2013), along with intrinsic factors such as generation times and standing genetic variation (Mitchell-Olds et al., 2007; Lohbeck et al., 2012). Accurately assessing the degree of acclimation and/or adaptation across space and time is difficult and constrains studying adaptive evolution in natural populations. There is a major gap in climate-change biology related to the study of evolutionary responses in complex and long-lived multicellular organisms. Insights on organismal acclimation, adaptation, and evolution rely on studies of small, short-lived marine organisms such as phytoplankton that divide rapidly and contain high genetic variation in large populations. (Schaum et al., 2016; Cavicchioli et al., 2019; Collins et al., 2020).

Experimental evolution suggests that microbial populations can rapidly adapt (i.e., over 1–2 years) to environmental changes mimicking projected effects of climate change (*medium confidence*). Phytoplankton adaptive mechanisms include intraspecific strain sorting and genetic changes (Bach et al., 2018; Hoppe et al., 2018b; Wolf et al., 2019). The evolutionary responses of microbes are conditioned by the number and characteristics of interacting drivers (*low confidence*) (Brennan et al., 2017). For example, in a high-salinity adapted strain of the phytoplankton *Chlamydomonas reinhardtii*, the selection intensity and the adaptation rate increased with the number of environmental drivers, accelerating the adaptive evolutionary response (Brennan et al., 2017). For this and other phytoplankton species, a few dominant drivers explain most of the phenotypic and evolutionary changes observed (Boyd et al., 2015a; Brennan and Collins, 2015; Brennan et al., 2017).

Adaptation can be impeded, delayed or constrained in eukaryotic microbial populations as a result of reduced genetic diversity, and/or the presence of functional and evolutionary trade-offs (Aranguren-Gassis et al., 2019; Lindberg and Collins, 2020; Walworth et al., 2020). In the marine diatom *Chaetoceros simplex*, a functional trade-off between high-temperature tolerance and increased nitrogen requirements underlies inhibited thermal adaptation under nitrogen-limited conditions (*low confidence*) (Aranguren-Gassis et al., 2019). When selection is strong due to unfavourable environmental conditions, microbial populations can encounter functional and evolutionary trade-offs evidenced by reducing growth rates while increasing tolerance and metabolism of reactive oxygen species (Lindberg and Collins, 2020). Other trade-offs can be observed in offspring quality and number (Lindberg and Collins, 2020). These findings contribute towards a mechanistic framework describing the range of evolutionary strategies in response to multiple drivers (Collins et al., 2020), but other hazards such as extreme events (e.g., MHWs) still need to be included because their characteristics may alter the potential for adaptation of species and populations to climate change (Gruber et al., 2021).

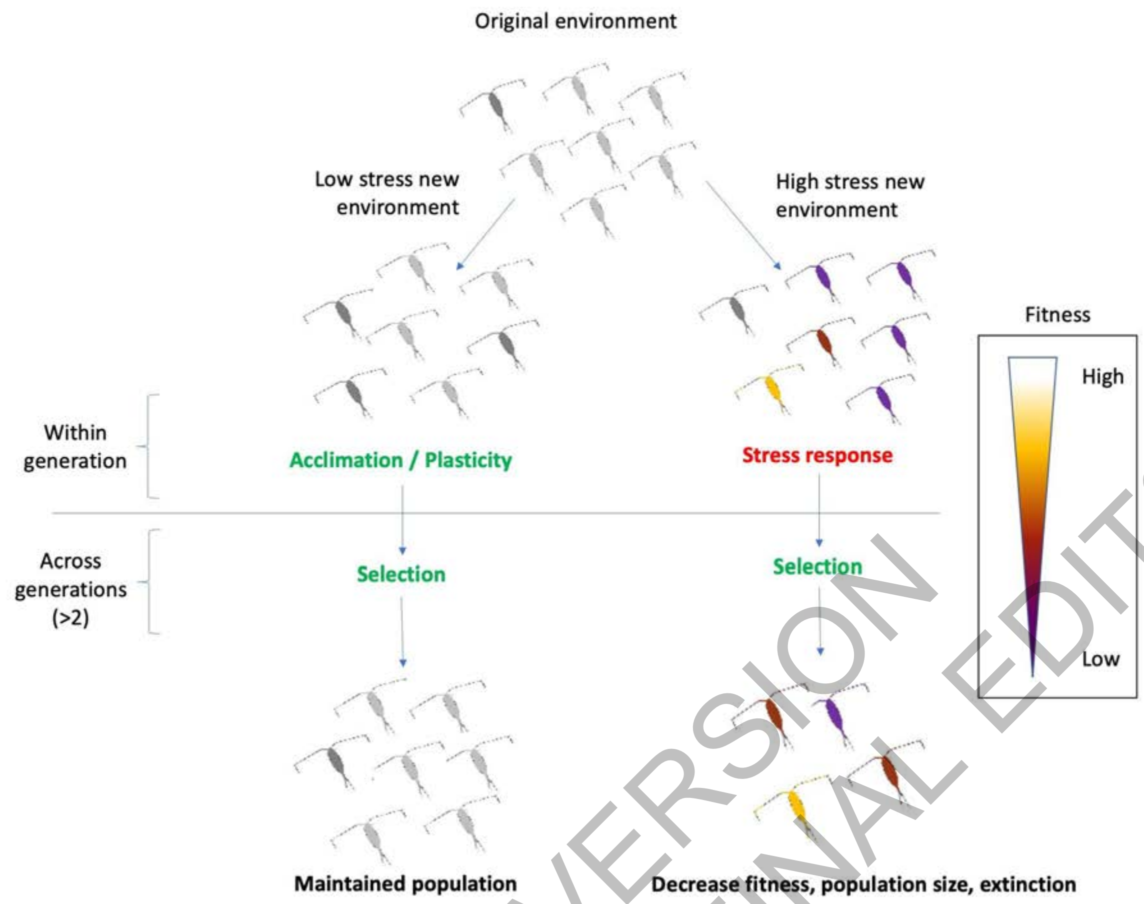

Figure 3.11: Micro-evolutionary dynamics in response to environmental change. Simplified conceptual framework shows two main eco-evolutionary trajectories for natural populations over time (vertical axis from top to bottom). If environmental stress is low, rapid responses (within a generation) through plastic phenotypic adjustments and selection (across generations) sustain fitness, enhancing maintenance of viable populations across generations. In contrast, if environmental stress is high, ongoing phenotypic plasticity and acclimation may be insufficient to buffer the negative effects, exacerbating the loss of fitness (change of colour to orange/yellow/red). Ultimately, very high stress conditions accelerate population decline, enhancing the risk of species extinction.

3.3.5 Ecological Response to Multiple Drivers

Assessing ecological responses to multiple climate-impact drivers requires a combination of approaches, including laboratory- and field-based experiments, field observations (e.g., natural gradients, climate analogues), study of paleo-analogues and the development of mechanistic and empirical models (Clapham, 2019; Gissi et al., 2021). Experimental studies of food-web responses are often limited to an individual driver, although recent manipulations have used a matrix of >1000-L mesocosms to explore ecological responses to both warming and acidification (Box 3.1, Nagelkerken et al., 2020). Hence, complementary approaches are needed to indirectly explore the mechanisms underlying ecosystem responses to global climate change (Parmesan et al., 2013). Observations from time series longer than modes of natural variability (i.e., decades) are essential for revealing and attributing ecological responses to climate change (e.g., Section 3.4, Barton et al., 2015b; Brun et al., 2019). Also, paleo records provide insights into the influence of multiple drivers on marine biota (Cross-Chapter Box PALEO in Chapter 1, Reddin et al., 2020). Specifically, associations between vulnerabilities and traits of marine ectotherms in laboratory experiments correspond with organismal responses to ancient hyperthermal events (*medium confidence*) (Reddin et al., 2020). This corroboration suggests that responses to multiple drivers inferred from the fossil record can help provide insights into the future status of functional groups and hence food webs under rapid climate change.

Multi-species and integrated end-to-end ecosystem models are powerful tools to explore and project outcomes to the often-interacting cumulative effects of climate change and other anthropogenic drivers (Section 3.1, Kaplan and Marshall, 2016; Koenigstein et al., 2016; Peck and Pinnegar, 2018; Tittensor et al., 2018; Gissi et al., 2021). These models can integrate some aspects of the knowledge accrued from manipulation experiments, paleo and contemporary observations, help test the relative importance of specific drivers and driver combinations, and identify synergistic or antagonistic responses (Koenigstein et al., 2016; Payne et al., 2016; Skogen et al., 2018; Tittensor et al., 2018). As these models are associated with wide-ranging uncertainties (SM3.2.2, Payne et al., 2016; Trolle et al., 2019; Heneghan et al., 2021) they cannot be expected to accurately project the trajectories of complex marine ecosystems under climate change. Hence, they are most useful for assessing overall trends and in particular for providing a plausible envelope of trajectories across a range of assumptions (Fulton et al., 2018; Peck et al., 2018; Tittensor et al., 2018). On a global scale, ecosystem models project a –5.7% ± 4.1% (*very likely range*) to –15.5% ± 8.5% decline in marine animal biomass with warming under SSP1-2.6 and SSP5-8.5, respectively, by 2080–2099 relative to 1995–2014, albeit with significant regional variation in both trends and uncertainties (*medium confidence*) (Section 3.4.34, Tittensor et al., 2021). Biological interactions may exacerbate or buffer the projected impacts. For instance, trophic amplification (strengthening of responses to climate-impact drivers at higher trophic levels), may result from combined direct and indirect food-web mediated effects (*medium confidence*) (Section 3.4.3.4, Lotze et al., 2019). Alternatively, compensatory species interactions can dampen strong impacts on species from ocean acidification, resulting in weaker responses at functional-group or community level than at species level (*medium confidence*) (Marshall et al., 2017; Hoppe et al., 2018b; Olsen et al., 2018; Gissi et al., 2021). Globally, the projected reduction of biomass due to climate-impact drivers is relatively unaffected by fishing pressure, indicating additive responses of fisheries and climate change (*low confidence*) (Lotze et al., 2019). Regionally, projected interactions of climate-impact drivers, fisheries and other regional non-climate drivers can be both synergistic and antagonistic, varying across regions, functional groups and species, and can cause non-linear dynamics with counterintuitive outcomes, underlining the importance of adaptations and associated trade-offs (*high confidence*) (Sections 3.5.3, 3.6.3.1.2, 4.5, 4.6, Weijerman et al., 2015; Fulton et al., 2018; Hansen et al., 2019; Trolle et al., 2019; Zeng et al., 2019; Holsman et al., 2020; Pethybridge et al., 2020; Gissi et al., 2021).

Given the limitations of individual ecological models discussed above, model intercomparisons, such as the Fisheries and Marine Ecosystem Model Intercomparison Project (Fish-MIP, Tittensor et al., 2018) show promise in increasing the robustness of projected ecological outcomes (Tittensor et al., 2018). Model ensembles include a greater number of relevant processes and functional groups than any single model and thus capture a wider range of plausible responses. Among the global Fish-MIP models, there is *high* (temperate and tropical areas) to *medium agreement* (coastal and polar regions) on the direction of change, but *medium* (temperate and tropical regions) to *low agreement* (coastal and polar regions) on magnitude of change (Lotze et al., 2019; Heneghan et al., 2021). Although model outputs are validated relative to observations to assess model skills (Payne et al., 2016; Tittensor et al., 2018), the Fish-MIP models under-represent some sources of uncertainty, as they often do not include parameter uncertainties, and do not usually include impacts of ocean acidification, oxygen loss, or evolutionary responses because there remains high uncertainty regarding the influences of these processes across functional groups. Ensemble model investigations like Fish-MIP have also identified gaps in our mechanistic understanding of ecosystems and their responses to anthropogenic forcing, leading to model improvement and more rigorous benchmarking. These investigations could inspire future targeted observational and experimental research to test the validity of model assumptions (Payne et al., 2016; Lotze et al., 2019; Heneghan et al., 2021). The state-of-the-art in such experimental research is presented in Box 3.1.

[START BOX 3.1 HERE]

Box 3.1: Challenges for Multiple-Driver Research in Ecology and Evolution

The majority of the examples in Section 3.3 are from studies mimicking projected conditions in the year 2100 that report the responses of an individual species or strain to multiple drivers. This powerful generic experimental approach has largely been restricted to single species because it is logistically complex to conduct experiments that straddle multiple trophic levels, and that also include more than two drivers (Figure Box3.1.1b); the need for multiple replicates, drivers, and treatment levels greatly increase the work required

(Parmesan et al., 2013; Boyd et al., 2018). It is challenging to apply this experimental approach to communities or ecosystems (Figure Box 3.1.1). To date, most research on community or ecosystem response to climate-impact drivers has been in large-volume (>10,000 L) mesocosms (Riebesell and Gattuso, 2014), or at natural analogues such as CO_2 seeps, in which only one driver (ocean acidification) is altered (see (4) in Figure Box 3.1.1). Only very recently have two drivers been incorporated into climate-change manipulation studies examining responses of primary producers to secondary consumers ((5) in Figure Box3.1.1a, Nagelkerken et al., 2020). Therefore, 'natural experiments' from the geological past (Reddin et al., 2020) provide insights into how food webs and their constituents respond to complex change involving multiple drivers. Contemporary observations are occasionally long enough (>5 decades) to capture community responses to complex climate change. For example, Brun et al. (2019) reported a shift in zooplankton community structure in the North Atlantic (1960–2014), with major biogeochemical ramifications.

Conducting sufficiently long manipulation experiments to study the effect of adaptation on organisms is equally difficult (Figure Box3.1.1b), with much research restricted to multi-year studies of the microevolution of fast-growing (>one division day^{-1}) phytoplankton species responding to single drivers (Lohbeck et al., 2012; Schaum et al., 2016). In a few experimental evolution studies, ((7) in Figure Box3.1.1a, Brennan et al., 2017), multiple drivers have been used, but none have used communities or ecosystems (Figure Box3.1.1b). Nevertheless, the fossil record provides *limited evidence* of adaptations to less rapid (relative to present-day) climate change (Jackson et al., 2018). Despite the need to explore ecological or biogeochemical responses to projected future ocean conditions, logistical challenges require that assessments of climate-change impacts at scales larger than mesocosms use large-scale, long-term *in situ* observational studies (as documented within Section 3.4).

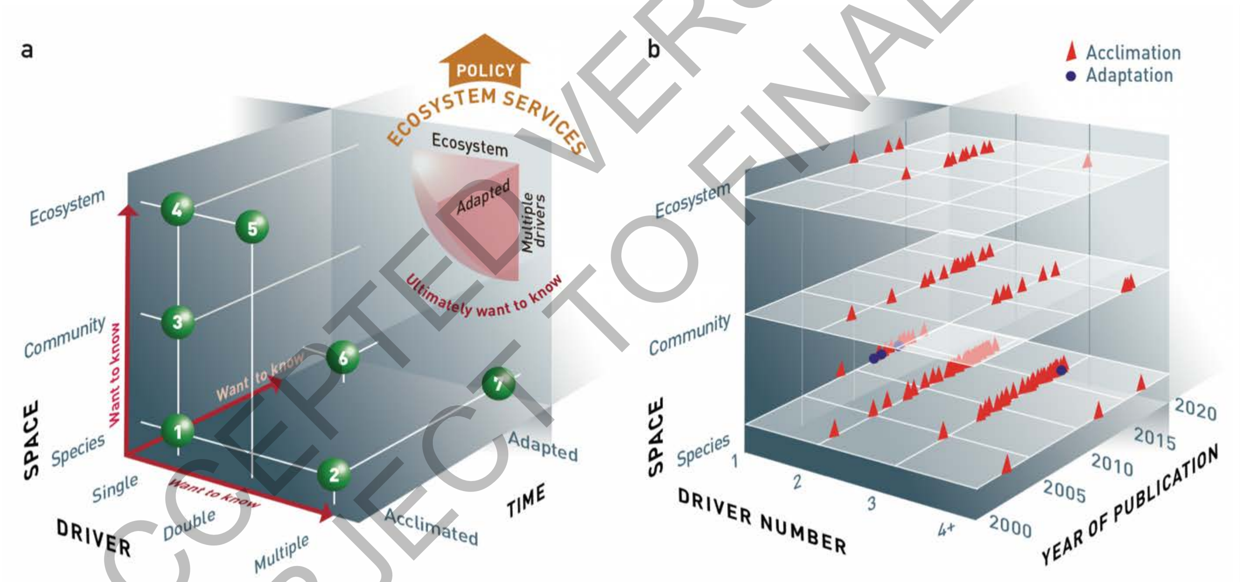

Figure Box 3.1.1: Knowledge gaps between current scientific understanding and that needed to inform policy. The conceptual space relating driver number, (Driver axis), ecological organisation (Space axis) and evolutionary acclimation state (Time axis), modified from Riebesell and Gattuso (2014). (a) Spheres indicate suites of studies that illustrate the progress of research, including multiple drivers (Sphere (1) one species and one driver, Hutchins et al. (2013) and (2) (one species and multiple drivers five, Boyd et al. (2015a)); ecology (Sphere (1) (one driver, one species), (3) (one driver, planktonic community, Moustaka-Gouni et al., 2016), (4) one driver (high-CO2 seep) and (benthic) ecosystem, Fabricius et al. (2014), and (5) two drivers and nearshore ecosystem, Nagelkerken et al. (2020)); and evolution (Sphere (1) (acclimated organism and one driver), (6) adapted organisms and one driver, Listmann et al. (2016) and (7) adapted organism and multiple drivers Brennan et al. (2017)). (b) Trends in research trajectories since 2000 from a survey of 171 studies, Boyd et al. (2018). Note the dominance of multiple-driver experiments at the species level (lower left cluster); the focus on acclimation (red triangle) rather than adaptation (blue dot); the focus of investigation on ≤3 drivers. Redrawn from Boyd et al. (2018).

[END BOX 3.1 HERE]

3.4 Observed and Projected Impacts of Climate Change on Marine Systems

3.4.1 Introduction

Ocean and coastal ecosystems and their resident species are under increasing pressure from a multitude of climate-impact drivers and non-climate drivers (Section 3.1, Figure 3.12, Bindoff et al., 2019). This section builds from the assessment of biological responses to climate-impact drivers (Section 3.3) to examine the new evidence about climate-change impacts at the level of marine ecosystems. It focuses on detection and attribution of observed changes to marine ecosystems and the projected changes under different future climate scenarios. This assessment considers emerging evidence on the effects of multiple non-climate drivers and physiological acclimation and/or evolutionary adaptation on these observations and projections.

The section focuses first on coastal ecosystems and seas (Section 3.4.2), which have high spatial variability in physical and chemical characteristics, are affected by many non-climate drivers (Section 3.1, Figure 3.12) and support rich fisheries, high biodiversity and high levels of species endemism. The assessment begins with warm-water coral reefs (Section 3.4.2.1) because these highly threatened systems are at the vanguard of research on acclimation and evolutionary adaptation among coastal ecosystems. It follows with the other shallow, nearshore ecosystems dominated by habitat-forming species (rocky shores, kelp systems) and then nearshore sedimentary systems (estuaries, deltas, coastal wetlands, and sandy beaches), before moving on to semi-enclosed seas, shelf seas, upwelling zones, and polar seas.

The section continues on to oceanic and cross-cutting changes (Section 3.4.3), which influence large areas of the epipelagic zone (<200 m depth), while also affecting the mesopelagic (200–1000 m), the perpetually dark bathypelagic (depth >1000 m) and the deep seafloor (benthic ecosystems at depths >200 m) zones. Assessed in this section are species range shifts (Section 3.4.3.1), phenological shifts and trophic mismatches (Section 3.4.3.2), changes in communities and biodiversity (Section 3.4.3.3.2), time of emergence of climate-impact signals in ecological systems from background natural variability (Section 3.4.3.3.4), and changes in biomass, primary productivity, and carbon export (Sections 3.4.3.4–3.4.3.6).

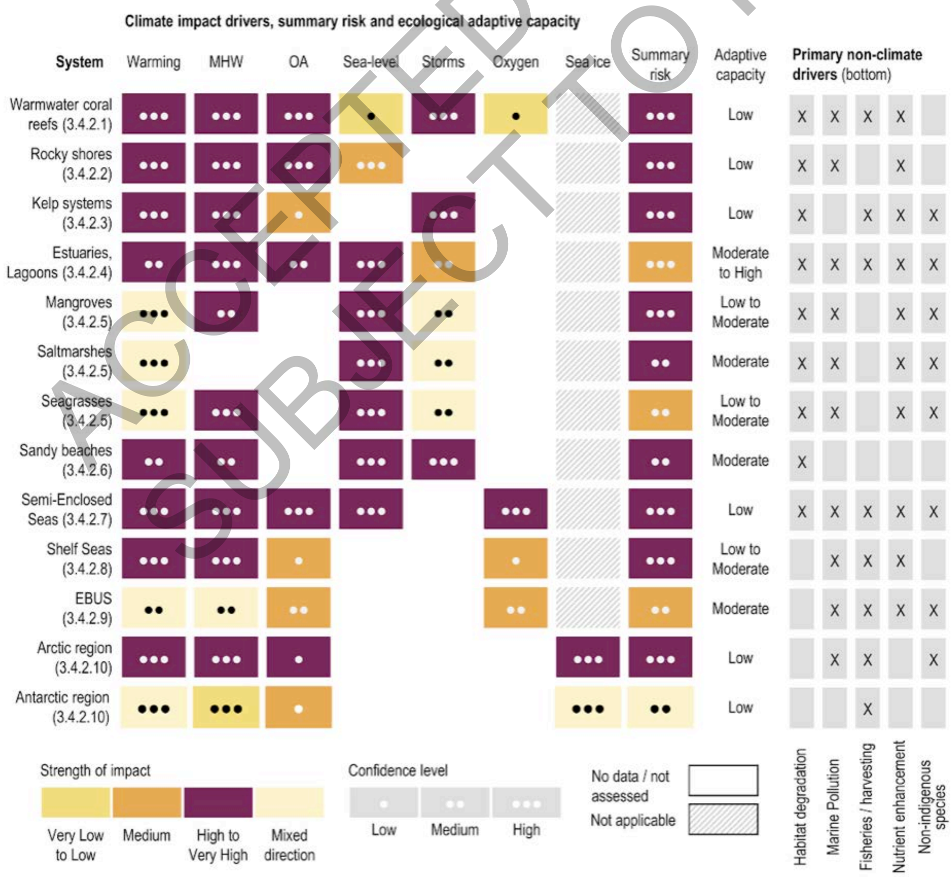

Figure 3.12: Summary assessment of observed hazards to coastal ecosystems and seas as assessed in Section 3.4.2.

3.4.2 Coastal Ecosystems and Seas

3.4.2.1 Warm-Water Coral Reefs

Warm-water coral reef ecosystems house one-quarter of the marine biodiversity and provide services in the form of food, income and shoreline protection to coastal communities around the world. These ecosystems are threatened by climate and non-climate drivers, especially ocean warming, MHWs, ocean acidification, SLR, tropical cyclones, fisheries/overharvesting, land-based pollution, disease spread and destructive shoreline practices (Hoegh-Guldberg et al., 2018a; Bindoff et al., 2019; Hughes et al., 2020). Warm-water coral reefs face near-term threats to their survival (Table 3.3), but research on observed and projected impacts is very advanced.

Table 3.3: Summary of previous IPCC assessments of coral reefs.

Observations	Projections
AR5 (Hoegh-Guldberg et al., 2014; Wong et al., 2014)	
Coral reefs are one of the most vulnerable marine ecosystems (*high confidence*), and more than half of the world's reefs are under medium or high risk of degradation. Mass coral bleaching and mortality, triggered by positive temperature anomalies (*high confidence*), is the most widespread and conspicuous impact of climate change. Ocean acidification reduces biodiversity and the calcification rate of corals (*high confidence*) while at the same time increasing the rate of dissolution of the reef framework (*medium confidence*). In summary, ocean warming is the primary cause of mass coral bleaching and mortality (*very high confidence*), which, together with ocean acidification, deteriorates the balance between coral reef construction and erosion (*high confidence*).	Coral bleaching and mortality will increase in frequency and magnitude over the next decades (*very high confidence*). Analysis of the Coupled Model Intercomparison Project 5 ensemble projects the loss of coral reefs from most sites globally by 2050 under mid to high rates of warming (*very likely*). Under the A1B scenario, 99% of the reef locations will experience at least one severe bleaching event between 2090 and 2099, with *limited evidence* and *low agreement* that coral acclimation and/or adaptation will limit this trend. The onset of global dissolution of coral reefs is at an atmospheric CO_2 of 560 ppm (*medium confidence*) and dissolution will be widespread in 2100 (Representative Concentration Pathway (RCP)8.5, *medium confidence*). A number of coral reefs could keep up with the maximum rate of sea-level rise (SLR) of 15.1 mm yr^{-1} projected for the end of the century, but lower net accretion and increased turbidity will weaken this capability (*very high confidence*).
SR15 (Hoegh-Guldberg et al., 2018a; IPCC, 2019c)	
Climate change has emerged as the greatest threat to coral reefs, with temperatures of just 1°C above the 1985–1993 long-term summer maximum for an area over 4–6 weeks being enough to cause mass coral bleaching and mortality (*very high confidence*). Predictions of back-to-back bleaching events have become reality over 2015-2017 as have projections of declining coral abundance (*high confidence*).	Multiple lines of evidence indicate that the majority (70–90%) of warm water (tropical) coral reefs that exist today will disappear even if global warming is constrained to 1.5°C (*very high confidence*). Coral reefs, for example, are projected to decline by a further 70–90% at 1.5°C (*high confidence*) with larger losses (>99%) at 2ºC (*very high confidence*).
SROCC (Bindoff et al., 2019)	
New evidence since AR5 and SR15 confirms the impacts of ocean warming and acidification on coral reefs (*high confidence*), enhancing reef dissolution and bioerosion (*high confidence*), affecting coral species distribution, and leading to community changes (*high confidence*). The rate	Coral reefs will face very high risk at temperatures 1.5ºC of global sea surface warming (*very high confidence*). Almost all coral reefs will degrade from their current state, even if global warming remains below 2ºC (*very high confidence*), and the remaining shallow coral reef

of SLR (primarily noticed in small reef islands) may outpace the growth of reefs to keep up, although there is *low agreement* in the literature (*low confidence*). Reefs are further exposed to other increased impacts, such as enhanced storm intensity, turbidity and increased runoff from the land (*high confidence*). Recovery of coral reefs resulting from repeated disturbance events is slow (*high confidence*). Only few coral reef areas show some resilience to global change drivers (*low confidence*).	communities will differ in species composition and diversity from present reefs (*very high confidence*). This will greatly diminish the services they provide to society, such as food provision (*high confidence*), coastal protection (*high confidence*) and tourism (*medium confidence*). The very high vulnerability of coral reefs to warming, ocean acidification, increasing storm intensity and SLR under climate, including enhanced bioerosion (*high confidence*), points to the importance of considering both mitigation and adaptation.

Global analyses published since AR5 show that mass coral bleaching events and disease outbreaks have increased due to more frequent and severe heat stress associated with ocean warming (*very high confidence, virtually certain*) (Donner et al., 2017; Hughes et al., 2018a; DeCarlo et al., 2019; Sully et al., 2019; Tracy et al., 2019). The mass coral bleaching, which occurred continuously across different parts of the tropics from 2014–2016, is considered the longest and most severe global coral bleaching event on record (Section 10.4.3, Box 15.2, Eakin et al., 2019). The Great Barrier Reef underwent mass bleaching three times between 2016–2020 (Box 11.2, Pratchett et al., 2021), validating past model projections that some warm-water coral reefs would encounter bleaching-level heat stress multiple times per decade by the 2020s (Hoegh-Guldberg, 1999; Donner, 2009).

Heat stress and mass bleaching events caused decreases in live coral cover (*virtually certain*) (Graham et al., 2014; Hughes et al., 2018b), loss of sensitive species (*extremely likely*) (Donner and Carilli, 2019; Lange and Perry, 2019; Toth et al., 2019; Courtney et al., 2020), vulnerability to disease (*extremely likely*) (van Woesik and Randall, 2017; Hadaidi et al., 2018; Brodnicke et al., 2019; Howells et al., 2020) and declines in coral recruitment in the tropics (*medium confidence*) (Hughes et al., 2019; Price et al., 2019). Recent observations also suggest that excess nutrients can increase the susceptibility of corals to heat stress (DeCarlo et al., 2020). Changes in coral community structure due to bleaching have caused declines in reef carbonate production (*high confidence*) (Perry and Morgan, 2017; Lange and Perry, 2019; Perry and Alvarez-Filip, 2019; Courtney et al., 2020; van Woesik and Cacciapaglia, 2021) and in reef structural complexity (*high confidence, very likely*) (Couch et al., 2017; Leggat et al., 2019; Magel et al., 2019), which increases water depth, reduces wave attenuation and increases coastal flood risk (Yates et al., 2017; Beck et al., 2018). Corals may also lose reproductive synchrony through climate change (Shlesinger and Loya, 2019), adding to their vulnerability. Bleaching and other drivers promote phase shifts to ecosystems dominated by macroalgae or other stress-tolerant species (*very high confidence*) (Graham et al., 2015; Stuart-Smith et al., 2018), leading to changes in reef-fish species assemblages (*high confidence*) (Richardson et al., 2018; Robinson et al., 2019a; Stuart-Smith et al., 2021).

Ocean acidification and associated declines in aragonite saturation state ($\Omega_{aragonite}$) decrease rates of calcification by corals and other calcifying reef organisms (*very high confidence*), reduce coral settlement (*medium confidence*) and increase bioerosion and dissolution of reef substrates (*high confidence*) (Hoegh-Guldberg et al., 2018a; Bindoff et al., 2019; Kline et al., 2019; Pitts et al., 2020). Warming can exacerbate the coral response to ocean acidification (Kornder et al., 2018) and accelerate the decrease in coral skeletal density (Guo et al., 2020). In addition, reefs with lower coral cover and a higher proportion of slow-growing species, because of bleaching, are more sensitive to acidification (net dissolution occurs $\Omega_{aragonite} = 2.3$ for 100% coral cover, and $\Omega_{aragonite} > 3.5$ for 30% coral cover, (Kline et al., 2019)). However, experimental evidence suggests that coral responses to ocean acidification are species-specific (*medium confidence*) (Fabricius et al., 2011; DeCarlo et al., 2018; Comeau et al., 2019). Evidence from experiments suggests that crustose coralline algae, which contribute to reef structure and integrity and may be resistant to warming at the RCP8.5 level by 2100 (Cornwall et al., 2019), are also sensitive to declines in $\Omega_{aragonite}$ (*high confidence*) (Section 3.4.2.3, Fabricius et al., 2015; Smith et al., 2020). The integrated effect of acidification, bleaching, storms and other non-climate drivers on corals, coralline algae and other calcifiers can further compromise reef integrity and ecosystem services (Rivest et al., 2017; Cornwall et al., 2018; Perry and Alvarez-Filip, 2019).

Since SROCC, there have been advances in experimental, field and modelling research on the projected response of coral cover and reef growth to bleaching and ocean acidification (Cziesielski et al., 2019; Morikawa and Palumbi, 2019; Cornwall et al., 2021; Klein et al., 2021; Logan et al., 2021; McManus et al., 2021), and on the effect of possible human interventions like assisted evolution on coral resilience (Section 3.6.3.2.2, Condie et al., 2021; Hafezi et al., 2021; Kleypas et al., 2021). New model projections incorporating physiological acclimation, larval dispersal, and evolutionary processes find limited ability to adapt this century at rates of warming at or exceeding that in RCP4.5 (*high confidence, very likely*) (Bay et al., 2017; Kubicek et al., 2019; Matz et al., 2020; McManus et al., 2020; Logan et al., 2021; McManus et al., 2021). For example, a global analysis (Logan et al., 2021) finds that increased thermal tolerance via evolution or switching to more stress-tolerant algal symbionts enable most (73–81%) coral to survive through 2100 under RCP2.6, but coral-dominated communities with a historical mix of coral taxa still disappear (0–8% coral survival) under RCP6.0 in simulations with adaptive mechanisms (Figure 3.13). Due to the impacts of warming, and to a lesser extent ocean acidification, global reef carbonate production is estimated to decline 71% by 2050 in SSP1-2.6, and the rate of SLR is estimated to exceed that of reef growth for 97% of reefs assessed, absent adaptation by corals and their symbionts (WGI AR6 Table 9.9, Cornwall et al., 2021; Fox-Kemper et al., 2021). The increased water depth due to coral loss and reef erosion, as well as reduced structural complexity, will limit wave attenuation and exacerbate the risk of flooding from SLR on reef-fringed shorelines and reef islands (Yates et al., 2017; Beck et al., 2018; Harris et al., 2018). Local coral reef fish species richness is projected to decline due to the impacts of warming on coral cover and diversity (*high confidence*), with declines up to 40% by 2060 in SSP5-8.5 (Strona et al., 2021).

These observed and projected impacts are supported by geological and paleo-ecological evidence showing a decline in coral reef extent and species richness under previous episodes of climate change and ocean acidification (Kiessling and Simpson, 2011; Pandolfi et al., 2011; Kiessling et al., 2012; Pandolfi and Kiessling, 2014; Kiessling and Kocsis, 2015). Major reef crises in the past 300 million years were governed by hyperthermal events (*medium confidence*) (Section 3.2.4.4, Cross-Chapter Box PALEO in Chapter 1) longer in timescale than anthropogenic climate change, during which net coral reef accretion was more strongly affected than biodiversity (*medium confidence*).

In response to the global-scale decline in coral reefs and high future risk, recent literature focuses on finding thermal refuges and identifying uniquely resilient species, populations or reefs for targeted restoration and management (Hoegh-Guldberg et al., 2018b). Reefs exposed to internal waves (Storlazzi et al., 2020), turbidity (Sully and van Woesik, 2020) or warm-season cloudiness (Gonzalez-Espinosa and Donner, 2021) are expected to be less sensitive to thermal stress. Mesophotic reefs (30–150 m) have also been proposed as thermal refugia (Bongaerts et al., 2010), although evidence from recent bleaching events, subsurface temperature records, and species overlap is mixed (Frade et al., 2018; Rocha et al., 2018b; Eakin et al., 2019; Venegas et al., 2019; Wyatt et al., 2020). A study of 2584 reef sites across the Indian and Pacific Oceans estimated that 17% had sufficient cover of framework-building corals to warrant protection, 54% required recovery efforts, and 28% were on a path to net erosion (Darling et al., 2019). There is *medium evidence* for greater bleaching resistance among reefs subject to temperature variability or frequent heat stress (Barkley et al., 2018; Gintert et al., 2018; Hughes et al., 2018a; Morikawa and Palumbi, 2019), but with trade-offs in terms of diversity and structural complexity (Donner and Carilli, 2019; Magel et al., 2019). There is *limited agreement* about the persistence of thermal tolerance in response to severe heat stress (Le Nohaïc et al., 2017; DeCarlo et al., 2019; Fordyce et al., 2019; Leggat et al., 2019; Schoepf et al., 2020). Recovery and restoration efforts that target heat-resistant coral populations and culture heat-tolerant algal symbionts have the greatest potential of effectiveness under future warming (*high confidence*) (Box 5.5 in SROCC Chapter 5, Bay et al., 2017; Darling and Côté, 2018; Baums et al., 2019; Bindoff et al., 2019; Howells et al., 2021); however, there is *low confidence* that enhanced thermal tolerance can be sustained over time (Section 3.6.3.3.2, Buerger et al., 2020). The effectiveness of active restoration and other specific interventions (e.g., reef shading) are further assessed in Section 3.6.3.3.2.

In sum, additional evidence since SROCC and SR15 (Table 3.3) finds that living coral and reef growth are declining due to warming and MHWs (*very high confidence*). Coral reefs are under threat of transitioning to net erosion with >1.5ºC of global warming (*high confidence*), with impacts expected to occur fastest in the Atlantic Ocean. The effectiveness of conservation efforts to sustain living coral area, coral diversity, and reef growth is limited for the majority of the world's reefs with >1.5ºC of global warming (*high confidence*) (Section 3.6.3.3.2, Hoegh-Guldberg et al., 2018b; Bruno et al., 2019; Darling et al., 2019).

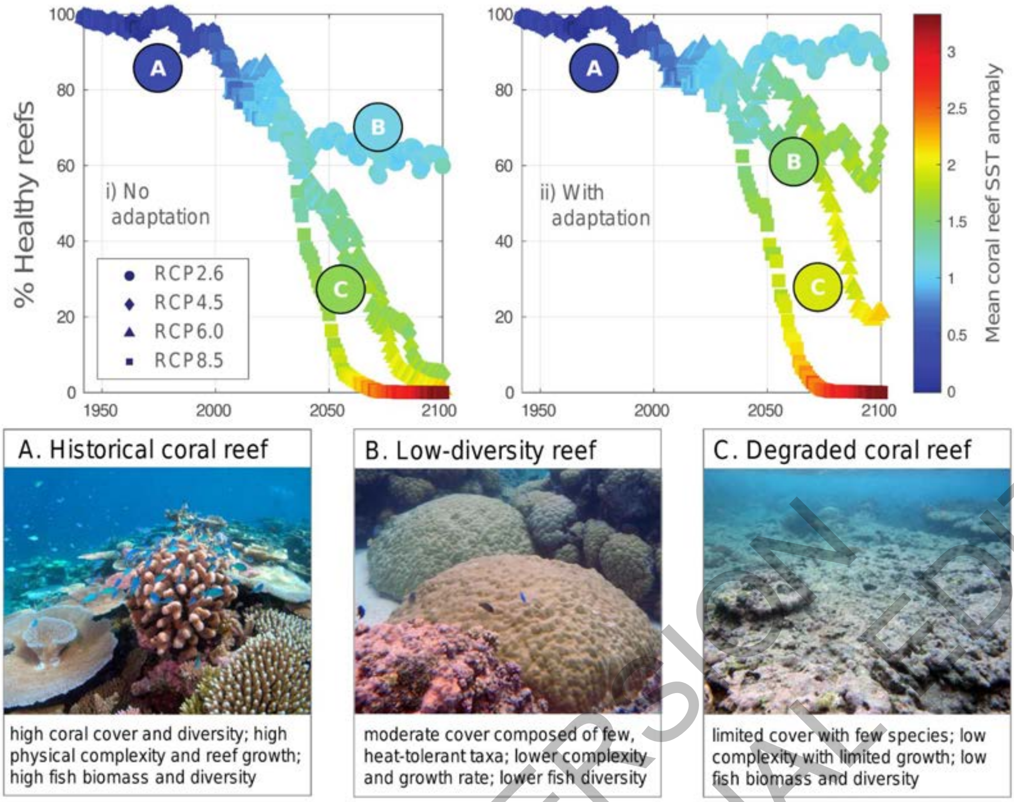

Figure 3.13: Coral reef futures, with and without adaptation. Graphs are based on a model of coral-symbiont evolutionary dynamics from (Logan et al., 2021), which simulates two coral types and symbiont populations for 1925 reef cells worldwide, from 1950–2100 drawn from simulations with National Oceanic and Atmospheric Administration-Geophysical Fluid Dynamics Laboratory Earth System Model (ESM2M) under four RCPs. Top panels show the simulated fraction of cells with healthy reefs, when both coral types are not in a state of severe bleaching or mortality, (i) without adaptive responses and (ii) with adaptive responses (symbiont evolution). Colours indicate maximum monthly sea-surface temperature increase across all reef cells, versus a 1861–2010 baseline. Panels (a,b,c) depict snapshots of coral reef conditions at time-points in the future each with different levels of warming, drawn from the model-projected cover of the two coral types, and from a literature assessment (Section 3.4.2.1, Hughes et al., 2018b; Bindoff et al., 2019; Darling et al., 2019; Leggat et al., 2019; Cornwall et al., 2021).

3.4.2.2 Rocky Shores

Rocky shore ecosystems refer to a range of temperate intertidal and shallow coastal ecosystems that are dominated by different foundational organisms, including mussels, oysters, fleshy macroalgae, hard and soft corals, coralline algae, bryozoans and sponges, which create habitat for species-rich assemblages of invertebrates, fish, marine mammals and other organisms. Rocky shores provide services including wave attenuation, habitat provision and food resources, and these support commercial, recreational, and Indigenous fisheries and shellfish aquaculture.

Observations since AR5 and SROCC (Table 3.4) find increased impacts of ocean warming on rocky shores. This includes extirpation of species at the warm edge of their ranges (Yeruham et al., 2015; Martínez et al., 2018), extension of poleward range boundaries (Sanford et al., 2019), mortality from climate extremes (Seuront et al., 2019), reduction in survival at shallower depths (Sorte et al., 2019; Wallingford and Sorte, 2019) and reorganisation of communities (Wilson et al., 2019; Mulders and Wernberg, 2020; Albano et al., 2021). Data collected after MHWs find ecological phase shifts (*moderate evidence, high agreement*) (e.g., California (Rogers-Bennett and Catton, 2019; McPherson et al., 2021)) and homogenisation of communities (*limited evidence*) (e.g., Alaska, (Weitzman et al., 2021)). For example, the collapse of sea star populations in the Northeast Pacific due to a MHW-related disease outbreak (Hewson et al., 2014; Menge et al., 2016; Miner et al., 2018; Schiebelhut et al., 2018), including 80–100% loss of the common predatory sunflower star, *Pycnopodia helianthoides* (*very high confidence*) (Harvell et al., 2019), triggered shifts from kelp- to urchin-dominated ecosystems (Schultz et al., 2016; Gravem and Morgan, 2017; McPherson et al., 2021).

Table 3.4: Summary of previous IPCC assessments of rocky shores.

Observations	Projections
AR5: (Wong et al., 2014)	
Rocky shores are among the better-understood coastal ecosystems in terms of potential impacts of climate variability and change. The most prominent effects are range shifts of species in response to ocean warming (*high confidence*) and changes in species distribution and abundance (*high confidence*) mostly in relation to ocean warming and acidification.	The abundance and distribution of rocky shore species will continue to change in a warming world (*high confidence*). For example, the long-term consequences of ocean warming on mussel beds of the northeast Pacific are both positive (increased growth) and negative (increased susceptibility to stress and of exposure to predation) (*medium confidence*).
The dramatic decline of biodiversity in mussel beds of the Californian coast has been attributed to large-scale processes associated with climate-related drivers (*high confidence*).	Observations performed near natural CO_2 vents in the Mediterranean Sea show that diversity, biomass, and trophic complexity of rocky shore communities will decrease at future pH levels (*high confidence*).
SR15 (Hoegh-Guldberg et al., 2018a)	
Changes in ocean circulation can have profound impacts on temperate marine ecosystems by connecting regions and facilitating the entry and establishment of species in areas where they were unknown before ('tropicalization') as well as the arrival of novel disease agents (*medium agreement, limited evidence*).	In the transition to 1.5°C, changes to water temperatures will drive some species (e.g., plankton, fish) to relocate to higher latitudes and for novel ecosystems to appear (*high confidence*). Other ecosystems (e.g., kelp forests, coral reefs) are relatively less able to move, however, and are projected to experience high rates of mortality and loss (*very high confidence*).
	In the case of 'less mobile' ecosystems (e.g., coral reefs, kelp forests, intertidal communities), shifts in biogeographical ranges may be limited, with mass mortalities and disease outbreaks increasing in frequency as the exposure to extreme temperatures have increased (*high agreement, robust evidence*)
SROCC (Bindoff et al., 2019)	
Intertidal rocky shores ecosystems are highly sensitive to ocean warming, acidification and extreme heat exposure during low tide emersion (*high confidence*).	Intertidal rocky shores are also expected to be at very high risk (transition above 3ºC) under the RCP8.5 scenario (*medium confidence*). These ecosystems have low to moderate adaptive capacity, as they are highly sensitive to ocean temperatures and acidification.
Sessile calcified organisms (e.g., barnacles and mussels) in intertidal rocky shores are highly sensitive to extreme temperature events and acidification (*high confidence*), a reduction in their biodiversity and abundance have been observed in naturally acidified rocky reef ecosystems (*medium confidence*).	Benthic species will continue to relocate in the intertidal zones and experience mass mortality events due to warming (*high confidence*). Interactive effects between acidification and warming will exacerbate the negative impacts on rocky shore communities, causing a shift towards a less diverse ecosystem in terms of species richness and complexity, increasingly dominated by macroalgae (*high confidence*).

Multiple lines of evidence find that foundational calcifying organisms such as mussels are at high risk of decline due to both the individual and synergistic effects of warming, acidification and hypoxia (*high confidence*) (Sunday et al., 2016; Sorte et al., 2017; Sorte et al., 2019; Newcomb et al., 2020). Warmer temperatures reduce mussel and barnacle recruitment (e.g., NW Atlantic (Petraitis and Dudgeon, 2020)) and the upper vertical limit of mussels (e.g., NE Pacific (Harley, 2011)) and (SW Pacific (Sorte et al., 2019)). Experiments show that ocean acidification negatively impacts mussel physiology (*very high confidence*), with evidence of reduced growth (Gazeau et al., 2010), attachment (Newcomb et al., 2020), biomineralisation (Fitzer et al., 2014) and shell thickness (Pfister et al., 2016; McCoy et al., 2018). Net calcification and abundance of mussels and other foundational species including oysters are expected to decline due to ocean acidification (*very high confidence*) (Kwiatkowski et al., 2016; Sunday et al., 2016; McCoy et al., 2018; Meng et al., 2018), causing the reorganisation of communities (*high confidence*) (Kroeker et al., 2013b; Linares et al., 2015; Brown et al., 2016; Sunday et al., 2016; Agostini et al., 2018; Teixidó et al., 2018). Experiments indicate that acidification can interact with warming and hypoxia to increase the detrimental effects on mussels (Gu et al., 2019; Newcomb et al., 2020). In regions where food is readily available to mussels, detrimental effects of ocean acidification may be dampened (Kroeker et al., 2016); however, recent findings are inconclusive (Brown et al., 2018a).

Coralline algae, foundational taxa that create habitat for sea urchins and abalone, form rhodolith beds in temperate to Arctic habitats, and bind together substrates, are expected to be highly susceptible to ocean acidification because they precipitate soluble magnesium calcite (Kuffner et al., 2008; Williams et al., 2021). Damage from acidification varies among species and regions, and can be due to direct physiological stress (Marchini et al., 2019) or interactions with non-calcifying competitors such as fleshy macroalgae (Smith et al., 2020). Experiments indicate that warming reduces calcification by coralline algae (*high confidence*) (Cornwall et al., 2019) and exacerbates the effect of acidification (Kim et al., 2020; Williams et al., 2021).

In contrast to warm-water coral reefs, there are no regional or global numerical models of rocky shore ecosystem response to projected climate change and acidification. Experiments suggest that existing genetic variation could be sufficient for some mussels (Bitter et al., 2019) and coralline algae (Cornwall et al., 2020) to adapt over generations to ocean acidification. Populations exposed to variable environments often have a greater capacity for phenotypic plasticity and resilience to environmental change (e.g., urchins (Gaitán-Espitia et al., 2017b) and coralline algae (Section 3.3.2, Rivest et al., 2017; Cornwall et al., 2018)). Although parental conditioning within and across generations is an acclimatisation mechanism to global change, there is *limited evidence* from experimental studies that this is applicable for marine invertebrates on rocky shores (Byrne et al., 2020).

This assessment concludes that MHWs, attributable to climate change (Section 3.2.2.1), can cause fatal disease outbreaks or mass mortality among some key foundational species (*high confidence*) and contribute to ecological phase shifts (*medium confidence*). The upper vertical limits of some species will also be constrained by climate change (*high confidence*). Experimental evidence since previous assessments further indicates that acidification decreases abundance and richness of calcifying species (*high confidence*), although there is *limited evidence* for acclimation in some species. Synergistic effects of warming and acidification will promote shifts toward macroalgal dominance in some ecosystems (*medium confidence*) and lead to reorganisation of communities (*medium confidence*).

3.4.2.3 Kelp Ecosystems

Kelp are temperate, habitat-forming marine macroalgae or seaweeds, mostly of the order *Laminariales*, which extend across one quarter of the world's coastlines (Assis et al., 2020; Jayathilake and Costello, 2020). The perennial species form dense underwater forest canopies and three-dimensional habitat that provides refuge for fish, crustaceans, invertebrates and marine mammals (Filbee-Dexter et al., 2016; Wernberg et al., 2019). Kelp ecosystems support fisheries, aquaculture, fertiliser, and food provision, including for local and Indigenous Peoples, along with regulating services in the form of wave attenuation and habitat provision. Kelp aquaculture can also buffer against local acidification (Xiao et al., 2021) and contribute to carbon storage (Froehlich et al., 2019).

Recent research (Straub et al., 2019; Butler et al., 2020; Filbee-Dexter et al., 2020b; Tait et al., 2021) supports the findings of previous assessments (Table 3.5) that kelp and other seaweeds in most regions are undergoing mass mortalities from high temperature extremes and range shifts from warming (*very high confidence*). Kelp are highly sensitive to the direct effect of high temperature on survival (Nepper-Davidsen et al., 2019) and indirect impact of temperature on herbivorous species (Ling, 2008; Vergés et al., 2016), upwelling and nutrient availability (Carr and Reed, 2015; Schiel and Foster, 2015). Synergies between warming, storms, pollution and intensified herbivory (due to removal or loss of predators including sea stars and otters that constrain herbivory by fish and urchin populations) can also cause physiological stress and physical damage in kelp, reducing productivity and reproduction (Rogers-Bennett and Catton, 2019; Beas-Luna et al., 2020; McPherson et al., 2021).

Table 3.5: Summary of previous IPCC assessments of kelp ecosystems.

Observations	Projections
AR5: (Wong et al., 2014)	
Kelp forests have been reported to decline in temperate areas in both hemispheres, a loss involving climate change (*high confidence*). Decline in kelp populations attributed to ocean warming has been reported in southern Australia and the North Coast of Spain.	Kelp ecosystems will decline with the increased frequency of heatwaves and sea temperature extremes as well as through the impact of invasive subtropical species (*high confidence*). Climate change will contribute to the continued decline in the extent of kelps in the temperate zone (*medium confidence*) and the range of kelp in the Northern Hemisphere will expand poleward (*high confidence*).
SR15 (Hoegh-Guldberg et al., 2018a) Observed movement of kelp ecosystems not assessed.	In the transition to 1.5°C, changes to water temperatures will drive some species (e.g., plankton, fish) to relocate to higher latitudes and for novel ecosystems to appear (*high confidence*). Other ecosystems (e.g., kelp forests, coral reefs) are relatively less able to move, however, and will experience high rates of mortality and loss (*very high confidence*).
SROCC (Bindoff et al., 2019)	
Kelp forests have experienced large-scale habitat loss and degradation of ecosystem structure and functioning over the past half century, implying a moderate to high level of risk at present conditions of global warming (*high confidence*). The abundance of kelp forests has decreased at a rate of ~2% yr^{-1} over the past half century, mainly due to ocean warming and marine heatwaves, as well as from other human stressors (*high confidence*). Changes in ocean currents have facilitated the entry of tropical herbivorous fish into temperate kelp forests decreasing their distribution and abundance (*medium confidence*). The loss of kelp forests is followed by the colonisation of turfs, which contributes to the reduction in habitat complexity, carbon storage and diversity (*high confidence*).	Kelp forests will face moderate to high risk at temperatures above 1.5ºC global sea surface warming (*high confidence*). Due to their low capacity to relocate and high sensitivity to warming, kelp forests are projected to experience higher frequency of mass mortality events as the exposure to extreme temperature rises (*very high confidence*). Changes in ocean currents have facilitated the entry of tropical herbivorous fish into temperate kelp forests decreasing their distribution and abundance (*medium confidence*). Kelp forests at low latitudes will continue to retreat due to intensified extreme temperatures, and their low dispersal ability will elevate the risk of local extinction under RCP8.5 (*high confidence*).

Trends in kelp abundance since 1950 are uneven globally (Krumhansl et al., 2016; Wernberg et al., 2019), with population declines (e.g., giant kelp *Macrocystis pyrifera* in Tasmania, (Butler et al., 2020), sugar kelp *Saccharina latissima* in the North Atlantic (Filbee-Dexter et al., 2020b)), more common than increases or no change (e.g., giant kelp *Macrocystis pyrifera* in southern Chile (Friedlander et al., 2020). Warming is driving range contraction and extirpation at the warm edge of species' ranges, and expansions at the cold range edge (*very high confidence*) (Smale, 2019; Filbee-Dexter et al., 2020b). Local declines in populations of kelp and other canopy-forming seaweeds driven by MHWs and other stressors have caused irreversible shifts to turf- or urchin-dominated ecosystems, with lower productivity and biodiversity (*high confidence*) (Filbee-Dexter and Scheibling, 2014; Filbee-Dexter and Wernberg, 2018; Rogers-Bennett and Catton, 2019; Beas-Luna et al., 2020; Stuart-Smith et al., 2021), ecosystems dominated by warm-affinity seaweeds or coral (*high confidence*) (Vergés et al., 2019), and loss of genetic diversity (Coleman et al., 2020a; Gurgel et al., 2020).

Species distribution models of kelp project range shifts and local extirpations with increasing levels of warming (Japan (Takao et al., 2015; Sudo et al., 2020)), (Australia (Table 11.6, Assis et al., 2018; Martínez et al., 2018; Castro et al., 2020)), (Europe (de la Hoz et al., 2019)), (North America (Wilson et al., 2019)), (South America (Figure 12.3)). There is *high agreement* on the direction but not the magnitude of change (Martínez et al., 2018; Castro et al., 2020), but effects of MHWs are not simulated. Where the length of higher-latitude coastlines is limited, range contractions are projected to occur, even with 2°C of global warming (i.e., SSP1-2.6) due to loss of habitat at the warm edge of species' ranges (Martínez et al., 2018). Poleward expansion of warm-affinity herbivores including urchins could further reduce warm-edge kelp populations (Castro et al., 2020; Mulders and Wernberg, 2020). Evidence from natural temperate CO_2 seeps suggests that ocean acidification at levels above those in RCP4.5 in 2100 could offset the increase in urchin abundance (Coni et al., 2021). Genetic analyses suggest that kelp populations at the midpoint of species' ranges will have lower tolerance of warming than implied by species distribution models, without assisted gene flow from warm-edge populations (King et al., 2019; Wood et al., 2021).

While reducing non-climate drivers can help prevent kelp loss from warming and MHWs, there is limited potential for restoration of kelp ecosystems after transition to urchin-dominant ecosystems (*high confidence*). Current restoration efforts are generally small-scale (<0.1 km^2) and less advanced than those in ecosystems like coral reefs (Coleman et al., 2020b; Eger et al., 2020; Layton et al., 2020). Although abundance of herbivores limits kelp populations, there is *limited evidence* that restoring predators of herbivores by creating marine reserves, or directly removing grazing species, will increase kelp forest resilience to warming and extremes (Vergés et al., 2019; Wernberg et al., 2019). Active reseeding of wild kelp populations through transplantation and propagation of warm-tolerant genotypes (Coleman et al., 2020b; Alsuwaiyan et al., 2021) can overcome low dispersal rates of many kelp species and facilitate effective restoration (*medium confidence*) (Morris et al., 2020c).

Building on the conclusions of SROCC, this assessment finds that kelp ecosystems are expected to decline and undergo changes in community structure in the future due to warming and increasing frequency and intensity of MHWs (*high confidence*). Risk of loss of kelp ecosystems and shifts to turf- or urchin-dominated ecosystems are highest at the warm edge of species' ranges (*high confidence*) and risks increase under RCP6.0 and RCP8.5 by the end of the century (*high confidence*).

3.4.2.4 Estuaries, Deltas and Coastal Lagoons

Estuaries, deltas and lagoons encounter environmental gradients over small spatial scales, generating diverse habitats that support myriad ecosystem services, including food provision, regulation of erosion, nutrient recycling, carbon sequestration, recreation and tourism, and cultural significance (D'Alelio et al., 2021; Keyes et al., 2021). Although these coastal ecosystems have historically been sensitive to erosion-accretion cycles driven by sea level, drought and storms (*high confidence*) (Peteet et al., 2018; Wang et al., 2018c; Jones et al., 2019b; Urrego et al., 2019; Hapsari et al., 2020; Zhao et al., 2020b), they were impacted for much of the 20th century primarily by non-climate drivers (*very high confidence*) (Brown et al., 2018b; Ducrotoy et al., 2019; Elliott et al., 2019; He and Silliman, 2019; Andersen et al., 2020; Newton et al., 2020; Stein et al., 2020). Nevertheless, the influence of climate-impact drivers has become more apparent over recent decades (*medium confidence*) (Table 3.6).

Table 3.6: Summary of previous IPCC assessments of estuaries, deltas and coastal lagoons.

Observations	Projections
AR5: (Wong et al., 2014)	
Humans have impacted lagoons, estuaries and deltas (*high to very high confidence*), but non-climate drivers have been the primary agents of change (*very high confidence*). In estuaries and lagoons, nutrient inputs have driven eutrophication, which has modified food-web structures (*high confidence*) and caused more-intense and longer-lasting hypoxia, more-frequent occurrence of harmful algal blooms, and enhanced emissions of nitrous oxide (*high confidence*).	Future changes in climate-impact drivers such as warming, acidification, waves, storms, sea-level rise (SLR), and runoff will have consequences for ecosystem function and services in lagoons and estuaries (*high confidence*), but with regional differences in magnitude of change in impact drivers and ecosystem response. Warming, changes in precipitation and changes in wind strength can interact to alter water-column salinity and

In deltas, land-use changes and associated disruption of sediment dynamics and land subsidence have driven changes that have been exacerbated by relative sea-level rise and episodic events including river floods and oceanic storm surges (*very high confidence*). Increased coastal flooding, erosion and saltwater intrusions have led to degradation of ecosystems (*very high confidence*).	stratification (*medium confidence*), which could impact water column oxygen content (*medium confidence*). Land-use change, SLR and intensifying storms will alter deposition-erosion dynamics, impacting shoreline vegetation and altering turbidity (*medium confidence*). Together with warming, these drivers will alter the seasonal pattern of primary production and the distribution of biota throughout the ecosystems (*medium to high confidence*), impacting associated ecosystem services. The projected impacts of climate change on deltas are associated mainly with pluvial floods and SLR, which will amplify observed impacts of interacting climate and non-climate drivers (*high confidence*).
SR15 (Hoegh-Guldberg et al., 2018a)	
Estuaries, deltas, and lagoons were not assessed in this report.	Under both a 1.5°C and 2°C of warming, relative to pre-industrial, deltas are expected to be highly threatened by SLR and localised subsidence (*high confidence*). The slower rate of SLR associated with 1.5°C of warming poses smaller risks of flooding and salinisation (*high confidence*), and facilitates greater opportunities for adaptation, including managing and restoring natural coastal ecosystems and infrastructure reinforcement (*medium confidence*). Intact coastal ecosystems may be effective in reducing the adverse impacts of rising sea levels and intensifying storms by protecting coastal and deltaic regions (*medium confidence*). Natural sedimentation rates are expected to be able to offset the effect of rising sea levels, given the slower rates of SLR associated with 1.5°C of warming (*medium confidence*). Other feedbacks, such as landward migration and the adaptation of infrastructure, remain important (*medium confidence*).
SROCC (Bindoff et al., 2019)	
Increased seawater intrusion caused by SLR has driven upstream redistribution of marine biotic communities in estuaries (*medium confidence*) where physical barriers such as the availability of benthic substrates do not limit availability of suitable habitats (*medium confidence*). Warming has driven poleward range shifts in species' distributions among estuaries (*medium confidence*). Interactions between warming, eutrophication and hypoxia have increased the incidence of harmful algal blooms (*high confidence*), pathogenic bacteria such as *Vibrio* species (*low confidence*), and mortalities of invertebrates and fish communities (*medium confidence*).	Salinisation and expansion of hypoxic conditions will intensify in eutrophic estuaries, especially in mid and high latitudes with microtidal regimes (*high confidence*). The effects of warming will be more pronounced in high-latitude and temperate shallow estuaries characterised by limited exchange with the open ocean and strong seasonality that already leads to development of dead zones (*medium confidence*). Interaction between SLR and changes in precipitation will have greater impacts on shallow than deep estuaries (*medium confidence*). Estuaries characterised by large tidal exchanges and associated well-developed sediments will be more resilient to projected SLR and changes in river flow (*medium confidence*). Human activities that inhibit sediment dynamics in coastal deltas increase their vulnerability to SLR (*medium confidence*).

Estuarine biota are sensitive to warming (*high confidence*), with recent responses including changes in abundance of some fish stocks (Erickson et al., 2021; Woodland et al., 2021), poleward shifts in distributions of fish species, communities and associated biogeographic transition zones (Table 12.3, Franco et al., 2020; Troast et al., 2020), recruits of warm-affinity species persisting into winter (Kimball et al., 2020), and changes in seasonal timing of peaks in species abundance (Kimball et al., 2020). MHWs can be more severe in estuaries than in adjacent coastal seas (Lonhart et al., 2019), causing conspicuous impacts (*very high confidence*), including mass mortality of intertidal vegetation (Section 3.4.2.5), range shifts in algae and animals (Lonhart et al., 2019), and reduced spawning success among invertebrates (Shanks et al., 2020).

RSLR extends the upstream limit of saline waters (*high confidence*) (Harvey et al., 2020; Jiang et al., 2020) and alters tidal ranges (*high confidence*) (Idier et al., 2019; Talke et al., 2020). Elevated water levels also alter submergence patterns for intertidal habitat (*high confidence*) (Andres et al., 2019), moving high-water levels inland (*high confidence*) (Peteet et al., 2018; Appeaning Addo et al., 2020; Liu et al., 2020e) and increasing the salinity of coastal water tables and soils (*high confidence*) (Eswar et al., 2021). These processes favour inland and/or upstream migration of intertidal habitat, where it is unconstrained by infrastructure, topography or other environmental features (*high confidence*) (Kirwan and Gedan, 2019; Parker and Boyer, 2019; Langston et al., 2020; Magolan and Halls, 2020; Saintilan et al., 2020). The spread of "ghost forests" along the North American east coast (Kirwan and Gedan, 2019) and elsewhere (Grieger et al., 2020) illustrates this phenomenon. Along estuarine shorelines, changing submergence patterns and upstream penetration of saline waters interact synergistically to stress intertidal plants, changing species composition and reducing above-ground biomass, in some cases favouring invasive species (Xue et al., 2018; Buffington et al., 2020; Gallego-Tévar et al., 2020). Overall, changing salinity and submergence patterns decrease the ability of shoreline vegetation to trap sediment (Xue et al., 2018), reducing accretion rates and increasing the vulnerability of estuarine shorelines to submergence by SLR and erosion by wave action (*medium confidence*) (Zhu et al., 2020b).

Drought and freshwater abstraction can reduce freshwater inflows to estuaries and lagoons, increasing salinity, reducing water quality (Brooker and Scharler, 2020) and depleting resident macrophyte communities (Scanes et al., 2020b). Changes in freshwater input and SLR, combined with land-use change, can alter inputs of land-based sediments, causing expansion (Suyadi et al., 2019; Magolan and Halls, 2020) or contraction (Andres et al., 2019; Appeaning Addo et al., 2020; Li et al., 2020b) of intertidal habitats. The same phenomena alter salinity gradients, which are the primary drivers of estuarine species distributions (*high confidence*) (Douglass et al., 2020; Lauchlan and Nagelkerken, 2020). Extreme reduction of freshwater input can extend residence time of estuarine water, leading to persistent HABs (Lehman et al., 2020) and converting estuaries to lagoons if the mouth clogs with sediment (Thom et al., 2020).

Acidification of estuarine water is a growing hazard (*medium confidence*) (Doney et al., 2020; Scanes et al., 2020a; Cai et al., 2021), and resident organisms display sensitivity to altered pH in laboratory settings (*medium confidence*) (Young et al., 2019a; Morrell and Gobler, 2020; Pardo and Costa, 2021). However, attribution of the biological effects of acidification is difficult because many biogeochemical processes affect estuarine carbon chemistry (Sections 3.2.3.1, 3.3.2). Warming can exacerbate the impacts of both acidification and hypoxia on estuarine organisms (Baumann and Smith, 2018; Collins et al., 2019b; Ni et al., 2020). These effects are further complicated by eutrophication, with high nitrogen loads associated with lower pH (Rheuban et al., 2019). Warming (including MHWs) and eutrophication interact to decrease estuarine oxygen content and pH, increasing the vulnerability of animals to MHWs (Brauko et al., 2020), and exacerbating the incidence and impact of dead zones (*medium confidence*) (Altieri and Gedan, 2015). The impacts of storms on estuaries are variable and are described in SM3.3.1.

All these impacts are projected to escalate under future climate change, but their magnitude depends on the amount of warming, the socio-economic development pathway, and implementation of adaptation strategies (*medium confidence*). Modelling studies (Lopes et al., 2019; Rodrigues et al., 2019; White et al., 2019; Zhang and Li, 2019; Hong et al., 2020; Krvavica and Ružić, 2020; Liu et al., 2020e; Shalby et al., 2020) suggest that responses of estuaries to SLR will be complex and context dependent (Khojasteh et al., 2021), but project that salinity, tidal range, storm-surge amplitude, depth and stratification will increase with SLR (*medium confidence*), and that marine-dominated waters will penetrate farther upstream (*high confidence*). Without careful management of freshwater inputs, sediment augmentation and/or the restoration of shorelines to more natural states, transformation and loss of intertidal areas and wetland vegetation will increase with SLR (*high confidence*) (Doughty et al., 2019; Leuven et al., 2019; Yu et al., 2019; Raw et al., 2020; Shih, 2020; Stein et al., 2020), with small, shallow microtidal estuaries being more vulnerable to impacts than deeper estuaries with well-developed sediments (*medium confidence*) (Leuven et al., 2019; Williamson and Guinder, 2021). Warming and MHWs will enhance stratification and deoxygenation in shallow lagoons (*medium confidence*) (Derolez et al., 2020) and will continue to drive range shifts among estuarine biota (*medium confidence*) (Veldkornet and Rajkaran, 2019; Zhang et al., 2020c), resulting in extirpations where thermal habitat is lost and potentially generating new habitat for warm-affinity species (*limited evidence, medium agreement*) (Veldkornet and Rajkaran, 2019).

3.4.2.5 Vegetated Blue Carbon Ecosystems

Mangroves, saltmarshes and seagrass beds (wetland ecosystems) are considered "blue carbon" ecosystems due to their capacity to accumulate and store organic-carbon rich sediments (Box 3.4, Macreadie et al., 2019; Rogers et al., 2019) and provide an extensive range of other ecosystem services (Box 3.4). Because these ecosystems are often found within estuaries and along sheltered coastlines, they share vulnerabilities, climate-impact (Table 3.7) and non-climate drivers with estuaries and coastal lagoons (Section 3.4.2.4).

Table 3.7: Summary of previous IPCC assessments of mangroves, saltmarshes and seagrass beds.

Observations	Projections
AR5: (Wong et al., 2014)	
Seagrasses occurring close to their upper thermal limits are already stressed by climate change (*high confidence*). Increased CO_2 concentrations have increased seagrass photosynthetic rates by 20% (*limited evidence, high agreement*).	Climate change will drive ongoing declines in the extent of seagrasses in temperate waters (*medium confidence*) as well as poleward range expansions of seagrasses and mangroves, especially in the Northern Hemisphere (*high confidence*). Beneficial effects of elevated CO_2 will increase seagrass productivity and carbon burial rates in salt marshes during the first half of the 21st century, but there is *limited evidence* that this will improve their survival or resistance to warming. As a result, interactions between climate change and non-climate drivers will continue to cause declines in estuarine vegetated systems (*very high confidence*).
SR15 (Hoegh-Guldberg et al., 2018a)	
Vegetated blue carbon systems were not assessed in this report.	Intact wetland ecosystems can reduce the adverse impacts of rising sea levels and intensifying storms by protecting shorelines (*medium confidence*) and their degradation could reduce remaining carbon budgets by up to 100 $GtCO_2$. Under 1.5°C of warming, natural sedimentation rates are projected to outpace SLR (*medium confidence*), but other feedbacks, such as landward migration of wetlands and the adaptation of infrastructure, remain important (*medium confidence*).
SROCC (Bindoff et al., 2019; Oppenheimer et al., 2019)	
Coastal ecosystems, including saltmarshes, mangroves, vegetated dunes and sandy beaches, can build vertically and expand laterally in response to SLR, though this capacity varies across sites (*high confidence*). These ecosystems provide important services that include coastal protection and habitat for diverse biota. However, because of human actions that fragment wetland habitats and	Seagrass meadows (*high confidence*) will face moderate to high risk at temperature above 1.5°C global sea surface warming. The transition from undetectable to moderate risk in salt marshes takes place between 0.7°C–1.2°C of global sea surface warming (*medium* to *high confidence*), and

restrict landward migration, coastal ecosystems progressively lose their ability to adapt to climate-induced changes and provide ecosystem services, including acting as protective barriers (*high confidence*).

Warming and SLR-driven salinisation of wetlands are causing shifts in the distribution of plant species inland and poleward. Examples include mangrove encroachment into subtropical salt marshes (*high confidence*) and contraction in extent of low-latitude seagrass meadows (*high confidence*).

Plants with low tolerance to flooding and extreme temperatures are particularly vulnerable, increasing the risk of extirpation (*medium confidence*).

Extreme weather events, including heatwaves, droughts and storms, are causing mass mortalities and changes in community composition in coastal wetlands (*high confidence*).

Severe disturbance of wetlands or transitions among wetland community types can favour invasive species (*medium confidence*).

The degradation or loss of vegetated coastal ecosystems reduces carbon storage, with positive feedbacks to the climate system (*high confidence*).

between 0.9°C–1.8°C (*medium confidence*) in sandy beaches, estuaries and mangrove forests.

The ecosystems at moderate to high risk under future emission scenarios are mangrove forests (transition from moderate to high risk at 2.5°C–2.7°C of global sea surface warming), estuaries and sandy beaches (2.3°C–3.0°C) and salt marshes (transition from moderate to high risk at 1.8°C–2.7°C and from high to very high risk at 3.0°C–3.4°C) (*medium confidence*).

Global coastal wetlands will lose between 20–90% of their area depending on emissions scenario with impacts on their contributions to carbon sequestration and coastal protection (*high confidence*).

Estuarine wetlands will remain resilient to modest rates of SLR where their sediment dynamics are unconstrained. But SLR and warming are projected to drive global loss of up to 90% of vegetated wetlands by the end of the century under the RCP8.5 (*medium confidence*), especially if landward migration and sediment supply are limited by human modification of shorelines and river flows (*medium confidence*).

Moreover, pervasive coastal squeeze and human-driven habitat deterioration will reduce the natural capacity of these ecosystems to adapt to climate impacts (*high confidence*).

Since AR5 and SROCC, syntheses have emphasised that the vulnerability of rooted wetland ecosystems to climate-impact drivers is exacerbated by non-climate drivers (*high confidence*) (Elliott et al., 2019; Ostrowski et al., 2021; Williamson and Guinder, 2021) and climate variability (*high confidence*) (Day and Rybczyk, 2019; Kendrick et al., 2019; Shields et al., 2019). Global rates of mangrove loss have been extensive but are slowing (*high confidence*) at least partially due to management interventions (Friess et al., 2020b; Goldberg et al., 2020). From 2000 to 2010 mangrove loss averaged 0.16% yr^{-1}, globally, but with greatest loss in Southeast Asia (*high confidence*) (Hamilton and Casey, 2016; Friess et al., 2019; Goldberg et al., 2020), and ubiquitous fragmentation leaving few mangroves intact (Bryan-Brown et al., 2020). Saltmarsh ecosystems have also suffered extensive losses (up to 60% in places, since the 1980s), especially in developed and rapidly developing countries (*medium confidence*) (Table 12.3, Gu et al., 2018; Stein et al., 2020). Similarly, 29% of seagrass meadows were lost from 1879–2006 due primarily to coastal development and degradation of water quality, with climate-change impacts escalating since 1990 (*medium confidence*) (Waycott et al., 2009; Sousa et al., 2019; Derolez et al., 2020; Green et al., 2021a). Local examples of habitat stability or growth (e.g., de los Santos et al., 2019; Laengner et al., 2019; Sousa et al., 2019; Suyadi et al., 2019; Derolez et al., 2020; Goldberg et al., 2020; McKenzie and Yoshida, 2020) indicate some resilience to climate change in the absence of non-climate drivers (*high confidence*). Nevertheless, previous declines have left wetland ecosystems more vulnerable to impacts from climate-impact and non-climate drivers (*high confidence*) (Friess et al., 2019; Williamson and Guinder, 2021).

Warming and MHWs have affected the range, species composition and survival of some wetland ecosystems. Warming is allowing some, but not all (Rogers and Krauss, 2018; Saintilan et al., 2018), mangrove species to expand their ranges poleward (*high confidence*) (Friess et al., 2019; Whitt et al., 2020). This expansion can affect species interactions (Guo et al., 2017; Friess et al., 2019), and enhance sediment accretion and carbon storage rates in some instances (*medium confidence*) (Guo et al., 2017; Kelleway et al., 2017; Chen et al., 2018b; Coldren et al., 2019; Raw et al., 2019). Drought, low sea levels and MHWs can cause significant die-offs among mangroves (*medium confidence*) (Lovelock et al., 2017b; Duke et al., 2021). Seagrasses are similarly vulnerable to warming (*high confidence*) (Repolho et al., 2017; Duarte et al., 2018; Jayathilake and Costello, 2018; Savva et al., 2018), which has been attributed as one cause of observed changes in distribution and community structure (*medium confidence*) (Hyndes et al., 2016; Nowicki et al., 2017). MHWs, together with storm-driven turbidity and structural damage, can cause seagrass die-offs (*high confidence*) (Arias-Ortiz et al., 2018; Kendrick et al., 2019; Smale et al., 2019; Strydom et al., 2020), shifts to small, fast-growing species (*high confidence*) (Kendrick et al., 2019; Shields et al., 2019; Strydom et al., 2020), and ecosystem collapse (Serrano et al., 2021).

The sensitivity of saltmarshes and mangroves to RSLR depends on whether they accrete inorganic sediment and/or organic material at rates equivalent to rising water levels (*very high confidence*) (Peteet et al., 2018; FitzGerald and Hughes, 2019; Friess et al., 2019; Gonneea et al., 2019; Leo et al., 2019; Marx et al., 2020; Saintilan et al., 2020). Otherwise, wetland ecosystems must migrate either inland or upstream, or face gradual submergence in deeper, increasingly saline water (*very high confidence*) (Section 3.4.2.4, Andres et al., 2019; Jones et al., 2019b; Cohen et al., 2020; Mafi-Gholami et al., 2020; Magolan and Halls, 2020; Sklar et al., 2021). Ability to migrate depends on local topography, the positioning of anthropogenic infrastructure, and structures placed to defend such infrastructure (Schuerch et al., 2018; Fagherazzi et al., 2020; Cahoon et al., 2021). Submergence drives changes in community structure (*high confidence*) (Jones et al., 2019b; Yu et al., 2019; Douglass et al., 2020; Langston et al., 2020) and functioning (*high confidence*) (Charles et al., 2019; Buffington et al., 2020; Stein et al., 2020), and will eventually lead to extirpation of the most sensitive vegetation (*medium confidence*) (Schepers et al., 2017; Scalpone et al., 2020) and associated animals (*low confidence*) (Rosencranz et al., 2018). The impacts of storms on wetlands are variable and are described in SM3.3.1.

As noted in SROCC, given the diversity of coastal wetlands as well as the dependence of their future vulnerability to climate change on adaptation pathways (Krauss, 2021; Rogers, 2021), projections of future impacts based on shoreline elevation estimated from satellite data and CMIP5 projections (Spencer et al., 2016; Schuerch et al., 2018) vary greatly. Although all approaches have individual strengths and weaknesses (Törnqvist et al., 2021), paleo-records provide some clarity because they yield estimates of wetland responses to changes in climate in the absence of other anthropogenic drivers and are therefore inherently conservative. On the basis of paleorecords (Table 3.8), we assess that mangroves and saltmarshes are *likely* at high risk from future SLR, even under SSP1-1.9, with impacts manifesting in the mid-term (*medium confidence*). Under SSP5-8.5, wetlands are *very likely* at high risk from SLR, with larger impacts manifesting before 2040 (*medium confidence*). By 2100, these ecosystems are at high risk of impacts under all scenarios except SSP1-1.9 (*high confidence*), with impacts most severe along coastlines with gently-sloping shorelines, limited sediment inputs, small tidal ranges and limited space for inland migration (*very high confidence*) (Cross-Chapter Box SLR in Chapter 3, Schuerch et al., 2018; FitzGerald and Hughes, 2019; Leo et al., 2019; Schuerch et al., 2019; Raw et al., 2020; Saintilan et al., 2020).

Table 3.8: Estimates of vulnerability of coastal wetlands to sea-level rise (SLR) on the basis of sediment cores.

Region	Habitat	Reference	Rates of SLR at which habitat loss is		WGI AR6 Table 9.9 estimate of SLR (Fox-Kemper et al., 2021)	
			Likely	*Very likely*	2040–2060	2090–2100
Global	Mangrove	(Saintilan et al., 2020)	4.2*	6.1	SSP1-1.9: 4.2 (2.9–6.1) mm yr^{-1}	4.3 (2.5–6.6) mm yr^{-1}
Southeastern USA	Saltmarsh	(Törnqvist et al., 2020)	3.5#	4.2#	SSP5-8.5: 7.3 (5.7–9.8) mm yr^{-1}	12.2 (8.8–17.7) mm yr^{-1}
UK	Saltmarsh	(Horton et al., 2018)	4.6*	7.1*		

* Estimate digitised from published figure
# Published figure digitised and remodelled as binomial generalised linear model (number drowned vs. not).

For seagrasses, recent projections for climate-change impacts vary by species and region. Warming is projected to increase the habitat available to *Zostera marina* on the east coast of the USA by 2100, but contract its southern range edge by 150–650 km under RCP2.6 and RCP8.5, respectively (Wilson and Lotze, 2019). Other species, such as *Posidonia oceanica* in the Mediterranean, might lose as much as 75% of their habitat by 2050 under RCP8.5 and become functionally extinct (*low confidence*) by 2100 (Chefaoui et al., 2018). Observed impacts of MHWs (Kendrick et al., 2019; Strydom et al., 2020; Serrano et al., 2021) indicate that increasing intensity and frequency of MHWs (Section 3.2.2.1) will have escalating impacts on seagrass ecosystems (*high confidence*). Habitat suitability can also be reduced by moderate RSLR, due to its impact on light attenuation (*medium confidence*) (Aoki et al., 2020; Ondiviela et al., 2020; Scalpone et al., 2020).

Overall, warming will drive range shifts in wetland species (*medium* to *high confidence*), but SLR poses greatest risk for mangroves and saltmarshes, with significant losses projected under all future scenarios by mid-century (*medium confidence*) and substantially greater losses by 2100 under all scenarios except SSP1-1.9 (*high confidence*). MHWs pose the greatest risk to seagrasses (*high confidence*). In all cases, losses will be greatest where accommodation space is constrained or where other non-climate drivers exacerbate risk from climate-impact drivers (*very high confidence*).

3.4.2.6 Sandy Beaches

Sandy beaches comprise unvegetated, fine- to medium-grained sediments in the intertidal zones that line roughly one-third of the length of the world's ice-free coastlines (Luijendijk et al., 2018). The amenity value of beaches as cultural, recreational and residential destinations has driven extensive urbanisation of beach-associated coastlines (Todd et al., 2019). Beaches also provide habitat for many resident species, nesting habitat for marine vertebrates, filtration of coastal waters and protection of the coastline from erosion (McLachlan and Defeo, 2018). These soft-sediment coastal ecosystems are particularly vulnerable to habitat loss caused by erosion, especially where landward transgression is inhibited by infrastructure (Table 3.9).

Table 3.9: Summary of previous IPCC assessments of sandy beaches.

Observations	Projections
AR5: (Wong et al., 2014)	
Globally, beaches and dunes have in general undergone net erosion over the past century or longer. Attributing shoreline changes to climate change is still difficult owing to the multiple natural and anthropogenic drivers contributing to coastal erosion.	In the absence of adaptation, beaches, sand dunes, and cliffs currently eroding will continue to do so under increasing sea level (*high confidence*). Coastal squeeze is expected to accelerate with sea-level rise (SLR). In many locations, finding sufficient sand to rebuild beaches and dunes artificially will become increasingly difficult and expensive as present supplies near project sites are depleted (*high confidence*). In the absence of adaptation measures, beaches and sand dunes currently affected by erosion will continue to be affected under SLR (*high confidence*).
SROCC (Bindoff et al., 2019)	
Coastal ecosystems are already impacted by the combination of SLR, other climate-related ocean changes, and adverse effects from human activities on ocean and land (*high confidence*). Attributing such impacts to SLR, however, remains challenging due to the influence of other climate-related and non-climate drivers such as infrastructure development and human-induced habitat degradation (*high confidence*). Coastal ecosystems, including saltmarshes, mangroves, vegetated dunes and sandy beaches, can build vertically and expand laterally in response to SLR, though this capacity varies across sites (*high confidence*) as a consequence of human actions that fragment wetland habitats and restrict landward migration, coastal ecosystems progressively lose their ability to adapt to climate-induced changes and	Sandy beach ecosystems will increasingly be at risk of eroding, reducing the habitable area for dependent organisms (*high confidence*). Sandy shorelines are expected to continue to reduce their area and change their topography due to SLR and increased extreme climatic erosive events. This will be especially important in low-lying coastal areas with high population and building densities (*medium confidence*). Assuming that the physiological underpinning of the relationship between body size and temperature can be applied to warming (*medium confidence*), the body size of sandy beach crustaceans is expected to decrease under warming (*low evidence, medium agreement*).

provide ecosystem services, including acting as protective barriers (*high confidence*). Loss of breeding substrate, including mostly coastal habitats such as sandy beaches, can reduce the available nesting or pupping habitat for land breeding marine turtles, lizards, seabirds and pinnipeds (*high confidence*). Overall, changes in sandy beach morphology have been observed from climate related events, such as storm surges, intensified offshore winds, and from coastal degradation caused by humans (*high confidence*), with impacts on beach habitats (e.g., benthic megafauna) (*medium confidence*).	Sandy beaches transition from undetectable to moderate risk between 0.9ºC–1.8ºC (*medium confidence*) of global sea surface warming and from moderate to high risk at 2.3ºC–3.0ºC of global sea surface warming (*medium confidence*). Projected changes in mean and extreme sea levels and warming under RCP8.5 are expected to result in high risk of impacts on sandy beach ecosystems by the end of the 21st century (*medium confidence*), taking account of the slow recovery rate of sandy beach vegetation, the direct loss of habitats and the high climatic sensitivity of some fauna. Under RCP2.6, the risk of impacts on sandy beaches is expected to be only slightly higher than the present-day level (*low confidence*). Coastal urbanisation lowers the buffering capacity and recovery potential of sandy beach ecosystems to impacts from SLR and warming and thus is expected to limit their resilience to climate change (*high confidence*). Coastal squeeze and human-driven habitat deterioration will reduce the natural capacity of these ecosystems to adapt to climate impacts (*high confidence*).

Since SROCC, observed trends in coastal erosion continue to be obscured by beach nourishment that replaces eroded sediment or by coastal protection of areas at risk of erosion (Section 3.6.3.1.1, Cross-Chapter Box SLR in Chapter 3). Nevertheless, RSLR, increases in wave energy and/or changes in wave direction, disruptions to sediment supplies (including sand mining), and other anthropogenic modifications of the coast have driven localised beach erosion (*very high confidence*) at rates up to 0.5–3 m yr^{-1} (Vitousek et al., 2017a; Vitousek et al., 2017b; Cambers and Wynne, 2019; Enríquez-de-Salamanca, 2020; Sharples et al., 2020). Corresponding analyses of coarse-scale (30-m resolution) global data estimate that 15% of tidal flats (including beaches) have been lost since 1984 (*medium confidence*) (Mentaschi et al., 2018; Murray et al., 2019) but with a corresponding number of the world's beaches accreting (28%) as eroding (24%) (*medium confidence*) (Luijendijk et al., 2018).

Progress is being made toward models that can project beach erosion under future scenarios despite inherent uncertainties and the presence of multiple confounding drivers in the coastal zone (Vitousek et al., 2017b; Le Cozannet et al., 2019; Cooper et al., 2020a; Vousdoukas et al., 2020b; Vousdoukas et al., 2020a). In the interim, models with varying levels of complexity estimate local loss of beach area to SLR by 2100 under RCP8.5-like scenarios, assuming minimal human intervention, ranging 30–70% (*low confidence*) (Vitousek et al., 2017b; Mori et al., 2018; Ritphring et al., 2018; Hallin et al., 2019; Kasmi et al., 2020). Within regions, projected impacts scale negatively with beach width and positively with the magnitude of projected SLR. None of these local studies, however, considered high-energy storm events, which are known to also impact sandy coasts (*high confidence*) (e.g., Burvingt et al., 2018; Garrote et al., 2018; Duvat et al., 2019; Sharples et al., 2020), and model structure often had more influence on projected shoreline responses than did physical drivers (Le Cozannet et al., 2019). Nevertheless, the most-advanced available models, which incorporate multiple coastal processes, including SLR, project that without anthropogenic barriers to erosion, 13.6–15.2% and 35.7–49.5% of the world's beaches *likely* risk undergoing at least 100 m of shoreline retreat (relative to 2010) by 2050 and 2100, respectively (*low confidence*) (Vousdoukas et al., 2020b). Aggregating these trends regionally suggests that relative rates of shoreline change under RCP4.5 and RCP8.5 diverge strongly after mid-century, with trends towards erosion escalating under RCP8.5 by 2100 (*medium confidence*) (Figure 3.14, Vousdoukas et al., 2020b). This trend supports the WGI AR6 assessment that projected SLR will contribute to erosion of sandy beaches, especially under high-emissions futures (*high confidence*) (WGI AR6 Technical Summary, Arias et al., 2021).

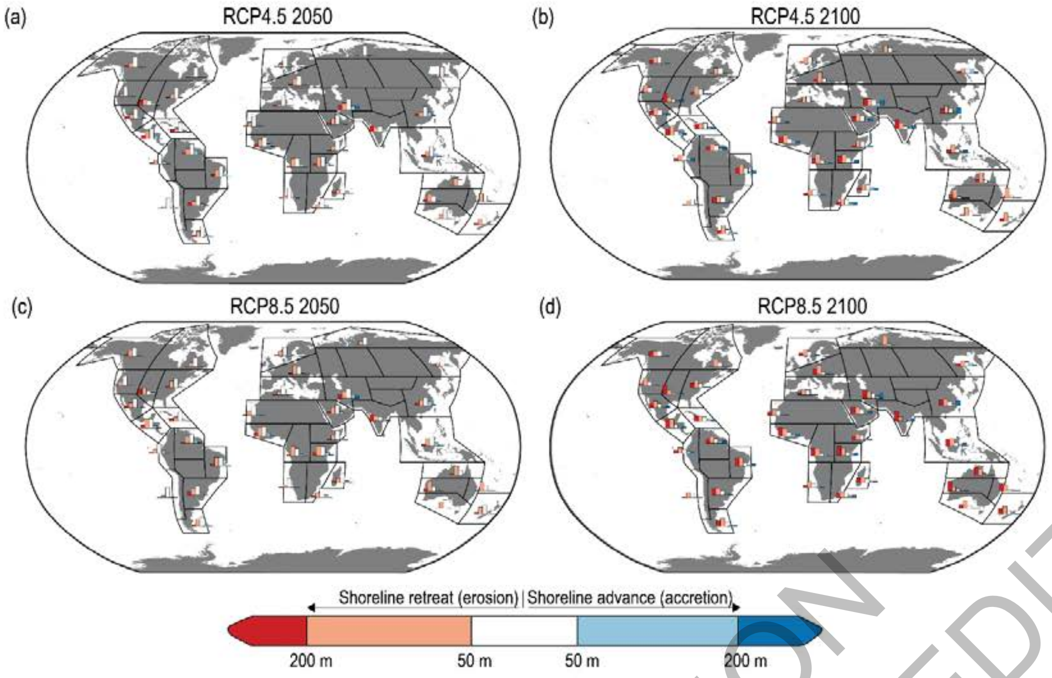

Figure 3.14: Relative trends in projected regional shoreline change (advance/retreat relative to 2010). Frequency distributions of median projected change by (a,c) 2050 and (b,d) 2100 under (a,b) RCP4.5 and (c,d) RCP8.5. Projections account for both long-term shoreline dynamics and sea-level rise and assume no impediment to inland transgression of sandy beaches. Data for small island states are aggregated and plotted in the Caribbean. Data from Vousdoukas et al. (2020b). Values for reference regions established in the WGI AR6 Atlas (Gutiérrez et al., 2021) were computed as area-weighted means from original country-level data. For model assumptions and associated debate, see Vousdoukas et al. (2020a) and Cooper et al. (2020a).

For beach fauna, *emerging evidence* links range shifts, increasing representation by warm-affinity species and mass mortalities to ocean warming (*limited evidence, high agreement*) (McLachlan and Defeo, 2018; Martin et al., 2019). But even amongst the best-studied taxa, such as turtles, vulnerability to warming (*high confidence*) and SLR (*medium confidence*) anticipated on the basis of theory (Poloczanska et al., 2009; Saba et al., 2012; Pike, 2013; Laloë et al., 2017; Tilley et al., 2019) yields only a few detected impacts in the field associated mainly with feminisation (female-skewed sex ratios driven by warmer nest temperatures) (Jensen et al., 2018; Colman et al., 2019; Tilley et al., 2019), phenology (Monsinjon et al., 2019), reproductive success (Bladow and Milton, 2019) and inter-nesting period (Valverde-Cantillo et al., 2019). Moreover, although established vulnerabilities imply high projected future risk for turtles (*high confidence*) (e.g., Almpanidou et al., 2019; Monsinjon et al., 2019; Patrício et al., 2019; Varela et al., 2019; Santidrián Tomillo et al., 2020), many populations remain resilient to change (Fuentes et al., 2019; Valverde-Cantillo et al., 2019; Laloë et al., 2020; Lamont et al., 2020), perhaps because variation in sand temperatures at nesting depth among beaches *very likely* exceeds the magnitude of warming anticipated by 2100, even under RCP8.5 (*medium confidence*) (Bentley et al., 2020a). As expected for a taxon with a long evolutionary history, turtles display natural adaptation, not only by virtue of broad geographic distributions that include natural climate-change refugia (Boissin et al., 2019; Jensen et al., 2019), but also because some initial responses to warming might counteract anticipated impacts. For example, although feminisation poses a significant long-term risk to turtle populations (*high confidence*), it might contribute to population growth in the near- to mid-term (*medium confidence*) (Patrício et al., 2019). Resilience to climate change might be further enhanced by range extensions, alterations in nesting phenology, and fine-scale nest-site selection (*medium confidence*) (Abella Perez et al., 2016; Santos et al., 2017; Almpanidou et al., 2018; Rivas et al., 2019; Laloë et al., 2020).

New literature since SROCC on climate impacts and risks has been scarce for most beach taxa besides turtles (the impacts of storms on beach fauna are variable and are described in SM3.3.1). Nevertheless, theoretical sensitivity to warming (Section 3.3.2), together with the projected loss of habitat under future climate scenarios, suggest substantial impacts for populations and communities of beach fauna into the future (*high confidence*). These impacts will be exacerbated by coastal squeeze along urbanised coastlines (*high* *confidence*), albeit with magnitudes that cannot yet be accurately projected (McLachlan and Defeo, 2018; Le Cozannet et al., 2019; Leo et al., 2019).

3.4.2.7 Semi-Enclosed Seas

This section assesses impacts on five SES, or seas larger than 200,000 km^2 with single entrances <120 km wide, including the Persian Gulf, the Red Sea, the Black Sea, the Baltic Sea and the Mediterranean Sea. These SES are largely landlocked and are thus heavily influenced by surrounding landscapes, local and global climate-impact drivers, as well as non-climate drivers (Section 3.1), making them highly vulnerable to cumulative threats. Key climate-impact drivers in SES are warming, increasing frequency and duration of MHWs, acidification, and the increasing in size and number of OMZs (Figure 3.12, Hoegh-Guldberg et al., 2014). In AR5, SES were recognised as regionally significant for fisheries and tourism, but highly exposed to both local and global stressors, offering limited options for organisms to migrate in response to climate change (Table 3.10).

Table 3.10: Summary of past IPCC assessments of semi-enclosed seas (SES).

Observations	Projections
AR5 (Hoegh-Guldberg et al., 2014)	
The surface waters of the SES exhibit significant warming from 1982 and most Coastal Boundary Systems show significant warming since 1950. Warming of the Mediterranean has led to the recent spread of tropical species invading from the Atlantic and Indian Oceans. SES are highly vulnerable to changes in global temperature on account of their small seawater volume and landlocked nature. Consequently, SES will respond faster than most other parts of the Ocean (*high confidence*). The impact of rising temperatures on SES is exacerbated by their vulnerability to other human influences such as over-exploitation, pollution, and enhanced runoff from modified coastlines. Due to a combination of global and local human stressors, key fisheries have undergone fundamental changes in their abundance and distribution over the past 50 years (*medium confidence*).	Projected warming increases the risk of greater thermal stratification in some regions, which can lead to reduced O_2 ventilation of underlying waters and the formation of additional hypoxic zones, especially in the Baltic and Black Seas (*medium confidence*). Changing rainfall intensity can exert a strong influence on the physical and chemical conditions within SES, and in some cases will combine with other climatic changes to transform these areas. These changes are *likely* to increase the risk of reduced bottom-water O_2 levels for Baltic and Black Sea ecosystems (due to reduced solubility, increased stratification, and microbial respiration), which is *very likely* to affect fisheries. Persian Gulf, Red Sea: Extreme temperature events such as heatwaves are projected to increase (*high confidence*) and temperatures are *very likely* to increase above established thresholds for mass coral bleaching and mortality (*very high confidence*).
SROCC (Bindoff et al., 2019) *Semi-enclosed seas were not assessed in this report.*	
	Projections from distribution models for multiple fish species show hotspots of decreased species richness in the Indo-Pacific region, and semi-enclosed seas such as the Red Sea and Persian Gulf (*medium evidence, high agreement*). In addition, geographic barriers such as land boundaries or lower oxygen water in deeper waters are projected to limit species range shifts in semi-enclosed seas, resulting in larger relative decrease in species richness (*medium confidence*).

Since AR5, there is evidence for increasing frequency and duration of MHWs, extreme weather events and a diversity of threats across depth strata causing mass mortality events, local extirpations and coral reef decline (*high confidence*) (Section 3.4.2.1, SM3.3.2, Buchanan et al., 2016a; Shlesinger et al., 2018; Wabnitz et al., 2018b; Garrabou et al., 2019). In most SES, non-climate drivers, including pollution, habitat destruction, and especially overfishing are decreasing the local adaptive capacity of organisms and the ability of ecosystems to cope with climate change impacts (*high confidence*) (Cramer et al., 2018; Hidalgo et al., 2018; Ben-Hasan and Christensen, 2019). SLR is accelerating faster than expected (*high confidence*) (Kulp and Strauss, 2019), posing a key risk to SES' coastal ecosystems and the services they provide in urban areas, including drinking water provision, housing, recreational activities, among others (Hérivaux et al., 2018; Reimann et al., 2018).

The size and number of OMZs are increasing worldwide and in most SES (*high confidence*) (Global Ocean Oxygen Network, 2018), with growing impacts on fish species diversity and ecosystem functioning. In the Persian Gulf and Red Sea, increasing nutrient loads associated with coastal activities and warming has increased the size of OMZs (*high confidence*) (Al-Said et al., 2018; Lachkar et al., 2019). OMZs represent an even greater problem in the Black and Baltic Seas, with broad implications for ecosystem function and services (Levin et al., 2009), especially where actions to reduce nutrient loading from land have been unable to reduce the OMZ coverage (*high confidence*) (Carstensen et al., 2014; Miladinova et al., 2017; Global Ocean Oxygen Network, 2018). In the Baltic Sea, OMZs are affecting the extent of suitable spawning areas of cod, *Gadus morhua* (*high confidence*) (Hinrichsen et al., 2016), while in the Black Sea, the combined effect of OMZs and warming is influencing the distribution and physiology of fish species, and their migration and schooling behavior in their overwintering grounds (*medium confidence*) (Güraslan et al., 2017). Cascading effects on food webs have been reported in the Baltic, where detrimental effects of changing oxygen levels on zooplankton production, pelagic and piscivorous fish are influencing seasonal succession and species composition of phytoplankton (*high confidence*) (Viitasalo et al., 2015).

In the Mediterranean Sea (Cross-Chapter Paper 4), the increase in climate extremes and mass mortality events reported in AR5 has continued (*very high confidence*) (Gómez-Gras et al., 2021). Extreme weather events (including deep convection, González-Alemán et al., 2019) and MHWs have become more frequent (Darmaraki et al., 2019) and are associated with mass mortality of benthic sessile species across the basin (*high confidence*) (Garrabou et al., 2019; Gómez-Gras et al., 2021). Since AR5, in the Persian Gulf and Red Sea, extreme temperatures, together with disease and predation, have continued to cause bleaching-induced mortality of corals, along with declines in the average coral colony size (*high confidence*) (Burt et al., 2019). Poleward migration and tropicalisation of species (Section 3.4.2.3) has also continued in the Mediterranean, and these phenomena have also become an issue in the Black Sea (*high confidence*) (Boltachev and Karpova, 2014; Hidalgo et al., 2018). Climate impacts on phytoplankton production and phenology show high spatial heterogeneity across the Mediterranean Sea (*medium evidence*) (Marbà et al., 2015b; Salgado-Hernanz et al., 2019), with consequent effects on the diversity and abundance of zooplankton and fish species (*medium confidence*) (Peristeraki et al., 2019). Changes in primary production and a decrease in river runoff have also altered the optimum habitats for small pelagic fish in the Mediterranean, from local to the basin scale (Piroddi et al., 2017). Evidence of impacts from ocean acidification is increasing, with the rates of coral calcification showing major decline in the Red Sea (*medium confidence*) (Section 3.4.2.1, Steiner et al., 2018; Bindoff et al., 2019). In the Mediterranean Sea, evidence of acidification events have been reported at local scale (Hassoun et al., 2015), with impacts on bivalves and coralligenous species (*medium confidence*) (Lacoue-Labarthe et al., 2016).

Climate models project increasing frequency and intensity of MHWs (*high confidence*) (Section 3.2.2.1), which will exacerbate warming-driven impacts in the Red Sea and Persian Gulf regions, and erode the resilience of Red Sea coral reefs (*high confidence*) (Osman et al., 2018; Genevier et al., 2019; Kleinhaus et al., 2020). In the Persian Gulf region, extreme temperatures, >35ºC (Pal and Eltahir, 2016), have been linked with high rates of extirpation and a decrease in fisheries catch potential (*medium confidence*) (Wabnitz et al., 2018b). In the Mediterranean Sea, east-west gradients in rates of warming are projected to trigger spatially different changes in primary production, which combined with the increasing arrival of non-indigenous species, may trigger biogeographical changes in fish diversity, increasing in the eastern and decreasing in the western Mediterranean (*medium to high confidence*) (Albouy et al., 2013; Macias et al., 2015). Projections also show greater impacts from SLR than originally expected in the Mediterranean and Baltic (e.g., Dieterich et al., 2019; Thiéblemont et al., 2019). In the Baltic Sea, under high nutrient load and warming climate scenarios, eutrophication is projected to increase in the future (2069–2098) compared to historical (1976–2005) periods. In contrast, under continued nutrient load reductions following present management regulations, environmental conditions and ecological state will continue to improve independently of the climate warming scenarios (*low to medium confidence*) (Saraiva et al., 2019).

3.4.2.8 Shelf Seas

Shelf seas overlie the continental margin, often with maximum depths of <200 m, and represent 7% of the global ocean by area (Simpson and Sharples, 2012). These ecosystems are found offshore of every continent, generate 10–30% (Mackenzie et al., 2000; Andersson and Mackenzie, 2004) of global marine net primary production and play a key role in global biogeochemical cycling, including the export of land-borne carbon and nutrients (Johnson et al., 1999; Nishioka et al., 2011; Li et al., 2019) to the deep ocean and recycling of fixed nitrogen back to the atmosphere via denitrification (Devol, 2015). The shelf seas are home to several of the world's major industrial capture fisheries, such as those of the mid-Atlantic Bight, Scotian Shelf, Eastern Bering Sea Shelf and North Brazil Shelf (Barange et al., 2018), and support other marine industries, including aquaculture, extractive industries (oil, gas, and mining), shipping, and renewable-energy installations.

Similar to other coastal ecosystems, evidence since SROCC (Table 3.11) suggests shelf-sea ecosystems and the fisheries and aquaculture they support are sensitive to the interactive effects of climate-impact drivers, as well as non-climate drivers, including nutrient pollution, sedimentation, fishing pressure and resource extraction (Table 3.12, Figure 3.12). Changes in freshwater, nutrient and sediment inputs from rivers due to both climate and non-climate drivers can influence productivity and nutrient limitation, ecosystem structure, carbon export and species diversity and abundance (Balch et al., 2012; Picado et al., 2014), and can result in reduced water clarity and light penetration (Dupont and Aksnes, 2013; McGovern et al., 2019). Seasonal bottom-water hypoxia occurs in some shelf seas (e.g., northern Gulf of Mexico, Bohai Sea, East China Sea) due to riverine inputs of freshwater and nutrients, promoting stratification, enhanced primary production, and organic carbon export to bottom waters (*high confidence*) (Zhao et al., 2017; Wei et al., 2019; Del Giudice et al., 2020; Große et al., 2020; Jarvis et al., 2020; Rabalais and Baustian, 2020; Song et al., 2020a; Xiong et al., 2020; Zhang et al., 2020a).

Table 3.11: Summary of past IPCC assessments of shelf seas.

Observations	Projections
AR5 (Hoegh-Guldberg et al., 2014)	
Primary productivity, biomass yields, and fish capture rates have undergone large changes within the East China Sea over the past decades (*limited evidence, medium agreement, low confidence*). Changing sea temperatures have influenced the abundance of phytoplankton, benthic biomass, cephalopod fisheries, and the size of demersal trawl catches in the northern South China Sea observed over the period 1976–2004 (*limited evidence, medium agreement*). Concurrent with the retreat of the "cold pool" on the northern Bering Sea shelf, bottom trawl surveys of fish and invertebrates show a significant community-wide northward distributional shift and a colonisation of the former cold pool areas by sub-Arctic fauna (*high confidence*). Observed changes in the phenology of plankton groups in the North Sea over the past 50 years are driven by climate forcing, in particular regional warming (*high confidence*).	Global warming will result in more frequent extreme events and greater associated risks to ocean ecosystems (*high confidence*). In some cases, projected increases will eliminate ecosystems, and increase the risks and vulnerabilities to coastal livelihoods and vulnerabilities for food security including Southeast Asia (*medium to high confidence*). Reducing stressors not related to climate change represents an opportunity to strengthen the ecological resilience within these regions, which may help biota survive some projected changes in ocean temperature and chemistry. Changes in eutrophication and hypoxia are *likely* to influence shelf seas, but there is *low confidence* in the understanding of the magnitude of potential changes and impacts on ecosystem functioning, fisheries and other industries.
SROCC (Bindoff et al., 2019)	
Species composition of fisheries catches since the 1970s in many shelf seas ecosystems of the world is increasingly dominated by warm water species (*medium confidence*). Estuaries, shelf seas and a wide range of other intertidal and shallow-water habitats play an important role in the	Direct anthropogenic impacts include coastal land-use change; indirect effects include increased nutrient delivery and other changes in river catchments, and marine resource exploitation in shelf seas. There is *high confidence* that these human-driven changes will continue, reflecting coastal settlement trends and global population growth.

global carbon cycle through their primary production by rooted plants, seaweeds (macroalgae) and phytoplankton, and also by processing riverine organic carbon. However, the natural carbon dynamics of these systems have been greatly changed by human activities (*high confidence*).

Table 3.12: Synthesis of interactive effects and their influence on shelf-sea ecosystems and the fisheries and aquaculture they support.

Oxygen concentration	Deoxygenation.	(Wei et al., 2019; Del Giudice et al., 2020)
River discharge	Change in plankton community structure.	(Shi et al., 2020)
Nutrient pollution	Enhanced primary production, change in plankton community structure.	(Kong et al., 2019; Nohe et al., 2020)
Sedimentation	Modified ocean chemistry.	(Hallett et al., 2018)
Fishing pressure	Increased vulnerability leading to changes in community structure.	(Maharaj et al., 2018; Wang et al., 2019c; Hernvann and Gascuel, 2020)
Resource extraction	Contamination, change in benthic community structure.	(Hall, 2002)

Key risks to shelf seas include shifts or declines in marine micro- and macro-organism abundance and diversity driven by eutrophication, HABs and extreme events (storms and MHWs), and consequent effects on fisheries, resource extraction, transportation, tourism and marine renewable energy (Figure 3.12). The combined effects of deoxygenation and warming can affect the metabolism, growth, feeding behaviour and mobility of fish species (Section 3.3.3). The increasing availability of observations mean that ecosystem changes in shelf seas can be increasingly attributed to climate change (*high confidence*) (Liang et al., 2018; Maharaj et al., 2018; Ma et al., 2019; Meyer and Kröncke, 2019; Bargahi et al., 2020; Bedford et al., 2020; Friedland et al., 2020b; Mérillet et al., 2020). Eutrophication and seasonal bottom-water hypoxia in some shelf seas have been linked to warming (*high confidence*) (Wei et al., 2019; Del Giudice et al., 2020) and increased riverine nutrient loading (*high confidence*) (Wei et al., 2019; Del Giudice et al., 2020). Since SROCC, some severe HABs have been attributed to extreme events, such as MHWs (Section 14.4.2, Roberts et al., 2019; Trainer et al., 2019). However, a recent worldwide assessment of HABs attributed the increase in observed HABs to intensified monitoring associated with increased aquaculture production (*high confidence*) (Hallegraeff et al., 2021).

Since SROCC, changes in the community structure and diversity of plankton, macrofauna and infauna have been detected in some shelf seas, although attribution has been regionally specific (e.g., bottom-water warming or hypoxia) (Meyer and Kröncke, 2019; Rabalais and Baustian, 2020). Detection of the picoplankton *Synechococcus* spp. in the North Sea is potentially linked to a summer decrease in copepod stocks and declining food-web efficiency (*low confidence*) (Schmidt et al., 2020). The seasonally distinct phytoplankton assemblages in the North Sea have begun to appear concurrently and homogenise (Nohe et al., 2020). Changes in abundance, species composition, and size of zooplankton have been detected in some shelf seas (Yellow Sea, North Sea, Celtic Sea, and Tasman Sea), including a decline in stocks of larger copepods, increased abundances of gelatinous and meroplankton, and a shift to smaller species due to warming, increased river discharge, circulation change, and/or extreme events (*high confidence*) (Wang et al., 2018a; Bedford et al., 2020; Evans et al., 2020; Shi et al., 2020; Edwards et al., 2021).

Ocean warming has shifted distributions of fish (Free et al., 2019; Franco et al., 2020; Pinsky et al., 2020b; Fredston et al., 2021) and marine mammal species (Salvadeo et al., 2010; García-Aguilar et al., 2018; Davis et al., 2020) poleward (*high confidence*) or deeper (*low* to *medium confidence*) (Section 3.4.3.1, Nye et al., 2009; Pinsky et al., 2013; Pinsky et al., 2020b). Warming has also tropicalised the pelagic and demersal fish assemblages of mid- and high-latitude shelves (*high confidence*) (Montero-Serra et al., 2015; Liang et al., 2018; Maharaj et al., 2018; Ma et al., 2019; Friedland et al., 2020a; Kakehi et al., 2021; Punzón et al., 2021). Fisheries catch composition in many shelf-sea ecosystems has become increasingly dominated by warm-water species since the 1970s (*high confidence*) (Cheung et al., 2013; Leitão et al., 2018; Maharaj et al., 2018; McLean et al., 2019). Warming has taxonomically diversified fish communities along a latitudinal gradient in the North Sea, but homogenised functional diversity (McLean et al., 2019). However, in some regions, changing predator or prey distributions, temperature-dependent hypoxia, population changes, evolutionary adaptation, and other biotic or abiotic processes, including species' exploitation, confound responses to climate-impact drivers, which must therefore be interpreted with caution (Frank et al., 2018). For example, although, most species' range edges are tracking temperature change on the northeast shelf of the USA (*medium confidence*) (Fredston-Hermann et al., 2020; Fredston et al., 2021), range edges of others are not.

A wide range of responses by fish and invertebrate populations to warming have been observed. The majority of responses have been detrimental, with the direction and magnitude of the response depending on ecoregion, taxonomy, life history, and exploitation history (Free et al., 2019; Yati et al., 2020). For example, fisheries productivity has strongly decreased in the North Sea (Free et al., 2019), and fisheries yields have also decreased in the Celtic Sea, attributed primarily to warming and secondarily to long-term exploitation (Hernvann and Gascuel, 2020; Mérillet et al., 2020). Conversely, fish species diversity and overall productivity have increased in the Gulf of Maine, even with warming (Le Bris et al., 2018; Friedland et al., 2020a; Friedland et al., 2020b). Fisheries yields have decreased in the Yellow Sea, East China Sea and South China Sea due primarily to overexploitation (Ma et al., 2019; Wang et al., 2019c), with warming exerting more influence on the yield of cold-water species than on temperate- and warm-water groups (Ma et al., 2019). The combined effects of exploitation and multi-decadal climate fluctuations make it difficult to assess global climate-change impacts on fisheries yields (Chapter 5, Ma et al., 2019; Bentley et al., 2020b; Johnson et al., 2020).

Since AR5, increasing spatial and temporal extent of hypoxia has been projected due to enhanced benthic respiration and reduced oxygen solubility from warming (Del Giudice et al., 2020). Similar to the open ocean, large shifts in the phenology of phytoplankton blooms have been projected for shelf seas throughout subpolar and polar waters (*medium confidence*) (Henson et al., 2018a; Asch et al., 2019). Zooplankton, which are important prey for many fish species and sea birds, are expected to decrease in abundance on the northeast shelf of the USA (Grieve et al., 2017). However, responses vary by shelf ecosystem (Chust et al., 2014b). Trends towards tropicalisation will continue in the future (*high confidence*) (Cheung et al., 2015; Stortini et al., 2015; Allyn et al., 2020; Maltby et al., 2020; Costa et al., 2021), but uncertainty of future projections of fisheries production increases substantially beyond 2040 (Maltby et al., 2020). Nevertheless, shelf-sea fisheries at lower latitudes are most vulnerable to climate change (Monnereau et al., 2017). Under future climate change marked by more frequent and intense extreme events and the influences of multiple drivers, more flexible and adaptive management approaches could reduce climate impacts on species while also supporting industry adaptation (*high confidence*) (Section 3.6.3.1.2, Shackell et al., 2014; Stortini et al., 2015; Hare et al., 2016; Stortini et al., 2017; Greenan et al., 2019; Ocaña et al., 2019; Maltby et al., 2020).

3.4.2.9 Upwelling Zones

EBUS comprise four important social-ecological systems in the Pacific (California and Peru-Humboldt) and Atlantic (Canary and Benguela) ocean basins. Each is characterised by high primary production, sustained by wind-driven upwelling that draws cold, nutrient-rich, generally low-pH and low-oxygen water to the surface

(Bindoff et al., 2019). Despite their small relative size, the primary productivity in EBUS supports a vast biomass of marine consumers, including some of the world's most productive fisheries (Pauly and Zeller, 2016), along with many species of conservation significance (Bakun et al., 2015).

Although upwelling is important in many other oceanic regions, we focus here on the most documented examples provided by the EBUS. Yet even here, observed changes in upwelling, temperature, acidification and loss of oxygen (Seabra et al., 2019; Abrahams et al., 2021; Gallego et al., 2021; Varela et al., 2021) cannot be robustly attributed to anthropogenic climate change, and projected future changes in upwelling are expected to be relatively small and variable among and within EBUS (Section 3.2.2.3, WGI AR6 Chapter 9, Fox-Kemper et al., 2021). We therefore have few updates to assessments provided by AR5 and SROCC (Table 3.13) and restrict our brief assessment to the limited amount of new evidence (Figure 3.12).

Table 3.13: Summary of previous IPCC assessments of eastern boundary upwelling systems (EBUS).

Observations	Projections
AR5 (Hoegh-Guldberg et al., 2014; Lluch-Cota et al., 2014)	
EBUS are vulnerable to changes that influence the intensity of currents, upwelling, and mixing (and hence changes in sea-surface temperature, wind strength and direction), as well as O_2 content, carbonate chemistry, nutrient content, and the supply of organic carbon to deep offshore locations (*high confidence*). Climate-change-induced intensification of ocean upwelling in some EBUS, as observed in the last decades, may lead to regional cooling rather than warming of surface waters and cause enhanced productivity (*medium confidence*), but also enhanced hypoxia, acidification, and associated biomass reduction in fish and invertebrate stocks. Owing to contradictory observations there is currently uncertainty about the future trends of major upwelling systems and how their drivers will shape ecosystem characteristics (*low confidence*). Declining O_2 and shoaling of the aragonite saturation horizon through ocean acidification increase the risk of upwelling water being low in pH and O_2, with impacts on coastal ecosystems and fisheries. These risks and uncertainties are *likely* to involve significant challenges for fisheries and associated livelihoods along the west coasts of South America, Africa, and North America (*low to medium confidence*). There is *robust evidence* and *medium agreement* that the California Current has experienced an increase of the overall magnitude of upwelling events from 1967 to 2010 (*high confidence*). This is consistent with changes expected under climate change yet remains complicated by the influence of decadal-scale variability (*low confidence*). Declining oxygen concentrations and shoaling of the hypoxic boundary layer *likely* reduced the available habitat for key benthic communities as well as fish and other mobile species. Together with the shoaling of the saturation horizon, these changes have increased the incidence of low O_2 and low pH water flowing onto the continental shelf (*high confidence*; 40 to 120 m), causing problems for industries such as the shellfish aquaculture industry.	Like other ocean sub-regions, EBUS are projected to warm under climate change, with increased stratification and intensified winds as westerly winds shift poleward (*likely*). However, cooling has also been predicted for some EBUS, resulting from the intensification of wind-driven upwelling. There is *medium agreement*, despite *limited evidence*, that upwelling intensity and associated variables (e.g., temperature, nutrient, and O_2 concentrations) from the Benguela system will change as a result of climate change. Any projected increase in upwelling intensity has potential disadvantages. Elevated primary productivity may lead to decreasing trophic transfer efficiency, thus increasing the amount of organic carbon exported to the seabed, where it is *virtually certain* to increase microbial respiration and hence increase low O_2 stress.

Despite its apparent sensitivity to environmental variability, there is *limited evidence* of ecological changes in the Benguela Current EBUS due to climate change.

SROCC (Bindoff et al., 2019; IPCC, 2019c; IPCC, 2019d)

Increasing ocean acidification and oxygen loss are negatively impacting two of the four major upwelling systems: the California Current and Humboldt Current (*high confidence*). Ocean acidification and decrease in oxygen level in the California Current upwelling system have altered ecosystem structure, with direct negative impacts on biomass production and species composition (*medium confidence*).

Three out of the four major Eastern Boundary Upwelling Systems (EBUS) have shown large-scale wind intensification in the past 60 years (*high confidence*). However, the interaction of coastal warming and local winds may have affected upwelling strength, with the direction of changes varies between and within EBUS (*low confidence*). Increasing trends in ocean acidification in the California Current EBUS and deoxygenation in California Current and Humboldt Current EBUS are observed in the last few decades (*high confidence*), although there is *low confidence* to distinguish anthropogenic forcing from internal climate variability. The expanding California EBUS oxygen minimum zone has altered ecosystem structure and fisheries catches (*medium confidence*).

Overall, EBUS have been changing with intensification of winds that drives the upwelling, leading to changes in water temperature and other ocean biogeochemistry (*medium confidence*).

The direction and magnitude of observed changes vary among and within EBUS, with uncertainties regarding the driving mechanisms behind this variability. Moreover, the high natural variability of EBUS and their insufficient representation by global Earth System Models gives *low confidence* that these observed changes can be attributed to anthropogenic causes.

Anthropogenic changes in EBUS will emerge primarily in the second half of the 21st century (*medium confidence*). EBUS will be impacted by climate change in different ways, with strong regional variability with consequences for fisheries, recreation, and climate regulation (*medium confidence*). The Pacific EBUS are projected to have calcium carbonate undersaturation in surface waters within a few decades under Representative Concentration Pathway (RCP)8.5 (*high confidence*); combined with warming and decreasing oxygen levels, this will increase the impacts on shellfish larvae, benthic invertebrates, and demersal fishes (*high confidence*) and related fisheries and aquaculture (*medium confidence*).

The inherent natural variability of EBUS, together with uncertainties in present and future trends in the intensity and seasonality of upwelling, coastal warming and stratification, primary production and biogeochemistry of source waters poses large challenges in projecting the response of EBUS to climate change and to the adaptation of governance of biodiversity conservation and living marine resources in EBUS (*high confidence*).

Given the high sensitivity of the coupled human-natural EBUS to oceanographic changes, the future sustainable delivery of key ecosystem services from EBUS is at risk under climate change; those that are most at risk in the 21st century include fisheries (*high confidence*), aquaculture (*medium confidence*), coastal tourism (*low confidence*) and climate regulation (*low confidence*).

For vulnerable human communities with a strong dependence on EBUS services and low adaptive capacity, such as those along the Canary Current system, unmitigated climate change effects on EBUS (complicated by other non-climatic stresses such as social unrest) have a high risk of altering their development pathways (*high confidence*).

The California EBUS is arguably the best-studied of the four ecosystems in terms of robust projections of climate change, although even here, there is *limited evidence* and *low agreement* among projections. For example, trends in outputs from high-resolution, downscaled models in the California EBUS generally reflect those from underlying coarser-scale ESMs, but projections for physical variables are more convergent among modelling approaches than are those for biogeochemical variables (*high confidence*) (Howard et al., 2020a; Pozo Buil et al., 2021). Models agree on general warming in the California EBUS, with concomitant declines in oxygen content (*medium confidence*) (Howard et al., 2020b; Fiechter et al., 2021; Pozo Buil et al., 2021). But implications for the future spatial distribution of species, including for some fisheries resources (Howard et al., 2020b; Fiechter et al., 2021), are confounded by local-scale oceanographic process (Siedlecki et al., 2021) and by lateral input of anthropogenic land-based nutrients (Kessouri et al., 2021), suggesting that such projections should be accorded *low confidence*.

More generally, changes in upwelling intensity are observed to affect organismal metabolism, population productivity and recruitment, and food-web structure (*medium confidence*) (van der Sleen et al., 2018; Brodeur et al., 2019; Ramajo et al., 2020). But *low confidence* in projected trends in upwelling make it difficult to extrapolate these results to understand potential changes in the ecology of EBUS. Projected changes in fish biomass within EBUS (Carozza et al., 2019) are therefore accorded *low confidence*. Finally, although MHWs are an important emerging hazard in the global ocean, with intensity, frequency and duration increasing strongly (Section 3.2.2.1), the number of MHW days yr^{-1} within EBUS has been increasing more slowly (or decreasing faster, in the case of the Peru-Humboldt system) than in surrounding waters (Varela et al., 2021). Notwithstanding these trends, EBUS remain vulnerable both to MHWs (*high confidence*) (Sen Gupta et al., 2020) and to their long-lasting impacts (*high confidence*) (Arafeh-Dalmau et al., 2019; Harvell et al., 2019; McPherson et al., 2021). On this basis, the suggestion that EBUS may represent refugia from MHWs is accorded *low confidence*.

Despite *low confidence* in detailed projections for ecological changes in EBUS, the WGI assessment (WGI AR6 Chapter 9, Fox-Kemper et al., 2021) that upwelling-favourable winds will weaken (or be present for shorter durations) at low latitude but intensify at high latitude (*high confidence*), albeit by no more than 20% in either case (*medium confidence*), presents some key risks to associated EBUS ecosystems. These include potential decreases in provisioning services, including fisheries and marine aquaculture (Bertrand et al., 2018; Kifani et al., 2018; Lluch-Cota et al., 2018; van der Lingen and Hampton, 2018), and cultural services such as nature-based tourism (Section 3.5).

3.4.2.10 Polar Seas

The polar seas cover ~20% of the global ocean and include the deep Arctic Ocean and surrounding shelf seas as well as the Southern Ocean south of the polar front. They play a significant role in ocean circulation and absorption of anthropogenic CO_2 (Meredith et al., 2019). The Arctic is characterised by polar seas surrounded by land, while the Antarctic comprises continental Antarctica surrounded by the Southern Ocean. These high-latitude ecosystems share key properties, including strong seasonality in solar radiation and sea-ice coverage. Sea ice regulates water-column physics, chemistry and biology, air-sea exchange, and is a critical habitat for many species. In spring, when solar radiation returns and sea ice melts, intense phytoplankton blooms fuel food webs that include rich communities of both resident and summer-migrant species, with typically high dependency on a few key species for trophic transfer (Meredith et al., 2019; Rogers et al., 2020). Over the last two decades, Arctic Ocean surface temperature has increased in line with the global average, while there has been no uniform warming across the Antarctic (*high confidence*) (WGI AR6 Chapter 9, Fox-Kemper et al., 2021). Thus, the rate of change due to warming, and associated sea-ice loss, is greater in the Arctic than in the Antarctic (*high confidence*) (Section 3.2, Table 3.14, WGI AR6 Chapter 9, Fox-Kemper et al., 2021). Both Arctic and Antarctic regions have a long history of living resource extraction, including some of the largest fisheries on the globe in terms of catches. However, only the Arctic hosts human populations, holding a rich Indigenous knowledge and Local knowledge on these socio-ecological systems (Cross-Chapter Paper 6, Meredith et al., 2019).

Previous assessments of polar seas (Table 3.14) concluded that climate change has already profoundly influenced polar ecosystems, through changing species distributions and abundances from primary producers to top predators, including both ecologically and economically important species (*high confidence*) and that it will continue to do so (Table 3.14).

Table 3.14: Summary of previous IPCC assessments for polar seas.

Observations	Projections
AR5 (Wong et al., 2014)	
Poleward species distributional shifts are due to climate warming (*medium to high confidence*). Impacts of shifts in ocean conditions affect fish and shellfish abundances in the Arctic (*high confidence*). Changes in sea ice and the physical environment to the west of the Antarctic Peninsula are altering phytoplankton stocks and productivity, and krill (*high confidence*).	Some marine species will shift their ranges in response to changing ocean and sea ice conditions in the polar regions (*medium confidence*). Loss of sea ice in summer and increased ocean temperatures are expected to impact secondary pelagic production in some regions of the Arctic Ocean, with associated changes in the energy pathways within the marine ecosystem (*medium confidence*).

	Ocean acidification has the potential to inhibit embryo development and shell formation of some zooplankton and krill in the polar regions, with potentially far-reaching consequences to food webs in these regions (*medium confidence*). Shifts in the timing and magnitude of seasonal biomass production could disrupt coupled phenologies in the food webs, leading to decreased survival of dependent species (*medium confidence*).
SR15 (Hoegh-Guldberg et al., 2018a)	
A fundamental transformation is occurring in polar organisms and ecosystems, driven by climate change (*high confidence*).	The losses in sea ice at 1.5°C and 2°C of warming will result in habitat losses for organisms such as seals, polar bears, whales and seabirds. There is *high agreement* and *robust evidence* that phytoplankton species will change because of sea ice retreat and related changes in temperature and light penetration, and this is *very likely* to benefit fisheries productivity in the Arctic spring bloom system. 'Unique and threatened systems' (RFC1), including Arctic and coral reefs, display a transition from high to very high risk of transition at temperatures between 1.5°C and 2°C of global warming, as opposed to at 2.6°C of global warming in AR5 (*high confidence*).
SROCC (Bindoff et al., 2019)	
Climate-induced changes in seasonal sea ice extent and thickness and ocean stratification are altering marine primary production (*high confidence*), with impacts on ecosystems (*medium confidence*). Changes in the timing, duration and magnitude of primary production have occurred in both polar oceans, with marked regional or local variability (*high confidence*). In both polar regions, climate-induced changes in ocean and sea ice conditions have expanded the range of temperate species and contracted the range of polar fish and ice-associated species (*high confidence*). Ocean acidification will affect several key Arctic species (*medium confidence*).	Future climate-induced changes in the polar oceans, sea ice, snow and permafrost will drive habitat and biome shifts, with associated changes in the ranges and abundance of ecologically important species (*medium confidence*). Projected range expansion of subarctic marine species will increase pressure for high-Arctic species (*medium confidence*), with regionally variable impacts. Both polar oceans will be increasingly affected by CO_2 uptake, causing corrosive conditions for calcium carbonate shell-producing organisms (*high confidence*), with associated impacts on marine organisms and ecosystems (*medium confidence*). The projected effects of climate-induced stressors on polar marine ecosystems present risks for commercial and subsistence fisheries with implications for regional economies, cultures and the global supply of fish, shellfish, and Antarctic krill (*high confidence*).

Since SROCC, evidence demonstrates that warmer oceans, less sea ice and increased advection results in increasing primary production in the Arctic, albeit with regional variation (*high confidence*), while trends remain spatially heterogeneous and less clear in the Antarctic (*medium confidence*) (Cross-Chapter Paper 6, Del Castillo et al., 2019; Lewis et al., 2020; Pinkerton et al., 2021; Song et al., 2021a). Furthermore, climate warming influences key mechanisms determining energy transfer between trophic levels including: (1) altered size spectra; (2) shifts in trophic pathways; (3) phenological mismatches; and (4) increased top-down trophic regulation (Table 3.15). However, the scale of impacts from changes in these mechanisms on ecosystem productivity in warming polar oceans remains unresolved and is hence assigned *low confidence*.

Table 3.15: Examples of mechanisms influencing transfer of energy between lower trophic levels in warmer polar oceans.

Mechanism	Examples	References
Altered size spectra	Shifts towards smaller algal cells and zooplankton in warmer and more stratified oceans results in longer and less-efficient food chains, with lower lipid content.	(Aarflot et al., 2018; Kimmel et al., 2018; Weydmann et al., 2018; Hop et al., 2019; Møller and Nielsen, 2020; Spear et al., 2020), but see Dong et al. (2021) and Vernet et al. (2017) for opposite trends.
Shifts in trophic pathways	Changes in microbial food-web interactions, including strengthening of microbial loop, may reduce overall productivity. Transitions from sea-ice algae to open-water phytoplankton production may reduce benthic-pelagic coupling and benthic production; transition from autotroph to heterotroph benthic production with increased water turbidity; shifts from krill-dominated to salp-dominated ecosystems in the Antarctic may have negative impacts on higher trophic levels.	(Cross-Chapter Paper 6, Fujiwara et al., 2016; Onda et al., 2017; Vernet et al., 2017; Grebmeier et al., 2018; Moore et al., 2018b; Cavan et al., 2019; Vaqué et al., 2019; Yurkowski et al., 2020)Braekcman et al 2021
Phenological mismatches	Mismatches in timing arise between spring phytoplankton blooms and zooplankton recruits.	(Søreide et al., 2010; Renaud et al., 2018; Dezutter et al., 2019)
Increased top-down trophic regulation	Increased predation efficiency and top-down regulation of zooplankton by zooplanktivorous fish (due to more light with less sea ice) disconnects zooplankton and phytoplankton production.	(Langbehn and Varpe, 2017; Kaartvedt and Titelman, 2018; Hobbs et al., 2021)

Major community shifts, both gradual and abrupt, are observed in polar oceans in response to warming trends and MHWs (Arctic only) (*high confidence*) (Cross-Chapter Paper 6, Figure 3.12, Beaugrand et al., 2019; Meredith et al., 2019; Huntington et al., 2020). In general, abundances and ranges of Arctic fish species are declining and contracting, while ranges of boreal fish species are expanding, both geographically and in terms of feeding interactions and ecological roles (*high confidence*) (Huserbråten et al., 2019; Meredith et al., 2019; Huntington et al., 2020; Pecuchet et al., 2020a), with variable outcomes for large commercial fish stocks (Cross-Chapter Paper 6, Kjesbu et al., 2014; Holsman et al., 2018; Free et al., 2019). The extreme seasonal solar radiation cycles of these high latitudes may both act as a barrier for species immigration and change predator-prey dynamics in previously ice-covered areas, factors not currently considered in projections (*limited evidence*) (Kaartvedt and Titelman, 2018; Ljungström et al., 2021). Responses by marine mammals and birds to the ongoing changes in polar ecosystems are both positive and negative (Meredith et al., 2019; Bestley et al., 2020). Phenological, behavioural, physiological, and distributional changes are observed in marine mammals and birds in response to altered ecological interactions and habitat degradation, especially to loss of sea ice (*high confidence*) (Box 3.2, Cross-Chapter Paper 6, Beltran et al., 2019; Cusset et al., 2019; Descamps et al., 2019; Meredith et al., 2019; Huntington et al., 2020). Reproductive failures and declining abundances attributed to warmer polar oceans and less sea-ice cover are observed in populations of polar bears, *Ursus maritimus*, seals, whales and marine birds (*high confidence*) (Box 3.2, Duffy-Anderson et al., 2019; Ropert-Coudert et al., 2019; Bestley et al., 2020; Chambault et al., 2020; Molnár et al., 2020; Stenson et al., 2020). The ongoing changes in polar marine ecosystems can lead to temporary increases in biodiversity and functional diversity (e.g., due to immigration of boreal species in the Arctic, *high confidence*), but reduced trophic-transfer efficiencies and functional redundancy, with uncertain consequences for ecosystem resilience and vulnerability (*limited evidence*, *low agreement*) (Griffith et al., 2019b; Alabia et al., 2020; du Pontavice et al., 2020; Alabia et al., 2021; Frainer et al., 2021).

Calcareous polar organisms are among the groups most sensitive to ocean acidification (*high confidence*) (Section 3.3.2). Niemi et al. (2021) reports that >80% of sampled sea snail, *Limacina helicina*, a key species in pelagic food webs, displayed signs of shell dissolution in the Amundsen Gulf. However, bacteria, phytoplankton, zooplankton and benthic communities are found to be detrimentally impacted, resilient, or even positively influenced by ocean acidification in observational and experimental studies (Section 3.3, Hildebrandt et al., 2016; Thor et al., 2018; Ericson et al., 2019; McLaskey et al., 2019; Meredith et al., 2019; Petrou et al., 2019; Renaud et al., 2019; Brown et al., 2020; Hancock et al., 2020; Henley et al., 2020; Johnson and Hofmann, 2020; Torstensson et al., 2021).While fish larval stages may be sensitive, adult fish are expected to have low vulnerability to projected acidification levels (Section 3.3.3, Hancock et al., 2020), although reduced swimming capacity in polar cod in an ocean acidification experiment has been observed (Kunz et al., 2018). Polar organisms' sensitivity to ocean acidification may increase with increasing light levels due to the loss of sea ice (algae, Donahue et al., 2019; Kvernvik et al., 2020), temperature stress (pteropods, Johnson and Hofmann, 2020), or indirectly via increased heterotrophic bacterial productivity (*limited evidence*) (Vaqué et al., 2019). Due to limited mechanistic understanding of observed effects, and mixed responses among Arctic species, future impacts of ocean acidification are assigned *medium confidence* for polar species, and *low confidence* for outcomes for polar ecosystems (Meredith et al., 2019; Green et al., 2021b).

While levels of pollutants in biota (e.g., persistent organic pollutants, mercury) have generally declined over the past decades, recent increasing levels are associated with release from reservoirs in ice, snow and permafrost, and through changing food webs and pathways for trophic amplification (*medium confidence*) (Box 3.2, Ma et al., 2016; Amélineau et al., 2019; Foster et al., 2019; Bourque et al., 2020; Kobusińska et al., 2020). Also, a warmer climate, altered ocean currents and increased human activities elevate the risk of invasive species in the Arctic (*medium confidence*), potentially changing ecosystems in this region (*high confidence*) (Chan et al., 2019; Goldsmit et al., 2020). In the remote Antarctic, there is a lower risk of invasive species (*limited evidence*) (McCarthy et al., 2019; Holland et al., 2021).

Fisheries are largely sustainably managed, yet are expanding polewards following sea-ice melt in the Arctic (*high confidence*) (Fauchald et al., 2021) and possibly in the Antarctic (*limited evidence*) (Santa Cruz et al., 2018). Tourism is increasing and expanding in both polar regions, while shipping and hydrocarbon exploration are growing in the Arctic, increasing the risks of compound effects on vulnerable and already stressed populations and ecosystems (*high confidence*) (Sections 3.6.3.1.3, 3.6.3.1.4, Cross-Chapter Paper 6, Hauser et al., 2018; Meredith et al., 2019; Helle et al., 2020; Rogers et al., 2020; Cavanagh et al., 2021).

Ensemble global model projections indicate future increases in primary production and total animal biomass towards 2100 under RCP2.6 (~ 5% and 50%, respectively) and RCP8.5 (~10% and 70%, respectively), in the Arctic (Bryndum-Buchholz et al., 2019; Lotze et al., 2019; Nakamura and Oka, 2019), highlighting opportunities for, and possibly conflicts over, new ecosystem services (Section 3.5). For the Southern Ocean, no overall trends are apparent, but greater variability in both primary production and total animal biomass are projected under RCP2.6, with a ~5% and 15% increase in primary production and total animal biomass under RCP8.5, respectively (Bryndum-Buchholz et al., 2019; Lotze et al., 2019; Nakamura and Oka, 2019). All projections presented exhibit high inter-model variability and hence uncertainty (Heneghan et al., 2021). Furthermore, regional models project significant distributional shifts and wide-ranging trends (i.e., relatively stable, increasing and declining) in productivity for key ecological and commercial species, and functional groups, with weak to strong dependence on emission scenarios, indicating *low confidence* in future outcomes for polar marine ecosystems and associated ecosystem services (Section 3.5, Piñones and Fedorov, 2016; Griffiths et al., 2017; Klein et al., 2018; Hansen et al., 2019; Meredith et al., 2019; Steiner et al., 2019; Tai et al., 2019; Alabia et al., 2020; Holsman et al., 2020; Reum et al., 2020; Veytia et al., 2020; Sandø et al., 2021). Potentially highly influential tipping points associated with Arctic sea-ice melt and Antarctic ocean circulation change adds to this uncertainty (Cross-Chapter Paper 6, Heinze et al., 2021). Nevertheless, increasing evidence supports that sustainable and adaptive ecosystem-based fisheries practices can reduce detrimental impacts of climate change on harvested populations (*medium confidence*) (Section 3.6.3.1.2, Klein et al., 2018; Free et al., 2019; Hansen et al., 2019; Holsman et al., 2020).

3.4.3 Oceanic Systems and Cross Cutting Changes

The oceanic zone, comprising >99% of the ocean's volume, is highly exposed to climate-impact drivers because of its proximity to the atmosphere (Section 3.2, Pörtner et al., 2014; Bindoff et al., 2019), while its relative distance from human settlements and coastal ecosystems decreases variability and interactions, and permits many phenomena to be detected clearly and attributed to climate change. This section assesses how climate-driven changes influence oceanic biological systems over very large spatial scales and notes how impacts on the epipelagic zone affect the mesopelagic, bathypelagic, and deep seafloor ecosystems.

3.4.3.1 Biogeography and Species Range Shifts

3.4.3.1.1 Observed species range shifts

Since previous assessments (Table 3.16), poleward range-shifts have remained a ubiquitous response to climate change (*high confidence*), moving species from warmer regions into higher-latitude ecosystems (Fossheim et al., 2015; Kumagai et al., 2018; Burrows et al., 2019; Lenoir et al., 2020).

Table 3.16: Summary of previous IPCC assessments of biogeography and species range shifts.

Observations	Projections
AR5: (Hoegh-Guldberg et al., 2014; Pörtner et al., 2014)	
The distribution and abundance of many fishes and invertebrates have shifted poleward and/or to deeper, cooler waters (*high confidence*). On average, species' distributions have shifted poleward by 72.0 ± 0.35 km per decade (*high confidence*).	Spatial shifts of marine species due to projected warming will cause high-latitude invasions and high local-extinction rates in the tropics and semi-enclosed seas (*medium confidence*).
SROCC (Bindoff et al., 2019)	
Ocean warming has contributed to observed changes in biogeography of organisms ranging from phytoplankton to marine mammals (*high confidence*). The direction of the majority of the shifts of epipelagic organisms are consistent with a response to warming (*high confidence*) but are also shaped by oxygen concentrations and ocean currents across depth, latitudinal and longitudinal gradients (*high confidence*). Geographic ranges have shifted since the 1950s by 51.5 ± 33.3 km per decade (mean and *very likely* range) and 29.0 ± 15.5 km per decade for organisms in the epipelagic and seafloor ecosystems, respectively.	Recent model projections since AR5 and SR15 continue to support global-scale range shifts of marine fishes at rates of tens to hundreds of km per decade in the 21st century, with rate of shifts being substantially higher under RCP8.5 than RCP2.6.

Thermal tolerances of epipelagic populations drive biogeographic change (Figures 3.10, 3.15), but the strength and direction of range shifts tend to be modulated by both climate and non-climate drivers (Pinsky et al., 2020b), including: interactive effects of hypoxia and ocean acidification (Sampaio et al., 2021); oceanic dispersal barriers (Choo et al., 2021), food and critical habitat availability (Alabia et al., 2020; Tanaka et al., 2021), geographic position (including depth, Mardones et al., 2021), and ocean currents (Sunday et al., 2015; Chapman et al., 2020; Fuchs et al., 2020). The difference between physiological thermal tolerances (Section 3.3.2) and local environmental conditions determines safety margins against future climate warming in ectotherms (Pinsky et al., 2019). Acclimation and evolution (Section 3.3.4) and life-history stage (Section 3.3.3) also alter species' thermal tolerances. Biogeographic responses are further modulated by other interacting factors (Table 3.17).

A large global meta-analysis of range shifts across multiple levels of the marine food web (Lenoir et al., 2020) estimates that marine species are moving poleward at a rate of 59.2 km per decade (*very likely* range: 43.7–74.7 km per decade), closely matching the local climate velocity (*high confidence*). In some cases, warming-related distribution shifts were followed by density-dependent use of these areas, influencing associated fisheries (Baudron et al., 2020), and in others, warming influenced competitive interactions: in the Arctic-Boreal Barents Sea, warming-induced increases in cod (*Gadus morhua*) abundance reduces haddock (*Melanogrammus aeglefinus*) abundance (Durant et al., 2020).

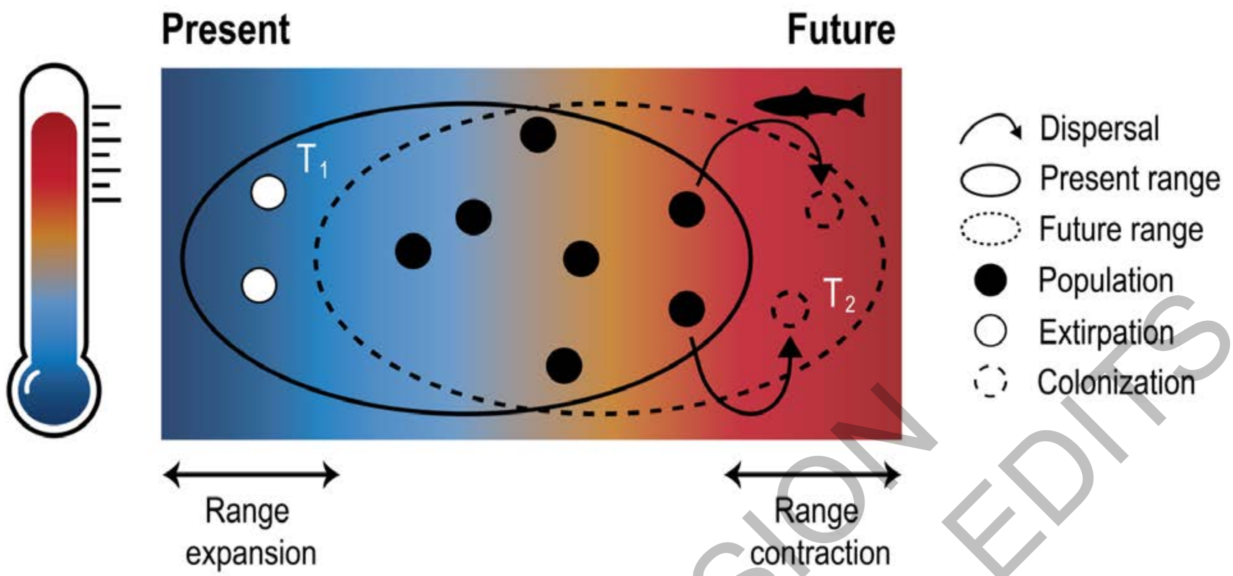

Figure 3.15: Schematic of range-shift dynamics in marine ectotherms in response to climate warming. As the ocean warms, conditions at the edge of the species' distribution may become warmer than the maximum thermal tolerance of the species (such as with T_2, see Figure 3.9), causing local populations to undergo a gradual decline in performance, a decreasing population size and ultimately their extirpation, resulting in a range contraction. Conversely, at the cool extreme of the distribution (such as with T_1), habitats beyond the current range of the species will become thermally suitable in the future (i.e., within the species' thermal tolerance range) and, providing the species can disperse to those locations, allow for the colonisation and consolidation of new populations and subsequent range expansion. These are processes conditioned by multiple drivers that interact with warming to ultimately define range shift responses; some of which are described in Table 3.17. Note that physiological thermal tolerances relate to body temperatures of the organism rather than ambient temperatures.

Table 3.17: Synthesis of selected processes conditioned by multiple environmental drivers that interact with warming to ultimately define range-shift responses.

Factor	Effect	Example references
Evolution and acclimation	Evolution of thermal tolerances and acclimation under local climatic conditions can increase resilience to future climate warming, slowing the loss of species at trailing (warm) range edges.	(Palumbi et al., 2014; Miller et al., 2020a)
Marine heatwaves (MHWs)	Influence the evolution of thermal tolerances by eliminating genotypes that are intolerant of elevated temperatures.	(Buckley and Huey, 2016; Sunday et al., 2019)
	MHWs can produce widespread die-offs of shallow-water benthic organisms triggering extensive contractions of their ranges.	(Smale and Wernberg, 2013)
	MHWs can facilitate range expansions by opening niches and/or enhancing recruitment of warm-affiliated species.	(Leriorato and Nakamura, 2019; Thomsen et al., 2019; Monaco et al., 2021)
	Cold-waves can halt or even reverse range expansions at leading edges.	(Leriorato and Nakamura, 2019)

Ocean currents	Influence range dynamics through their effect on dispersal, depending on their magnitude, direction and seasonal patterns.	(Hunt et al., 2016; Kumagai et al., 2018; Fuchs et al., 2020)
	Where currents align with spatial gradients of warming, range expansions track thermal changes more closely. Conversely, directional mismatches result in consistently slower expansion rates and larger response lags; an effect more acute for benthic organisms relying on passive dispersion of larvae and propagules.	(García Molinos et al., 2017)
	Rates of range contraction across taxa decreased (increased) under directional agreement (mismatch) with ocean currents, possibly associated with enhanced (reduced) flows of adaptive genes to warming in downstream (upstream) populations within the distributional range.	(García Molinos et al., 2017)
Climatic refugia	Areas of locally stable climatic conditions, such as deeper waters or regions with internal tides or localised upwelling, can buffer the effects of regional warming, facilitating species persistence and conserving genetic diversity at rear edge populations.	(Smith et al., 2014; Assis et al., 2016; Lourenço et al., 2016; Wyatt et al., 2020)
	Distributional shifts into deeper, cooler habitats can offer an effective alternative response to latitudinal shifts, because sharper thermal gradients mean vertical displacements, needed to compensate for the same amount of warming, are several orders of magnitude smaller than planar displacements.	(Smith et al., 2014; Assis et al., 2016; Lourenço et al., 2016)
Oxygen availability	Oxygen supersaturation may extend ectotherm survival to extreme temperatures and increase thermal tolerances by compensating for the increasing metabolic demand at high temperatures.	(Giomi et al., 2019)
	Oxygen deprivation increases metabolic demand and respiration rates. Shallowing of oxygen dead zones and subsequent hypoxic avoidance can render deep thermal refuges unsuitable for organisms.	(Brown and Thatje, 2015; Roman et al., 2019; Hughes et al., 2020)
Habitat availability and quality	The availability and quality of habitat (underwater light conditions, adequate substrate, nutrient and food supply) set limits to the distribution of organisms and range shift dynamics (e.g., resilience of populations to climate warming and the consolidation of range expansions).	(Krause-Jensen et al., 2019; Tamir et al., 2019)
Biotic interactions, including food availability	Species interactions can confer resilience to warming by retarding habitat degradation and buffering the impacts of warming on organisms.	(Falkenberg et al., 2015; Giomi et al., 2019)

	Changes in biotic interactions (e.g., altered predation rates, food availability, competition or trophic mismatches) induced by climate warming can modify range-shift dynamics.	(Selden et al., 2018; Westerbom et al., 2018; Figueira et al., 2019; Pinsky et al., 2020b; Monaco et al., 2021)

Biogeographic shifts lead to novel communities and biotic interactions (*high confidence*) (Zarco-Perello et al., 2017; Pecuchet et al., 2020b), with concomitant changes in ecosystem functioning and servicing (*high confidence*) (Vergés et al., 2019; Nagelkerken et al., 2020; Peleg et al., 2020). For instance, temperature-driven changes in distribution and abundance of copepods, the dominant zooplankton, were observed between 1960–2014 in the North Atlantic. These changes subsequently affect biogenic carbon cycling through alteration of microbial remineralisation and carbon sequestration in deep water (*medium confidence*) (Section 3.4.3.6, Pitois and Fox, 2006; Brun et al., 2019).

3.4.3.1.2 Observed vertical redistributions

Epipelagic isotherms have recently (1980–2015) deepened at an average of 6.6 ± 18.8 m per decade (Pinsky et al., 2019) but, there is *low agreement* on whether species move deeper in pursuit of thermal refuge. Prior studies suggested range shifts to depth (Dulvy et al., 2008; Pinsky et al., 2013; Yemane et al., 2014), but increasing evidence suggests that fish and planktonic communities across large parts of the North Atlantic, sub-Arctic and northeast Pacific Ocean redistribute horizontally with horizontal climate velocity, except where vertical temperature gradients are particularly steep. There is *low confidence* for temperature-driven depth shifts in the epipelagic zone (Burrows et al., 2019; Campana et al., 2020; Caves and Johnsen, 2021). At the same time, decreasing oxygen concentrations and the vertical expansion of OMZs have already decreased suitable habitat of pelagic fishes, including tuna and billfishes, by ~15% primarily due to vertical compression of environmental niches (Stramma et al., 2012; Deutsch et al., 2015).

3.4.3.1.3 Projected changes in species range shifts

Continued changes in the biogeography of marine predators and prey are anticipated under future climate change, with climate velocity in the epipelagic zone during 2050–2100 under RCP8.5 projected to be sevenfold faster than that during 1955–2005 (*medium confidence*) (Figure 3.4, Brito-Morales et al., 2020). This have substantial ecological implications, as projections suggest near-elimination of overlaps between the distributions of certain predator-prey pairs in the northeast Atlantic Ocean when their current joint distributions (1989–2014) are compared with those projected (2037–2062) under RCP8.5 (Sadykova et al., 2020).

Deepening of epipelagic isotherms is projected to accelerate over 2006–2100 to rates of 8.5 m per decade under RCP4.5 and 32 m per decade under RCP8.5 (Jorda et al., 2020). Although vertical redistribution of thermal niches is three to four orders of magnitude slower than horizontal displacement, maximum depth limits imposed by the seafloor and photic layer (both of which are projected to be reached in this century) will *likely* vertically compress suitable habitat for most marine organisms (*medium confidence*) (Dueri et al., 2014; Jorda et al., 2020).

Projections from coupled biogeochemical and ecosystem models suggest a general decline in mesopelagic biomass (Lefort et al., 2015), although this may vary among ocean basins. The volume of OMZs have been expanding at many locations (*high confidence*), and the oxygen content of the subsurface ocean is projected to decline to historically unprecedented conditions over the 21st century (*medium confidence*) (Section 3.2.3.2, WGI AR6 Section 5.3.3.2, Canadell et al., 2021) at a rate of 10–15 µM per decade in OMZs (Section 3.2.3.2, Breitburg et al., 2018). Oxygen availability and the effects of ocean acidification (Sections 3.3, 3.4.2) on zooplankton might become a dominant constraint in the upper ocean's metabolic index, which is projected to decrease globally by 20% by 2100 (Deutsch et al., 2015; Steinberg and Landry, 2017). In addition, extremely rapid acceleration of climate velocities projected in the mesopelagic under all emissions scenarios suggest that species in this ocean stratum will be even more exposed to future warming than species in the epipelagic (Figure 3.4, Brito-Morales et al., 2020). But projections also suggest that warming-related increases in trophic efficiency lead to a 17% increase in the biomass of the deep scattering layer (zooplankton and fish in the mesopelagic) by 2100 (low *confidence*) (Bindoff et al., 2019); observational studies appears to show that mesopelagic fishes adapted to warm water increased in abundance and distribution in the California Current associated with warming and the expansion of OMZ (Koslow et al., 2019), suggesting that some mesopelagic fish stocks might be resilient to a changing climate (*medium confidence*).

3.4.3.2 Phenological shifts & trophic mismatches

3.4.3.2.1 Observed changes

SROCC reported *high confidence* in phenological shifts towards earlier onset of biological events (Table 3.18), with phenological shifts among epipelagic species attributed to ocean warming (*high confidence*).

Table 3.18: Summary of previous IPCC assessments of phenological shifts & trophic mismatches

Observations	Projections
AR5 WGII (Hoegh-Guldberg et al., 2014; Larsen et al., 2014)	Projections of phenological shifts and trophic mismatches were not assessed in this report.
Changes to sea temperature have altered the phenology, or timing of key life-history events such as plankton blooms, and migratory patterns and spawning in fish and invertebrates, over recent decades (*medium confidence*). There is *medium to high agreement* that these changes pose significant uncertainties and risks to fisheries, aquaculture, and other coastal activities. The highly productive high-latitude spring bloom systems in the northeastern Atlantic are responding to warming (*medium evidence, high agreement*), with the greatest changes being observed since the late 1970s in the phenology, distribution, and abundance of plankton assemblages, and the reorganisation of fish assemblages, with a range of consequences for fisheries (*high confidence*). Observed changes in the phenology of plankton groups in the North Sea over the past 50 years are driven by climate forcing, in particular regional warming (*high confidence*). On average, spring events in the ocean have advanced by 4.4 ± 0.7 days per decade (mean ± SE). Shifts in the timing and magnitude of seasonal biomass production could disrupt matched phenologies in the food webs, leading to decreased survival of dependent species (*medium confidence*). If the timing of primary and secondary production is no longer matched to the timing of spawning or egg release, survival could be impacted, with cascading implications to higher trophic levels. This impact would be exacerbated if shifts in timing occur rapidly (*medium confidence*). There is *medium to high confidence* that climate- induced disruptions in the synchrony between timing of spawning and hatching of some fish and shellfish and the seasonal increases in prey availability can result in increased larval or juvenile mortality or changes in the condition factor of fish and shellfish species in the Arctic marine ecosystems.	
SROCC (Bindoff et al., 2019)	
Phenology of marine ectotherms in the epipelagic systems are related to ocean warming (*high confidence*) and that	Projections of phenological shifts and trophic mismatches were not assessed in this report.

the timing of biological events has shifted earlier (*high confidence*). Timing of spring phenology of marine organisms is shifting to earlier in the year under warming, at an average rate of 4.4 ± 1.1 days per decade, although it is variable among taxonomic groups and among ocean regions.	
WGI AR6 Chapter 2 (Gulev et al., 2021)	
Phenological metrics for many species of marine organisms have changed in the last half-century (*high confidence*), though many regions and many species of marine organisms remain under-sampled or even unsampled. The changes vary with location and with species (*high confidence*). There is a strong dependence of survival in higher trophic-level organisms (fish, exploited invertebrates, birds) on the availability of food at various stages in their life cycle, which in turn depends on phenologies of both (*high confidence*). There is a gap in our understanding of how the varied responses of marine organisms to climate change, from a phenological perspective, might threaten the stability and integrity of entire ecosystems.	Projections of phenological shifts and trophic mismatches were not assessed in this report.

Since SROCC, field data have continued to show that the phenology of biological events in the ocean is *very likely* (*high* to *very high confidence*) advancing in response to climate change, with 71.9% of published observations consistent with these anticipated effects (Figure 3.16a,b; Table 3.19), although most reports (95.6%) were from the Northern Hemisphere (Figure 3.16a). Biological events that are shifting earlier in response to climate change include phytoplankton blooms (Scharfe and Wiltshire, 2019; Chivers et al., 2020) such as those of HAB species (Forsblom et al., 2019; Bucci et al., 2020); peaks in zooplankton abundance (Chevillot et al., 2017; Forsblom et al., 2019); the migration (Otero et al., 2014; Kovach et al., 2015; Chust et al., 2019) and spawning of commercial fish (McQueen and Marshall, 2017; Kanamori et al., 2019) including crabs and squid (Henderson et al., 2017); and breeding of marine reptiles (Mazaris et al., 2008; Cherkiss et al., 2020). Moreover, different trophic levels within epipelagic food webs are responding at different rates (*very high confidence*) (Table 3.19, Figure 3.16b,c), with greater and more consistent responses by lower trophic levels (phytoplankton, holozooplankton and meroplankton), but less consistent, weaker and more varied responses by higher trophic levels. There were too few independent time series to make robust estimates for benthic invertebrates, plants, marine reptiles and mammals. This differential response across trophic levels could lead to trophic mismatches (Neuheimer et al., 2018), where predators and their prey respond asynchronously to climate change (Edwards and Richardson, 2004; Rogers and Dougherty, 2019; Rubenstein et al., 2019; Émond et al., 2020), with potential population-level consequences, including declines in fish recruitment (Burthe et al., 2012; Chevillot et al., 2017; McQueen and Marshall, 2017; Asch et al., 2019; Durant et al., 2019; Régnier et al., 2019). Available evidence also suggests that feeding relationships could modulate species responses to climate change, as seen in breeding of surface-feeding and deeper-diving seabirds (Descamps et al., 2019). These differential responses could determine ‘winners’ and ‘losers’ under future climate change (Lindén, 2018).

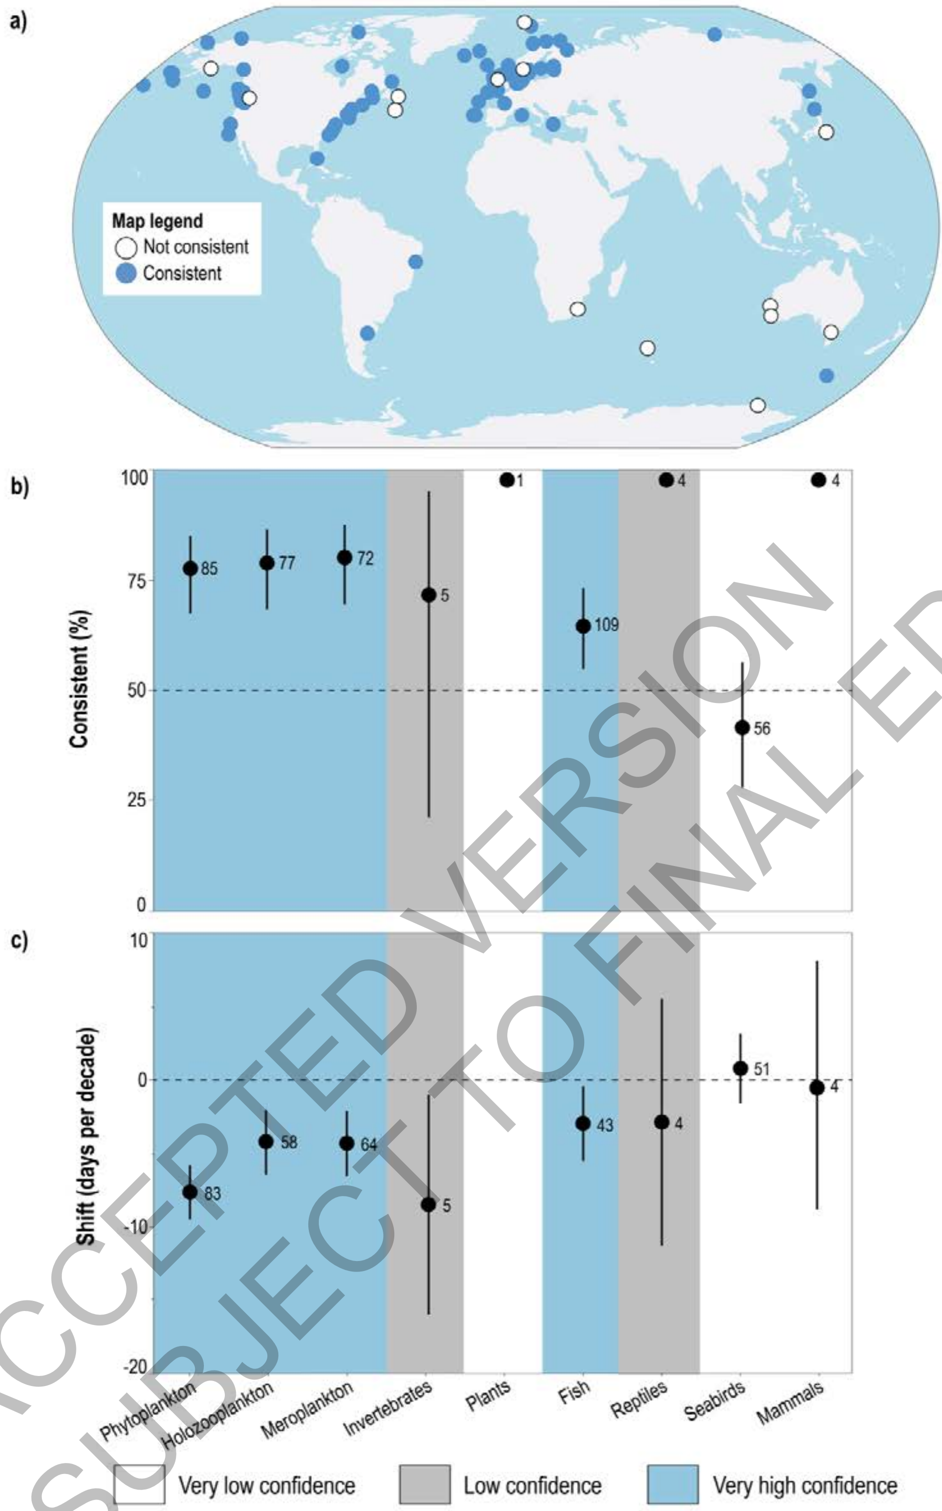

Figure 3.16: Observed responses to climate change based on a systematic Web of Science review of marine phenology studies exceeding 19 years in length to update the assessment in WGII AR5 Chapter 30 (Hoegh-Guldberg et al., 2014). Error bars indicate 95% confidence limits (i.e., the *extremely likely* range). (a) Global data showing changes in seasonal cycles of biota that are attributed (at least partly) to climate change (blue, n=297 observations), and changes that are inconsistent with climate change (white, n=116 observations). Each circle represents the centre of a study area. (b) The proportion of phenological observations (showing means and *extremely likely* ranges) that are attributed to climate change (i.e., generally showing earlier timing) by taxonomic group. (c) Observed shift in timing (days per decade, showing means and *extremely likely* ranges), by taxonomic group, that are attributed to climate change. Negative shifts are earlier, positive shifts are later. Details and additional plots are presented in SM3.3.3, Figure SM3.3 and Table SM3.1.

Table 3.19: Assessment of phenological shifts by taxon based on time series from field observations spanning at least 19 years published over the past 25 years.

Taxon	Rate of consistency of observations with climate change	Estimated mean rate of change in seasonal timing	Confidence	Notes
Phytoplankton	78.41% (n=85)	–7.5 days per decade (n=83)	*Very high confidence*	*Evidence most robust* for changes in timing of blooms in the North Atlantic (e.g., Chivers et al., 2020) and Baltic (e.g., Scharfe and Wiltshire, 2019; Wasmund et al., 2019), with *limited evidence* from the Southern Hemisphere.
Holozooplankton	79.74% (n=77)	–4.27 days per decade (n=58)	*Very high confidence*	*Evidence most robust* in the northeast Atlantic (e.g., Chevillot et al., 2017), but sparse elsewhere.
Meroplankton (taxa that are only temporarily in the plankton)	81.06% (n=72)	–4.34 days per decade (n=64)	*Very high confidence*	Includes earlier peak abundance of fish larvae in upwelling systems (e.g., Asch, 2015).
Benthic invertebrates	72.34% (n=5)	–8.5 days per decade (n=5)	*Low confidence* (*limited evidence, medium agreement*)	*Evidence is limited*, uncertainty levels are high. Rate of consistency of responses with climate change is not significantly different from random chance.
Plants	100% (n=1)	No estimate available	*Very low confidence*	Just a single study for seagrasses, and only for consistency (Diaz-Almela et al., 2007).
Fish	65.48% (n=109)	–3.02 days per decade (n=43)	*Very high confidence*	Includes earlier appearance of migratory fish in estuaries (e.g., Chevillot et al., 2017), earlier spawning migrations for anadromous fish such as salmon (e.g., Rubenstein et al., 2019), earlier migrations for sole (e.g., Fincham et al., 2013) and tuna (e.g., Dufour et al., 2010), and earlier spawning of key commercial demersal (bottom-dwelling) species such as cod (e.g., McQueen and Marshall, 2017).

Marine reptiles	100.0% (n=4)	–2.89 days per decade (n=4)	*Low confidence* (*limited evidence, low agreement*)	*Evidence is limited*, uncertainty levels are high. Mean phenological shift is not significantly different from zero.
Seabirds	42.36% (n=56)	+0.77 days per decade (n=51)	*Very low confidence* (*limited evidence, low agreement*)	Neither the rate of consistency with climate change nor the phenological shift differ significantly from null expectations (50% consistency and no shift). Many seabirds are breeding earlier (Byrd et al., 2008; Sydeman et al., 2009), while breeding among others in temperate and polar regions has been delayed, which has been linked to later sea-ice breakup or limited prey resources (Barbraud and Weimerskirch, 2006; Wanless et al., 2009; Chambers et al., 2014). Although the response of lifecycle events for many seabird species is variable in direction, there has usually been a more complex driver associated with climate that has been considered to be responsible (Sydeman et al., 2015). For many species, seasonal timing is moving earlier, especially in the Arctic (e.g., Byrd et al., 2008; Descamps et al., 2019), but for many species in the Southern Ocean, it is not (Barbraud and Weimerskirch, 2006; Chambers et al., 2014). This could be because of a much slower rate of warming in most of the Southern Ocean than in the Arctic.
Marine mammals	100.0% (n=4)	–0.34 days per decade (n=4)	*Very low confidence* (*limited evidence, low agreement*)	All studies of phenological changes for marine mammals have focused on whales (e.g., Ramp et al., 2015; Hauser et al.,

2017; Loseto et al., 2018) or polar bears (e.g., Cherry et al., 2013; Atwood et al., 2016; Escajeda et al., 2018) and have related timing to aspects of sea ice dynamics, highlighting the complexity of such processes. Mean phenological shift is not significantly different from zero at the global scale.

3.4.3.2.2 Projected changes

The CMIP6 ESM ensembles project that, by 2100, 18.8% ± 19.0% (mean ± *very likely* range) and 38.9% ± 9.4% of the ocean surface will *very likely* undergo a change of 20 days or more (advance or delay) in the start of the phytoplankton growth period under SSP1-2.6 and SSP5-8.5, respectively (Figure 3.17a,b) (*low confidence* due to the dependence with the projected changes in phytoplankton biomass which trends are reported with *low confidence*) (Section 3.4.3.4 and SROCC Section 5.2.3, Bindoff et al., 2019). Phytoplankton growth is projected to begin later in the Northern Hemisphere subtropics, and earlier at high latitudes in some regions around the Antarctic Peninsula, and over large areas in the Northern Hemisphere (*low to medium confidence* as there are improved constraints from historical variability in this region and consistency with CMIP5-based studies results) (Henson et al., 2018b; Asch et al., 2019). There is *high agreement* in model projections that the start of the phytoplankton growth period will *very likely* advance in the Arctic Ocean under a high-emission scenario for CMIP5 and CMIP6 (Figure 3.17b, Henson et al., 2018b; Asch et al., 2019; Tedesco et al., 2019; Lannuzel et al., 2020). The CMIP6 ensemble projections further show limited changes in phenology across most of the Southern Ocean, but large regional variations in the tropics (Figure 3.17). Overall, the regional patterns are qualitatively similar under SSP1-2.6 and SSP5-8.5, but with greater magnitude and larger areas under SSP5-8.5 (*low confidence*).

At latitudes >40ºN, temperature-linked phenology of fish reproduction with high geographic fidelity to spawning grounds (geographic spawners) is projected to change at double the rate of that for phytoplankton, which will *likely* cause phenological mismatches resulting in increased risk of starvation for fish larvae (*medium* to *high confidence*) (WGI AR6 Section 2.3.4.2.3, Asch et al., 2019; Durant et al., 2019; Régnier et al., 2019; Gulev et al., 2021; Laurel et al., 2021). Furthermore, under RCP8.5, trophic mismatch events exceeding ±30 days (Asch et al., 2019) leading to fish recruitment failure are expected to increase 10-fold for geographic spawners across much of the North Atlantic, North Pacific and Arctic Ocean basins (*low confidence*) (Neuheimer et al., 2018). In contrast, temporal mismatches between fish that relocate spawning grounds in response to environmental variations (environmental spawners) and phytoplankton blooms are projected to remain shorter and less varied, suggesting that across ocean basins, range shifts by environmental spawners may increase their resilience. Nevertheless, this compensation mechanism might fail at locations where phytoplankton bloom phenology is not controlled by temperature-driven water-column stratification, leading to a possible six-fold local increase in extreme mismatches under climate change (Asch et al., 2019).

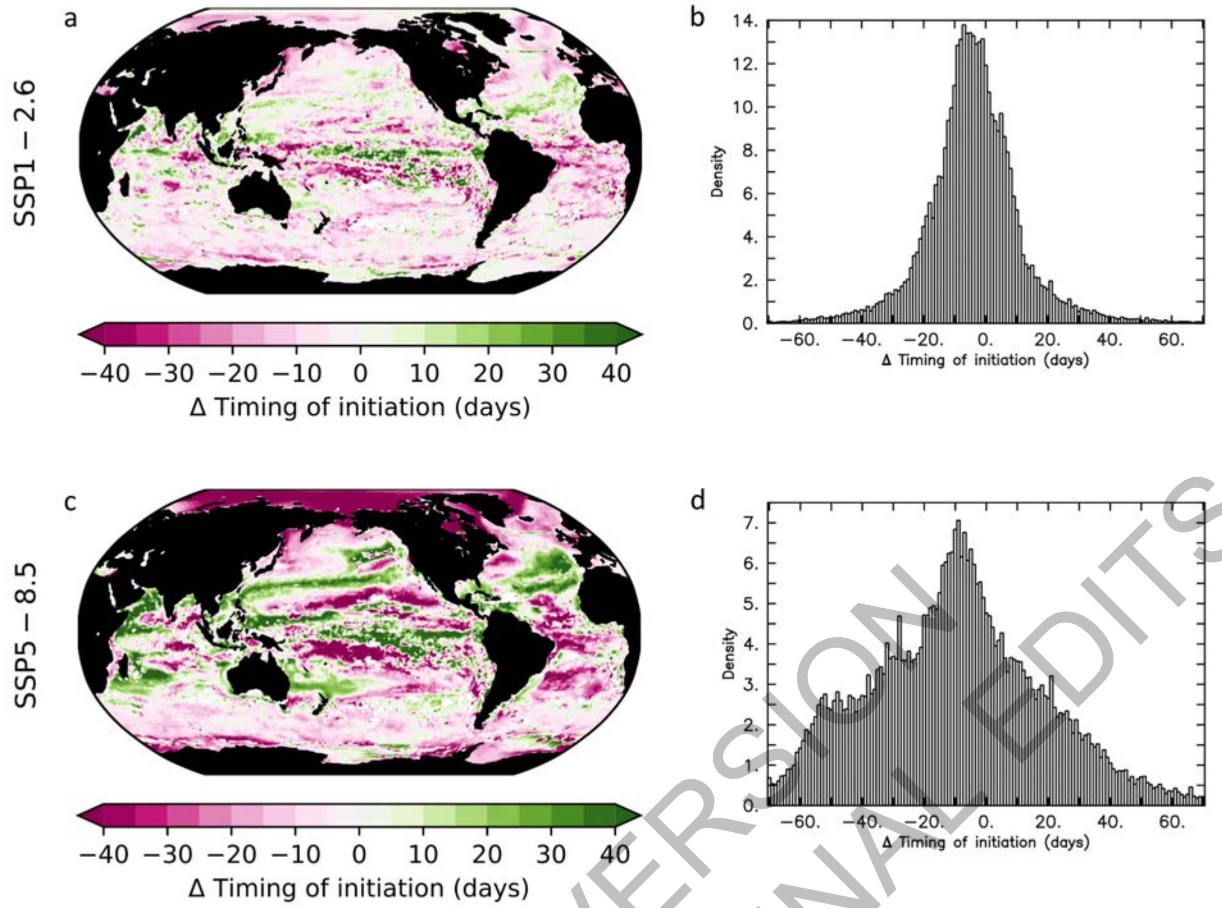

Figure 3.17: Projected phytoplankton phenology. (a,c) Spatial patterns and (b,d) density distributions of projected change in phytoplankton phenology by 2100 under Shared Socioeconomic Pathway (SSP)1-2.6 and SSP5-8.5, respectively. Difference in the start of the phytoplankton growth period is calculated as 2090–2099 minus 1996–2013. Negative (positive) values indicate earlier (later) start of the phytoplankton growth period by 2100. The ensemble projections of global changes in phytoplankton phenology include, under SSP1-2.6 and SSP5-8.5, respectively, a total of five Coupled Model Intercomparison Project 6 Earth System Models containing coupled ocean biogeochemical models that cover a wide range of complexity (Kwiatkowski et al., 2019). The phenology calculations are based on Racault et al. (2017) using updated data.

3.4.3.3 Changes in Community Composition and Biodiversity

3.4.3.3.1 Evidence of natural adaptive capacity based on species' responses to past climate variability

Responses to abrupt climate change in the geological past suggest that adaptive capacity is limited for marine animals (Cross-Chapter Box PALEO in Chapter 1). Temperatures during the last Interglacial (~125 ka), which were warmer than today, led to poleward range shifts of reef corals (*medium confidence*) (Kiessling et al., 2012; Jones et al., 2019a). Temperature has also driven marine range shifts over multi-million-year timescales (*medium confidence*) (Gibbs et al., 2016; Reddin et al., 2018). Warming climates, even with low ocean warming rates, inevitably decreased tropical marine biodiversity compared with mid-latitudes (*high confidence*) (Mannion et al., 2014; Crame, 2020; Yasuhara et al., 2020; Raja and Kiessling, 2021).

The paleo record confirms that marine biodiversity has been vulnerable to climate warming both globally and regionally (*very high confidence*) (Cross-Chapter Box PALEO in Chapter 1, Stanley, 2016). In extreme cases of warming (e.g., >5.2°C), marine mass extinctions occurred in the geological past, and there may be a relationship between warming magnitude and extinction toll (*medium confidence*) (Song et al., 2021b). A combination of warming and spreading anoxia caused marine extinctions in ancient episodes of rapid climate warming (*high confidence*) (Bond and Grasby, 2017; Benton, 2018; Penn et al., 2018; Them et al., 2018; Chen and Xu, 2019). The role of ocean acidification in ancient extinctions is yet to be resolved (*low confidence*) (Clapham and Payne, 2011; Clarkson et al., 2015; Jurikova et al., 2020; Müller et al., 2020).

3.4.3.3.2 Community Structure and Biodiversity

Observed contemporary changes

Ocean temperature is a major driver of species richness in the global ocean at evolutionary timescales (Tittensor et al., 2010; Chaudhary et al., 2021). This, together with temperature-driven range and phenology shifts evident across taxa and ocean ecosystems (Sections 3.4.3.1, 3.4.3.2), suggests that recent ocean warming (Section 3.2.2.1) should alter biodiversity at regional to global scales. Since previous assessments (Table 3.20), the most common evidence supporting these expected changes is replacement of cold-adapted species by warm-adapted species within an ecosystem as waters warm (Worm and Lotze, 2021). Known as tropicalisation (Section 3.4.2.3), this phenomenon has been attributed to ocean warming (*medium* to *high confidence*) in communities as diverse as kelp, invertebrates, plankton and fish (Burrows et al., 2019; Flanagan et al., 2019; Ajani et al., 2020; Villarino et al., 2020; Punzón et al., 2021; Smith et al., 2021).

Table 3.20: Summary of previous IPCC assessments of community composition and biodiversity.

Observations	Projections
AR5: (Hoegh-Guldberg et al., 2014; Pörtner et al., 2014)	
The paleoecological record shows that global climate changes comparable in magnitudes to those projected for the 21st century under all scenarios resulted in large-scale biome shifts and changes in community composition; and that for rates projected under RCP6 and 8.5 were associated with species extinctions in some groups (*high confidence*). Loss of corals due to bleaching has a potentially critical influence on the maintenance of marine biodiversity in the tropics (*high confidence*).	Spatial shifts of marine species due to projected warming will cause high-latitude invasions and high local-extinction rates in the tropics and semi-enclosed seas (*medium confidence*). Species richness and fisheries catch potential are projected to increase, on average, at mid and high latitudes (*high confidence*) and decrease at tropical latitudes (*medium confidence*). Shifts in the geographical distributions of marine species cause changes in community composition and interactions. Thereby, climate change will reassemble communities and affect biodiversity, with differences over time and between biomes and latitudes (*high confidence*). Models are currently useful for developing scenarios of directional changes in net primary productivity, species distributions, community structure, and trophic dynamics of marine ecosystems, as well as their implications for ecosystem goods and services under climate change. However, specific quantitative projections by these models remain imprecise (*low confidence*).
SROCC (Bindoff et al., 2019)	
Ocean warming has contributed to observed changes in biogeography of organisms ranging from phytoplankton to marine mammals (*high confidence*), consequently changing community composition (*high confidence*), and in some cases, altering interactions between organisms and ecosystem function (*medium confidence*).	Poleward range shifts are projected to decrease species richness in tropical oceans, counterbalanced by increases in mid to high-latitude regions, leading to global-scale species turnover (*medium confidence* on trends, *low confidence* on magnitude because of model uncertainties and limited number of published model simulations). The projected intensity of species turnover is lower under low-emission scenarios (*high confidence*). Projections from multiple fish species distribution models show hotspots of decrease in species richness in the Indo-Pacific region, and semi-enclosed seas such as the Red Sea and Persian Gulf (*medium evidence, high agreement*). In addition, geographic barriers, such as land, bounding the poleward species range edge in semi-enclosed seas or low-oxygen water in deeper waters are projected to limit range shifts, resulting in larger relative decrease in species richness (*medium confidence*).

	The large variation in sensitivity of different zooplankton taxa to future conditions of warming and ocean acidification suggests elevated risk to community structure and inter-specific interactions of zooplankton in the 21st century (*medium confidence*).

At local to regional scales, tropicalisation often increases species richness where warm-water species extend their ranges to overlap with existing communities, and decreases species richness where warming waters extirpate species (*medium* to *high confidence*) (Friedland et al., 2020a; Chaudhary et al., 2021; Worm and Lotze, 2021). Latitudinal estimates from catalogued observations show declining species richness in equatorial waters over the past 50 years, with concomitant increases in species richness at mid-latitudes; the pattern is especially prominent in free-swimming pelagic species (Figure 3.18, Chaudhary et al., 2021). Similar patterns among marine animals have been described previously for historical warming events (Song et al., 2020b). Tropicalisation is associated with increased representation of herbivorous species (Vergés et al., 2016; Zarco-Perello et al., 2020; Smith et al., 2021), although observations and theory suggest that dietary generalism can also favour range-shifting species (Monaco et al., 2020; Wallingford et al., 2020).

Projected changes

At the community level, the magnitude and shape of biodiversity changes differ, depending on what groups are considered (*medium confidence*) (Chaudhary et al., 2021). Molecular-based richness measures indicate that the most dramatic increases in diversity relative to current conditions are expected for photosynthetic eukaryotes and copepods in the Arctic Ocean (Ibarbalz et al., 2019). However, component eukaryotic taxa, for example diatoms Busseni et al. (2020), are projected to lose diversity by 2100 under RCP8.5. Ecosystem models project a decline in nutrient supply that drives the disappearance of less-competitive and larger phytoplankton types, leading to extinction of up to 30% of diatom types, particularly in the northern hemisphere, by 2100 under RCP8.5 (Henson et al., 2021). Models further suggest that high latitudes are *likely* to encounter entirely novel phytoplankton communities by 2100 under RCP8.5 (100% change in community composition, Dutkiewicz et al., 2019; Reygondeau et al., 2020). At the polar edges, the increased richness is projected to coincide with high species turnover and increasing dominance of smaller phytoplankton types (Henson et al., 2021). These imply pronounced changes to both the oceans' ecological and biogeochemical function, as regions dominated by small phytoplankton typically support less-productive food webs (Section 3.4.3.4, Stock et al., 2017; Armengol et al., 2019) and sequester less particulate organic carbon in the deep ocean (Section 3.4.3.5, Mouw et al., 2016; Cram et al., 2018) than areas dominated by larger size classes (*high confidence*).

The profound climatic and environmental changes projected for the Arctic region by 2100 (Cross-Chapter Paper 6) are also anticipated to alter the composition of apex assemblages like marine mammals (Albouy et al., 2020, Box 3.2). Under both RCP2.6 and 8.5 scenarios the most vulnerable marine mammal species will be the North Pacific right whale (*Eubalaena japonica*, listed as an endangered species (IUCN, 2020)) and the gray whale (*Eschrichtius robustus*, which has critically endangered subpopulations (IUCN, 2020)). The extinction of the most-vulnerable species will disproportionately eliminate unique and important evolutionary lineages as well as functional diversity, with consequent impacts throughout the entire marine ecosystem (section 3.3.4). More generally, future warming and acidification simulated in mesocosm experiments support projections of a substantial increase in biomass and productivity of primary producers and secondary consumers, but a decrease by >40% of primary consumers (Nagelkerken et al., 2020). On longer time scales, alteration of energy flow through marine food webs may lead to ecological tipping points (Wernberg et al., 2016; Harley et al., 2017) after which the food web collapses into shorter, bottom-heavy trophic pyramids (*medium confidence*).

Global projections anticipate a *likely* future reorganisation of marine life of variable magnitude, contingent on emission scenario (Beaugrand et al., 2015; Jones and Cheung, 2015; Barton et al., 2016; García Molinos et al., 2016; Nagelkerken et al., 2020; Henson et al., 2021). Marine organism redistributions projected under RCP4.5 and RCP8.5 include extirpations and range contractions in the tropics, strongly decreasing tropical biodiversity, and range expansions at higher latitudes, associated with increased diversity and homogenisation of marine communities (Figure 3.18b). Under continuing climate change, the projected loss of biodiversity may ultimately threaten marine ecosystem stability (*medium confidence*) (Albouy et al., 2020;

Nagelkerken et al., 2020; Henson et al., 2021), altering both the functioning and structure of marine ecosystems and thus affecting service provisioning (*medium confidence*) (Section 3.5, Ibarbalz et al., 2019; Righetti et al., 2019).
