Inequality, poverty and informality shaping cities in the region increase vulnerability to climate change (*high confidence*) (Romero-Lankao et al., 2014; Rasch, 2017; Filho et al., 2019), and can hinder adaptation (Section 12.5.7.1), while interventions addressing these social challenges and the existing development deficits (e.g., build or improve infrastructure and housing applying climate-adapted patterns), can go hand in hand with adaptation and mitigation (*medium confidence: high agreement, medium evidence*) (Section 12.5.7.3; Creutzig et al., 2016; Le, 2020; Satterthwaite et al., 2020). Over 20% of urban population in LAC lives in slums and many in other forms of precarious and segregated neighbourhoods, settled in risk areas and lacking infrastructure (Rasch, 2017; UN-Habitat, 2018; Rojas, 2019). This vulnerable condition is boosted by unstable political and governmental institutions, which recurrently suffer from corruption, weak governance and reduced capacity to finance adaptation (Rasch, 2016). Facing governance challenges by including diverse stakeholders and encouraging and learning from community-based experiences has been also an opportunity to improve adaptation strategies (Archer et al., 2014). The Regional Climate Change Adaptation Plan of Santiago is an example of this (Krellenberg and Katrin, 2014).

12.5.5.2 Governance and Financing

Lack of a high multilevel and intersectoral governance capacity with strong multi-players horizontal and vertical coordination and long-term support are limiting adaptation in the region (*high confidence*) (Anguelovski et al., 2014; Bai et al., 2016; Chu et al., 2016; Schaller et al., 2016; Miranda Sara et al., 2017). The ability to enrol stakeholders and include community based initiatives can be determinant for adaptation success particularly considering its impact in the decision-making arena (*high confidence*) (Section 12.5.8.1; Section 6.4; Anguelovski et al., 2014; Archer et al., 2014; Chu et al., 2017; Rosenzweig et al., 2018) .

Lima's Climate Action Strategy is an example (Metropolitan Municipality of Lima, 2014). It was approved after a participatory and consultative process with the technical group on climate change from the Metropolitan Environmental Commission, focusing on the reduction of water vulnerabilities to drought and heavy rain, on the basis of which 10 (out of 51 with Callao) Lima districts municipalities are developing and starting to implement their adaptation measures (Foro Ciudades Para la Vida, 2021). In 2021 Lima Municipality also approved its Local Climate Change Plan (Metropolitan Municipality of Lima, 2021) under a similar process. The engagement of local players was central to spreading and mobilizing different types of knowledge and creating networks able to support adaptation (Section 12.6.3; Miranda Sara and Baud, 2014; Miranda Sara et al., 2017) . The inclusive process is also a goal on the example of Chile Municipalities Network Facing Climate Change (RedMuniCC) engaged in developing participatory strategic plans for climate adaptation and mitigation (RedMuniCC, 2021).

New forms of financing and leadership focused on community-based approaches have been developed to overcome the funding challenge and enable adaptation in the region (*medium confidence: medium evidence, medium agreement*) (Castán Broto and Bulkeley, 2013; Archer et al., 2014; Paterson and Charles, 2019). Also systems for measuring, reporting and verifying adaptation financing, as in Colombia (Guzmán et al., 2018), as much as national legislation geared to adaptation can help access funds. Peruvian Law on the Retribution Mechanism of Eco-Systemic Services and Code (Miranda Sara and Baud, 2014; MINAM Peru, 2016) in addition to the Ley Marco de la Gestión y Prestación de los Servicios de Saneamiento and its Code (Ministerio de Vivienda, 2017), allowed the potable water companies to add 1% to the tariff to guarantee ecosystem services, water treatment and reuse with green infrastructure. Another 4% of tariffs go to develop and implement adaptation plans and measures (Government of Peru, 2016).

12.5.5.3 Adaptation options in urban design and planning

Both the shape and activities of the city have an impact on carbon emissions, adaptation and mitigation opportunities (*high confidence*) (Raven et al., 2018; Satterthwaite et al., 2018). Combining urgent measures, strategic action (Chu et al., 2017) to long-term planning is central for a transformative adaptation and to avoid maladaptation (Filho et al., 2019). Urban planning, considering climate risk assessments, and regulation (e.g., land-use and building codes), including climate-adapted parameters, are central to coordinate and foster private and public investments in adaptation, reducing risks related to the built environment conditions (infrastructure and buildings) and the occupation of risk areas (e.g., threatened by floods and landslides) (Rosenzweig et al., 2018). Lack of information at local scale, human resources and clear liability for climate change response planning can limit adaptation (Aylett, 2015).

Strategic adaptation approaches have been adopted by many cities in dealing with the multilevel and intersectoral complexity of urban systems, with gains in fostering leadership and facing the predominant pattern of uneven urban development in the region (*medium confidence: limited evidence, high agreement*) (Chu et al., 2017). Medellin's metropolitan green belt, for example, focuses on problems such as irregular settlements, inequality and poor governance, articulating programs and projects of the Municipality of Medellin and the municipalities of the Vale do Aburra in a strategic long-term planning. Places with informal and precarious settlements were aimed to be transformed with the belt's integration areas: eco parks and eco-gardens (Alcaldía de Medellín, 2012; Chu et al., 2017).

12.5.5.3.1 Housing, informality and risk areas

Informality and precariousness in housing is one of the most sensitive issues for adaptation in CSA cities (*medium confidence: medium evidence, high agreement*) (Satterthwaite et al., 2018; UN-Habitat, 2018). Housing deficit in 2009, as a regional baseline, estimated that 37% of households suffered from quantitative or qualitative deficiencies, due to the high cost of housing and the incidence of poverty (Blanco Blanco et al., 2014; McTarnaghan et al., 2016; NU CEPAL et al., 2016; Vargas et al., 2018a; Rojas, 2019).

Policies and programs have been implemented accumulating good practices and reducing the percentage of population in informal and precarious settlements (33.7% in 1990 to 21% in 2014) (NU CEPAL et al., 2016; Satterthwaite et al., 2018; Teferi and Newman, 2018; UN-Habitat, 2018). Slum Upgrading and built-environment interventions (housing and infrastructure improvement and provision) in informal settlements can enhance adaptation (*high confidence*) (Teferi and Newman, 2018; Núñez Collado and Wang, 2020; Satterthwaite et al., 2020) while reducing floods, landslides and cascading impacts of storms, floods and epidemics, as observed on the "incremental housing approach" in Quinta Monroy (Rojas, 2019) and the "social urbanism" in Medellin (Garcia Ferrari et al., 2018).

The climate adaptation plans of several large CSA cities include efficient land use and occupation planning and urban control systems (comprising regulation, monitoring), fostering interlocution with housing and environmental policy (by means of intersectoral and multilevel governance), inhibiting and reducing the occupation of risk areas (mainly flooding and landslides risks); increasing population density in areas already served by infrastructure; expanding slums urbanization and technical assistance programs for improvements and expansion of social housing (*high confidence*) (Municipio del Distrito Metropolitano de Quito, 2020; Prefeitura Municipal do Salvador, 2020; Municipalidad de Lima, 2021; Prefeitura da Cidade do Rio de Janeiro, 2021; Prefeitura do Município de São Paulo, 2021).

Housing programs and initiatives that consider resilient construction, and site selection strategies, are still in nascent stages (Martin et al., 2013). Initiatives in slum upgrading, social housing improvement and regularizing land tenure, associated with infrastructure provision, do not usually focus on adaptation, although they often focus on risk reduction. Those initiatives, associated with a housing policy that guarantees access to land and decent housing, a comprehensive intervention in vulnerable neighbourhoods for their adaptation to climate change, and CbA (community-based adaptation) strategies, including housing self-management and the participation of cooperatives, shows the need and opportunity to move to an transformative urban agenda that encompasses sustainable development, poverty reduction, disaster-risk reduction, climate-change adaptation, and climate-change mitigation (*high confidence*) (Muntó, 2018; UN-Habitat, 2018; Valadares and Cunha, 2018; Bárcena et al., 2020b; Núñez Collado and Wang, 2020; Satterthwaite et al., 2020).

Several large cities are implementing municipal risk management plans and management and restoration plans for hydrologically relevant areas, considering threats of drought and heat waves, integrated watershed management and flood control programs (*high confidence*) (Municipio del Distrito Metropolitano de Quito, 2020; Prefeitura Municipal do Salvador, 2020; Municipalidad de Lima, 2021; Prefeitura da Cidade do Rio de Janeiro, 2021; Prefeitura do Município de São Paulo, 2021). Quito and Rio de Janeiro are considered two examples of comprehensive and effective city-level climate action that includes creating environment protected areas, managing appropriate land use, household relocation and EWS in vulnerable to high-precipitation areas associate to EbA, such as reforestation projects, to face natural hazards (ELLA, 2013; Anguelovski et al., 2014; Calvello et al., 2015; Alcaldía de Quito, 2017; Sandholz et al., 2018; Prefeitura da Cidade do Rio de Janeiro, 2021) (Section 12.6.1). EWS and the use of mapping tools experienced in La Paz showed to be an effective adaptation measure facing increasing hydro-climatic extreme events (Aparicio-Effen et al., 2018).

12.5.5.3.2 Green and grey infrastructure

Hybrid solutions, combining green and grey infrastructure (GGI), have been adopted for better efficiency in flooding control (Ahmed et al., 2019; Drosou et al., 2019; Romero-Duque et al., 2020), sanitation, water scarcity, landslide prevention and coastal protection (*high confidence*) (Section 12.5.6.4; Mangone, 2016; Depietri and McPhearson, 2017; Leal Filho et al., 2018; McPhearson et al., 2018). The adoption of nature-based solutions (NbS), which embraces well-known approaches such as green infrastructure (GI) and ecosystem-based adaptation (EbA) (Pauleit et al., 2017; Le, 2020) has increased (Box 1.3). The Fund for the Protection of Water (FONAG) and the Participative Urban Agriculture (AGRUPAR) are initiatives using NbS in Quito (Section 12.6.1). Example of GGI is a stormwater detention pond, as a water storage solution to flooding prevention, also allowing multiple uses of an urban space, adapting and revitalizing a degraded area in Mesquita, Rio's metropolitan region (Jacob et al., 2019). These systemic and holistic solutions still need to overcome governance and sectorial barriers to be more widely adopted (Herzog and Rozado, 2019; Wamsler et al., 2020; Valente de Macedo et al., 2021).

Managing water in cities in an adaptive way has been central to reducing impacts such as floods and contributes to water security (*high confidence*) (Van Leeuwen et al., 2016; Okumura et al., 2021). Many cities facing frequent heavy storms that impact mostly underprivileged communities, slums and vulnerable areas could benefit from the integrated NbS for disaster risk reduction and adaptation (*high confidence*) (Sandholz et al., 2018; Ronchi and Arcidiacono, 2019). A study covering 70 Latin American cities estimates that 96 million people would benefit from improving main watersheds with green infrastructure (Tellman et al., 2018). In several municipal climate plans, NbS were introduced mainly to enhance rainwater management, reduce energy consumption and urban heat areas, water quality, prevent landslides and offer green areas (*high confidence*) (Gobierno de la Ciudad de Buenos Aires, 2020; Municipio del Distrito Metropolitano de Quito, 2020; Prefeitura Municipal de Curitiba, 2020; Alcaldía de Medellín, 2021; Municipalidad de Lima, 2021; Prefeitura da Cidade do Rio de Janeiro, 2021; Prefeitura do Município de São Paulo, 2021). Sao Paulo's project for Jaguaré river proposes a large-scale landscape transformation applying innovative multifunctional NbS instead of exclusively large, expensive and monofunctional hard engineered solutions to manage stormwater (Marques et al., 2018; Herzog and Rozado, 2019). In Bogotá, the Humedales foundation has restored wetlands to enhance areas near the reserve Van Der Hammen to improve water quality and quantity, restore habitat for biodiversity, and provide flood protection (Portugal Del Pino et al., 2020). In Petrópolis, a medium-sized city in the hills of Rio de Janeiro state, the water service company has implemented 10 NbS multifunctional micro wastewater treatment plants in low-income areas, helping to reduce cascading impacts of storms, floods and epidemics (Herzog and Rozado, 2019). In Costanera Sur, Buenos Aires, a public initiative to protect an auto-regenerated Plata riverbank, which had received demolition material to create land, nowadays offers numerous ecosystem services for residents and attract visitors activating the tourist industry and helping reducing riverine floods (Bertonatti, 2021; OICS, 2021).

Hybrid solution on water management that can merge traditional interventions on urban areas with sustainable urban drainage systems (SUDS) (Davis and Naumann, 2017), considering small scale low-impact development (LID) measures scattered over the watershed instead of concentrate huge hydraulic grey structures, can help reduce the risk and damage of flooding (*high confidence*) (Miguez et al., 2014; Miguez et al., 2015a; Depietri and McPhearson, 2017; Da Silva et al., 2018a; de Macedo et al., 2018). Quito's climate plan explicitly cites the strategy for implementing blue and grey infrastructure to reduce risk due to extreme precipitation and its associated impacts such as flooding and landslides and the possible impact of water scarcity (Municipio del Distrito Metropolitano de Quito, 2020). The Integrated Iguaçu-Sarapuí River Basin Flood Control Master Plan, in Rio's metropolitan area, combined different solutions for flood protection, focusing on river restoration by retrofitting levee systems combined with adapting land use to provide a multifunctional landscapes as an alternative to bring together green and grey solutions, composing urban parks to prevent further paving and avoid irregular occupation of river banks and provide storage capacity for damping flood peaks (Miguez et al., 2015b).

Many cities are implementing adaptation measures on integrated water and flood management systems (Sarkodie and Strezov, 2019), improving basic sanitation services (*medium confidence: medium evidence, high agreement*). Main strategies are established by NAPs recurrently focusing on improving water distribution network and reservoir systems, as Honduras (Government of Honduras, 2018) and Ecuador (Mills-Novoa et al., 2020), sewage and effluent treatment, as Guatemala, Brazil and Paraguay (Government of Brazil, 2007; Government of Guatemala, 2016; Government of Paraguay, 2017), facing water scarcity and environmental degradation. Local authorities follow this guideline as in the effort to maintain and upgrade existing drainage systems in Georgetown (Mycoo, 2014), or in Medellin, focusing on improving drainage systems to prevent landslides or flooding (Núñez Collado and Wang, 2020; Alcaldía de Medellín, 2021). Rio de Janeiro has constructed three large stormwater detention reservoirs to deal with frequent flood, (Prefeitura da Cidade do Rio de Janeiro, 2015), adopting a set of exclusively grey solutions, not combined to NbS that could improve urban flood resilience (Rezende et al., 2019). The main proposed actions still consider the traditional approach in improving the hydraulic capacity of urban drainage systems as an adaptive measure (*high confidence*) (Gobierno de la Ciudad de Buenos Aires, 2020; Prefeitura Municipal do Salvador, 2020; Municipalidad de Lima, 2021; Prefeitura da Cidade do Rio de Janeiro, 2021). In addition to this strategy, several local plans propose actions for the retention and storage of rainwater, both in the urban drainage network with a smaller intervention scale (Prefeitura Municipal de Curitiba, 2020), as well as along rivers and canals with large-scale works (*medium confidence: medium evidence, high agreement*) (Gobierno de la Ciudad de Buenos Aires, 2020; Prefeitura Municipal de Curitiba, 2020; Alcaldía de Medellín, 2021; Prefeitura da Cidade do Rio de Janeiro, 2021).

12.5.5.3.3 Mobility and transport system

Mobility and transport systems have a key role in urban resilience (*high confidence*) (Walker et al., 2014a; Caprì et al., 2016; Espinet et al., 2016; Lee and Lee, 2016; Ford et al., 2018; Mehrotra et al., 2018; Quinn et al., 2018). Examples reported in scientific literature assessed are focusing on mitigation strategies even when labelled as adaptation (da Silva and Buendía, 2016; Di Giulio et al., 2018; Valderrama et al., 2019; Goes et al., 2020).

The integration of transport and land use planning and the improvement of public transport, also as important mitigation actions, appears as a consensus in countries' adaptation plans, nevertheless the emphasis on mobility and transport systems on the many NAP published is low (*medium confidence: medium evidence, high agreement*). Honduras, Costa Rica and El Salvador's NAP are not approaching adaptation or mitigation in the sector, while Peru, Ecuador, Guatemala and Paraguay ones focus on mitigation only. Chile, Colombia and Brazil's NAP focus on both mitigation and adaptation of mobility and transport systems. Chile and Colombia's plans dedicated specific action lines to adapt mobility and transport systems to climate change, whilst Brazil published a NAP's complementary volume dedicated exclusively to the sectoral strategies, although presents only general guidelines (Government of Peru, 2010; Government of Chile, 2014; Government of Ecuador, 2015; Government of Brazil, 2016; Government of Colombia, 2016; Government of Guatemala, 2016; Government of Paraguay, 2017; Government of Costa Rica, 2018; Government of Honduras, 2018; Government of El Salvador, 2019).

In municipal scale, assessing the biggest cities, São Paulo, Rio de Janeiro Lima and Santiago stands out for including mobility and transport as one of the strategic axes of its climatic plans, but yet prioritizing mitigation, while Buenos Aires and Bogotá do not deepen the issue in their plans (Gobierno de la Ciudad de Buenos Aires, 2015; Prefeitura da Cidade do Rio de Janeiro, 2016; Alcaldía Mayor de Bogotá D.C., 2018; Municipalidad de Lima, 2021; Municipalidad de Santiago, 2021; Prefeitura do Município de São Paulo, 2021). Most of those same cities have sectoral mobility plans, which are key tools to urban resilience. Those plans, however, do not focus on adaptation actions, although emphasizing mitigation (Government of Peru, 2005; Gobierno de la Ciudad de Buenos Aires, 2011; Prefeitura do Município de São Paulo, 2015; Alcaldía Mayor de Bogotá D.C., 2017; Ilustre Municipalidad de Santiago, 2019; Município de Rio de Janeiro, 2019).

12.5.6 Health and Wellbeing

The most common adaptation strategies include the development of climate services such as epidemic forecast tools, integrated climate-health surveillance and observatories and forecasting climate-related disasters (floods, heat waves). GIS technologies are being used to identify locations where vulnerable populations are exposed to climate hazards and associated health risks.

12.5.6.1 Climate services for health

The measures most directly linked to diminishing risk are those related to climate services for health (*high confidence*). Climate services provide tailored, sector-specific information from climate forecasts to support decision making (WHO and WMO, 2016); they allow decision makers and practitioners to plan interventions in anticipation of a weather/climate event (Mahon et al., 2019). More recently, climate services, such as early warning systems (EWS) and forecast models, have been promoted for the health sector (WHO and WMO, 2012; WMO, 2014; WHO and WMO, 2016; Thomson and Mason, 2018) and are an important adaptation measure to reduce the impacts of climate on health (*high confidence*). To guide this process, the Global Framework for Climate Services (GFCS) issued a Health Exemplar (Lowe et al., 2014; WMO, 2014) which aims for stakeholder engagement between health and climate actors at all levels to promote the effective use of climate information within health research, policy and practice.

There exist at least 24 EWS in SA to avoid deaths and injuries from floods in the countries such as Argentina, Colombia, Ecuador, Bolivia, Brazil, Peru, Uruguay and Venezuela (Bravo et al., 2010; Bidegain, 2014; Moreno et al., 2014; Dávila, 2016; del Granado et al., 2016; López-García et al., 2017; Carrizo Sineiro et al., 2018). A total of 149 emergency prevention and response systems are reported in CA (UNESCO, 2012). In addition, some countries implement programs for the relocation of families who are in risk condition, like in Bogotá and Medellin, Colombia (World Bank, 2014; Watanabe, 2015).

Epidemic forecast tools are an example of an adaptation measure being developed and/or implemented in this region (*high confidence*). Climate-driven forecast models have been developed for dengue in Ecuador, Puerto Rico, Peru, Brazil, Mexico, Dominican Republic, and Colombia (Lowe et al., 2013; Eastin et al., 2014; Johansson et al., 2016; Lowe et al., 2017; Johansson et al., 2019); for Zika virus infections across the Americas (Muñoz et al., 2017); for cutaneous leishmaniasis in Costa Rica and Brazil (Chaves and Pascual, 2006; Lewnard et al., 2014); for Aedes-borne diseases across the Americas (Muñoz et al., 2020b); and a nowcast model for chikungunya virus infections across the Americas (Johansson et al., 2014). In Ecuador, a prototype system utilized forecasts of seasonal climate and ENSO forecasts of to predict dengue transmission, providing the health sector with warnings of increased transmission several months ahead of time (Stewart-Ibarra and Lowe, 2013; Lowe et al., 2017). Despite these advances, few tools have become operational and mainstreamed in decision making processes. However, Brazil and Panama have been able to operationalize an early warning system for the surveillance of dengue fever transmission (Codeço et al., 2016; McDonald et al., 2016).

One of the most promising climate services for the health sector are heat and cold early warning and alert systems (*medium confidence*). These have been developed by the national meteorological institutes in Peru, Argentina, and Uruguay (Bidegain, 2014). A heat alert system was implemented in Argentina in 2017 and daily alerts are issued for 57 localities across the country. A stoplight colour scheme is used to issue alerts, identifying specific groups at risk and actions to be taken to reduce the risk (Herrera et al., 2018b).

The public dissemination of climate-health warnings via bulletins, websites, and other outlets can be an adaptation measure to climate change and weather variability to diminish health risk (*high confidence*). The information produced is systematized to be communicated to the authorities and general public. The Caribbean Health-Climatic Bulletin has been issued quarterly since 2018 to health ministries across the region, including CA and NSA. Regional climate and health authorities meet to review 3 month climate forecasts and issue statements about the probable impacts on health (Trotman et al., 2018). In Panamá, information on dengue is distributed in a monthly bulletin that is used by health authorities to inform vector control activities (McDonald et al., 2016). Another example was the climate-driven forecast of dengue risk that was produced prior to Brazil's 2014 FIFA World Cup to inform disease prevention interventions (Lowe et al., 2014; Lowe et al., 2016). In Colombia, the Intersectoral National Technical Commission for Environmental Health publishes a monthly bulletin with regional weather forecast and potential effects on health (CONASA, 2019). Paraguay improves epidemiological surveillance and trains first level health staff via information campaigns on the prevention of climate sensitive diseases, and promotes health networks with the participation of civil society (Environmental Secretariat of Paraguay, 2011).

12.5.6.2 Integrated climate-health surveillance and observatories

Integrated health-climate surveillance systems are another key adaptation strategy (*medium confidence*). This information can be used by the health sector to inform decision making about when and where to deploy a public health intervention. It can also feed into an EWS, particularly if the data are compatible in format and spatiotemporal scales. An integrated health-climate surveillance system for vector borne disease control was developed in southern coastal Ecuador through a partnership among the climate and health sectors and academia (Borbor-Cordova et al., 2016; Lowe et al., 2017). Additionally, an interdisciplinary multinational team working at the border of Ecuador and Peru created a cooperation network for climate-informed dengue surveillance (Quichi et al., 2016) and successful binational collaboration resulted in the local elimination of malaria (Krisher et al., 2016). Similar is the innovative community-based data collection to understand and find solutions to rainfall-related diarrheal diseases in Ecuador (Palacios et al., 2016).

Climate and health observatories are a promising strategy being developed at subnational, national (e.g., Brazil, Argentina) and regional levels (*high confidence*) (Muñoz et al., 2016; Rusticucci et al., 2020). The Brazilian Observatory of Climate and Health brings together climate and health information for the Amazon region of Manaus (Barcellos et al., 2016). At a national level, Brazil has created the climate and health observatory, where information and data visualizations are available for various climate-sensitive health indicators (Ministério da Saúde and FIOCRUZ, 2021).

12.5.6.3 Vulnerability and risk maps

Vulnerability and risk maps have been widely used as an adaptation strategy to understand the potential impacts of climate on health outcomes both directly (e.g., maps of disease risk) and indirectly (e.g., maps of populations vulnerable to climate disasters) (*high confidence*). There are many examples where climate services have been used to construct vulnerability maps for health outcomes, including maps in the aforementioned Climate-Health Observatories. Dengue, malaria, and Zika vulnerability maps using climate, social, and environmental information has been developed in Brazil and Colombia (Cunha et al., 2016b; López-Álvarez, 2016; Pereda, 2016; IDEAM, 2017). Argentina is focused on improving the health system by using Climate Change Risk Map System as a tool that identifies the risks and allows assessing their management (OPS and WHO, 2018).

Vulnerability and risk maps for climate disasters have been developed at the city level, for example in Bogotá, Cartagena de Indias, and Mocoa in Colombia (Yamin et al., 2013; Guzman Torres and Barrera Arciniegas, 2014; Tehelen and Pacha, 2017; Zamora, 2018); and for the metropolitan district of Quito in Ecuador (Tehelen and Pacha, 2017). In addition, vulnerability maps were created for the primary road network of Colombia (Tehelen and Pacha, 2017). At the regional level, vulnerability maps using climate change probability, disaster risk and food insecurity variables has been produced for the Andean region (WFP, 2014). In Brazil, vulnerability maps considering exposure, sensitivity, and adaptive capacity, coupled to climate scenarios, were designed to support the National Adaptation Plan on a municipal scale (Chang and Garcia, 2018; Duval et al., 2018; Marinho and Silva, 2018; Menezes, 2018; Santos and Marinho, 2018; Silva et al., 2018). A Climate Change Vulnerability Index was used to generate vulnerability maps for countries of Latin American and Caribbean region (Vörösmarty et al., 2013; CAF, 2014).

12.5.6.4 Other adaptation actions

Diverse adaptation measures are being implemented through public policies, private households' responses, or communal management that directly or indirectly reduce the impacts of climate change on human health (*high confidence*) (Table 12.9). Private and communal management measures could be considered indirect measures, because they might be adopted even in the absence of climate change.

Table 12.9: Hazards from climate change that impact human health and examples of adaptation strategies proposed or implemented in CSA. Based in McMichael et al. (2006); Miller et al. (2013a); Miller et al. (2013b); Miller et al. (2013c); Miller et al. (2013d); Hardoy et al. (2014); IPCC (2014); Janches et al. (2014); Lee et al. (2014); Mejia (2014); Sosa-Rodriguez (2014); Vergara et al. (2014); Lemos et al. (2016); Villamizar et al. (2017); Magoni and Munoz (2018); Zhao et al. (2019).

Hazard and impacts on human health	**Examples of adaptation strategies**		
	Public	**Private**	**Communal**
Extreme heat and cold: deaths / illness by thermal stress	• Creation of urban green spaces/ • Health promotion campaigns. • Establish shelters during heat waves • Technology transfer for home heating	• Cooling by swamp coolers, air conditioning, open windows, wet the floors, shade trees. • Bioclimatic building design	• Training of community health volunteers to recognize and treat heat strain.
Extreme rainfall, wildfire, wind speed: injury / deaths from floods, storms, cyclones, bushfires and landslides (Key risk 2, Table 12.6).	• Early warning systems (EWS) for extreme climate events. • Safe housing programs and relocation • Green-grey infrastructure (e.g., channels, drainage systems)	• Green-grey infrastructure to prevent landslides. • Insurance mechanisms and financing for long-term recovery.	• Communal efforts to clear debris from canals to reduce flood risk • Cooperative efforts to rebuild following a flood event
Drought and dryness: poor nutrition due to reduced food yields and dehydration due to limited or inadequate management of freshwater (Key risk 1, Table 12.6).	• Formalizing land ownership for small farmers and Indigenous people. • Address emerging water conflicts.	• Water infrastructure and irrigation. • Soil moisture retention techniques • Insurance mechanisms. • Selection of drought resistant crops.	• Incorporation of local stakeholders in formulating adaptation responses. • Recognition of Indigenous and local wisdom and knowledge.

Changes in climate that promote microbial proliferation: food poisoning, and unsafe drinking water (Key risk 3, Table 12.6).	• Restoration of watersheds • Integrated health-climate surveillance • Improve access to drinking water, drainage, sanitation and waste removal.	• Water disinfection: boiling, chlorination. • Purchasing water or water filters.	• Participatory water management strategies, including protection of drinking water sources.
Changes in climate that affect vector-pathogen host relations and infectious disease geography/seasonality (Key risk 4, Table 12.6).	• Vector control • EWS for epidemics • Nature-based solutions (NbS) (e.g., forest conservation)	• Use of bed nets and screens • Use of repellent and insecticides. • Elimination of standing water.	• Community volunteers to collect blood smears for malaria diagnosis • Community-led elimination of vector habitat.
Sea level rise and storm surges: impaired crop, livestock and fisheries yields; unsafe drinking water, leading to impaired nutrition (Key risk 8, Table 12.6).	• Improve governance of water utilities. • Address emerging water conflicts. • Protection, restoration and soil conservation to recharge aquifers.	• Improve water efficiency in agriculture.	• Incorporation of local stakeholders in formulating adaptation responses. • Recognition of Indigenous and local wisdom and knowledge.
Environmental degradation: loss of livelihoods and displacement leading to poverty and adverse health outcomes (related to Key risk 6, Table 12.6).	• Long-term risk management planning for cities. • Sustainable forestry programs. • Protection and restoration of lacustrine areas.	• Identification of alternative livelihoods.	• Community-led efforts to reforest and restore/protect watersheds.

Participatory management can be relevant in the case of mosquito-borne disease prevention (e.g., dengue fever or malaria), where the reduction in mosquito habitat in one area or 'hot spot' can reduce the risk for all surrounding households. This approach is also relevant when considering new places where vector-borne diseases can emerge because of changes in climate (Andersson et al., 2015).

Adaptation strategies implemented by the public sector include a diverse suite of strategies ranging from creation of green spaces in urban areas, relocation of families located in disaster prone areas, ecosystem restoration, improved access to clean water, among many others (*high confidence*) (Table 12.9). Building green-grey infrastructure (GGI) has been a popular public adaptation measure to reduce deaths and injuries because of floods (Section 12.5.5.3.2). Infrastructure has been improved at schools, public buildings and drainage systems in cities such as Bogota, Colombia (World Bank, 2014) and La Paz, Bolivia (Fernández and Buss, 2016). In Brazil, channel works were implemented to reduce the flooding of the Tiete River, which crosses the metropolitan area of Sao Paulo; these projects were designed based on simulated flood scenarios (Hori et al., 2017).

Another example of a public adaptation measure is protection and restoration of natural areas, which have the potential to decrease the transmission of water- and vector-borne infectious diseases (*medium confidence: robust evidence, low agreement*). Studies have shown that these measures can diminish the cases of malaria and diarrhoea in Brazil, and cases of diarrhoea in children in Colombia (Bauch et al., 2015; Herrera et al., 2017; Chaves et al., 2018). However, deforestation and malaria have a complex relationship that relies on local context interactions, where land use and land cover change present an important role due to vector ecology alterations and social conditions of human settlements (Rubio-Palis et al., 2013). Forest conservation can improve hydrological cycle control and soil erosion that can help to improve water quality and reduce the burden of water-borne diseases. In addition, forest cover can help to diminish the habitat for larval mosquitoes that transmit malaria. These measures can help to design policies in sites where these problems do not currently exist but can emerge as a consequence of climate change and the increase in the frequency of weather extreme events.

12.5.6.5 Challenges and opportunities

Despite the proliferation of disaster EWS in the region, only 37 can be considered operational, because many of these systems are not operating or functioning properly, or do not meet the requirements to be considered EWS (UNESCO, 2012). Sustainable financing and political support are needed to ensure the functioning of disaster EWS (*high confidence*) (Table 12.11). Several studies identified difficulties in implementing disaster EWS due to a lack of community engagement and response to the alerts that are issued (del Granado et al., 2016; López-García et al., 2017). To address these challenges, the document "Developing Early Warning Systems: A Checklist" provides guidance for the implementation of a *people centred approach to early warning systems* as proposed in the Hyogo Framework for Action 2005–2015 (Wiltshire, 2006).

With respect to the development of climate-driven epidemic forecasts, efforts are needed to improve the utility of such forecasts for the health sector. Few such forecasts have been operationalized to inform health sector decision making. A review of 73 studies that predicted and forecasted Zika virus infections (42% from the Americas) identified a high degree of variation in access, reproducibility, timeliness, and incorporation of uncertainty (Kobres et al., 2019). A recent systematic review of epidemic forecasting and prediction studies found that no reporting guidelines exist; the development of guidance to improve transparency, quality and implementation of forecast models in the public health sector was recommended (Pollett et al., 2020). An earlier review of dengue early warning models found that few models incorporated both spatial and temporal aspects of disease risk (Racloz et al., 2012), limiting their potential application as an adaptation strategy by the health sector. Advances have been made in the last decade with respect to modelling and computing tools, increasing access to digital climate information and health records, and the use of earth observations to forecast climate sensitive diseases (Fletcher et al., 2021; Wimberly et al., 2021).

The growing field of implementation science –defined as "a discipline focused on systematically examining the gap between knowledge and action"– is another opportunity to address the challenges and barriers to using climate information for health sector decision making (Boyer et al., 2020). Implementation science in the health sector in CSA is nascent; research in this area could help to address barriers to mainstreaming climate information in the health sector as an adaptation strategy (Table 12.11; Table SM12.7).

12.5.6.6 Governance and Financing.

A description of the governance and financing dimensions of the feasibility of implementing EWS is presented in Table 12.11 and Table SM12.7.

12.5.6.6.1 National Health Plans

Some countries have developed national plans on health including the role of climate. Chile has a Climate Change Adaptation Plan of the Health Sector that proposes several actions to enhance monitoring, institutions and citizens information and education (Ministry of Health of Chile and Ministry of Environment of Chile, 2016). Based on the identification of vulnerability to climate change, Colombia has developed eleven regional adaptation plans to strengthen institutional capacities; climate change education for behavioural changes; and cost estimation to promote health resilience (WHO and UNFCCC, 2015). In addition, El Salvador implemented actions to strengthen health infrastructure through high latrines for housing in flood communities, as well as other measures focused on water supply and quality based on an education and awareness program (Ministry of Environment and Natural Resources of El Salvador, 2013). Only Brazil and Peru have implemented actions so far in the region derived from national health adaptation plans, and only Brazil completed a national assessment of impacts, vulnerability and adaptation for health (Watts et al., 2018). Some countries include health as a priority sector in their National Adaptation Plans, as is the case of Ecuador, and Costa Rica, which has a national plan addressing the prevention and care of climate-sensitive diseases coupled to a National Health Plan (2016-2020) (Ministry of Health Costa Rica, 2016; Jiménez, n.d.).

12.5.6.6.2 National Disaster Management Plans

National Risk Management Plans or National Disaster Response Plans are tools for adapting to climate change that can help to diminish death and injuries because of disasters (*high confidence*). These Plans are generally promoted by governments as national instruments that guide the processes of estimating, preventing and reducing disaster risk. An updated national risk management plans has been found for Guatemala (CONRED, 2014), Honduras (COPECO, 2014), El Salvador (Ministry of Health of El Salvador, 2017), Costa Rica (CNE, 2016), Ecuador (SGR, 2018), Peru (SGRD et al., 2014), Argentina (Ministerio de Seguridad de Argentina, 2018), Bolivia (VIDECI, 2017), Chile (ONEMI, 2015) and Colombia (UNGRD, 2015). It has been shown in Brazil that information on drought conditions can be used to reduced health impacts of drought using a national disaster risk reduction framework (Sena et al., 2016).

12.5.7 Poverty, Livelihood and Sustainable Development

Climate change impacts are increasing and exacerbating poverty and social inequalities, affecting those already vulnerable and disfavoured, generating new and concatenated risk challenging climate resilient development pathways (*high confidence*) (Section 8.2.1.4; Shi et al., 2016; Otto et al., 2017; Johnson et al., 2021) (). Poverty, high levels of inequalities and pre-existing vulnerabilities also can be worsened by climate change policies (Antwi-Agyei et al., 2018; IPCC, 2018; Roy et al., 2018; Eriksen et al., 2021). Those already suffering are losing their livelihoods and reducing their development options; poor populations and countries are more vulnerable and have lower adaptive capacity to climate change (*very high confidence*) (Section 8.5.2.1; Rao et al., 2017).

Inequality is growing, being a CSA structural characteristic; Gini index average for Latin American countries (including Mexico) was decreasing to 0.466 in 2017, where 1% richest got 22 times more income than 10% poorest (ECLAC, 2019b; Busso and Messina, 2020), but in 2018, 29.6% of Latin America were poor population (increased to 182 million) and extreme poverty 10.2%; in 2018 (increased to 63 million) (ECLAC, 2019b) and in 2020, due to COVID crisis, Gini coefficient projection of increases are ranging from 1.1% to 7.8% (ECLAC and PAHO, 2020), poverty increased to 33.7% (209 millions) and extreme poverty to 12.5% (78 millions) (ECLAC and PAHO, 2020; ECLAC, 2021). Those poverty and extreme poverty rates are higher among children, young people, women, Indigenous Peoples (Reckien et al., 2017; Busso and Messina, 2020), migrant (Dodman et al., 2019) and rural population. Climate change impacts in differentiated ways, even within a household there may be important differences in relation to age, gender, health and disability; these factors may intersect with one another (*high confidence*) (Reckien et al., 2017; Busso and Messina, 2020).

In IPCC's TAR, AR4 and AR5, WG II recognized higher risks associated with poor living conditions, substandard housing, inadequate services, location in hazardous sites due to no alternatives and the need to work more strongly on strengthening governance structures involving residents, community organizations amongst others (Wilbanks et al., 2007; Revi et al., 2014). The AR5 CSA chapter stated that poverty levels remained high (45% for CA and 30% for SA in 2010) despite years of sustained economic growth. Poor and vulnerable groups are disproportionately affected in negative ways by climate change (Section 8.2.1.4; Section 8.2.2.3; SR15 Section 5.2 and Section 5.2.1, Roy et al., 2018)) due to physical exposure derived from the place where they live or work, illiteracy, low income and skills, political and institutional marginalization tied to lack of recognition of informal settlements and employments, poor access to good quality services and infrastructure, resources, information, and other factors (*very high confidence*) (UN-Habitat, 2018; SR15 Sections 5.2.1, 5.6.2, 5.6.3, 5.6.4, Roy et al., 2018).

International agreements aim for climate resilient development pathways where efforts to eradicate poverty, reduce inequalities and promote fair and cross-scalar adaptation and mitigation are strengthened. The Sustainable Development Goals (SDG) first and second objectives aim to reduce poverty leaving no one behind (UN General Assembly, 2015). Although researchers argue that poverty is mischaracterized having multiple dimensions (Castán Broto and Bulkeley, 2013) (Section 8.1.1), that biodiversity loss, climate change and pollution will undermine efforts on 80% of assessed SDG targets, that biodiversity and climate change must be tackle together (Pörtner et al., 2021; United Nations Environment Programme, 2021) and LAC countries due to COVID crisis have uneven SDG progress (*high confidence*) (ECLAC, 2020).

12.5.7.1 Challenges and Opportunities

Climate change exacerbates pre-existing conditions and moving in the opposite direction in the search for resilience, equity and sustainable development (Tanner et al., 2015b; Bartlett and Satterthwaite, 2016; Kalikoski et al., 2018; Bárcena et al., 2020a). Existing inequalities in the provision and consumption of services are bound to be exacerbated by future risks and uncertainties associated with climate change scenarios (Miranda Sara et al., 2017). Climate change will be a major obstacle in reducing poverty (*high confidence*) (Bartlett and Satterthwaite, 2016; Allen et al., 2017a; Hallegatte et al., 2018; UN-Habitat, 2018; United Nations Environment Programme, 2021), even affecting wealthier populations that become vulnerable facing climate change scenarios (WGI AR6 Chapter 12, Ranasinghe et al., 2021), dragging them into poverty, erasing decades of work and asset accumulation.

CSA is highly urbanized, the poor vast majority live in urban areas (except in Central America) while urban extreme poverty is becoming more relevant (Rosenzweig et al., 2018; Dodman et al., 2019; Almansi et al., 2020; Sette Whitaker Ferreira et al., 2020), with those living in informal settlements and working within informal economy are critical on each city's economy (Satterthwaite et al., 2018; Satterthwaite et al., 2020). Many households in the region's cities live in precarious neighbourhoods with insufficient infrastructure and substandard housing (Adler et al., 2018; Rojas, 2019). On average, between 21% and 25% of the urban population lives in informal settlements (Jaitman, 2015; UN-Habitat, 2015; Rojas, 2019; Sandoval and Sarmiento, 2019). This hides important disparities: Habitat III reports by individual countries the percentage of urban population living in informal settlements ranged from 5% to 60%; in absolute terms 105 million people living in precarious conditions (106 million estimated in 1990) (Section 12.5.5; Sandoval and Sarmiento, 2019).

High levels of inequality and informality remain the biggest challenges for adaptation measures being effective (Rosenzweig et al., 2018; Dodman et al., 2019). The interaction of projected impacts with existing vulnerabilities in the region (as hunger, malnutrition and health inequalities, arising from its social, economic and demographic profile), affect CSA development and well-being in different ways (Reyer et al., 2017) increasing poverty and inequality risking the paths for sustainable development (Section 18.1.1; Reckien et al., 2017).

The uneven enforcement of land-use regulations, relocations and evictions on behalf of environmental risk management and climate adaptation is contested (Brockington and Wilkie, 2015; Lavell, 2016; Quimbayo Ruiz and Vásquez Rodríguez, 2016a; Quimbayo Ruiz and Vásquez Rodríguez, 2016b; Anguelovski et al., 2018; Anguelovski et al., 2019; Shokry et al., 2020; Chávez Eslava, 2021; Oliver-Smith, 2021). This points to caution in framing climate adaptation and resilience related interventions as equally benefiting everyone (*high confidence*) (Brown, 2014; Chu et al., 2016; Connolly, 2019; Romero-Lankao and Gnatz, 2019; Johnson et al., 2021) and the need for incorporating equality and justice dimensions (*very high confidence*) (Section 18.1.2.2; Agyeman et al., 2016; Meerow and Newell, 2016; Romero-Lankao et al., 2016; Shi et al., 2016; Reckien et al., 2017; Leal Filho et al., 2021) ().

Poor rural households in marginal territories with low productive potential and/or far away from markets and infrastructure are highly vulnerable to climate change and easily fall into poverty-environment traps (*high confidence*) (Barbier and Hochard, 2019; Heikkinen, 2021). Climate change is one of the main threats to rural livelihoods in Central America, being agriculture a pillar for rural economies and food security, especially for the poorest sectors that rely on subsistence crops in areas with low soil fertility and rainfall seasonality (Bouroncle et al., 2017).

Impacts are likely to occur simultaneously, exacerbating those of the poorer but also creating new groups at-risk (Miranda Sara et al., 2016; Rosenzweig et al., 2018; Dodman et al., 2019). The material basis for poor and vulnerable urban and rural populations' adaptation are in a critical state across the CSA region, magnifying extreme events' impacts, making CSA less resilient. The consequences in terms of social vulnerability and livelihood will be widely felt, insofar the security and protection of critical assets (housing, infrastructure, services - water, land and ecosystem services) continues to lay behind. Small businesses are usually conducted within the same home and if the house is affected so is the business (Stein and Moser, 2015) adding another layer of vulnerability for them.

As productivity declines, they seek outside income generation opportunities and rely on resource extraction for subsistence and as an income generation activity, further increasing their vulnerability to climate change (Barbier and Hochard, 2018a). Cycles of declining productivity, environmental degradation, wildlife poaching and trafficking, search of outside employment, reduced incomes, livelihood opportunities and poverty have been registered in rural El Salvador, Honduras, Amazonia (López-Feldman, 2014; Graham, 2017; Barbier and Hochard, 2018a). The protection of communities that defend and are dependent on wildlife and natural environments requires immediate attention. In Latin America there are 8 million forest-dependent people which represents about 82% of the region's rural extreme poor (FAO and UNEP, 2020).

Poverty and disaster risk reduction interlinked with climate change adaptation share a focus on identifying and acting on local risks and their root causes, even having different lenses through which to view risk (*very high confidence*) (IPCC, 2014; Allen et al., 2017a; Satterthwaite et al., 2018; UN-Habitat, 2018; Satterthwaite et al., 2020). Construction of climate knowledge and risk perceptions affect decision-making to define implementation priorities; the poor are less able to cope and to adapt avoiding "adaptation injustices" (*high confidence*) (Mansur et al., 2016; Miranda Sara et al., 2017; Reckien et al., 2017; Hardoy et al., 2019).

Adaptation, social policies, poverty reduction and inequality are weakly articulated to daily or chronic risk reduction. Poor residents are often caught in 'risk traps', accumulated cycles of everyday risks and small-scale disasters (*medium confidence: medium evidence, high agreement*) (Bartlett and Satterthwaite, 2016 ; Mansur et al., 2016; Allen et al., 2017a; Leal Filho et al., 2021), being exacerbated by climate risks and COVID pandemic with the most vulnerable populations suffering. Chronic and every day risks (poor access to infrastructure, services, incomes, housing, tenure, education, security, location and poor-quality environment, networks and having a voice) are often exacerbated and generate new unknown risks by climate change (*medium confidence: medium evidence, high agreement*) (Bartlett and Satterthwaite, 2016; Mansur et al., 2016; Satterthwaite et al., 2018; Leal Filho et al., 2021), extreme events and risks related to ENSO oscillation. All these risks need to be considered simultaneously (UN-Habitat, 2018). Risks are seldom distributed equally highlighting socioeconomic inequalities and governance failures (*high confidence*) (IPCC, 2014; Bartlett and Satterthwaite, 2016; Rasch, 2016; Romero-Lankao et al., 2018).

Adaptation, disaster risk reduction together with social and poverty reduction policies contribute to sustainable development (Hallegatte et al., 2018; Satterthwaite et al., 2020), and improve prospects of climate resilient pathways (Section 18.1.1). Without pro-poor interventions, adaptation options could reinforce poverty cycles (Kalikoski et al., 2018). Secure locations, good quality infrastructure, services and housing are critical to reduce risks from extreme climate events (Satterthwaite et al., 2018; Dodman et al., 2019).

12.5.7.2 Governance and Finance

Poor and most vulnerable groups evidence limited political influence, fewer capacities and opportunities to participate in decision and policy making, are less able to leverage government support to invest on adaptation measures linked with poverty, inequality and vulnerability reduction (*very high confidence)* (Chapter 8; Miranda Sara et al., 2017; Reyer et al., 2017; Kalikoski et al., 2018; Dodman et al., 2019; Satterthwaite et al., 2020).

Existing unbalances on power relations, corruption, structural historic problems and high levels of risk tolerance (Miranda Sara et al., 2016) constitute climate governance barriers for implementing more effective adaptation and preventive measures. Corruption, particularly in the construction and infrastructure sector, has proven to be a barrier for CSA development even reproducing and reconstructing risks (French and Mechler, 2017; Vergara, 2018; Durand, 2019). Critical infrastructure and valuable assets continue to be placed in vulnerable areas (Calil et al., 2017; Escalante Estrada and Miranda, 2020) evidencing the persistence of maladaptation and adaptation deficit (Villamizar et al., 2017).

Social organization, participation and governance reconfiguration are essential for building climate resilience (*very high confidence*) (Stein and Moser, 2015; Kalikoski et al., 2018; Satterthwaite et al., 2018; Stein et al., 2018; Hardoy et al., 2019; Stein, 2019; Satterthwaite et al., 2020; Miranda Sara, 2021). Adaptation measures have trade-offs that need to be acknowledged and acted upon, most importantly by developing the capacity to convene discussions that draw in all key actors and commit them to do things differently (Almeida et al., 2018; Hardoy et al., 2019). Collaborative approaches integrating groups and organizations (e.g., saving, women's groups, clubs, vendor associations, cooperatives) contributing to the exchange of information, to visibilize people's needs, to generate safety networks, and to negotiate for improvements and enhance adaptive capacity.

12.5.7.3 Adaptation options

Effective adaptation can be achieved by addressing pre-existing development deficits, particularly the needs and priorities of informal settlements and economies (Revi et al., 2014; UN-Habitat, 2018). There is urgency for social systems to better respond to climate related risks and increase their adaptive capacity (Lemos et al., 2016) focus on path dependency, lock ins and poor specific needs (Leal Filho et al., 2021).

The linkages between climate adaptation and poverty are not clearly addressed at national level (Kalikoski et al., 2018). A revision of some NDCs presented by CSA countries (https://unfccc.int), shows that NDCs are developed with almost no connection to poverty and livelihoods. Exceptions include Bolivia whose NDC developed the "Good life" concept, as an alternative development pathway, supporting sustainable livelihoods as a mean to eradicate poverty; Honduras asserts that climate action should improve living conditions; Peru defined a poverty and vulnerability reduction approach and El Salvador conditioned its NDCs to macroeconomic stability, economic growth and poverty reduction. A sustainable development approach permeates in proposed actions for sectors as energy, agriculture, transport, water, and forestry.

Adaptive capacity is linked to addressing climate related risks (specific capacity) and structural deficits (generic capacity), synergies and a strategic balance between both is necessary (Eakin et al., 2014; Lemos et al., 2016). Adaptation institutional context can undermine one form of capacity with repercussions on the other compromising overall adaptation and sustainable development (Eakin et al., 2014).

Literature assessing the effectiveness of pro-poor or community based adaptation practices and livelihood options continues to be weak, even though are increasingly documented, as in AR5 (Magrin et al., 2014). Great variety of measures are being applied, financial instruments to strengthen and protect livelihoods and assets; collective insurance schemes, micro-credits, financial instruments for transferring risks, as agricultural insurance and Payments for Ecosystem Services (PES) (Dávila, 2016; Hardoy and Velásquez, 2016; Lemos et al., 2016; Porras et al., 2016; Kalikoski et al., 2018). Small-scale household running businesses in poor neighbourhoods develop adaptation strategies to keep business going, showing how household level adaptation strategies are multipurpose (Stein et al., 2018; Stein, 2019). There are emerging interinstitutional communities of practice with the purpose of sharing practices and lessons learned (ECLAC, 2013; ECLAC, 2015; ECLAC, 2019a).

There is also increasing evidence of human mobility associated with climate change and disaster risk (IOM, 2021) and the adoption of sustainable tourism, diversification of livelihoods strategies, climate forecasts, appropriate construction techniques, neighbourhood layout, integral urban upgrading initiatives, territorial and urban planning, regulatory frameworks, water harvesting and nature-based solutions (NbS) (Stein and Moser, 2014; Hardoy and Mastrangelo, 2016; Almeida et al., 2018; Barbier and Hochard, 2018a; Desmaison et al., 2018; Satterthwaite et al., 2018; Villafuerte et al., 2018; Hidalgo, 2020; Satterthwaite et al., 2020). Mostly, socio-economical and socio-political factors which show safety and continuity measures are critical enablers of adaptation.

At municipal level study in Central America highlighted that adaptive capacity in rural areas is associated with basic needs satisfaction (safe drinking water, school, quality dwelling, gender parity index), access to resources for innovation and action (road density, economically active population with non-agricultural employment, and rural demographic dependency ratio), and access to credit and technical support (Bouroncle et al., 2017).

CSA adaptation initiatives to reduce poverty, improve livelihoods and achieve sustainable development range in scale and scope, from planned and collective interventions to autonomous and individual actions. Many of them are bottom up, community-led initiatives together with civil society organizations; others are government-led, including local governments, or a combination of them (McNamara and Buggy, 2017; Berrang-Ford et al., 2021). Vulnerable groups are a focus to achieve equity at planning and as a target including mainly rural low-income, Indigenous Peoples and women and migrants in most references. Responses detected were focused on behavioural and cultural, followed by ecosystem-based responses, institutional, and technological/infrastructural responses. Out of 55 articles analysed from CSA (Berrang-Ford et al., 2021) about poverty, equity and adaptation options, half of them covered adaptation planning and early implementation but only 2% could show evidence of risk reduction associated with adaptation efforts.

Tensions and conflicts may result from differing perceptions and knowledge on vulnerabilities and risk which can hinder the acceptance of adaptation measures and implementing stronger adaptive or preventive actions (Miranda Sara et al., 2016). There is a need to better understand complex interactions and community responses to climate change in the Amazonian and Andean region. Climate change hotspot impacts, showed that poverty reduction measures alone were not enough to improve adaptive capacity, as people will not necessarily invest to enhance them (Pinho et al., 2014; Filho et al., 2016; Nelson et al., 2016; Lapola et al., 2018; Zavaleta et al., 2018). Current adaptation strategies and methods may be neglecting cultural values, even eroding them, in Peruvian Andes, pointing that success of adaptation practices is tied to deep cultural values (Walshe and Argumedo, 2016).

Limits to adaptation include access to land, territory and resources (Mesclier et al., 2015), poor labour opportunities coupled with knowledge gaps, weak multi actor coordination, and lack of effective policies and supportive frameworks (Berrang-Ford et al., 2021).

Low participation of women in income earning opportunities contrasts with their role in unpaid activities (ECLAC, 2019b). Despite progresses, gender differences in labour markets remain an unjustifiable form of inequality (OIT, 2019) and women easily fall back to the informal labour market during crisis situations such as those generated by climate events (Collodi et al., 2020).

Participatory processes are leveraging adaptation measures throughout CSA; they contribute to prioritization of specific adaptation measures as well as strengthening local capacities. Showing that climate adaptation needs to be part of larger transformation processes to reduce vulnerability drivers (Stein and Moser, 2015; Stein et al., 2018; Stein, 2019) but stronger national policies interlinking poverty and inequality reduction to adaptation, considering the coupled human-environmental systems to comprehend poor and vulnerable groups' capacity to adapt are urgent. CSA does not fare very well, and several downward trends might become even more acute. More effective decisive actions need to be undertaken coupled with inclusive long-term planning to protect the poor and improve their underlying conditions, to meet the SDG.

12.5.8 Cross-cutting Issues in the Human Dimension

12.5.8.1 Public policies, social movements and participation

Public policies related to adaptation must be seen in the wider context of environmental policies and governance, as they usually address climatic processes in synergy with other environmental and socioeconomic drivers (*very high confidence*) (Ding et al., 2017; Aldunce Ide et al., 2020; Comisión Europea, 2020; Lampis et al., 2020; Scoville-Simonds et al., 2020). Some people rather point to education, sanitation or social assistance, among other sectors (Bonatti et al., 2019). In Brazil, for example, it would be difficult to clearly separate climate change adaptation and urban policies (*high confidence*) (PBMC, 2016; Barbi and da Costa Ferreira, 2017; Marques Di Giulio et al., 2017; Empresa de Pesquisa Energética, 2018; Checco and Caldas, 2019; Canil et al., 2020).

Many public policies related to climate change have become symbolic, in conflict with prevailing economic policies and practices (*medium confidence: low evidence, high agreement*). Urban adaptation plans can be in conflict with other policies and there may exist insufficient support in multiple areas such as social attitudes and behaviour, knowledge, education and human capital, finance, governance, institutions and policy (Villamizar et al., 2017; Koch, 2018). Some policies around climatic related displacements and migrants have been considered in NDCs (Priotto and Salvador Aruj, 2017; Yamamoto et al., 2018; de Salles Cavedon-Capdeville et al., 2020).

As there are asymmetries among populations regarding the vulnerability and benefits of adaptation, along the lines of gender, age, socioeconomic conditions and ethnicity, it has been noticed that adaptation policies and programs must be adequate to diverse conditions and actors (*very high confidence*) (Kaijser and Kronsell, 2014; Walshe and Argumedo, 2016; Baucom and Omelsky, 2017; Harvey et al., 2018).

Effective adaptation and mitigation depend on policies and measures at multiple scales, especially on the involvement of the more exposed and vulnerable people. The participation of experts, communities and citizens has shown to be effective (FAO and Fundación Futuro Latinoamericano, 2019) particularly through partnership of grassroots organizations with impoverished communities providing valued expertise and capacities to support the implementation of government climate resilience strategies (World Bank Group, 2015). More inclusive planning processes correspond to higher climate equity and justice outcomes in the short term, but also an emphasis on building dedicated multi-sector governance institutions may enhance long-term programs stability, while ensuring civil society voice in adaptation planning and implementation (Chu et al., 2016). Some local organizations and people have succeeded when they were in charge of their own resiliency efforts, where international projects and protocols proved less effective (Doughty, 2016). At times, decentralized governmental programs have tried to increase public responsiveness to the adaptation needs of people; however, proving to only be mildly successful and provoking the mobilization of communities against existing governance structures (Thompson, 2016).

Indigenous knowledge and local knowledge (IK and LK) participation is thought to be more considered in adaptation policies, as it has good results (*high confidence*) (Nagy et al., 2014b; Jurt et al., 2015; Arias et al., 2016; Stensrud, 2016). IK has been adaptive for long periods in the Andes (Cuvi, 2018), but there might be limits to adaptation in the face of present climatic and other environmental and socioeconomic drivers (Postigo, 2019). Approaches integrating IK with more formal sciences, to address research and policies, have improved adaptation processes, but they are no exempt of complications (*high confidence*) (Doswald et al., 2014; Metternicht et al., 2014; Tengö et al., 2014; Drenkhan et al., 2015; Keenan, 2015; Lasage et al., 2015; Camacho Guerreiro et al., 2016; Hurlbert and Gupta, 2016; Roco et al., 2016; Santos et al., 2016; Walshe and Argumedo, 2016; Uribe Rivera et al., 2017; Kasecker et al., 2018; Cuesta et al., 2019; Ulloa, 2019; Ariza-Montobbio and Cuvi, 2020). More interdisciplinary and transdisciplinary research helps to better understand and manage the relationship between governance, implementation, management priorities, wealth distribution and trade-offs between adaptation, mitigation and the Sustainable Development Goals (SDG).

Representations of climate change can also emerge as critiques and resistances, that expose that climate change labelled politics or interventions have posed even bigger risks, or do not address poverty issues (*medium confidence: medium evidence, high agreement*) (Lampis, 2013; Pokorny et al., 2013; Ojeda, 2014). Indigenous and social movements have joined with climate justice activists, claiming for action against climate change (Hicks and Fabricant, 2016; Ruiz-Mallén et al., 2017; Charles, 2021). The Bolivian Platform against Climate Change, a coalition of civil society and social movement organizations working to address the effects of global warming in Bolivia and to influence the broader global community, reflects an innovative dimension that, albeit at time conflictual, has flagged how increasing climate variability hinders the right of Indigenous Peoples to the conservation of their culture and practices and illustrates how grass-root movements are increasingly appropriating climate change policy in the region (Hicks and Fabricant, 2016). Social movements have engaged with international networks as Blokadia, which surged after COP 23, whose vindications try to go beyond the protection of the environment, delving into issues of democracy and resource control (Martínez-Alier et al., 2018).

Many social movements address adaptation to climate change. Some engage and participate in policy and planning, often having good results at the local level. On the contrary, top-down approaches without participation have shown to be less effective (*high confidence*) (Krellenberg and Katrin, 2014; Nagy et al., 2014b; Stein and Moser, 2014; Ruiz-Mallén et al., 2015; Sherman et al., 2015; Waylen et al., 2015; Bizikova et al., 2016; Chelleri et al., 2016; Merlinsky, 2016; Villamizar et al., 2017).

Some conflicts in which the direct biophysical impacts of climate change play a major role can unleash social protests and strengthen social movements (Section 12.6.4). In Cartagena, since 2010, the increase in precipitation increasingly impacted the *barrio* Policarpa, causing the residents to claim solutions for the problems caused by the coupled effect of flooding and industrial pollution. Also, in El Cambray II, in Guatemala City, in 2015 the nearby hill collapsed, causing the death of 280 people, 70 disappeared and the destruction of hundreds of homes. The affected community entered into a conflict with the municipality asking for resettlement and a reform of land-use planning (Stein Heinemann, 2018).

12.5.8.2 Perceptions

Perception and understanding of climate change can be seen as an adaptive feature. In CSA, the consciousness of it as a threat is burgeoning, a situation related to a growth in climate justice activism, as well as to the occurrence of extreme weather events of all kinds (*high confidence*) (Forero et al., 2014; Magrin et al., 2014; Capstick et al., 2015). Perception is positively associated across countries with the Human Development Index and ND-Gain Readiness Index, and negatively associated with the Vulnerability Index, and within countries, with the education level, while they are negatively associated with the degree of political affinity for the market economy (Azócar et al., 2021). Anyhow, some communities do not associate their problems with the scientific concept, so discussions as if it is human induced, the causes, or relations with other problems, can become irrelevant (Sapiains Arrué and Ugarte Caviedes, 2017). Even communities affected by the same changes do not necessarily perceive them in the same way (Bonatti et al., 2016). The interpretations of change, its causes and effects, can widely vary (Paerregaard, 2018; Scoville-Simonds, 2018). Rather than adapting to climate change, some peoples adapt climate change to their social worlds (Rasmussen, 2016a).

Perceptions tend to be different in rural and urban areas (Sherman et al., 2015). In the rural areas, it is highly related with temperature rise and changes in rainfall patterns, changes in agriculture (pests, calendars), biodiversity loss, solar radiation or changes in the oceans, and their impacts sometimes are related or even more attributed to socioeconomic and environmental drivers, and also related with financial negative outcomes (*high confidence*) (Infante and Infante, 2013; Postigo, 2014; Jacobi et al., 2015; Barrucand et al., 2017; Harvey et al., 2018; Martins and Gasalla, 2018; Meldrum et al., 2018; Córdoba Vargas et al., 2019; Leroy, 2019; Viguera et al., 2019; Gutierrez et al., 2020; Iniguez-Gallardo et al., 2020; Lambert and Eise, 2020). In places as the Amazonia, there is an increased perception with age (Funatsu et al., 2019). In Mediterranean Chile, younger, more educated producers and those who own their land tend to have a clearer perception than older, less educated, or tenant farmers, but they do not have a clear perception or how it may affect their yields and farming operation (Roco et al., 2015). In some dry and humid Ecuadorian montane forests, peasants perceive in the same way as scientific data, but they are at odds to predict the changes and consider that they may not be prepared and only can be reactive (Herrador-Valencia and Paredes, 2016). In an Andean community, perceptions of climate change are homogeneous and do not vary according to gender, age or ethnicity (Cáceres-Arteaga et al., 2020). Among representatives of five municipalities of Lima, it was found that climate change is not well understood and they have trouble distinguishing it from other environmental issues (Siña et al., 2016). In an Amazonian region, farmers provided a more accurate description than regional institutions of how it affects the local livelihood system (Altea, 2020). In Cuenca Auqui peasants attribute recently experienced challenges in agricultural production mainly to perceived changes in precipitation patterns, but statistical analyses of daily precipitation records at nearby stations do not corroborate those perceived changes (Gurgiser et al., 2016).

12.5.8.3 Gender and intersectionality

There is ample empirical evidence that the impacts of climate change are not of equal scope for men and women. Women, particularly the poorest, are more vulnerable and are impacted in greater proportion. Often, for several economic and social reasons, they have less capacity to adapt, further widening structural gender gaps (*high confidence*) (Box 7.4; Arana Zegarra, 2017; Casas Varez, 2017; Segnestam, 2017; Acosta et al., 2019; Aldunce Ide et al., 2020; Olivera et al., 2021; Silva Rodríguez de San Miguel et al., 2021). Gender equity is thought to be central to discussions on climate change adaptation policies. In issues such as drinking water, energy, natural disasters, impacts on health and agriculture, capacity to migrate, women (poor women in particular) are affected in greater proportion, further widening structural gender gaps. In a rural community vulnerable to drought, short-term coping was more common among the women, especially among female heads of household, while adaptive actions were more usual among the men; there are gendered inequalities in access to and control over different forms of capital that lead to a gender-differentiated capacity to adapt, where men are better able to adapt and women experience a downward spiral in their capacity to adapt and increasing vulnerability to drought (Segnestam, 2017).

However, women are not always the more vulnerable group. While in a broad sense climate change impacts more severely on women, there are situations where they have reacted, adapted better to, and been more resilient. Grassroots women self-help groups can be active agents of change for their communities, designing and delivering gender-responsive adaptation solutions (Huairou Commission, 2019). Some studies suggest that women establish a friendlier relationship with the environment and towards natural resources; studies on masculinities and environment confirm this tendency (Brough et al., 2016). In a multi country study, some female headed households tend to be slightly less vulnerable and more resilient than male headed households, even though some exceptions were found when looking at sub-groups (Andersen et al., 2017). In Chile, women are more likely to modernize irrigation and infrastructure, and gender appears as an important element for drought adaptation (Roco et al., 2016). A change to agro-ecological practices has improved gender equalities and adaptive capacity to climate change (Cáceres-Arteaga et al., 2020).

Recent studies emphasize that a gender approach to social inequalities ought to move beyond just looking at men and women as experiencing the impacts in a differentiated manner; rather, an intersectional analysis illuminates how different individuals and groups relate differently to climate change, due to their situatedness in power structures based on context-specific and dynamic social categorizations (*high confidence*) (Kaijser and Kronsell, 2014; Djoudi et al., 2016; Thompson-Hall et al., 2016; Olivera et al., 2021). Thus, the relationship between gender and adaptation demands an analytical framework that connects environmental problems with social inequalities in a complex way (Godfrey, 2012). An intersectional approach contributes to better capture the diversity of adaptive strategies that men and women adopt vis-à-vis climate change. Particular constellations of race, gender, class, age or nationality reveal more complex realities (*high confidence*).

12.5.8.4 Migrations and displacements

Migration and displacements are multi-causal phenomena, and climate may exacerbate political, social, economic or other environmental drivers (*high confidence*) (Kaenzig and Piguet, 2014; Brandt et al., 2016; Priotto and Salvador Aruj, 2017; Sudmeier-Rieux et al., 2017; Radel et al., 2018; Heslin et al., 2019; Hoffmann et al., 2020; Silva Rodríguez de San Miguel et al., 2021). In the region there are many case studies, but data to assess and monitor precisely the effects of climate -and weather- related disasters in migration and displacements in a broad perspective is still inaccurate (Priotto and Salvador Aruj, 2017; Abeldaño Zuñiga and Fanta Garrido, 2020). The most common climatic drivers include tropical storms and hurricanes, heavy rains, floods and droughts (Kaenzig and Piguet, 2014). Positive climatic conditions also can facilitate migration (Gray and Bilsborrow, 2013). Peru, Colombia and Guatemala are amongst the countries with the largest average displacements caused by hydro meteorological causes; Brazil had 295,000 people displaced because of disasters in 2019 (Global Internal Displacement Database, https://www.internal-displacement.org/database/displacement-data).

These processes can be interpreted as impacts in vulnerable peoples, but also as adaptation strategies to manage the risks and reduce the exposure, when people continue with their lives, temporary or permanently, in a different but stable situation, or when members of the families send remittances to those that remain in the affected areas (Section 7.4.3.2; Cross-Chapter Box MIGRATE in Chapter 7). The remittances create opportunities for adaptive capacity building, as they reduce some vulnerabilities in the form of infrastructures, agricultural supplies, food, education or health, as in northern CA (NU CEPAL, 2018). Anyhow, migration as adaptation is not available to everyone (Kaenzig and Piguet, 2014), and the idea has also been contested as it may not help to overcome structural problems or point to *in situ* options (Radel et al., 2018; Ruiz-de-Oña et al., 2019). The causal processes are complex. Surveys of migrants usually find that the main reported reason for migration is to find a job or to increase the household income (Wrathall and Suckall, 2016; OIM, 2017; Radel et al., 2018), but the underlying reason for the lack of job or income is rarely examined, and at times may be related with climatic hazards.

Migration most often originates in rural areas, with people moving to other rural or urban areas within their home countries (Table Cross-Chapter Box MIGRATE 1 in Chapter 7). In the Amazon, approximately 80% of the population is concentrated in cities due to rural-urban migrations in search of better income, livelihoods and services, in cases associated with extreme floods and droughts (Pinho et al., 2015). In Ecuador, environmental variables are most likely to enhance international than internal migration (Gray and Bilsborrow, 2013). Hurricanes have been seen as positive triggers for international migration in CA (Spencer and Urquhart, 2018). In the highlands of Peru, there are different patterns, including daily circular migration to combine the scarce income from agricultural production with urban income, rather than abandoning the farming land (Milan and Ho, 2014; Zimmerer, 2014; Bergmann et al., 2021).

Migration to cities can mean opportunities for migrants and for the urban areas, but also can worsen the problems, as urban poor people can become even more exposed and vulnerable, and the pressure on urban capacities may not be well absorbed (*high confidence*) (Chisari and Miller, 2016; Gemenne et al., 2020). Internal migration to cities is likely to exacerbate pre-existing vulnerabilities related to inequality, poverty, indigence and informality (Warn and Adamo, 2014). Immigration can make cities/residents more vulnerable to climate change risks (Section 12.5.5; Section 12.5.7). Groups as children, Indigenous Peoples or the poor are usually amongst the most vulnerable in the migrations and displacements, which poses challenges to national policies and international aid (Sedeh, 2014; Gamez, 2016; Ulla, 2016; Priotto and Salvador Aruj, 2017; Ramos and de Salles Cavedon-Capdeville, 2017; Amar-Amar et al., 2019; Gemenne et al., 2020). In forced migration or displacement by climatic effects, women are prone to lose their leadership, autonomy and voice, especially in new organizational structures imposed by authorities. This is especially the case in temporary accommodation camps created after disasters, exacerbating differentiated vulnerabilities existing (Aldunce Ide et al., 2020). International migration has become more dangerous and difficult as border controls have become stricter, but programs such as the one of temporary agricultural workers from Guatemala to Canada have proven to be successful (Gabriel and Macdonald, 2018). At the same time, emigration may lead to the loss of IK and LK for adaptation (Moreno et al., 2020b).

Some areas are more sensitive to generate climatic migration: the Andes, the dry areas of the Amazonia, northern Brazil, and the northern countries in CA (*high confidence*). Northeast Brazil would lose population that will move to the south, deepening the existing inequalities (Oliveira and Pereda, 2020). In a study of 8 countries around the world, including Guatemala and Peru, a link was found between rainfall variability and food insecurity which could lead to migration in areas of high prevalence of rainfed agriculture and low diversification (Warner and Afifi, 2014). In CA, younger individuals are more likely to migrate in response to hurricanes and especially to droughts (Baez et al., 2017).

The perception of gradual changes lowers the likelihood for internal migration, while sudden-onset events increase movement (Koubi et al., 2016). On the other hand, it has been seen that extreme events like floods or droughts can hinder population mobility, immobilizing them in their localities (Thiede et al., 2016). These immobilized populations are supposed to face a double set of risks: they are unable to move away from environmental threats, and their lack of capital makes them especially vulnerable to environmental changes (Black et al., 2011). In CSA, migrating to the U.S. is becoming dangerous and expensive, as that country is restricting the entries; these trends expose local populations to the risk of becoming immobile in the near future in a place where they are extremely vulnerable (Ruano and Milan, 2014; McLeman, 2019). A survey in Guatemala found no correlation between migration to the U.S. and severe food insecurity in households, but the correlation became significant if the level of food insecurity was moderate, suggesting that families in extreme hardship did not have the resources to migrate (Aguilar et al., 2019). At the same time, some populations just have chosen not to move, as in Peru, where immobility in dissatisfied people is more likely to be caused by attachment to place than resource constraints (Adams, 2016; Correia and Ojima, 2017). Some populations have chosen to adapt relying in their IK and LK (Boillat and Berkes, 2013).

Migration is often the last resort for rural communities facing water stress problems (Magrin et al., 2014; Ruano and Milan, 2014). In Bolivia, glacial retreat has not triggered new migration flows and had a limited impact on the existing migratory patterns (Kaenzig, 2015). In SA, climatic variability increases the likelihood of inter-province migration, rather than trapping populations. In a study of interprovincial migration motivated by temperature, an exception arose in Bolivia, and even if that could suggest an immobilized population (Thiede et al., 2016), it is not clear if they want to stay and adapt. In some cases, people want to move but wait for relocation after the climate related disasters (Priotto and Salvador Aruj, 2017).

12.5.8.5 Financing

Climate change financing is unequally distributed among CSA countries (*high confidence*). Financing of climate change adaptation remains very much delegated to multilateral and bilateral cooperation and the governments in the region have heavily relied on it. Still, there are some concerns regarding justice in the distribution of these funds (Khan et al., 2020). The UNFCCC has created financing mechanisms throughout its functioning years, but there is a wide range of issues that can present challenges for access by the recipients (Hickmann et al., 2019). These include; lack of technical capacity; difficulties in following the procedures established by the various financial entities; and low levels of awareness about the need for action, as well as the different sources of funds available. The fiscal policies of the different countries have contributed to government financing in the fight against climate change (World Bank, 2021). Since the Paris Agreement, countries have pledged NDCs which introduce the need to design and implement carbon budgets with respective consideration of the efficiency and costs and benefits involved in each mitigation or adaptation to climate change projects (Fragkos, 2020).

According to UNFCCC, Latin America and the Caribbean, for the period 2015–2016 obtained 22% of climate finance from multilateral climate funds. In this section we use data from: https://climatefundsupdate.org/data-dashboard, most of the reported information for Latin-American and the Caribbean includes Mexico, since the scope of this chapter does not includes Mexico we have rely in the raw data included in the data-dashboard mentioned in the link (see also: Guzmán et al. (2016)). 76% went to mitigation projects with the remaining 24% going to adaptation. Of the total finance provided by the multilateral climate funds to the Region, 51% took the form of concessional loans, while 47% was provided as grants. For the region, approvals in the 2015–2016 period were concentrated in Argentina, Chile, Brazil, and Colombia, where large-scale mitigation projects were launched supported by the Green Climate Fund (GCF) and the Clean Technology Fund (CTF). For the period 2003-2019, total contribution to South America and the Caribbean is about USD 3,558 million. The largest contributors to climate finance in the region come from the GCF, which approved USD 824.2 million for 23 projects. Brazil is the top recipient with USD 195 million, followed by Argentina with about USD 162 million. The second provider is the Amazon Fund with USD 717 million assigned to 102 projects in Brazil. In 2018, the CTF has become the third source of financing with USD 483 million dollars approved for 24 projects; the main recipient is Chile with USD 16,207 million followed by Colombia with USD 170 million. The five largest projects approved in the region in 2018 were through the GCF. Brazil (USD 195 million) received support for reducing energy intensity across Brazilian cities, while Argentina (USD 103 million) received support to scale up investments by Small and Medium sized Enterprises (SMEs) in renewable energy and energy efficiency. In both cases finance is predominantly provided as concessional loans.

Climate financing in CSA is mainly focused on mitigation actions (*high confidence*). In South America and the Caribbean, 73% (USD 2,579 million) of funding to date has supported mitigation. Only 21% (USD 761 million) of the funding supports adaptation projects and the remaining 4% (USD 217 million) supports multi-focus projects. Of the 51 new projects in South America and the Caribbean approved in 2018-2019, the GCF financed USD 508 million in ten projects. Amazon Fund was next with USD 81 million in 10 projects. While 32 the GCF focuses on large and transformative projects and programs and on a broader reform of the policy framework in the Region, the Amazon Fund targets smaller project interventions.

Climate finance in the region is concentrated in Brazil receiving one third of the region's funding, and 41 mitigation activities receiving more than six times that of adaptation from multilateral climate funds. By the size of its PGB, Brazil is receiving the largest amount of financing; this leaves the poorest countries with little or no financing and therefore reinforces a vicious circle of poverty and vulnerability. If this is due to Brazil being more successful presenting eligible projects, lack of commitment from other developing countries or some other structural factors is an open question. In any case, compensation schemes for the most vulnerable countries appear as required, given the differences in vulnerability to climate damages (Antimiani et al., 2017). This is aggravated by the fact that funds management is in the hands of supranational entities while inequalities remain in regions within a country, particularly in countries highly centralized as is the case for countries in the region.

COVID-19 recovery plans can present synergistic effects for climate change adaptation (*medium confidence: low evidence, high agreement*). A key decision point for adaptation will be how the world responds to the pandemic. The global recovery can serve as a catalyst to increased and more equitable climate financing. Globally, recovery packages will likely have the power to change the global trajectory towards meeting the targets of the Paris Agreement and building a more just future (Forster et al., 2020). Several factors are relevant to the design of economic recovery packages: the long run economic multiplier, contributions to the productive asset base and national wealth, speed of implementation, affordability, simplicity, impact on inequality, and various political considerations (Hepburn et al., 2020). A key objective of any recovery package is to stabilize expectations, restore confidence, and to channel surplus desired savings into productive investment. However, 'business as usual' implies temperature increases over 3°C, implying great future uncertainty, instability, and climate damages. An alternative way to restore confidence is to steer investment towards a productive and balanced portfolio of sustainable physical capital, human capital, social capital, intangible capital, and natural capital assets (Zenghelis et al., 2020), consistent with global goals on climate change. Finally, any recovery package, including climate-friendly recovery, is unlikely to be implemented unless it also addresses existing societal and political concerns—such as poverty alleviation, inequality, and social inclusion—which vary from country to country.

12.5.9 Adaptation Options to Address Key Risks in CSA

This section integrates, in the table 12.10 below, the sectoral assessment of adaptation options (see Sections 12.5.1 to 12.5.8) with the eight key risks assessed in the region (see Section 12.4). Table 12.10 presents a list of the summarized adaptation options, which are detailed in their adaptation sections, from 12.5.1 to 12.5.8 in this chapter.

Table 12.10: Adaptation options addressing key risks organized by sector. See the note at the end for descriptions of the sector names abbreviations.

1. Risk of food insecurity due to frequent/extreme droughts	
T&F. ecosystems	Ecosystem-based adaptation (EbA): Agroecosystem resilience practices
O&C ecosystems	Not Assessed (NA)
Water	Water infrastructure and irrigation; Nature-based solution (NbS) & Payment for ecosystem services (PES); Participatory water management; Multi-purpose water use
Food	Climate information services; Early warning system (EWS); Insurance; Land use planning; Low-Carbon Agriculture (LCA) strategies; Agroforestry; Indigenous Knowledge and Local knowledge (IK and LK)
Cities	NA
Health and wellbeing	EWS; Insurance; Participatory water management; Water infrastructure and irrigation
Poverty and SD	Community-based adaptation (CbA); Government and institutional support
Human Dimension	Participatory management; Incorporation of IK and LK in water and crop management; Education and communication
2. Risk to life and infrastructure due to floods and landslides	
T&F ecosystems	NA
O&C ecosystems	NA
Water	NbS; Land-use regulation; EWS; Integrated risk management.
Food	NA

Cities	Urban planning; Climate-adapted parameters in land use and building regulation; Intersectoral and multilevel governance; Slum upgrading; Social housing improvement; Urban control systems; CbA; Risk management plans; Integrated watershed management; Flood control programs; Environment protected areas; Households relocation; EWS; NbS; Mapping tools; Green-grey infrastructure (GGI); Water storage solutions; Wetland restoration; sustainable urban drainage systems (SUDS); low-impact development (LID); River restoration; Multifunctional landscapes; Improving basic sanitation services
Health and wellbeing	EWS; GGI; Community led and managed relocation; Insurance
Poverty and SD	Secure location; Social housing policies; EWS
Human dimensions	Education and communication
3. Risk of water insecurity	
T&F ecosystems	Monitoring Systems; EbA; Forest protection and restoration; Watershed protection
O&C ecosystems	CbA; Land use and development regulation
Water	Water infrastructure and irrigation; NbS & PES; Participatory water management; Multi-purpose water use
Food	Management and planning; NbS; Soil and water conservation
Cities	Intersectoral and multilevel governance; CbA; Risk management plans; Integrated watershed management; Environment protected areas; NbS; GGI; Wetland restoration; Improving basic sanitation services; Reservoir system
Health and wellbeing	Protection and restoration; National Adaptation Plans; Participatory water management
Poverty and SD	NbS: Water harvesting; Equitable water distribution
Human dimensions	Participatory management; Incorporation of IK and LK in water management; Education and communication
4. Risk of severe health effects due to increasing epidemics	
T&F ecosystems	NA
O&C ecosystems	NA
Water	Water infrastructure; Sanitation improvement
Food	NA
Cities	NA
Health and wellbeing	EWS; Health-climate surveillance systems; National plans on health; Communal management; GGI; Protection and Restoration.
Poverty and SD	CbA; Transparent democratic governance; Equitable services; Education
Human dimensions	Education and communication

5. Systemic risks of surpassing infrastructure and public service systems	
T&F ecosystems	NA
O&C ecosystems	EWS; EbA; Territorial planning; CbA; Land use and development regulation; GGI
Water	Water infrastructure; Land-use regulation; Water retention capacity; EWS; Capacity building
Food	NA
Cities	Urban planning; Climate-adapted parameters in land use and building regulation; Intersectoral and multilevel governance; Slum upgrading; Social housing improvement; CbA; Improving basic sanitation services; Micro wastewater treatment plants
Health and wellbeing	EWS; Vulnerability and risk maps; National Adaptation Plans; GGI
Poverty and SD	Transparent, democratic governance
Human dimensions	NA
6. Risk of large-scale changes and biome shifts in the Amazon	
T&F ecosystems	Monitoring Systems; EbA; Protected areas; Forest protection and restoration and restoration; Watershed protection
O&C ecosystems	NA
Water	Integrated water resource management
Food	Territorial planning
Cities	NA
Health and wellbeing	Protection and restoration
Poverty and SD	Insurance; Micro-credits; PES; CbA
Human dimensions	Participatory management; Incorporation of IK and LK in forest management; Education and communication
7. Risk to coral reef ecosystems due to coral bleaching	
T&F ecosystems	NA
O&C ecosystems	Zoning schemes; MPAs; EbA; CbA; Adhesion of international treaties
Water	NA
Food	NA

Cities	NA
Health and wellbeing	Protection and restoration
Poverty and SD	NA
Human dimensions	NA
8. Risks to coastal socio-ecological systems due to sea level rise, storm surges and coastal erosion	
T&F ecosystems	NA
O&C ecosystems	EbA; Planned relocation; GGI
Water	NA
Food	NA
Cities	Urban planning; Climate-adapted patterns in land use and building regulation; Intersectoral and multilevel governance; CbA; Risk management plans; Households relocation; NbS; GGI
Health and wellbeing	GGI; Communal management; Protection and restoration
Poverty and SD	Secure location; CbA relocation
Human dimensions	Participatory management; Education and communication

Table Notes:
Some sectors are presented by abbreviations: Terrestrial and freshwater ecosystems and their services (T&F. ecosystems); Ocean and coastal ecosystems and their services (O&C ecosystems); Food, fibre and other ecosystem products (Food); Cities, settlements and key infrastructure (Cities); Poverty, livelihood and sustainable development (Poverty and SD); Cross cutting issues in the Human Dimension (Human Dimensions).

12.5.10 Feasibility Assessment of Adaptation Options

This section assesses the feasibility of selected adaptations options by sector, relevant for CSA, in five dimensions (economic, technological, institutional, social, environmental and geophysical), according to the methodology developed by Singh et al. (2020a). Table 12.11 shows the summary of results and Table SM12.7 the details of the assessment and the supporting literature.

Table 12.11: Feasibility assessment of selected adaptation options for CSA region.

System	Adaptation option	Evidence	Agreement	Dimension assessed					
				Economic	Technological	Institutional	Social	Environmental	Geophysical

Food, fibre and other ecosystem products	Agroforestry	*Medium*	*High*	Insignificant barriers	Mixed effect	Significant barriers	Mixed effect	Insignificant barriers	Mixed effect
Health and wellbeing	Early warning systems	*Robust*	*High*	Insignificant barriers	Mixed effect	Significant barriers	Mixed effect	Insignificant barriers	Mixed effect
Water	Multi-use of water storage approaches	*Robust*	*Medium*	Insignificant barriers	Mixed effect	Mixed effect	Mixed effect	Mixed effect	Insignificant barriers
Freshwater and terrestrial ecosystems	Ecosystem-based adaptation (EbA)	*Medium*	*High*	Insignificant barriers	Mixed effect	Mixed effect	Insignificant barriers	Insignificant barriers	Insignificant barriers

12.5.10.1 Food, fibre and other ecosystem products - Agroforestry

For the agri-food systems, the adoption of agroforestry provides a more diverse and sustainable agricultural production, where farmers maintain or improve their current production by incorporating suitable trees that ameliorate climatic conditions. Thus, in the same unit of land, these systems incorporate exotic tree species or managed native forests into farming systems allowing the simultaneous production of trees, crops and livestock with different spatial arrangements or temporal sequences. On the other hand, it is recognized that the initial investment and time until trees start to produce may create economic vulnerability. Therefore, there is a need to design adequate programs and allocate resources for agroforestry systems implementation, as well technical assistance and training (*medium confidence*). Also, some market schemes such as payment for ecosystem services and certification can assist to reduce this vulnerability.

12.5.10.2 Health and Wellbeing - Early Warning Systems

For the health sector, we assessed the barriers and facilitators for the implementation of climate-driven early warning systems under natural disasters and epidemic situations. We found institutional dimensions as potential barriers, including the legal and regulatory feasibility, the institutional capacity and administrative feasibility, transparency, and political acceptability (*high confidence*). The fewest barriers were identified for the economic and environmental dimensions.

One of the main institutional challenges is the lack of policy with climate-health linkages. Opportunities include a national plan for the health sector to address the impacts of climate by formalizing collaborations via agreements (MOUs). Another key barrier is that relatively few institutions in the region have the human technical and administrative capacity to implement and operate an EWS. Regional platforms may provide a solution for technical assistance at national levels.

On the other hand, the economic dimensions had relatively few barriers, although the initial costs of designing, implementing, equipping, and maintaining the system are a potential barrier for health sectors with reduced budgets. However, the health benefits and economic savings (due to averted epidemics or damages from disasters) may offset these costs. The resilience built in the health sector by these systems may be applicable to other economic sectors that can benefit from an early warning of an oncoming extreme event and associated health impacts.

12.5.10.3 Water - Multi-use of water storage approaches

For the water sector, geophysical and economic dimensions do not pose a major barrier due to the potential reduction of flood hazard exposure, physical-technical viability of project implementation, different suitable economic mechanisms for joint public-private financing and more efficient water use. However, limited institutional capacities and the social-environmental impacts of large water infrastructure (Section 12.5.3) reduce the institutional, social, environmental and, to some extent, technological feasibility. This may be a potential barrier to the adaptive approach of multi-use water storage (*medium confidence*).

12.5.10.4 Freshwater and terrestrial ecosystems - Ecosystem-based adaptation (EbA)

In the terrestrial and freshwater ecosystems sector, we assessed the feasibility of implementing EbA options in the CSA region. Given that EbA encompasses a wide range of projects, techniques and political and socioeconomic arrangements, extreme care should be taken to apply these general findings to particular cases. EbA can enhance food sovereignty and carbon stocks and foster SDG by protecting and restoring ecosystems health and productivity. EbA is a strategy that frequently involves bottom-up decision making and local communities' empowerment and usually contributes to inequality reduction. EbA tends to benefit vulnerable groups, but aspects such as the impact on socioeconomic inequalities when implemented should be taken into account.

In general, EbA does not require high technologies for local communities. However, limitations in technical assistance and funding for specific key technologies and training may act as a barrier for EbA adoption (*medium confidence*). EbA practices can reduce risk in several ways by increasing awareness among communities and providing food diversity and production. EbA is recognized as a desirable policy for most stakeholders in CSA, particularly for being a strategy that incorporates environmental and social concerns. Nonetheless, it is important that all stakeholders agree on the goals and methods for EbA to be effective. Lack of institutional coordination, clear goals and strategies were identified as a potential barrier for EbA implementation. EbA is heavily based in local and Indigenous knowledge, as well as ecological academic knowledge.

For the adaptation options analysed, significant barriers and mixed effects were observed for the institutional dimension, which indicates the relevance of the design and implementation of public policies and institutional arrangements for effective adaptation in the region. Considering the results, there is a need to advance initiatives, programs and projects that facilitate adaptation to climate change. In the same way, barriers were evidenced in the technological dimension, which indicates the importance of increasing access and diffusion of appropriate techniques and technologies in order to face the challenges of climate change in the region.

12.6 Case Studies

12.6.1 Nature-based Solutions in Quito, Ecuador

Nature-based Solutions (NbS) are related to the maintenance, enhancement, and restoration of biodiversity and ecosystems as a means to address multiple concerns simultaneously (Kabisch et al., 2016). NbS can trigger sustainability transitions. For example, conservation and restoration of natural ecosystems are prone to promote synergy between mitigation, adaptation and sustainable development. Ecosystem-based Adaptation- EbA can be seen as a type of NbS deployed in response to climate change vulnerability and risk (Greenwalt et al., 2018), combining the objectives of reducing the vulnerability of human and increasing the resilience of natural systems (IPCC, 2014).

The Municipal Quito District in Ecuador covers 4235 km^2 of mountainous territory that ranges from 500 to 5000 m.a.s.l. That territory has followed a pattern of urbanization common in Latin America: its population has increased from around 500,000 people in the 1970s, to nearly 3 million inhabitants by 2020, of which

80% live in urban areas (Municipio del Distrito Metropolitano de Quito, 2016). A massive inflow of people immigrated in the early 1970s due to various causes, including the search for the rents created as a result of the oil boom in the Ecuadorian Amazon, better working conditions, health, education and cultural services, in comparison with the rural areas or in mid-sized cities. As a result, the city underwent an exponential growth, claiming valuable agricultural and forestry areas, and natural ecosystems, in the peripheries. Many of the new neighbourhoods were established through land invasions or informal markets, in many cases over steep slopes, in water sources and agricultural or conservation areas (*high confidence*) (Cuvi, 2015; Gómez Salazar and Cuvi, 2016). That exponential population growth, coupled with urban sprawl, poses many challenges to the city, including those related to climate change.

Mean air temperature and annual rainfall (measured through instruments since 1891 and inferred through historical records of rogation ceremonies since 1600), are increasing, combined with an increase in seasonality (i.e., longer periods of drought) and extreme weather events, particularly stronger precipitations (Serrano Vincenti et al., 2017; Domínguez-Castro et al., 2018). Two impacts related to warmer air conditions are the displacement of the freezing line currently placed at 5100 m.a.s.l. (Basantes-Serrano et al., 2016), followed by glacier retreat and the upward displacement of mountainous ecosystems (*very high confidence*) (Vuille et al., 2018; Cuesta et al., 2019). The key ecosystem that regulates water provision for the city is the paramo, and only about 5% of this process is related with glaciers, so the combined effects of climate change on both systems, coupled with land use change and fires, can reduce the availability of water for agriculture, human consumption and hydropower. Other important climatic hazards and impacts are the increase of solar radiation, the heat island effect and fires (*high confidence*) (Anderson et al., 2011; Armenteras et al., 2020; Ranasinghe et al., 2021). Almost half of the days of each year, Quito's population is exposed to levels of UV radiation above 11 according to the World Health Organization scale (Municipio del Distrito Metropolitano de Quito, 2016).

Various policies, programs and projects have been created for the promotion of urban green spaces, protected areas, water sources and watersheds monitoring, conservation and ecosystem restoration, air pollution monitoring and control, and urban agriculture. Among those actions, three recent are commonly highlighted. The first is the Fund for the Protection of Water (FONAG), established in 2000 with funds of national and international organizations, to promote the protection of the water basins that supply most of the drinking water. It is a PES-Scheme (Payment for Ecosystem Services) enabled through a public-private escrow. The projects include conservation, ecological restoration, and environmental education for a new culture of water, in a context opposed to the commodification of natural resources (Kauffman, 2014; Bremer et al., 2016; Coronel T, 2019). FONAG was innovative in the use of trust funds in a voluntary, decentralized mechanism and has inspired more than 21 other water funds in the region; nevertheless, its narrative of success has also been said to over-simplify and misrepresent some complex interactions between stakeholders as well as within communities and their land management practices (Joslin, 2019).

The second highlighted initiative is the project AGRUPAR (Participative Urban Agriculture), launched as a public initiative in 2002 with international cooperation funds at the beginning. It was aimed to provide assistance to poorer urban and peri-urban populations, to initiate and manage orchards as well as domestic animals such as chickens and guinea pigs, dedicated for self-sustenance and commerce. AGRUPAR provides and finances training, seeds and seedlings, greenhouses, certifications and marketing support, spaces where farmers can sell directly their products to consumers. In 2016, AGRUPAR gave assistance to more than 4000 farmers managing orchards of various scales that combined produce, annually, more than 500 tonnes. The program has direct impacts on nutrition, generation of work for women, production of healthy food, reduction of runoff, recycling of organic waste, social cohesion, among others (*very high confidence)* (Thomas, 2014; Cuvi, 2015; Rodríguez-Dueñas and Rivera, 2016; Clavijo Palacios and Cuvi, 2017).

A third initiative is the creation of a municipal system of protected areas, locally named Áreas de Conservación y Uso Sustentable (ACUS). This system covers an area of 1320 km², nearly one third of the Municipal Quito District. Half of this landscape (680 km^2) is covered by montane forests and *paramos* (Torres and Peralvo, 2019). These forests provide direct water, food and fibres for about 20,000 people, and indirectly a rural landscape for a growing number of urban citizens and foreign tourists that practice ecotourism and look for fresh and healthy food. During the last three decades, this area has witnessed a high density of public and private conservation and restoration efforts that aim to regain ecological integrity and improve human well-being in deforested and degraded landscapes (Mansourian, 2017; Zalles, 2018; Wiegant et al., 2020). Quito's system of protected areas constitutes a primary strategy for fostering links between urban and rural citizens as a means of understanding the ecological dependence of urban metropolises to their surrounding natural landscapes. Along the same lines, these areas constitute a key element to increase the adaptive capacity of rural livelihoods and contribute to mitigating climate change through landscape restoration, sustainable production and forest conservation (*high confidence*).

Other NbS' actions have been the restoration of small basins, locally named quebradas, under different schemes of management and participation (*medium evidence, very high agreement*) (da Cruz e Sousa and Ríos-Touma, 2018), or the transformation since 2013 of a larger portion of the old Quito airport into an urban park. Nevertheless, Quito city still has to deal with challenges in social, economic, infrastructural and environmental spheres. A major pending environmental issue is air pollution, as there is a high level of pollutants affecting the city in general, and specially the most vulnerable groups (*high confidence*) (Zalakeviciute et al., 2018; Alvarez-Mendoza et al., 2019; Estrella et al., 2019; Hernandez et al., 2019; Rodríguez-Guerra and Cuvi, 2019). Another major issue is the continuous sprawl of new neighbourhoods, mainly through informal processes, that diminish the urban resilience because of the destruction of conservation and food production areas, sources of water, and the dispersion of settlements without primary services, among other consequences (Gómez Salazar and Cuvi, 2016).

12.6.2 Anthropogenic Soils, an Option for Mitigation and Adaptation to Climate Change in Central and South America. Learning from the "Terras Pretas de Índio" in the Amazon

Amazon Dark Earths (ADEs), also known as "Terras Pretas de Índio", are anthropogenic soils derived from the activities associated to settlements and agricultural practices of pre-Hispanic societies in the Amazon (Woods and McCann, 1999; Lehmann et al., 2003; Sombroek et al., 2003). Most of the ADEs identified so far are 500 to 2500 years old (de Souza et al., 2019). According to Maezumi et al. (2018a) polyculture agroforestry allowed the development of complex societies in the eastern Amazon around 4500 years ago. Agroforestry was combined with the cultivation of multiple crops and the active and progressive increase in the proportion of edible plant species in the forest, along with hunting and fishing. The formation of ADEs, as a result of these activities, provided the basis for a food production system that supported a growing human populations in the area (Maezumi et al., 2018a).

Amazon Dark Earths are the result of the accumulation and incomplete combustion of waste materials such as ceramic artefacts and organic residues from harvest, weeding, food processing (including cooking) and other activities (Lima et al., 2002; Hecht, 2003; Kämpf et al., 2003). ADEs are characterized by their increased fertility in relation to adjacent soils; with high contents of organic carbon (C) (mainly as charcoal) as well as inorganic nutrients, especially phosphorus (P) and calcium (Ca); and high Carbon/Nitrogen ratios (*high confidence*) (Moline and Coutinho, 2015; Alho et al., 2019; Barbosa et al., 2020; Pandey et al., 2020; Soares et al., 2021; Zhang et al., 2021). They also exhibit high cation exchange capacity (CEC) and moisture retention among others properties (Hecht, 2003; Kämpf et al., 2003; Falcão et al., 2009). Charcoal content is a key indicator of pre-Hispanic fire activity and sedentary occupation, which is evidence of the anthropic origin of these soils (*high confidence*) (Hecht, 2017; Maezumi et al., 2018b; Alho et al., 2019; Barbosa et al., 2020; Iriarte et al., 2020; Montoya et al., 2020; Shepard et al., 2020).

Accumulation of organic residues and low intensity fires management are recognized as key elements for ADEs formation. ADEs originating around settlements show a relatively high density of ceramic artefacts and are named *Terras pretas.* They present a higher content of Ca and P than those originated from agriculture activities which are known as *Terras mulatas* (Hecht, 2003).

There is a robust and growing body of research from different disciplines that gives high relevance to ADEs in the region. It has been shown through archaeological and paleoclimatic data that Amazonian societies which based their agricultural management on "Terras Pretas de Índio", were more resilient to the changing climate due to increased soil fertility and water retention capacity (de Souza et al., 2019). Additionally, low organic carbon degradability over long time periods, associated with high contents of charcoal or pyrogenic carbon, makes these soils an important C sink (*medium confidence*: *robust evidence, medium agreement*) (Lehmann et al., 2003; Guo, 2016; Trujillo et al., 2020), which is particularly relevant in an area like the Amazon, that could change from a net carbon sinks to a net carbon source as a consequence of anthropogenic climate change (Maezumi et al., 2018b).

The Indigenous agricultural practices which originated ADEs are thought to be associated with a more sedentary agricultural model than the current slash and burn and shifting cultivation practices. Although this is a controversial topic, as the precise definition of slash and burn and shifting cultivation is presently under discussion (Hecht, 2003); several present-day local and Indigenous agricultural practices, including in-field burning and nutrient additions from food processing and residue management, have been recognized as promoting high organic carbon and nutrient soil contents similar to the ones found in ADEs (Hecht, 2003; Winklerprins, 2009).

At present, ADEs are estimated to cover up to 3.2% of the Amazon basin and are highly valued for their persistent fertility, becoming a key resource for sustainable agriculture for Amazon communities in a climate change context (Altieri and Nicholls, 2013; Maezumi et al., 2018a; de Souza et al., 2019). Based on the lessons learned from the Terras Pretas de Índio, some researches have proposed the development of technologies to promote a new generation of anthropogenic soils (e.g., Kern et al. (2009); Lehmann (2009); Schmidt et al. (2014); Bezerra et al. (2016); Kern et al. (2019)). Among the technologies based on ADEs learnings Biochar, obtained by slow pyrolysis of agricultural residues, is the most explored application found in literature (Mohan et al., 2018; Matoso et al., 2019; Amoah-Antwi et al., 2020). The dual purpose of increased soil fertility and carbon sequestration is considered an important goal in order to develop sustainable agriculture in a climate change context (Kern et al., 2019).

Preservation of the practices and knowledge associated with these soils is vital for sustainable agriculture in a climate change scenario in the Amazon. It will greatly contribute to the preservation of valuable Indigenous knowledge as well as the contribution to the development of new adaptation and mitigation technologies among other unexplored solutions.

12.6.3 Towards a Metropolitan Water-related Climate Proof Governance (re)configuration? The case of Lima, Perú

Lima-Callao Metropolitan City, capital of Perú is facing recurrent climate disasters showing lessons on water-related climate-proof governance reconfiguration: 1) when disasters affect the poor and rich population, dominant actors prioritize the integral city's resilience and development, and coordinate and collaborate within a *concertation* manner across institutional levels and geographical scales (Hommes and Boelens, 2017; Miranda Sara, 2021), even having different ideas, discourses, and power, recognizing that no one single actor has enough power; 2) water-related climate change scenarios require comprehensive, transverse, multi-sectoral, multi-scalar, multiple types of actor´s knowledge (expert, tacit, codified and contextual embedded (Pfeffer, 2018) and transparent information to manage the tensions and even conflicts when some knowledge is not shared or restricted particularly when lower risk perception and higher risk tolerance are present; 3) a *concertative* (processes which involve a variety of actors and has become mandatory in Peru) strategy to *localize* the climate action shows quicker, more effective and transparent results (*medium confidence, robust evidence, medium agreement*) (Miranda Sara and Baud, 2014; Pepermans and Maeseele, 2016; Siña et al., 2016; Miranda Sara et al., 2017).

Being the second driest city in the world, Lima is highly vulnerable to drought and heavy rainfall in the nearby Andean highlands (Schütze et al., 2019). Located on the Pacific Coast with more than 10 million inhabitants, suffers from both flooding, mudslides disasters and water stress, being more frequently affected by heavy rain peak events (1970, 1987, 1998, 2012, 2014, 2015 and 2017) (*very high confidence*) (Mesclier et al., 2015; Miranda Sara et al., 2016; French and Mechler, 2017; Vázquez-Rowe et al., 2017; Escalante Estrada and Miranda, 2020). In addition to water unequal distribution in quantity and pricing, one million inhabitants lack water connections (Ioris, 2016; Miranda Sara et al., 2017; Vázquez-Rowe et al., 2017) as a result of a lack of long-term city planning and lack of integration with water and risk management. Climate change scenarios were ignored or denied, particularly when the budget allocation for preventive actions was necessary (*high confidence*) (Miranda Sara et al., 2016; Allen et al., 2017a).

In 2014, the Water Company (SEDAPAL) together with the Lima Metropolitan Municipality (LMM), ANA, and other organizations agreed on a Lima Action Plan for Water (Schütze et al., 2019). The same year, the Lima Metropolitan Municipality (LMM) approved the Climate Change Strategy defining adaptation and mitigation measures (Miranda Sara and Baud, 2014), based on technical and scientific action research within interactive, and iterative *concertation* multi-actor processes.

However, in 2015, municipal elections shifted Lima's and later Peru's political power to parties associated with climate deniers at a high cost to the people, city infrastructure, and housing. Beginning of 2017, buildings along rivers, ravines, and slopes suffered from floods, *huaycos* (mudslides), the whole city suffered potable water cuts (Vázquez-Rowe et al., 2017) and vector-borne diseases affecting particularly the poorer but also richer inhabitants.

"Coastal Niño", affected the whole country, as a consequence, in 2018, the Peruvian government passed the Framework Law for Climate Change, Law No. 30754, a unique political decision, to assure the integration of climate change concerns in public policies and investment projects. The law defines local governments mandates on Local Climate Action Plans. The 2019 municipal elections brought new local authorities to Lima and by 2020, 19 district municipalities developed their Adaptation Measures adopting the Metropolitan Climate Change Strategy with support of Cities for Life Foro and GIZ (Foro Ciudades Para la Vida, 2021), in 2021 LMM approved its Local Climate Change Plan (LCCP) and other 10 (out of 51 with Callao) municipalities concluded the elaboration of their LCCP with support of the Global Covenant of Mayors and the European Union.

The institutionalized culture of participation in Peru did lead to a broader concept of *concertation*, wherein practices of collaborative planning were developed to allow actors to build up socially supported agreements, decisions and take actions without losing sight of their principles. These processes have been applied to reduce risks, to adapt and to anticipate uncertain and unknown futures; and introducing climate change concerns within a complex political and institutional environment surrounded by corruption scandals (Vergara, 2018; Durand, 2019) and growing political polarization.

Several processes have been set in motion to engage citizen participation and promote climate action planning: 1) The LMM with the Climate Action Plan processes reopened the Climate Change Technical Group of the Municipal Environmental Commission whose work ended in the approval of the Lima Local Action Plan of Climate Change (MML, 2021), 2) The River Basin Council is developing the River Basin Management Plan led by the National Authority of Water (ANA); 3) The Metropolitan Lima Urban Development Plan is finalizing a citizen consultation, with the support of a high-level Consultation Group.

Such processes include strong discussions, conflicts, and the recognition of other's discourses and types of knowledge, to build up scenarios that "visualize" and anticipate what might happen. These processes require democratic, transparent, and decentralized institutions, providing clear mandates and strong political will to support them, so the views of the poor and vulnerable are included, being able to make themselves heard, even if their power remains limited (Chu et al., 2016). Opportunities for the reconfiguration of socio-political and technological water governance are emerging based on socially supported agreements (Miranda Sara and Baud, 2014; Miranda Sara, 2021). Although the water governance configuration faces the paradox that current water demands of all users combined may no longer be feasible within ecological limits and future climate change consequences (Miranda Sara et al., 2016; Schütze et al., 2019).

12.6.4 Strengthening Water Governance for Adaptation to Climate Change: Managing Scarcity and Excess of Water in the Pacific Coastal area of Guatemala

Guatemala experiences high climate inter-annual variability now increased from the effect of climate change (INSIVUMEH, 2018; Bardales et al., 2019). Impacts on human settlements, agriculture and ecosystems result from both excess and reduced precipitation (*high confidence*) (Section 12.3.1.4). Guerra (2016) argues that deficient integrated water resource management in the country is the main reason for those impacts. A case in point is that of rivers Madre Vieja and Achiguate where an intense El Niño event triggered dryer conditions and, in turn, a crisis and conflict that reached national proportions. Progress in local water governance helped to solve that crisis and contributed to tackle challenges posed by reduced precipitation and flood risk in southern Guatemala.

The ENSO event that started in November 2014 and ended in July 2016 (CIIFEN, 2016) has been the most intense since records commenced in 1950 (NOAA, 2019). Its effects were felt in different parts of the world and, Guatemala and the rest of Central America experienced an intense water scarcity due to a significant reduction in rainfall (*high confidence*) (IICA, 2015; Scientific American, 2015). River flow in the dry months is related to precipitation levels in the previous rainy season and thus, ENSO has an effect on river flow rates. Two of the main rivers in the Pacific coast of Guatemala, Madre Vieja and Achiguate, dried out completely at the beginning of 2016, triggering a nearly violent local conflict that caught attention at the national level (Guerra, 2016; Gobernación de Escuintla et al., 2017). In addition to the severe drought, the rivers dried because of over-extraction by multiple users (60 in the case of Madre Vieja). This had happened before to a lesser extent in the last 20 years during the critical months of the dry season. Lack of regulation, coordination mechanisms, information, and other elements of water governance was the root cause of the problem, exacerbated by the drier conditions during the intense El Niño resulting in the intensification of an existing conflict (*high confidence*) (Guerra, 2016).

Roundtables were set up to foster dialogue between numerous stakeholders including communities, agri-export companies, governmental organisations, municipalities, all led by the local governor (Gobernación de Escuintla et al., 2017). Agreements included: to keep a minimum of the rivers flowing all the way to the sea; to set up a monitoring and verification system for levels of river flow; and to restore riparian forests. A system was set up to monitor river flow in different points along the rivers on a daily basis in the dry season using a simple WhatsApp-based system to communicate the warnings and monitor compliance. Four years on, the rivers had not dried out and conflict was kept to a minimum. Rural communities can use rivers for recreational purposes and for fishing all year round, whilst plantations (large and small) can use water for irrigation (rationally) and keep producing. Similar schemes and interactions started happening in other rivers in the Pacific coast of Guatemala, with positive results, particularly keeping the rivers flowing all through the dry season as can be seen in the report of river flows for years 2017, 2018 and 2019 (ICC, 2019b).

A key actor in the improvement of water governance has been the Private Institute for Climate Change Research (ICC). This is a unique initiative that was created in 2010 and is funded primarily by the private sector of Guatemala to help the country advance in climate change mitigation and adaptation (Guerra, 2014). The institute works alongside local governments, communities and private companies in several topics apart from integrated water management. Its role is merely technical-scientific, being in charge of the water monitoring system, generating data on weather and hydrology, and providing support to other stakeholders.

Local governance was also essential for the implementation of flood risk management actions (*high confidence*). Guerra et al. (2017) explained how impacts were significantly reduced in the Coyolate river watershed, also in the Pacific coast of Guatemala, thanks to flood protection that was designed and implemented in a technical and integrated manner. This was a result of strong and active participation of local communities, companies and the local municipality who demanded the central government to invest effectively. The stakeholders provided some resources (financial and in-kind) and inspected the works. Some flat areas of the lower Coyolate watershed used to flood annually causing economic damage for communities. The areas covered by flood risk measures have not flooded which has avoided losses as well as created conditions for investment to come and create jobs, improving life conditions for locals. Other processes of participation and interaction between the authorities, the private sector and communities have taken place in other watersheds for planning, action and investment for flood risk management. The ICC has played a role by studying flood-prone areas, building capacities in communities, fostering public-private coordination mechanisms, and providing much-needed technical assistance to local governments (ICC, 2019a).

Although some may argue that water governance is in the realm of development, it has made contributions in reducing direct and indirect impacts of climate events and therefore, it can be seen as a key element for climate adaptation (*high confidence*).

12.7 Knowledge Gaps

Data deficiencies and heterogeneity in quantity, quality and geographical bias in knowledge limit the understanding of climate change, the evaluation of its impacts, and the implementation of adaptation and mitigation measures (Harvey et al., 2018) in CSA. The number of publications is not representative with respect to the sensitivity to climate change and vulnerability contexts of different subregions and sectors.

This lack of representation in the mainstream literature may lead to a bias and, therefore, an underestimation of the overall climate-related impact for some CSA subregions (Sietsma et al., 2021). The reason for relatively few quantitative studies might be the complexities of socio-demographic and economic factors, and the lack of long-term and reliable data in these areas (Harvey et al., 2018), along with other social, economic and technical constraints.

Most studies that assess vulnerability to climate change do not yet follow the concept adopted since the Fifth Assessment Report (AR5) which separates exposure as an external variable (WGII AR5 Figure SPM 1) (IPCC, 2014), and many still use the A and B system of climate change scenarios from AR4, as adoption of the RCP models has been slow. There is still limited literature on severe risks and little specific and explicit consideration of risk drivers in the region. Moreover, limits to adaptation and the effectiveness of adaptation measures in CSA remain largely understudied.

The research of the interactions between climate change and socioeconomic processes is underdeveloped (Barnes et al., 2013; Leichenko and O'Brien, 2019; Thomas et al., 2019). There is limited understanding of the multilevel synergistic effects of climate change and other drivers including economic development from household to country level (Wilbanks and Kates, 2010; Leichenko and Silva, 2014; Tanner et al., 2015a; Carey et al., 2017). In the region, this deficit is deeper for sectors other than agriculture, water and food.

12.7.1 Knowledge Gaps in the Subregions

The knowledge gaps in the eight subregions are quite heterogeneous. In CA, climate change research is notably insufficient in all sectors included in this report, considering that climatic change, variability, and extremes are and will severely impact this subregion, and the vulnerability of the social and natural systems is high. Data deficiencies must be overcome as renewed research on climate change updates models, scenarios, and projected impacts across sectors and levels (i.e., household to country). In NWS, there is a lack of studies on the relationships with increased fire events, and the impacts on the infrastructure of all kinds, on certain lowland, marine and coastal ecosystems, and on ecosystem functioning and the provision of environmental services. Experimental studies are rare, most necessary to identify critical ecological thresholds to support the decision-making processes, linking glacier retreat to its consequences on biodiversity and ecosystems, combined with different land-use trajectories. Complex interactions with processes such as peace agreements in Colombia are yet to be studied (Salazar et al., 2018). In NSA, there is still a limited amount of peer-reviewed literature, addressing the implications of climate change on Indigenous cultures and their livelihoods. In SAM, further data are needed on the vulnerability of traditional populations, impacts on water availability and soil degradation, risks to biodiversity and resilience of ecosystems, attributed to climate change.

There is a knowledge gap about the likely impact of climate change on NES biodiversity, soil degradation, and best adaptation measures. SES is the most urbanized sub-region of CSA, but there is a strong knowledge deficits related to the design, implementation and evaluation of adaptation policy plans to climate change. Forecasts related to risk prevention require new studies that address down-scaled climate change models with concrete solutions to increase the city's resilience. In SWS, there is a lack of long-term studies addressing climate change impacts in terrestrial, freshwater and marine ecosystems which is mainly due to the lack of integrated observational systems. There is a lack of studies projecting future impacts of climate change on the cryosphere, water resources, hazards, risks and disasters on natural and human systems. This is mainly due to the lack of systematic documentation, analysis and evaluation of adaptation strategies adopted, as well as their limitations and the lessons learned from maladaptation processes. There is low evidence about transformational adaptation to climate change and systems resilience. In SSA, there is a need for information related to vulnerability and impacts of the direct effects of future climate change on cities, energy infrastructure and health. Also, there is a gap of knowledge about financing of climate change adaptation in SSA.

12.7.2 Knowledge Gaps by Sector

12.7.2.1 Terrestrial and Freshwater Ecosystems and their Services

Advances on scientific knowledge on risks of climate change impact, vulnerability and resilience of ecosystems is needed (Bustamante et al., 2020). Persistent climate change in tropical rainforest needs further understanding, overall on the role of nutrients, deep-water availability and biodiversity. Further research is needed to understand feedback to the climate systems of large-scale changes in the land surface in South America biomes. The region has important freshwater Global-200 Ecoregions, including the Orinoco River and Flooded Forests, Upper Amazon river and streams, and Amazon River and Flooded Forests being, therefore, a priority for freshwater biodiversity conservation at a global scale (Manes et al., 2021) (Cross-Chapter Paper 1; Figure 12.8). There is, however, a clear knowledge gap on the impacts of climate change on freshwater biodiversity in the region (Cross-Chapter Paper 1.2.3; Manes et al., 2021) . Lastly, more interdisciplinary research is needed regarding conservation strategies and stable financial resources focusing on adaptation of ecosystems in the region (Mistry et al., 2016; Gebara and Agrawal, 2017; Ruggiero et al., 2019; To and Dressler, 2019).

12.7.2.2 Ocean and Coastal Ecosystems and their Service

There is an important lack of knowledge about the health state of the ocean and coastal ecosystems along CSA (i.e., social-ecological data integration, poor sampling efforts, lack of information about the value of ecosystem services, lack of information about ecosystems cover and distribution, lack of studies about climate change perception and social concerns), including marine fisheries (i.e., landing statistics not available, lack of reliable information on the scope of resource extraction, among others). Poor or absent monitoring programs (physical, environmental and biological variables) that feed alert and surveillance systems are missing for CSA. There is a general absence of a continuous line of scientific research or an adequate baseline information about the impacts of climate change, as well as a continuous monitoring of the adaptation plans adopted in ocean and coastal ecosystems which limit the formulation of adequate conservation and management programs. When studies are performed, inadequate access to data limits the analyses of the existing information making difficult to detect climate change trends and impacts, as well as the development of effective adaptation strategies.

12.7.2.3 Water

As in other sectors and environmental systems, for the water sector there are important limitations in terms of monitoring and data collection. High-quality, long-term hydrological data are unevenly available for different subregions and limit a better understanding of changes in river runoff, lake or groundwater changes. Groundwater data is particularly scarce. There are important gaps related to projections of water resources for the future. Much of the current knowledge on future changes in water resources and water scarcity and flood risks is based on information from global-scale studies because studies specific to this region are scarce. Several elements which are important for integrated water resource management such as water quality, water demand, privatization and other economic dynamics, and nutrient, pollutant and sediment flux, are poorly known currently due to missing data and insufficient efforts to monitor them.

12.7.2.4 Food, Fibre and other Ecosystem Products

Integrative evaluation on impacts on food security, including agricultural production, distribution and access, leading to adaptation strategies is limited within the region. Limited information regarding cost-benefit analyses of adaptation in the food production sector is available in the region. It is also important to advance in a better understanding of the adaptation effects to avoid maladaptation and promote site-specific and dynamic adaptation options considering available technologies. Compiling and systematizing existing scientific and local knowledge on the relationship between forest, land cover/use, and hydrological services, is a gap to be filled, in a broader perspective in the region, that can contribute to provide recommendations and inform restoration practices and policies. The literature also highlights widespread gaps between farmers' information needs and services that are routinely available. There is evidence that when Climate Information Services are constructed with farmer input and are targeted in a timely and inclusive manner, they are a positive determinant of adaptation through the adoption of more resilient farm level practices. However, currently assessments of the economic impact of Climate Information Services are scarce; hence increased frequency of such studies is needed

12.7.2.5 Cities, Settlements and Infrastructure

Despite the high level of urbanization in the region, studies on urban adaptation initiatives are still underreported by municipalities and several practical results have not yet been demonstrated (Araos et al., 2016). It is particularly relevant to medium sized cities, as most of the literature and data available on adaptation refers to the major capital cities. The potential of applying new resilient parameters in building and land use regulation for adaptation is virtually underreported. The same can be said about the impact of housing improvement and slum upgrading on climate resilience, even when initiatives are focused on reducing environmental and climate risk. Also relevant in the region is a gap in research about NbS applied to urban areas adaptation, as in the case of the urban forestry potential for adaptation (Barona et al., 2020). Even though the importance of urban ecological infrastructure in providing ecosystem services, as flood control, is reasonably documented, its practical application in urban planning in CSA is still limited (Romero-Duque et al., 2020). Added to this is the lack of monitoring data on adaptation initiatives in general, and in particular, on adaptation initiatives in water systems, that have already been implemented, and its effects on risk reduction. Lack of monitoring data contributes to the lack of information about maladaptation in urban areas and its consequences. Mobility and transport systems adaptation options are virtually non-studied, while mitigation options receive a lot of attention.

12.7.2.6 Health and Wellbeing

There is a growing body of evidence that climate variability and climate change (CVC) cause harm to human health in CSA. However, there is a lack of information about the current and future projected impact of CVC events on overall illness and death in this region. It is challenging to attribute specific health outcomes to CVC in models and field experiments due multiple factors including:

- lack of long-term high-quality health surveillance data
- multiple interacting infectious disease and chronic health issues
- mismatch in the spatial and temporal scales of CVC and health measurements
- complex climate and human system dynamics including nonlinear time-lags
- limited longitudinal data on non-climate factors that influence health outcomes (e.g., public health interventions, migration of human populations, seasonal patterns in livelihoods).

The uncertainty inherent in predictive models also makes it challenging to expand current localized knowledge on the impacts of infectious diseases associated with CVC to other regions or future climate scenarios (UNEP, 2018).

Improved risk assessments based on better models and empirical research are needed to bridge the knowledge gap and inform the design of adaptation strategies. A systematic multi-scalar analysis of the impact of CVC on human health is needed across distinct social-ecological contexts. Data collection systems need to be strengthened to accurately estimate the burden of mortality and morbidity from heat and extreme events. The data deficit is a common problem in functioning civil registration and vital statistics systems, including lack of information on causes of death (UNEP, 2018). In addition, there is a lack of consensus on globally accepted and operational definitions for both climate-related extremes and exposures/outcomes.

For infectious disease (vector-borne and water-borne), the technology available to estimate current and future risk areas is often limited by human or financial resource constraints in developing countries. There is a geographical mismatch between the areas producing the technology and knowledge (in the global north), and the areas most affected by CVC (in the global south). User-friendly tools that bring together climate and health information—without the need for modelling or GIS expertise— are needed for health sector decision makers.

There is a lack of studies that assess the feasibility of health adaptation measures (see Section 12.5.10), thus limiting the ability of decision makers to compare different health interventions and identify bottlenecks for implementation. The growing field of implementation science could help to address barriers to mainstreaming climate information in the health sector as an adaptation strategy.

Finally, there is an almost complete void of studies that address relationships of climate change with wellbeing in CSA, broadly understood as including emotions and moods, satisfaction with life, sense of meaning, and positive functioning, including the capacity for unimpaired cognitive functioning and economic productivity (Section 7.1.4.1).

12.7.2.7 Poverty, Livelihood and Sustainable Development

Climate change is becoming a major obstacle in reducing poverty and overcoming poverty traps. There is a need to better understand how poor and vulnerable communities are affected and the more effective ways to prevent it. The large majority of the poor in the region are living in urban areas (UNDESA, 2019); urban extreme poverty is increasingly more relevant, including the needs and priorities of informal settlements and economies, but less studied within the interaction with climate change. There is little reporting of major adaptation options implemented by or for vulnerable and poor urban dwellers (Ryan and Bustos, 2019; Berrang-Ford et al., 2021).

Adaptation options are progressively being documented for poverty-related impacts in spite of the uncertain context from climate impacts not being uniform across communities and the very local scale of the type of adaptation responses needed (Miranda Sara et al., 2016; Rosenzweig et al., 2018; Dodman et al., 2019). There is a huge gap in understanding how the poor are responding to climate change, what is needed to support them, and the interconnections between development policies, poverty and risk reduction with climate change actions (Ryan and Bustos, 2019; Satterthwaite et al., 2020).

The literature to assess the effectiveness of pro-poor or low-income adaptation options continues to be weak, a very small proportion show results associated with adaptation efforts (Magrin et al., 2014; Berrang-Ford et al., 2021). Without this kind of approach and in depth understanding there is the risk that top down climate change adaptation options could reinforce poverty cycles and neglect cultural values, even eroding them (Bartlett and Satterthwaite, 2016; Walshe and Argumedo, 2016; Allen et al., 2017a; Hallegatte et al., 2018; Kalikoski et al., 2018; UN-Habitat, 2018).

The impacts of climate change on vulnerable groups are still understudied. There is little or no climate data on remote mountain regions of CSA as well as research measuring the vulnerability of smallholders living there, making it hard to assess the expected changes or the possible adaptation measures (Pons et al., 2017; Donatti et al., 2019).

12.7.2.8 Cross Cutting Issues it the Human Dimension

There is a significant number of studies addressing the impacts of climate change on the Amazon forest (Brienen et al., 2015; Doughty et al., 2015; Feldpausch et al., 2016; Rammig, 2020; Sullivan et al., 2020); however, the assessment of tangible and intangible impacts of climate change on Indigenous Peoples cultures and livelihoods in this forest, need to be further advanced (Brondízio et al., 2016; Hoegh-Guldberg et al., 2018).

Studies on the perception of climate change in rural and urban populations throughout the region have increased, but there is a lack of more specific research on the perception of specific groups, such as economic or political actors, that influence public institutions and policies at the local, national level and regional.

While studies on climate change gender differentiated impacts have grown over the past ten years in Central and South America, studies on how gender intersects with other dimensions such as race, ethnicities, age or rural/urban settings are still needed. This will help to further understand how gender inequalities are connected to broader power structures of societies and, thus, to produce evidence on the importance of an intersectional approach to climate change.

Regarding the relation of social movements and climate change adaptation, institutions and politics, two major issues stem out: youth movements for climate change and the resistances, mainly urban, to climate change adaptation policies. Little connection is found in research concentrating on resistance to climate change adaptation policies and their interaction with the politics of place. Conflictivity related to climate change is another under-studied issue.

Although there are several case studies on migrations and displacements caused by strong and immediate climatic threats, such as hurricanes or floods, and on slow-onset impacts, such as droughts or temperature increase, there are gaps in the attribution or relative weight of climate change in these processes.

Still important to note is that synergies between mitigation, adaptation, risk reduction and sustainable development have not been jointly explored, which would better facilitate adaptation policy approaches.

There are critical knowledge gaps in the interlinkages between social and environmental dynamics that are important for climate change adaptation, as in Andean forest landscapes. A salient knowledge gap in this thematic area is the need to characterize how multilevel and multi-actor governance systems can enable sustainable land management practices, including ecosystem restoration (Mathez-Stiefel et al., 2017). More capacities are needed to increase the generation of relevant knowledge. Even small grant programs can sustain research projects that target the linkages between knowledge and decision making at multiple scales (Báez et al., 2020).

12.8 Conclusion

Central and South America (CSA) is a broadly heterogeneous region in its topography, ecosystems, urban and rural territories, demography, economy, cultures and climates. The region relies on a strong agrarian economy in which small producers and large industries participate, but also large industrialized urban centres, oil production and mining. The region is one of the most urbanized of the world and home to many Indigenous Peoples, some still in isolation, and exhibits one of the highest rates of inequality, which is a structural and growing characteristic in CSA. Poverty and extreme poverty rates are higher among children, young people, women, Indigenous Peoples, migrant and rural populations but urban extreme poverty is also growing (*very high confidence*). Socioeconomic challenges are intensified by COVID crisis. Most countries in CA are already ranked as the highest risk level worldwide due to its exposure combined to high vulnerability and low adaptive capacity; the lack of climate data and proper downscaling are challenging the adaptation process (*high confidence*).

Many extreme events are already impacting the region and projected to intensify including warming temperatures and dryness, sea level rise, coastal erosion, ocean and lake acidification resulting in coral bleaching, and increasing frequency and severity of droughts in some regions, with associated decrease in water supply, that impact agricultural production, traditional fishing, food security and human health (*high confidence*). In Central America (CA), 10.5 million people are living in the so-called Dry Corridor, a region with an extended dry season and now more erratic rainfall patterns. A water crisis in Brazil affected the major cities of the country between 2014 and 2016, becoming more frequent since then. Severe droughts have also been reported in Paraguay and Argentina. In contrast, the urbanised areas of Northern South America (NSA) are highly exposed to extreme floods (41% of urban population in the Amazon Delta and Estuaries). Urban areas in the region are vulnerable for many reasons, notably high rates of poverty and informality, poor and unevenly distributed infrastructure, housing deficits, and the recurrent occupation of risk areas (*high confidence*).

Socio-ecological systems in the region are highly vulnerable to climate change, which acts in synergy with other drivers such as land use change and deep socioeconomic inequalities. Most biodiversity-rich spots in the region will be negatively impacted. The Cerrado and the Atlantic Forest (two important biodiversity-rich spots where about 72% of Brazil's threatened species can be found) are exposed to different hazards (extreme events, mean temperature increase) due to climate change. Many coastal areas and its concentrated urban population and assets are exposed to sea level rise. Climate change is threatening several systems (glaciers in the Andes, coral reefs in Central America, the Amazon forest) that are already approaching critical conditions under risk of irreversible damage.

Extreme heat, droughts and floods will seriously affect CSA terrestrial and freshwater ecosystems. The high poverty level increases the vulnerability to droughts, both in cities and rural areas, where people already suffer from natural water scarcity (*high confidence*). The conversion of natural ecosystems to other land uses exacerbate the adaptation challenges. Indigenous knowledge and local knowledge play an important role in adaptation but are also threatened by climate change (*high confidence*). Ecosystem-based Adaptation (EbA) and Community-based Adaptation (CbA) have increased since AR5, with emphasis on freshwater ecosystems and forests, including protected areas. Inadequate access to finance and technology are widely identified as adaptation barriers (*high confidence*).

Many impacts in the economy are expected from climate change. Subsistence farmers and urban poor are expected to be the most impacted by droughts and variable rainfall in the region (*high confidence)*. The increasing water scarcity is and will continue to impact food security, human health and well-being. The impacts of the many landslides and floods affect mainly the urban poor neighbourhoods and are responsible for the majority of the deaths related to natural disasters. Sea-level rise and intense storm surges are expected to impact the tourism and industry in general. Internal and international migrations and displacements are expected to increase (*high confidence*). Climatic drivers such as droughts, tropical storms and hurricanes, heavy rains and floods, interact with social, political, geopolitical and economical drivers (*high confidence*).

The common patterns and problems, however, highlight also the possibilities for collaboration and learning among the countries and institutions in the region in order to strengthen the interface between knowledge and policy in climate change adaptation. All countries in the region have submitted their first and updated NDC, and many have published their NAP, establishing priorities and formulating their own policies to cope with climate change.

Various adaptation initiatives have been initiated in different sectors, focused on reducing poverty, improving livelihood and achieving sustainable and resilient development. There is an increase in planned and autonomous initiatives, led by community, government or the combination of both, engineering or Nature-based Solutions (NbS). Climate smart agriculture is an effective option, in several conditions and regions, to mitigate negative impacts of climate change. Disaster reduction solutions are increasingly used, such as Early Warning Systems (EWS). Many and diverse initiatives are still poorly reported and evaluated in the scientific literature, leading to challenges in its assessment and improvements, including the consideration of the tacit Indigenous knowledge and Local Knowledge (IK and LK). The lack of climate data and proper downscaling, weak governance, hindrance on financing, and inequality are constraining the adaptation process (*high confidence*).

Adaptation measures have been increased and improved since AR5 in ocean and coastal ecosystems. The majority of these measures are focused on EbA application through the application of protection and recovery of already impacted ecosystems. Another battery of measures is focused on the management and sustainability of marine resources subjected to fisheries, however these measures are not assessing current and future climate change impacts but they are focused on decreasing the impact of other non-climate factors such as overfishing or pollution. To date, along CSA there is an important lack of long-term research addressing ocean and coastal ecosystems health and their species through continuous monitoring which is one of the main barriers to adaptation. The number and type of adaptation measures for ocean and coastal ecosystems and their contributions to humans are highly different among CSA countries which highlight in number those measures related to increase the scientific research and monitoring followed by the conservation of biodiversity, and changes in legislation (*high confidence*). On the other hand, those measures that include the changes in financing (an important barrier) or the incorporation of traditional knowledge are not always considered in national adaptation plans by CSA countries.

In the water sector a lack of systematic analysis and evaluation of adaptation measures prevail, although important progress has been made since the AR5 in terms of understanding interlinkages between climate change, human vulnerabilities, governance, policies and adaptation success (*high confidence*). NbS, Payment for Ecosystems Services (PES), integrated water resource management, and integration of IK and LK have proven potential of success, in particular if adopting approaches with inclusive negotiation formats for water management with clear, just and transparent rights and responsibilities.

Climate change poses several challenges to the agri-food sector, impacting the agricultural production and productivity, and posing at risk the food and nutritional security and the economy (*high confidence*). Adapting agriculture while conserving the environment is a challenge for a sustainable and resilient food production (*high confidence*). Adaptation in the region presents persistent barriers and limitations (Table 12.8), associated with investments and knowledge gaps (*medium confidence*). Climate change urges to advance in initiatives to improve education, technology and innovation of farming systems in the CSA region.

Urban adaptation is limited by financing constraints, weak intersectoral and multilevel governance, and deficits in the housing and infrastructure sectors, the overcoming of which is an opportunity for transformative adaptation (*high confidence*). Short-term interventions are prevailing over long-term planning (*high confidence*). Adaptation experiences in planning, land use and building regulation, urban control systems and risk management have taken place throughout the region. Initiatives in social housing are reducing risk, overcoming urgent deficits, but also adding to a transformative adaptation pathway (*high confidence*). Hybrid (green-grey) infrastructure has been adopted for better efficiency in flood control, sanitation, water scarcity and landslide prevention and coastal protection (*high confidence*). NbS including green infrastructure and EbA are increasing in urban areas (*high confidence*), although isolated engineering solutions are still widely practiced. The integration of transport and land use plans and the improvement of public transport are key to urban adaptation; mitigation prevails over adaptation in the sector (*high confidence*).

There is a growing body of evidence that climate variability and climate change are causing harm to human health in CSA – including the increasing transmission of vector borne and zoonotic diseases, heat stress, respiratory illness associated with fires, food and water insecurity associated with drought, among others (*medium confidence*). In response, countries in the region are developing innovative adaptation strategies to inform health decision making such as integrated climate-health surveillance systems and observatories, forecasting of climate-related disasters, and epidemic forecast tools. However, institutional barriers (limited resources, administrative feasibility, and political mandates) need to be addressed to ensure the sustained implementation of adaptation strategies (*high confidence*).

Poor and vulnerable groups evidence limited political influence, fewer capacities and opportunities to participate in decision and policy making being less able to leverage government support to invest on adaptation measures (*very high confidence*). Participatory processes are developing adaptation measures strengthening local capacities; literature assessing the success of such initiatives remains limited. Limits to adaptation include access to land, territory and resources, labour and livelihood opportunities, knowledge gaps and poor multi actor coordination. Social organization, participation and governance reconfiguration are essential for building climate resilience (*very high confidence*).

Social organization, participation, governance, education and communications to increase perception and knowledge, are essential for building the resilience to adapt and overcome expected and unexpected climate impacts (*very high confidence*). The focus on inclusion and enrolling of the full range of actors in adaptation processes, including vulnerable populations, has shown good results in the region (*high confidence*). However, existing poverty and inequality, unbalances on power relations, corruption, weak governance and institutions, structural problems and high levels of risk tolerance may reinforce poverty and inequality cycles (*high confidence*). In addition, the continued exposure of critical infrastructure and valuable assets are signs of persisting maladaptation.

The development model prevailing in the region for the last decades has proven to be unsustainable, with the emphasis on financial sources based on natural resource depletion and extraction and the persistence and growing inequality. It is well recognized that climate adaptation measures, if carefully selected considering the coupled human-environment systems, will provide significant contributions to the sustainable development pathways of the region and to achieve the sustainable development goals (SDG) if implemented together with comprehensive strategies to reduce poverty, inequality, and risks (*high confidence*). Adaptation and the construction of resilience offer not only an opportunity to reduce climate change impacts, but also the opportunity to reduce inequality and development gaps, to achieve dynamic economies, and to regulate the sustainable use and transformation of the territory.

[START FAQ 12.1 HERE]

FAQ 12.1: How are inequality and poverty limiting options to adapt to climate change in Central and South America?

Poverty and inequality decrease human capacity to adapt to climate change. Limited access to resources may reduce the ability of individuals, households and societies to adapt to the impacts of climate change and variability because of the narrow response portfolio. Inequality limits responses available to vulnerable segments as most adaptation options are resource-dependent.

Though poverty in Central and South America has decreased over the last 12 years, inequality remains as a historic and structural characteristic of the region. In 2018, 29.5% of Latin America's population (including Mexico) were poor (182 million) and 10.2% were extremely poor (63 million), more than half of them living in urban areas. In 2020, due to COVID crisis Gini coefficient projection of increases is ranging from 1.1% to 7.8%, poverty increased to 33.7% (209 millions) and extreme poverty to 12.5% (78 millions).

Poor populations have little or no access to good quality education, information, health systems and financial services. They have lower chances to access resources such as land and water, good quality housing, risk reducing infrastructure and services such as running water, sanitation and drainage. Their lack of political clout and endowments limit their access to assets for withstanding and recovering from shocks and stresses. Poverty, inequality, and high vulnerability to climate change are inter–related processes. Poor populations are highly vulnerable to impacts from climate change and are usually located in areas of high exposure to extreme events. The constant loss of assets and livelihoods both in urban and rural areas drives communities into chronic poverty traps, exacerbating local poverty cycles and creating new ones.

For instance, climate–related reduced yields in crops, fisheries, and aquaculture have a substantial impact on the livelihoods and food security of families and affect their options to cope and adapt to climate change and variability. The impact of climate change in agriculture for Central and South America depends on determinants such as availability of natural resources, access to markets, diversity of inputs and production methods, quality and coverage of infrastructure, as well as socioeconomic characteristics of the population. Impacts from climate change on small–scale farmers compromise the livelihoods and food security of rural areas and consequently the food supply for urban areas.

Governments in the region have implemented several poverty–reduction programs. However, policies of income redistribution and poverty alleviation do not necessarily improve climate risk management, hence complementary policies integrating both social and material conditions are required. A study in Northern Brazil shows risk management strategies for droughts and food insecurity did not change poverty incidences between 1997–1998 and 2011–2012. Major shocks, such as climate and weather extreme events (e.g., floods, heavy rains, droughts, frosts), reduce and destroy public and private property. For instance, the ENSO event of 2017 in Peru caused losses estimated between USD 6 to 9 billion, affected more than a million inhabitants and generated 370,000 new poor. In total, losses by unemployment, deaths, destruction and damage of infrastructure and houses were around 1.3% of the Gross Domestic Product of Peru.

Low public expenditure on social infrastructure (health, education etc.), ethnic discrimination and social exclusion reduce healthcare access, leaving poor people in entire regions mostly undiagnosed or untreated. In a context of privatization policies of health care systems, research shows marginal people lack identifying documents needed to access public services in Buenos Aires (Argentina), Mexico City (Mexico) and Santiago de Chile (Chile), some of the most developed cities in the region. Consequences of this situation are under reporting, low diagnosis, and low treatment of diseases such as vector–borne diseases such as dengue and risk of diarrheal diseases originated by frequent floods in Amazonian riverine communities. Bias on reporting access to health–care and incidence of diseases in marginal populations are usually region–dependent. For example, in Brazil's Amazonian North in 2018, there were 2.2 medical doctors per 1000 inhabitants, while 4.95 medical doctors per 1000 inhabitants in São Paulo and 9.52 doctors in Santa Catarina. Another example: pregnant women in remote Amazonian municipalities receive less prenatal care than women in urban areas. These social inequities underlie systemic biases in health data–quality hindering reliable estimation of disease burdens such as distribution of disease or birth and death registrations. For Example, in Guatemala alternative Indigenous healthcare systems are responding to local needs by Mayan communities. However, this remains unrecognized. The existence of health institutions based on Indigenous knowledge can reinforce the lack of universal coverage by central government healthcare, addressing the miscalculation of morbidity, mortality, and cause–of–death among disadvantaged groups.

Inequality, informality and precariousness are particularly relevant barriers for adaptation. A significant part of the construction sector in the region is informal and does not follow regulations for land use and construction safety codes, and there is a lack of public strategies for housing access. Adaptive construction is based upon up–to–date regulation and codes, appropriate design and materials, and access to infrastructure and services. Decreasing inequality and eradicating poverty are crucial for achieving proper adaptation to climate change in the region. Some experiences to fight poverty such as savings groups, microfinance for improving housing or assets and community enterprises may also support specific adaptive measures. These mechanisms should be widely accessible to poor groups and be complemented by comprehensive poverty alleviation programs that include climate change adaptation.

[START FAQ 12.2 HERE]

FAQ 12.2: How have urban areas in Central and South America adapted to climate change so far, which further actions should be considered within the next decades and what are the limits of adaptation and sustainability?

Cities are becoming focal points for climate change impacts. The rapid urbanization in Central and South America, together with accelerating demand for housing, resource supplies and social and health services, put pressure on the already stretched physical and social infrastructure. In addition, migration is negatively affecting the opportunities of cities to adapt to climate change.

Central and South America is the second most urbanized region in the world after North America with 81% percent of its population being urban. 129 secondary cities with 500,000 inhabitants concentrate half of the region's urban population (222 million). Another 65 million people live in megacities over 10 million each. The population migrates among cities, resulting in more secondary cities and creating mega regions and urban corridors.

Rapid growth in cities has increased the urban informal housing sector (e.g., slums, marginal human settlements and others), which increased from 6 to 26 percent of the total residences from 1990 to 2015. Coastal areas in Central and South America increasingly concentrate more urban centres. Researchers indicate that between 3 to 4 million inhabitants will experience coastal flooding and erosion from sea–level rise in all emission scenarios by 2100 considering Southern America alone.

A study on cities with more than 100,000 inhabitants shows the number of coastal cities significantly increased from 42 to 420 between 1945 and 2014; they are located close to fragile ecosystems such as bays, estuaries and mangrove forests, resulting in higher concentrations of population and economic activities. This process degraded the ability of coastal ecosystems, such as mangroves, to reduce risks and provide essential ecosystem services which help to prevent coastal erosion or maintain fish stocks. Moreover, it reduced ports, tourism, along with income opportunities.

Climate change impacts on cities in Central and South America are strongly influenced by El Niño Southern Oscillation (ENSO) associated with an increase of more extreme rainfall events. Urban areas are increasingly dealing with floods, landslides, storms, tropical cyclones, water stress, fires, spread of vector–borne and infectious diseases, damaging infrastructure, economic activities, built and natural environments and the population's overall well–being.

Glacier retreat in the mountains will affect water runoff and water provision to Metropolitan cities such as Lima, La Paz, Quito and Santiago who rely on rivers that originate in the high Andes. Lima, the second driest capital city in the world, is vulnerable to drought and heavy rain peak events associated with climate change. In Bogota lower precipitations and a tendency of increasing extreme events are expected in the coming decades. Hence, the protection of fragile ecosystems such as 'paramo' (fields at 3000 to 4000 m.a.s.l.) will be crucial for water supply to the city.

Sea level rise impacts cities located in low elevation coastal zones, not only because of direct coastal flooding, coastal erosion and subsidence; but also because it aggravates the impact of storm surges, heat wave energy and saltwater intrusion. 68 percent of the population of Surinam and 31 percent of the population in Guyana live below 5 meters above sea level, while many sectors of Georgetown, the capital of Guyana, are below sea level. Floods with increased frequency and severity of storm surges will also impact the Rio de la Plata estuary and lower delta of the Parana River where Metropolitan Buenos Aires is located.

Over 80 percent of losses associated with climate-related risks concentrate in urban areas, and between 40 and 70 percent losses occur in cities with less than 100,000 inhabitants, most probably as a result of limited capacities to manage disaster risks and low level of investments.

Despite consistent political and economic barriers, many cities in the region have adopted sustainable local development agendas, which work to address a balanced urban development. The shortcomings of poor development patterns are still very present in the cities and present important obstacles to adaptation investment, as public investment in basic needs (mainly housing and sanitation) must be prioritized.

Cities struggle to address the immediate needs of their population while addressing longer–term needs associated with climate adaptation, emissions reduction and sustainable development. Some cities are moving forward to transformative adaptation, addressing drivers of vulnerability, building robust systems and anticipating impacts. Besides government–led adaptation planning and action, individuals, communities and enterprises have been incrementally adapting to climate changes autonomously over time. Municipalities from Argentina, Peru, Chile, Equator, Brazil and Costa Rica are developing and implementing their Local Climate Action Plans, experimenting and displaying best practices in adaptation. Both anticipatory adaptation measures–choosing safe locations, building structurally–safe houses, choosing elevated places to store valuables, building on stilts–and reactive adaptation measures are used; the latter incorporating measures such as relocation, stabilization of slopes, afforestation, and greening of riverbanks. With variations, these cities have included mechanisms to work across sectors and actors understanding it is collective planning and actions, which will ensure that long term programs continue independently of particular city administrations.

Cities are interconnected systems operating beyond administrative boundaries. Improved collaboration and coordination is needed for integrated responses. Aside from good planning, cities need access to external adaptation funds. Climate change adaptation requires long–term funding and investments, which are beyond cyclical political terms. It is key to re–think how to make international adaptation funds reach cities and innovate. For example, member cities of Global Covenant of Mayors in the region, together with Cities for Life Forum in Peru, the Red Argentina de Municipios por el Cambio Climático (RAMCC), the Capital Cities of the Americas facing Climate Change (CC35) and others, are pursuing this goal and applying directly for international grants. New funding sources are required to help local governments and civil society. Cities and locally driven adaptation initiatives can be funded by national governments and international organizations.

[END FAQ 12.2 HERE]

[START FAQ 12.3 HERE]

FAQ 12.3: How do climatic events and conditions affect migration and displacement in Central and South America, will this change due to climate change, and how can communities adapt?

Migration and displacements associated with climatic hazards are becoming more frequent in Central and South America, and it is expected they will continue to increase. These complex processes require comprehensive actions in the places of origin and reception, both to improve adaptation in the more affected places, and the conditions of the mobilizations.

Migration of individuals, families and groups, voluntary and involuntary, is common in Central and South America. People migrate nationally and internationally, temporarily or permanently, predominantly from rural areas – often immersed in poverty – to urban areas. Common social drivers of migration in the region are the economy, politics, land tenure and land management change, lack of access to markets, lack of infrastructures, and violence; environmental drivers include loss of water, crops and livestock, land degradation and sudden or gradual onset of climate hazards.

The increasing frequency and magnitude of droughts, tropical storms, hurricanes, and heavy rains producing landslides and floods, have amplified internal movements, overall rural to urban. For instance, rural to urban migration in Northern Brazil, or international migration from Guatemala, Honduras and El Salvador to North America, are partly a consequence of prolonged droughts, which have increased the stress of food availability in these highly impoverished regions. Diminished access to water is also a result of privatization of that resource. In Central America, the majority of migrants are young men, reducing the labour force in the places of origin. However, the migrants send back substantial amounts of money that have become the main source of foreign exchange for their countries, and the main source of income for their families.

As poor people have less resources to adapt to changing conditions, they are usually the most impacted by climate hazards, as they are already struggling to survive under normal conditions. These populations are the most susceptible to migration, chiefly because of the loss of their livelihoods, their precarious housing and settlements and the lack of money and international aid. Other important factors are the minimal governmental support and assistance through social safety nets and extension services, the scarcity and low quality of education and health services, the isolation and marginality, and the insecurity of land rights. These same conditions, though, may hinder their mobility or even render them immobile. Nevertheless, in some cases, despite worsening conditions, people decide not to move.

The magnitude and frequency of droughts and hurricanes are projected to keep increasing by 2050, which may force millions of people to leave their homes. Climate models show some dry regions will become even dryer in the coming decades, increasing the stress on small farmers who rely on rainfall to water their fields. Glacier retreat and water scarcity are becoming strong drivers of migration in the Andes. Sea level rise influences activities such as fishing and tourism, which will foster further migration. In Brazil, at least 0.9 million more people will migrate inter–regionally under future climate conditions.

Addressing migration and displacement requires diverse interventions: in dry regions it is recommended to improve the water management in the places of origin of migration, including storage, distribution and irrigation. Wet regions, lowlands, and floodplains will benefit from preventing construction on areas prone to landslides and flooding. Government and international aid are also important for improving people's options to adapt and enhance their resilience to climate impacts. In northern Brazil, for example, government financial support has significantly reduced the migration caused by droughts. Between Guatemala and Canada there is a temporary migration program to bring in migrant workforce during the harvest season. The United States is also increasing these types of legal temporary migration.

[END FAQ 12.3 HERE]

[START FAQ 12.4 HERE]

FAQ 12.4: How is climate change impacting and expected to impact food production in Central and South America in the next 30 years and what effective adaptation strategies are and can be adopted in the region?

Agriculture is a fundamental sector to the development of societies from the economic and social perspectives, and so it is a major component of the adaptive strategies for Central and South America countries. Implementation of sustainable agriculture practices such as improved management on native grasslands or agroforestry systems for crop and livestock production, can increase productivity while improving adaptability.

Over the last two decades, countries throughout Central and South America have been developing rapidly. The agriculture sector is fundamental to this development from economic and social perspectives. Some countries of the region are amongst major food exporters in the world:

- Corn: three of the top ten exporters are Brazil, Argentina and Paraguay;
- Soybean exports: Brazil and Argentina are among the top five; Paraguay and Bolivia figure within the twelfth;
- Coffee exports: five of the top ten export countries are Brazil, Colombia, Honduras, Peru and Guatemala;
- Fruits: two of the top 10 fresh fruit export countries are Chile and Ecuador,
- Fishmeal exports globally are led by Peru, Chile and Ecuador;
- Beef: four of the top exporting countries are from this region – Brazil, Argentina, Uruguay and Paraguay.

CSA is one of the regions with the highest potential to increase food supplies particularly to more densely populated regions in Asia, Middle East and Europe. Better understanding the impact of the economy on the environment and the contribution of the environment to the economy, is critical to identify opportunities for innovation and promoting activities that could lead to sustainable economic growth without depleting natural resources and increasing sensitivity to climate change and climate variability. The consideration of food as a commodity instead of a common resource, leads to the accumulation of under-priced food resources at the expense of natural capital. Without serious emissions reduction measures, climate models project an average 1 to 4°C increase in maximum temperatures, and a 30 percent decrease in rainfall towards 2050, across Central and South America. Tropical South America is projected to warm at higher rates than the southern part of South America. Given these circumstances, some regions in Central and South America (Andes region and Central America) will just meet, or fall below, the critical food supply/demand ratio for their population. Meanwhile, the more temperate part of South America in the south is projected to have agricultural production surplus. The challenge for this region will be to retain the ability to feed and adequately nourish its internal population as well as making an important contribution to the food supplies available to the rest of the world.

The Nationally Determined Contributions (NDCs) of most of the countries of Central and South America expressly included agriculture as a major component of their adaptive strategy. From the recommendations presented, five general adaptive themes, or imperatives, emerge: 1) inclusion of climate change projections as a key element for Ministries of Agriculture and research institutes in their decision-making processes; 2) support research and adoption of drought- and heat-tolerant crop varieties; 3) promotion of sustainable irrigation as an effective adaptive strategy; 4) recovery of degraded lands and sustainable intensification of agriculture to prevent further deforestation; and 5) implementation of climate smart practices and technologies to increase productivity while improving adaptability.

Climate smart-practices provide a framework to operationalize actions aimed at understanding synergies among productivity, adaptation and mitigation. Significant amount of evidence supports the potential for climate smart-practices technologies to produce such triple wins as natural pastoral systems in the southern region of South America. Such systems allow the combination of food production and environmental sustainability. The production of meat based on native grasslands with grazing management that optimizes forage allowance can achieve high production levels, while providing multiple ecosystem benefits. Optimal forage allowance means offering the animals enough forage in order to meet requirements and while avoiding overgrazing. This management practice simultaneously increases productivity, reduces greenhouse gas emissions while improving soil carbon sequestration, and minimizes other environmental impacts such as excess of nutrients, fossil energy use, and biodiversity loss. Pastoral farming systems that manage grazing and feeding efficiently, are an example of integration between food security, environmental conservation and nature-based adaptation to climate change.

Agroforestry systems are present in the tropical region of Central and Southern America. Trees are present in a large part of the agricultural landscape of this region, either dispersed or in lines; supporting the production of coffee, cocoa, fruits, pastures and livestock in various agroforestry configurations. In Central America, shade-grown coffee reduces weed control and improves quality and taste of the product. Agroforestry uses nitrogen-fixing trees (*Leguminosae*), such as Leucaena in Colombia, Inga in Brazil, to restore soil nitrogen fertility. Tropical forest soils are generally nutrient-poor and unsuited to long-term agricultural use. Land converted to agriculture by cutting and burning natural vegetation tends to remain productive for only a few years. Agroforestry and the so called silvopastoral systems, which incorporate trees into crop and livestock systems, have been shown to make a dramatic impact on the maintenance and restoration of long term productivity in agricultural landscapes, including degraded and abandoned land. Agroforestry systems can provide major benefits through enhanced food security, stronger local economies, and increased ecosystem services such as carbon storage, regulation of climate and water cycles, control of pests and diseases, and maintenance of soil fertility. Because of these multiple goods and services, agroforestry practices are considered one of the key strategies for the development of climate smart agriculture.

[START FAQ 12.5 HERE]

FAQ 12.5: How can Indigenous knowledge and practices contribute to adaptation initiatives in Central and South America?

Indigenous Peoples have knowledge systems and practices that allow them to adapt to many climatic changes. Adaptation initiatives based on Indigenous knowledge and practices are more sustainable and legitimate among local communities. It is important to build effective and respectful partnerships among Indigenous and non–indigenous researchers to co–produce climate relevant knowledge to enhance adaptation planning and action in the region.

There are 28 million Indigenous Peoples in Central and South America (around 6.6% of the whole population of the region). They belong to more than 800 groups living in territories covering a wide range of ecosystems – from drylands to tropical forests to savannahs, coasts to mountains – and that share the land with many other cultural and ethnic groups. In the region, Indigenous Peoples are often categorized as a group highly vulnerable to climate change as they are frequently affected by socioeconomic inequalities and the dominance by external powers. They often experience internal and external pressures over their communal lands in forms of pollution, oil and mining, industrial agriculture, and urbanization. On the other hand, it is important to recognize that Indigenous Peoples have knowledge systems and practices that allow them to adapt to many climatic changes. Increasing scientific evidence shows that adaptation initiatives based on Indigenous knowledge and practices are more sustainable and legitimate among local communities.

The wide range of adaptation practices based on Indigenous knowledge in the region include, among others: increasing species and genetic diversity in agricultural systems through community seed exchanges; promotion of highly diverse crop systems; ancient systems to collect and conserve water; fire prevention strategies; observing and monitoring changes in communal ecological–agricultural calendar cycles; recognizing changes in ecological indicators like migration patterns in birds, behaviour of insects and other invertebrates and phenology of fruit and flowering species; and systematization and knowledge exchange among communities. These practices represent a valuable cultural and biological heritage.

The Kichwa in the Ecuadorian Amazon cultivate Chakras (plots) within the rainforest. These plots combine crops and medicinal herbs for both self–consumption and selling. Similar systems, like the Chakras in the high Andes, the Milpas in Central America, and the Conucos in northern South America have been resilient to social and environmental disturbances due to their outstanding agrobiodiversity (more than 40 species and varieties can be present in one plot), microhabitat management and the associated knowledge and institutions.

Traditional fire management among Indigenous Peoples of Venezuela, Brazil and Guyana is another adaptation strategy based on a fine–tuned understanding of environmental indicators, associated with their culture and worldviews. In these countries, Indigenous lands have the lowest incidence of wildfires, significantly contributing to maintaining and enhancing biodiversity. These traditional practices have helped to prevent large–scale and destructive wildfires, reducing the risk from rising temperature and dryness due to climate change.

Traditional agriculture of Mapuche Indigenous Peoples in Chile includes a series of practices that result in a system more resilient to climate and non–climate stressors. Practices include water management, native seed conservation and exchange with other producers (trafkintu), crop rotation, polyculture, and tree–crop association. Similar practices can be found in Mayan communities in Guatemala at the other end of the subcontinent.

Despite the increasing recognition and integration of Indigenous knowledge in adaptation practices and policies in the region, important barriers for a more effective and transformative integration remain. Some of the most relevant barriers include limited participation of Indigenous Peoples and local communities in adaptation planning and the lack of sufficient consideration of non–climatic socioeconomic drivers of vulnerability such as poverty and inequality. Also, scientific knowledge is commonly prioritized over traditional, Indigenous knowledge, and local knowledge. However, some transformative efforts are emerging Bolivian Indigenous organizations provide a notable example by contesting normative conceptions of development as economic growth with more comprehensive views like harmony with Mother Earth and "Sumak Kawsay" or "Good Living".

Several strategies have been proposed to overcome existing barriers, including building effective and respectful partnerships among Indigenous and non–indigenous researchers to co–produce climate change–relevant knowledge, and recognizing Indigenous Peoples as active actors who are continually developing autonomous strategies to preserve their practices, beliefs and knowledge. The implementation of these and other strategies can significantly enhance adaptation planning and action in the region.

Executive Summary

Where are we now?

Our current 1.1°C warmer world is already affecting natural and human systems in Europe (*very high confidence*[1]). Since AR5, there has been a substantial increase in detected or attributed impacts of climate change in Europe, including extreme events (*high confidence*). Compound hazards of warming and precipitation have become more frequent (*medium confidence*). Climate change has resulted in losses of and damages to people, ecosystems, food systems, infrastructure, energy and water availability, public health, and the economy (*very high confidence*) {13.1.4;13.2.1;13.3.1;13.4.1;13.5.1;13.6.1;13.7.1;13.8.1;13.10.1}.

As impacts vary both across and within European regions, sectors, and societal groups (*high confidence*), inequalities have deepened (*medium confidence*). Southern regions tend to be more negatively affected, while some benefits have been observed, alongside negative impacts in northern and central regions. Traditional lifestyles, for example in the European Arctic, are threatened already (*high confidence*). Poor households have lower capacity to adapt to, and recover from, impacts (*medium confidence*) {13.5.1;13.6.1;13.7.1;13.8.1.;13.8.2;13.10.1;Box 13.2}.

The range of options available to deal with climate-change impacts has increased in most of Europe since AR5 (*high confidence*). Growing public perception and adaptation knowledge in public and private sectors, increasing number of policy and legal frameworks, and dedicated spending on adaptation are all clear indications that the availability of options has expanded (*high confidence*). Information provision, technical measures, and government policies are the most common adaptation actions implemented. Nature-based solutions (NbS) that restore or recreate ecosystems, build resilience and produce synergies with adaptation and mitigation are increasingly used. Many cities are taking adaptation action, but with large differences in level of ambition and implementation (*high confidence*) {13.2.2;13.3.2;13.4.2;13.5.2;13.6.2;13.7.2;13.8.2;13.10.2;13.11.1;13.11.2;13.11.3}.

Observed adaptation actions are largely incremental with only a few examples of local transformative action; adaptation actions have demonstrated different degrees of effectiveness in reducing impacts and feasibility of implementation *(high confidence*). For example, adaptation actions such as flood defences and early warning systems have reduced flood damages and heat-related mortality in parts of Europe. Despite progress on adaptation, impacts are observed. Adaptation actions in the private sector are limited, with many businesses and regions remaining under-prepared. A gap remains between planning and implementation of adaptation action (*high confidence*) {13.2.2;13.5.2;13.6.2;13.7.2;13.11}.

What are the future risks?

Warming in Europe will continue to rise faster than the global mean, widening risk disparities across Europe in the 21st century (*high confidence*). Largely negative impacts are projected for southern regions (e.g., increased cooling needs and water demand, losses in agricultural production, and water scarcity) and some short-term benefits anticipated in the north (e.g. increased crop yields and forest growth) {13.1.4;13.2.1;13.3.1;13.4.1;13.5.1;13.6;13.7.1;13.10.2}.

Four key risks (KR) have been identified for Europe, with most becoming more severe at 2°C GWL compared to 1.5°C GWL in scenarios with low to medium adaptation (*high confidence*). From 3°C GWL and even with high adaptation, severe risks remain for many sectors in Europe (*high confidence*). Key risks are: mortality and morbidity of people and ecosystems disruptions due to heat (KR1: heat); loss in agricultural production due to combined heat and droughts (KR2: agriculture); water scarcity across sectors (KR3: water scarcity); impacts of floods on people, economies and infrastructure (KR4: flooding) {13.10.2}.

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

KR1: The number of deaths and people at risk of heat stress will increase two- to threefold at 3°C compared to 1.5°C GWL (*high confidenc*e). Risk consequences will become severe more rapidly in Southern and Western Central Europe and urban areas (*high confidence*). Thermal comfort hours during summer will decrease significantly (*high confidence*), by as much as 74% in Southern Europe at 3°C GWL. Above 3°C GWL, there are limits to the adaptation potential of people and existing health systems, particularly in Southern Europe and Eastern Europe and areas where health systems are under pressure (*high confidence*) {13.6.1;13.6.2;13.7.1;13.7.2;13.8.1;13.10.2.1}.

KR1: Warming will decrease suitable habitat space for current terrestrial and marine ecosystems and irreversibly change their composition, increasing in severity above 2°C GWL (*very high confidence*). Fire-prone areas are projected to expand across Europe, threatening biodiversity and carbon sinks (*medium confidence*). Adaptation actions, e.g. habitat restoration and protection, fire and forest management, and agroecology, can increase the resilience of ecosystems and their services. Trade-offs between adaptation and mitigation options (e.g., coastal infrastructure and Nature based Solutions) will result in risks for the integrity and function of ecosystems (*medium confidence*) {13.3.1;13.3.2;13.4.1;13.4.2;13.10.2.1; Cross-Chapter Box SLR in Chapter 3; Cross-Chapter Box NATURAL in Chapter 2}.

KR2: Due to a combination of heat and drought, substantive agricultural production losses are projected for most European areas over the 21st century, which will not be offset by gains in Northern Europe (*high confidence*). Yield losses for maize will reach 50% in response to 3°C GWL, especially in Southern Europe. Yields of some crops, e.g. wheat, may increase in Northern Europe when warming does not exceed 2°C (*medium confidence*). While irrigation is an effective adaptation option for agriculture, the ability to adapt using irrigation will be increasingly limited by water availability, especially in response to GWL above 3°C (*high confidence*) {13.5.1;13.5.2;13.10.2.2}.

KR3: Risk of water scarcity will become high at 1.5°C and very high at 3°C GWL in Southern Europe (*high confidence*) and increase from moderate to high in Western Central Europe (*medium confidence*). In Southern Europe, more than a third of the population will be exposed to water scarcity at 2°C GWL; under 3°C GWL, this risk will double, and significant economic losses in water and energy dependent sectors may arise (*medium confidence*). The risk of water scarcity is strongly increasing for Western Central and Southern Europe, and many cities under 3°C GWL. Adaptation becomes increasingly difficult at 3°C GWL and above, due to geophysical and technological limits; hard limits are *likely*[2] first reached in parts of Southern Europe {13.2.1;13.2.2;13.6.1;13.10.2.3}.

KR4: Due to warming, changes in precipitation and sea level rise, risks to people and infrastructures from coastal, riverine, and pluvial flooding will increase in Europe (*high confidence*). Risks of inundation and extreme flooding will increase with accelerating pace of sea level rise along Europe's coasts (*high confidence*). Above 3°C GWL, damage costs and people affected by precipitation and river flooding may double. Coastal flood damage is projected to increase at least 10-fold by the end of the 21st century, and even more or earlier with current adaptation and mitigation (*high confidence*). Sea level rise represents an existential threat for coastal communities and their cultural heritage, particularly beyond 2100 {13.2.1;13.2.2;13.6.2;13.10.2.4;Box 13.1; Cross-Chapter Box SLR in Chapter 3).

European cities are hotspots for multiple risks of increasing temperatures and extreme heat, floods, and droughts (*high confidence*). Warming beyond 2°C GWL is projected to result in widespread impacts on infrastructure and businesses (*high confidence*). These include increased risks for energy supply (*high confidence*) and transport infrastructure (*medium confidence*), increases in air conditioning needs (*very high confidence*), and high water demand (*high confidence*) {13.2.2;13.6.1;13.7.1;13.10.2}.

---

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

European regions are affected by multiple key risks, with more severe consequences in the south than in the north (*high confidence*). These risks may co-occur and amplify each other, but there is uncertainty about their interactions and their quantifications. There is *high confidence* that consequences for socio-economic and natural systems will be substantial; the number of people exposed to KRs and economic losses are projected to at least double at 3°C GWL compared to 1.5°C GWL (*medium confidence*); and increased risks are also projected for biodiversity and ecosystem services, such as carbon regulation. The risks resulting from changes in climatic and non-climatic drivers in many sectors is a key gap in knowledge (high confidence). This gap prevents the precise assessment of systemic risks, socio-ecological tipping points and limits to adaptation {13.10.2;13.10.3;13.10.4}.

Climate risks from outside Europe are emerging due to a combination of the position of European countries in the global supply chain and shared resources (*high confidence*). There is emerging evidence that climate risks in Europe may also impact financial markets, food production and marine resources beyond Europe. Exposure of European countries to interregional risks can be reduced by international governance and collaboration on adaptation in other regions (*medium confidence*){13.5.2;13.9.1; 13.9.2;13.11; Cross-Chapter Box INTEREG in Chapter16}.

What are the solutions, limits and opportunities of adaptation?

There is a growing range of adaptation options available today to deal with future climate risks (*high confidence*). Examples for adaptation to the key risks include: behavioural change combined with building interventions, space cooling and urban planning to manage heat risks (KR1); restoration, expansion and connection of protected areas for ecosystems, while generating adaptation and mitigation benefits for people (KR1: heat); irrigation, vegetation cover, changes in farming practices, crop and animal species, and shifting planting (KR2: agriculture); efficiency improvements, water storage, water reuse, early warning systems, and land use change (KR3: water scarcity); early warning systems, reserving space for water and ecosystem based adaptation, sediment or engineering based options, land use change and managed retreat (KR4: flooding). Nature-based solutions for flood protection and heat alleviation are themselves under threat from warming, extreme heat, drought and sea level rise (*high confidence*) {13.2.2;13.3.2;13.4.2;13.5.2;13.6.2;13.7.2;13.8.2;13.9.4;13.10.2;13.11}.

In many parts of Europe, existing and planned adaptation measures are not sufficient to avoid the residual risk, especially beyond 1.5°C GWL (*high confidence*). Residual risk can result in losses of habitat and ecosystem services, heat related deaths (KR1), crop failures (KR2), water rationing during droughts in SEU (KR3), and loss of land (KR4) (*medium confidence)*. At 3°C GWL and beyond, a combination of many, maybe even all, adaptation options are needed, including transformational changes, to reduce residual risk (*medium confidence*). {13.2.2;13.3.2;13.4.2;13.5.2;13.6.2;13.7.2;13.8.2;13.9.4;13.10.2;13.11}.

Although adaptation is happening across Europe, it is not implemented at the scale, depth and speed needed to avoid the risks (*high confidence*). Many sectors and systems, such as flood risk management, critical infrastructure and reforestation, are on self-reinforcing development paths that can result in lock-ins and prevent changes needed to reduce risks in the long term and achieve adaptation targets. Forward-looking and adaptive planning can avoid path-dependencies, maladaptation, and ensure timely action (*high confidence*). Monitoring climate change, socio-economic developments and progress on implementation is critical to assess if and when further actions are needed, and evaluating whether adaptation is successful {13.2.2;13.10.2;13.11.1;13.11.2;13.11.3;Cross-Chapter Box DEEP in Chapter 17}.

Systemic barriers constrain the implementation of adaptation options in vulnerable sectors, regions and societal groups (*high confidence*). Key barriers are limited resources, lack of private sector and citizens engagement, insufficient mobilisation of finance, lack of political leadership, and low sense of urgency. Most of the adaptation options to the key risks depend on limited water and land resources, creating competition and trade-offs, also with mitigation options and socio-economic developments (*high confidence*). Europe will face difficult decisions balancing these trade-offs. Novel adaptation options are pilot tested across Europe, but upscaling remains challenging. Prioritisation of options and transitions from incremental to transformational adaptation are limited due to vested interests, economic lock-ins, institutional path-dependencies, and prevalent practices, cultures, norms, and belief systems {13.11.1;13.11.2;13.11.3}.

Several windows of opportunity emerge to accelerate climate resilient development (CRD) (*medium confidence*). Such windows are either institutionalised (e.g. budget cycles, policy reforms and evaluations, infrastructure investment cycles), or open unexpectedly (e.g. extreme events, COVID-19 recovery programs). These windows can be used to accelerate action through mainstreaming and transformational actions (*medium confidence*). CRD is visible in European cities, particularly in green infrastructure, energy-efficient buildings and construction, and where co-benefits (e.g. to health, biodiversity) have been identified. Private sector adaptation takes place mostly in response to extreme events or regulatory, shareholder, or consumer pressures and incentives (*medium confidence*) {13.11.3; Box13.3;Cross-Chapter Box COVID in Chapter 7}.

Closing the adaptation gap requires moving beyond short-term planning and ensuring timely and adequate implementation (*high confidence*). Inclusive, equitable and just adaptation pathways are critical for climate resilient development. Such pathways require consideration of SDGs, gender, and Indigenous knowledge and local knowledge and practices. The success of adaptation will depend on our understanding of which adaptation options are feasible and effective in their local context (*high confidence*). Long lead times for nature-based and infrastructure solutions or planned relocation require implementation in the coming decade to reduce risks in time. To close the adaptation gap, political commitment, persistence and consistent action across scales of government, and upfront mobilization of human and financial capital is key (*high confidence*), even when the benefits are not immediately visible {13.2.2;13.8;13.11;Cross-Chapter Box GENDER in Chapter 18}.

13.1 Point of Departure

13.1.1 Introduction and Geographical Scope

This regional chapter on climate-change impacts, vulnerabilities and adaptations in Europe examines the impacts on the sectors, regions and vulnerable populations of Europe, assesses the causes of vulnerability, and analyses ways to adapt, thereby considering socio-economic developments, land use change, and other non-climatic drivers. Compared to AR5 and in the context of the Paris Agreement (2015), we have placed emphasis on the planned and implemented solutions, assessed their feasibility and effectiveness, considered the Sustainable Development Goals (SDG) and shared socioeconomic pathways (SSPs). Global warming level (GWL) refers to global climate change emissions relative to preindustrial levels, expressed as global surface air temperature (Chen et al., 2021, 1.6.2).

The chapter generally follows the overall structure of AR6 WGII. We first present our point of departure (13.1) followed by the key sectors, starting with water, as water is interconnected and of fundamental importance to subsequent sections (13.2-13.8). For each section, we assess the observed impacts and projected risks, solution space and adaptation options, and knowledge gaps. The solution space is defined as the space within which opportunities and constraints determine why, how, when, and who adapts to climate risks (Haasnoot et al., 2020a). Section 13.9 discusses impacts and adaptation beyond Europe, followed by the key risks for Europe (13.10). The chapter ends with an assessment of adaptation solution space, climate resilient development pathways, and SDGs (13.11), although recognizing that scientific literature on these aspects is only slowly beginning to emerge.

With the rapidly growing body of scientific literature since WGII AR5 (Callaghan et al., 2020) our assessment prioritized systematic reviews, meta-analyses, and synthesis papers and reports. Feasibility and effectiveness assessments used revised methods developed for the Special Report of Global warming of 1.5° (de Coninck et al., 2018; Singh et al., 2020). Protocols, as well as supporting material for figures and tables, can be found in the Supplementary Material.

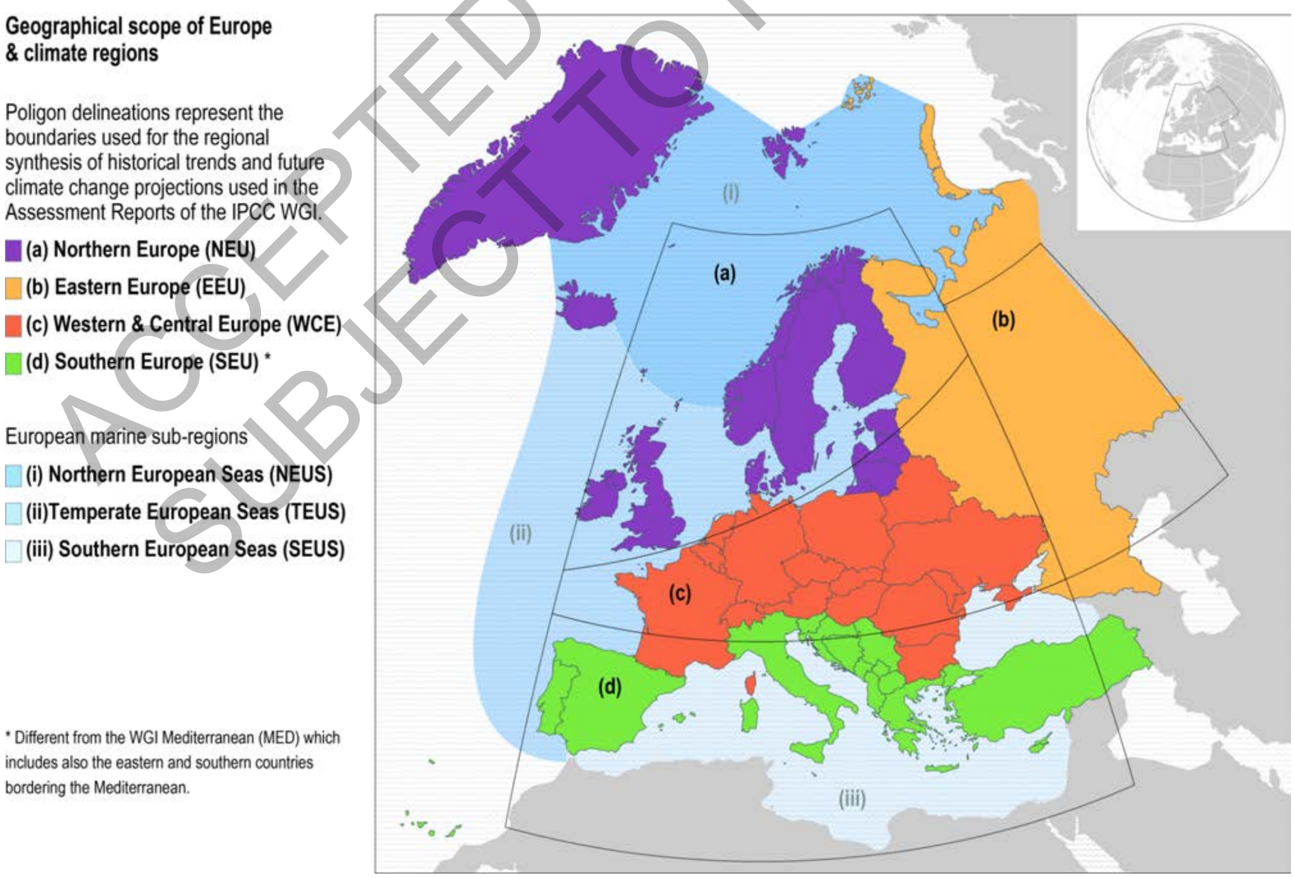

Figure 13.1: Geographical subdivision of land (a, b, c, d) and ocean (i, ii, iii) regions of Europe. The overlay represents the WGI AR6 subdivisions for climate-change projections of land, while the colour coding indicates the European

countries (or, in case of the Russian Federation, the European part of the country (EEU) used for this chapter. Note that for WGI AR6 region MED includes both southern Europe and northern Africa while this chapter only includes the northern (European) part of the MED region.

The geographical scope and subdivision of European land, coastal and ocean regions is largely the same as in WGII AR5 Chapter 23 (Kovats et al., 2014): Southern Europe (SEU), Western Central Europe (WCE), Eastern Europe (EEU) and Northern Europe (NEU). Note that WGI assesses a larger region for the Mediterranean (MED) which includes north Africa and the Middle East compared to the assessment in this chapter (SEU). The European part of the Arctic region is not systematically assessed here as it is extensively captured in Cross-Chapter Paper (CCP) 6. Information relevant to Europe is also synthesised in the CCPs, including European biodiversity hotspots (CCP 1), coastal cities and settlements (CCP 2), Mediterranean region (CCP 4) and mountains (CCP 5). European seas are broadly divided by latitude into (i) European Arctic waters (NEUS), (ii) European Temperate Seas (TEUS) and (iii) Southern Seas with the Mediterranean and Black Sea (SEUS) (Figure 13.1).

13.1.2 Socio-Economic Boundary Conditions

The adaptive capacity, as measured by GDP per capita, tends to be higher in northern and western parts of Europe (Figure 13.2a). In the last decades, climate change has led to substantial losses and damages to people and assets across Europe, mostly from riverine flooding, heatwaves, and storms (Figure 13.2b). Public concern about climate change, which is an indicator of the intention to mitigate and adapt, is particularly high in parts of Southern and Western Central Europe (Figure 13.2c). Current vulnerability to extreme weather and climatic events in European countries is low to moderate compared to the rest of the world (Figure 13.2d).

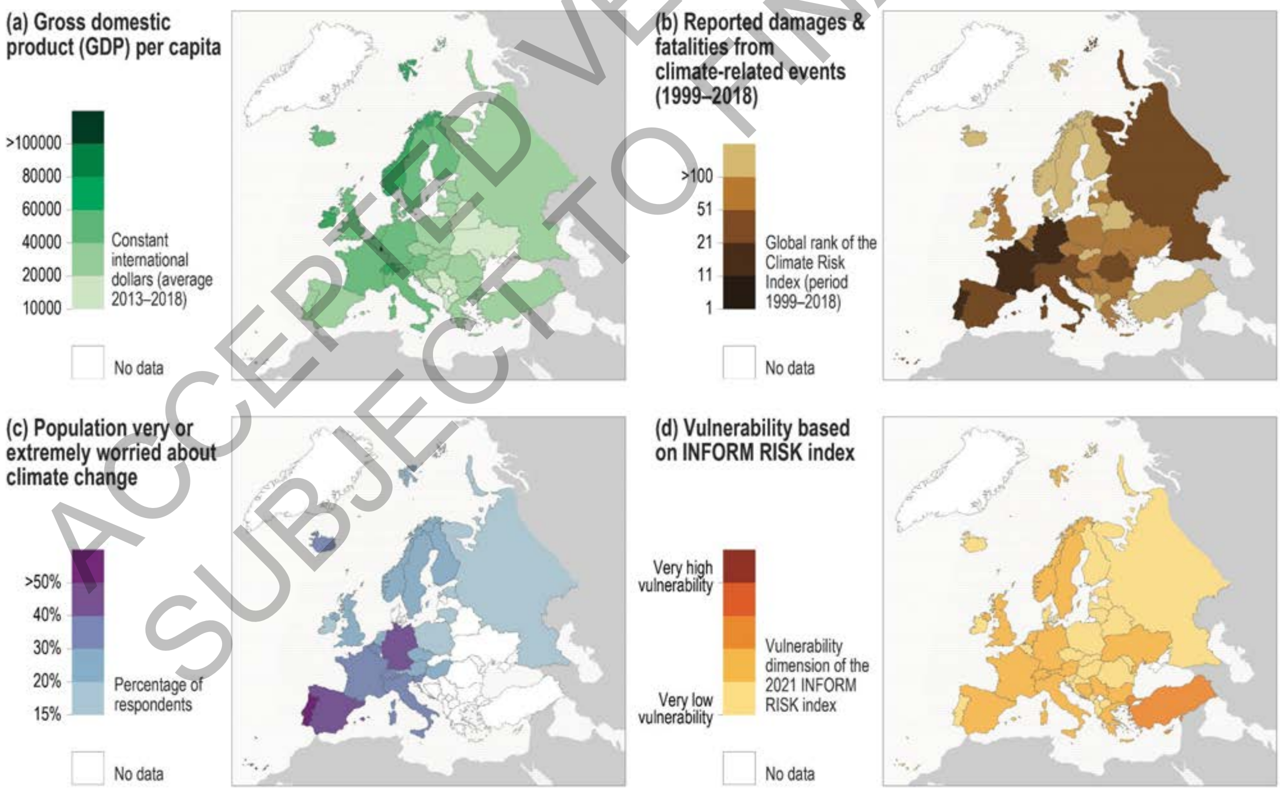

Figure 13.2: Indicators of reported damages to people and assets, vulnerability and adaptive capacity across European countries: (a) GDP per capita (average 2013-2018), in constant 2011 international dollars (WorldBank, 2020); (b) Exposure as measured by the global rank of the Climate Risk Index, which is based on economic damages and fatalities due to climate-related extreme weather events between 1999 and 2018 (Germanwatch, 2020); (c) Level of climate change concern among a representative weighted sample of residents 15 years and older in private households (European Social Survey, 2020) and (d) Vulnerability to disasters and humanitarian crisis in 2021; the index is based on socioeconomic factors (development, inequality, aid dependency) and vulnerable groups (DRMKC, 2020).

13.1.3 Impact Assessment of Climate Change based on Previous Reports

The main findings of previous reports, particularly the WGII AR5 (Kovats et al., 2014) and the Special Report of Global warming of 1.5°C GWL (Hoegh-Guldberg et al., 2018), highlighted the impacts of warming and rainfall variations and their extremes on Europe, particularly southern Europe and mountainous areas. At 2°C GWL, 9% of Europe's population was projected to be exposed to aggravated water scarcity, and 8% of the territory of Europe were characterized to have a high or very high sensitivity to desertification (UNEP/UNECE, 2016). These impacts are driven by changes in temperature, precipitation, irrigation developments, population growth, agricultural policies, and markets (EEA, 2017a). Heat is a main hazard for high-latitude ecosystems (Kovats et al., 2014; Jacob et al., 2018; Hock et al., 2019). The majority of mountain glaciers lost mass during the last two decades, and permafrost in the European Alps and Scandinavia is reducing (Hock et al., 2019). In central Europe, Scandinavia and Caucasus, mountain glaciers were projected to lose 60% to 80% of their mass by the end of the 21st century (Hock et al., 2019). The combined impacts on tourism, agriculture, forestry, energy, health and infrastructure were suggested to make southern Europe highly vulnerable and increase the risks of failures and vulnerability for urban areas (Kovats et al., 2014). Previous reports stated that the adaptive capacity in Europe is high compared to other regions of the world, but that there are also limits to adaptation from physical, social, economic, and technological factors. Evidence suggested that staying within 1.5°C GWL would strongly increase Europe's ability to adapt to climate change (de Conick and Revi, 2018).

13.1.4 European Climate: Main Conclusions of WGI AR6

Changes of several climatic impact-drivers have already emerged in all regions of Europe: increases in mean temperature and extreme heat and decreases of cold spells (Ranasinghe et al., 2021; Seneviratne et al., 2021). Lake and river ice has decreased in NEU, WCE and MED and sea ice in NEUS (Fox-Kemper et al., 2021; Ranasinghe et al., 2021). With increasing warming, confidence in projections is increasing for more drivers (Figure 13.3). Mean and maximum temperatures, frequencies of warm days and nights, and heat waves have increased since 1950, while the corresponding cold indices have decreased (*high confidence*) (Ranasinghe et al., 2021; Seneviratne et al., 2021). Average warming will be larger than the global mean in entire Europe, with largest winter warming in NEU and EEU and largest summer warming in the MED (*high confidence*) (Gutiérrez et al., 2021; Ranasinghe et al., 2021). An increase of hot days and a decrease of cold days are *very likely* (Figure 13.4.a,b). Projections suggest a substantial reduction of European ice glacier volumes and of snow cover below elevations of 1500-2000 m, as well as further permafrost thawing and degradation, during the 21st century even at a low GWL (*high confidence*) (Ranasinghe et al., 2021).

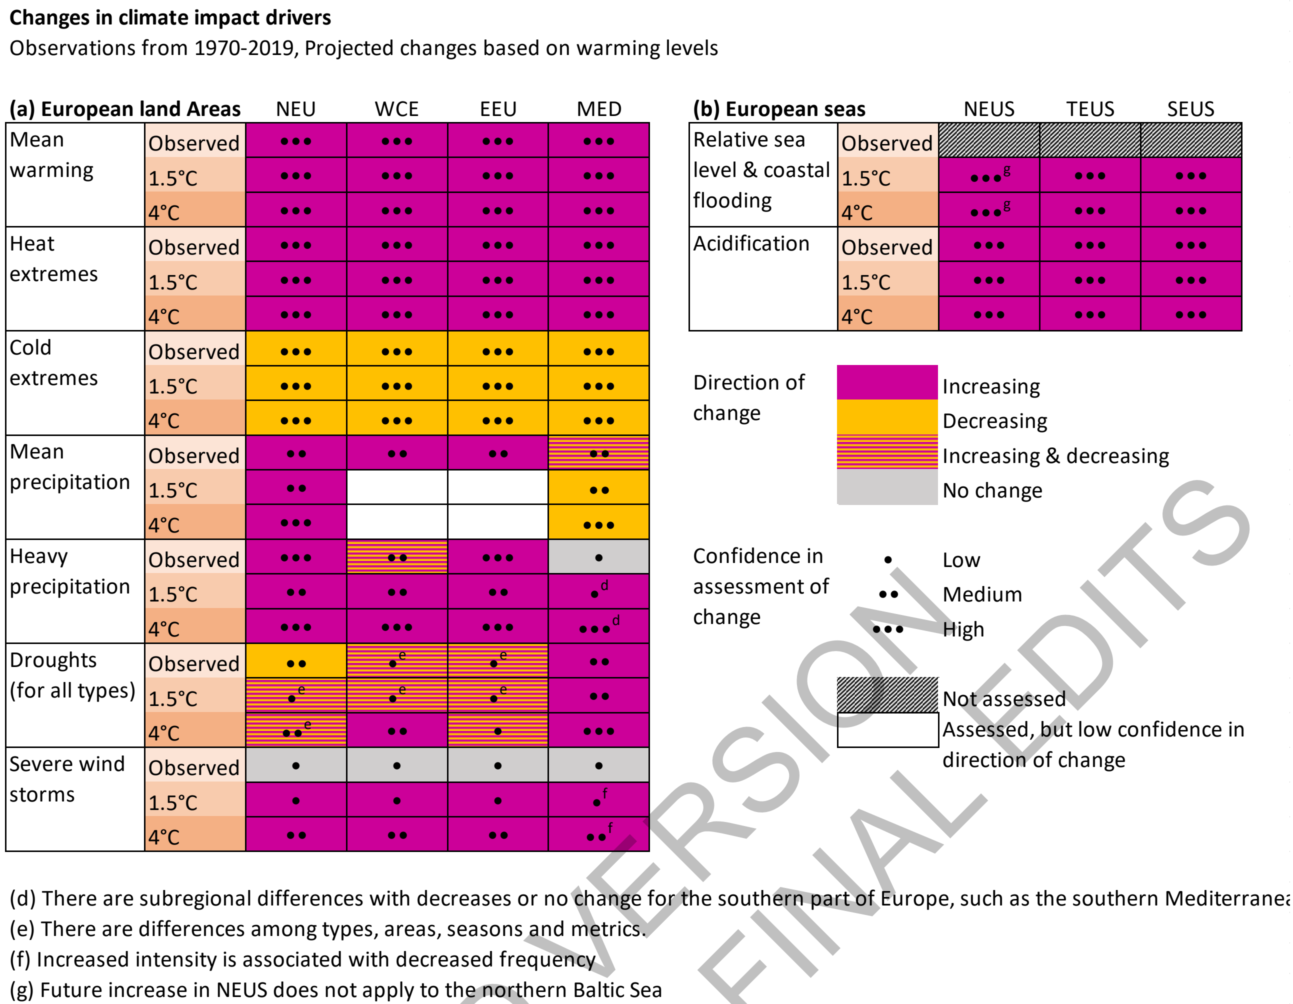

Figure 13.3: Observed and projected direction of change of climate impact drivers at 1.5°C and 4°C GWL for European sub-regions and European Seas (assessment from Gutiérrez et al., 2021; Ranasinghe et al., 2021; Seneviratne et al., 2021)

The assessment of climate change in WGI AR 6 concludes that during recent decades mean precipitation has increased over NEU, WCE and EEU, while magnitude and sign of observed trends depend substantially on time period and study region in MED (*medium confidence*) (Douville et al., 2021; Gutiérrez et al., 2021; Ranasinghe et al., 2021). Precipitation extremes have increased in NEU, and EEU (*high confidence*) (Seneviratne et al., 2021), vary spatially in WCE (*medium confidence*), and have not changed in MED *(low confidence*). For >2°C GWL, of mean precipitation in NEU in winter is increasing and decreasing in MED in summer (*high confidence*). A widespread increase of precipitation extremes is projected for > 2°C GWL for all subregions (*high confidence)*, except for MED where no change or decrease is projected in some areas (Figure 13.4c,d, Gutiérrez et al., 2021; Ranasinghe et al., 2021). WGI assessed projections for meteorological, agricultural/ecological, hydrological drought (Ranasinghe et al., 2021) with *low confidence* in the direction of change in NEU, WCE, EEU at 1.5°C GWL. MED is projected to be most affected within Europe with all types of droughts increasing for 1.5°C (*medium confidence*) and 4°C GWL (*high confidence*). At 4°C GWL, hydrological droughts in NEU, WCE and EEU will increase (*medium confidence*). Projections for the 21[st] century show increases of storms across all Europe (*medium confidence*) for >2°C GWL with a decrease of their frequency in the MED (Ranasinghe et al., 2021).

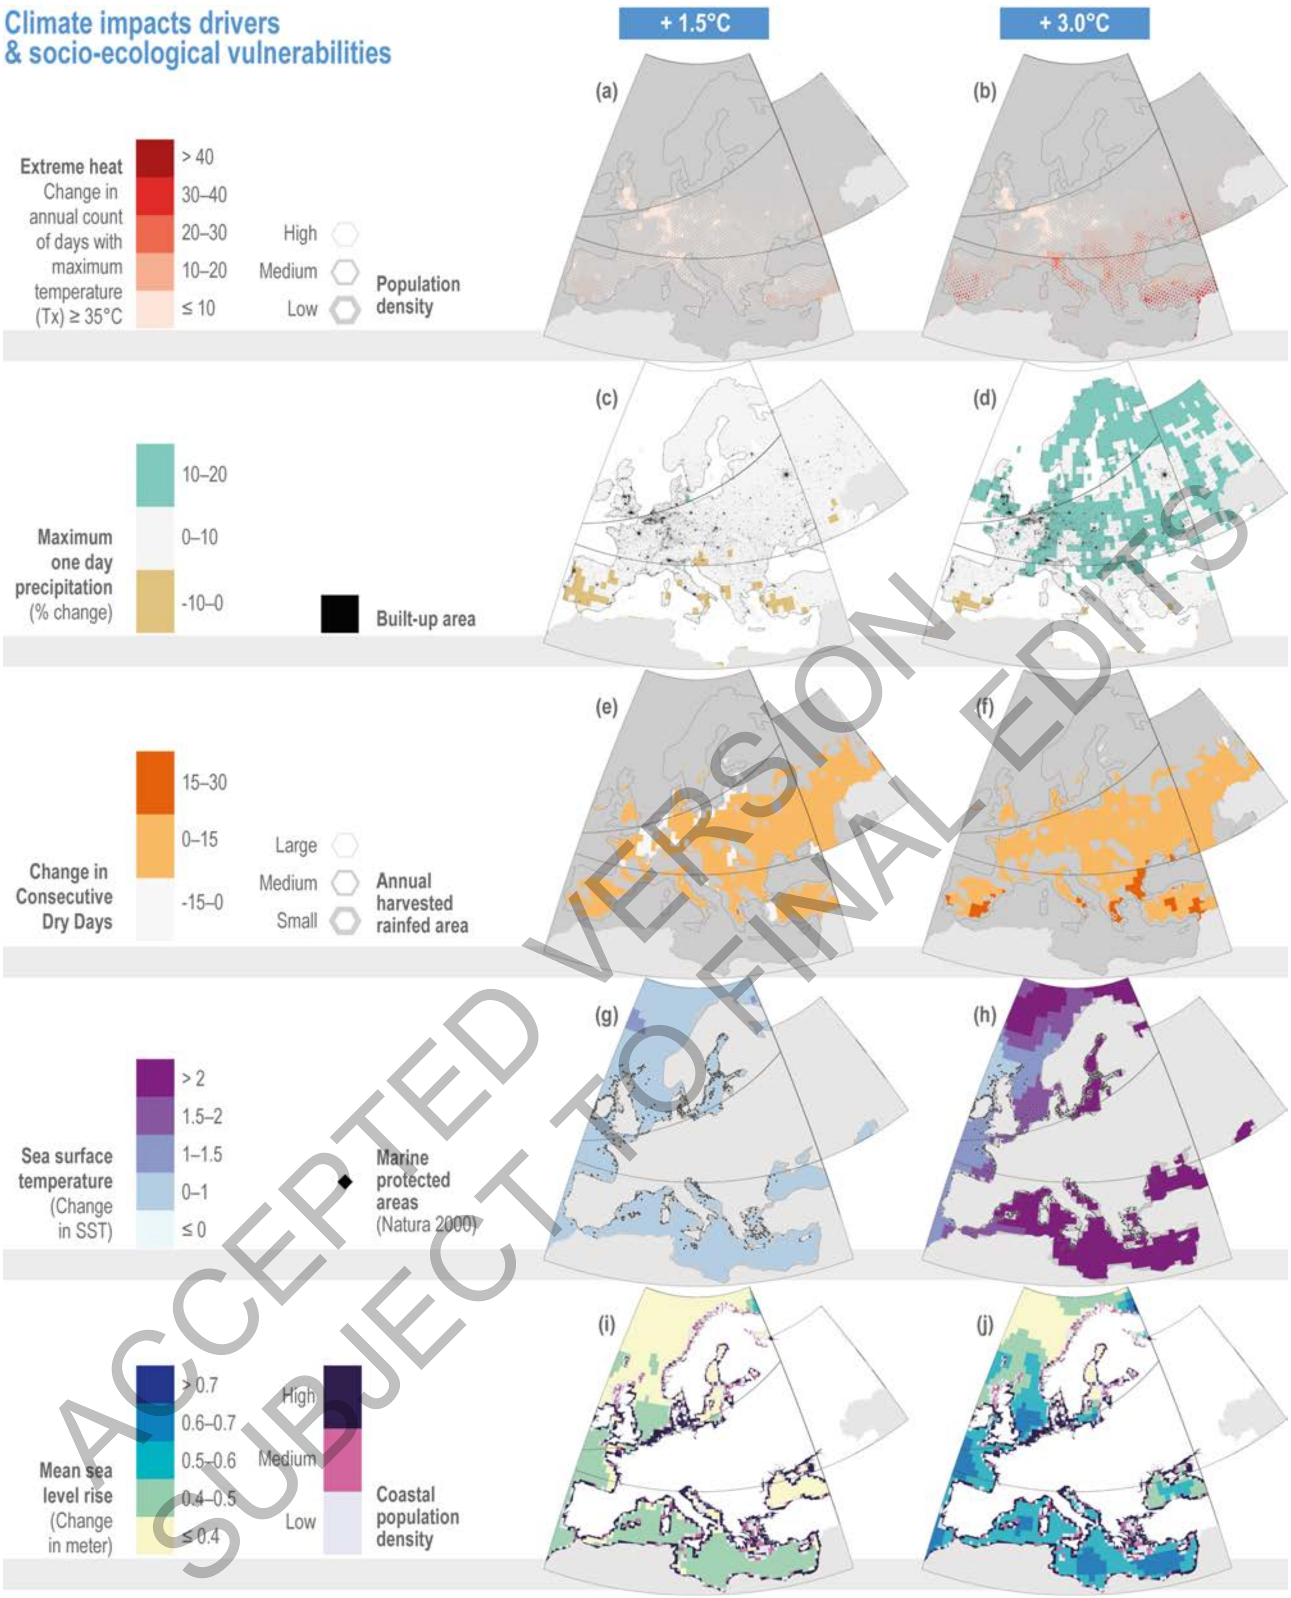

Figure 13.4: Changes of climate hazards with respect to the CMIP6 baseline (Gutiérrez et al., 2021) for global warming levels of 1.5°C and 3°C GWL and present exposure or vulnerability: (a,b) number of days with temperature maximum above 35°C (TX35) and population density (European Comission, 2019); (c,d) daily precipitation maximum (Rx1day) and built up area (JRCdatacatalogue, 2018); (e,f) consecutive dry days (CDD) and annual harvested rainfed area (Portmann et al., 2010); (g,h) sea surface temperature (TOS) and Marine Protected Areas (EEA, 2021b); and (k,l) sea level rise (SLR) and coastal population (Merkens et al., 2016). SLR data consider the long term period (2081-2100) and SSP1-2.6 for (i) and SSP3-7.0 for (j).

Sea surface warming between 0.25°C and 1°C has been observed in all regions over the last decades (*high confidence*) (Ranasinghe et al., 2021) and projected to continue increasing (*high confidence*), particularly in the SEUS and at the NEUS (Figure 13.4 g,h, Gutiérrez et al., 2021). Salinity has increased in the SEUS and decreased in northern European seas and projected to continue (*medium confidence*) (Fox-Kemper et al., 2021). European waters have been and will continue acidifying (*virtually certain*) (Eyring et al., 2021; Naik et al., 2021), resulting in a mean decrease of surface pH of about 0.1 and 0.3 pH units at 1.5°C and 3.0°C GWL with largest changes at high latitudes (Gutiérrez et al., 2021).

Relative sea level has risen along the European coastlines (Ranasinghe et al., 2021), regionally mitigated by post-glacial rise of land masses in Scandinavia (Fox-Kemper et al., 2021). SLR will *very likely* continue to increase during the 21st century (Figure 13.4 k,l) (*high confidence*), with regional deviations from global mean sea level rise (*low confidence*). Extreme water levels, coastal floods, and sandy coastline recession are projected to increase along many European coastlines (*high confidence*) (Ranasinghe et al., 2021).

13.2 Water

13.2.1 Observed Impacts and Projected Risks

13.2.1.1 Risk of Coastal Flooding and Erosion

Almost 50 million European citizens live within 10 m above mean sea level (Vousdoukas et al., 2020; McEvoy et al., 2021). Without further adaptation (section 13.2.2), flood risks along Europe's low-lying coasts and estuaries will increase due to sea level rise (SLR) compounded by storm surges, rainfall and river runoff (*high confidence*) (Mokrech et al., 2015; Arns et al., 2017; Sayol and Marcos, 2018; Vousdoukas et al., 2018a; Bevacqua et al., 2019; Couasnon et al., 2020). The population at risk of a 100-year flood event starts to rapidly increases beyond 2040 (Vousdoukas et al., 2018a) reaching 10 million people under RCP8.5 by 2100 but stays just below the 10 million under RCP2.6 by 2150 (Figure 13.5, Haasnoot et al., 2021b) assuming present population and protection. The number of people at risk is projected to increase and risk to materialise earlier particularly under SSP5 due to increasing population trends(Vousdoukas et al., 2018a; Haasnoot et al., 2021b). Under high rates of SLR resulting from rapid ice-sheet loss from Antarctica, risks may increase by a third by 2150 (Haasnoot et al., 2021b). Expected annual (direct) damages due to coastal flooding are projected to rise from €1.3 billion today to €13–39 billion by 2050 between 2°C and 2.5°C GWL and €93–960 billion by 2100 between 2.5° and 4.4°C GWL, largely depending on socio-economic developments (Cross-Chapter Box SLR in Chapter 3, Vousdoukas et al., 2018a) (*high confidence* in the sign; *low confidence* in the numbers). UNESCO World Heritage sites in the coastal zone are at risk due to SLR, coastal erosion and flooding (CCP4, Section 13.8.1.3, Marzeion and Levermann, 2014; Reimann et al., 2018b) as are coastal landfills and other key infrastructure in Europe (AR6/SROCC, Brand et al., 2018; Beaven et al., 2020).

Observations indicate that soft cliffs and beaches are most affected by erosion in Europe, with e.g. 27 to 40% of Europe's sandy coast eroding today, without climate change being identified as the main driver so far (Pranzini et al.; Luijendijk et al., 2018; Mentaschi et al., 2018; Oppenheimer et al., 2019). SLR will increase coastal erosion of sandy shorelines (*high confidence*) (Ranasinghe et al., 2021), but there is *low confidence* in quantitative values assessment of erosion rates and amounts (Athanasiou et al., 2019; Le Cozannet et al., 2019; Thieblemont et al., 2019). Without nourishment or other natural or artificial barriers to erosion, sandy shorelines can retreat by about 100m in Europe at 4°C GWL; limiting warming to 3°C GWL can reduce this value by one third (Vousdoukas et al., 2020).

[START BOX 13.1 HERE]

Box 13.1: Venice and its Lagoon

Venice and its lagoon are a UNESCO World Heritage Site. This socio-ecological system is the result of millennia of interactions between people and the natural environment. It is exposed to climatic and non-climatic hazards: more frequent floods, warming, pollution, invasive species, reduction of salt marshes, hydrodynamic and bathymetric changes, and waves generated by cruise ships and boat traffic.

The elevation of the average city pedestrian level and of its inner historic area are respectively 105cm and 55cm above the present relative mean sea level (RMSL). Consequently, even small surges and compound events cause floods when they coincide with high tide (Lionello et al., 2021a). During the 20th century, RMSL has risen at about 2.5 mm/yr due to SLR and land subsidence (Zanchettin et al., 2021). The frequency of floods affecting the city has increased from once per decade in the first half of the 20th century to 40 times per decade in the period 2010-2019 (Figure Box 13.1.1a).

In 1973, the Italian government established a legal framework for safeguarding Venice and its lagoon. Construction of the flood protection system started in 2003 and were used for the first time in October 2020 to protect the city from floods (Lionello et al., 2021b). This system of mobile barriers (MoSE) closes the lagoon inlets to avoid floods when needed, while under normal conditions they lay on the seabed, thus allowing ship traffic and the exchange between the lagoon and the sea (Molinaroli et al., 2019). To prevent the flooding of the central monument area, additional measures are proposed including inlets, expansion of saltmarshes, and pumping seawater into deep brackish aquifers to raise the city's level (Umgiesser, 1999; Umgiesser, 2004; Teatini et al., 2011).

Without adaptation, potential economic damages between €7 and €17 billion have been estimated for the next 50 years (Caporin and Fontini, 2016). Additionally, the ecosystem is vulnerable to warming (Solidoro et al., 2010) and sea level rise (Day Jr et al., 1999; Marani et al., 2007). The duration of the closure of the lagoon inlets is expected to increase from 2 to 3 weeks per year for RMSL rises of 30 cm, to 2 months per year for 50 cm and 6 months per year for 75cm (Umgiesser, 2020; Lionello et al., 2021b) (Figure Box 13.1.1b), resulting in disconnection from the sea for most of the time for RMSL rise exceeding 75 cm. Frequent closures of the inlets would prevent ship traffic and in/outflow of water. For Venice, adaptation pathways considering the full range of plausible RMSL (Figure Box 13.1.1c) levels are not available, indicating a long-term adaptation gap. As planning and implementation of adaptation of this extent can take several decades (Haasnoot et al., 2020b, Cross-Chapter Box SLR in Chapter 3) this increases the risk that the city will not be prepared in case of rapid sea level rise.

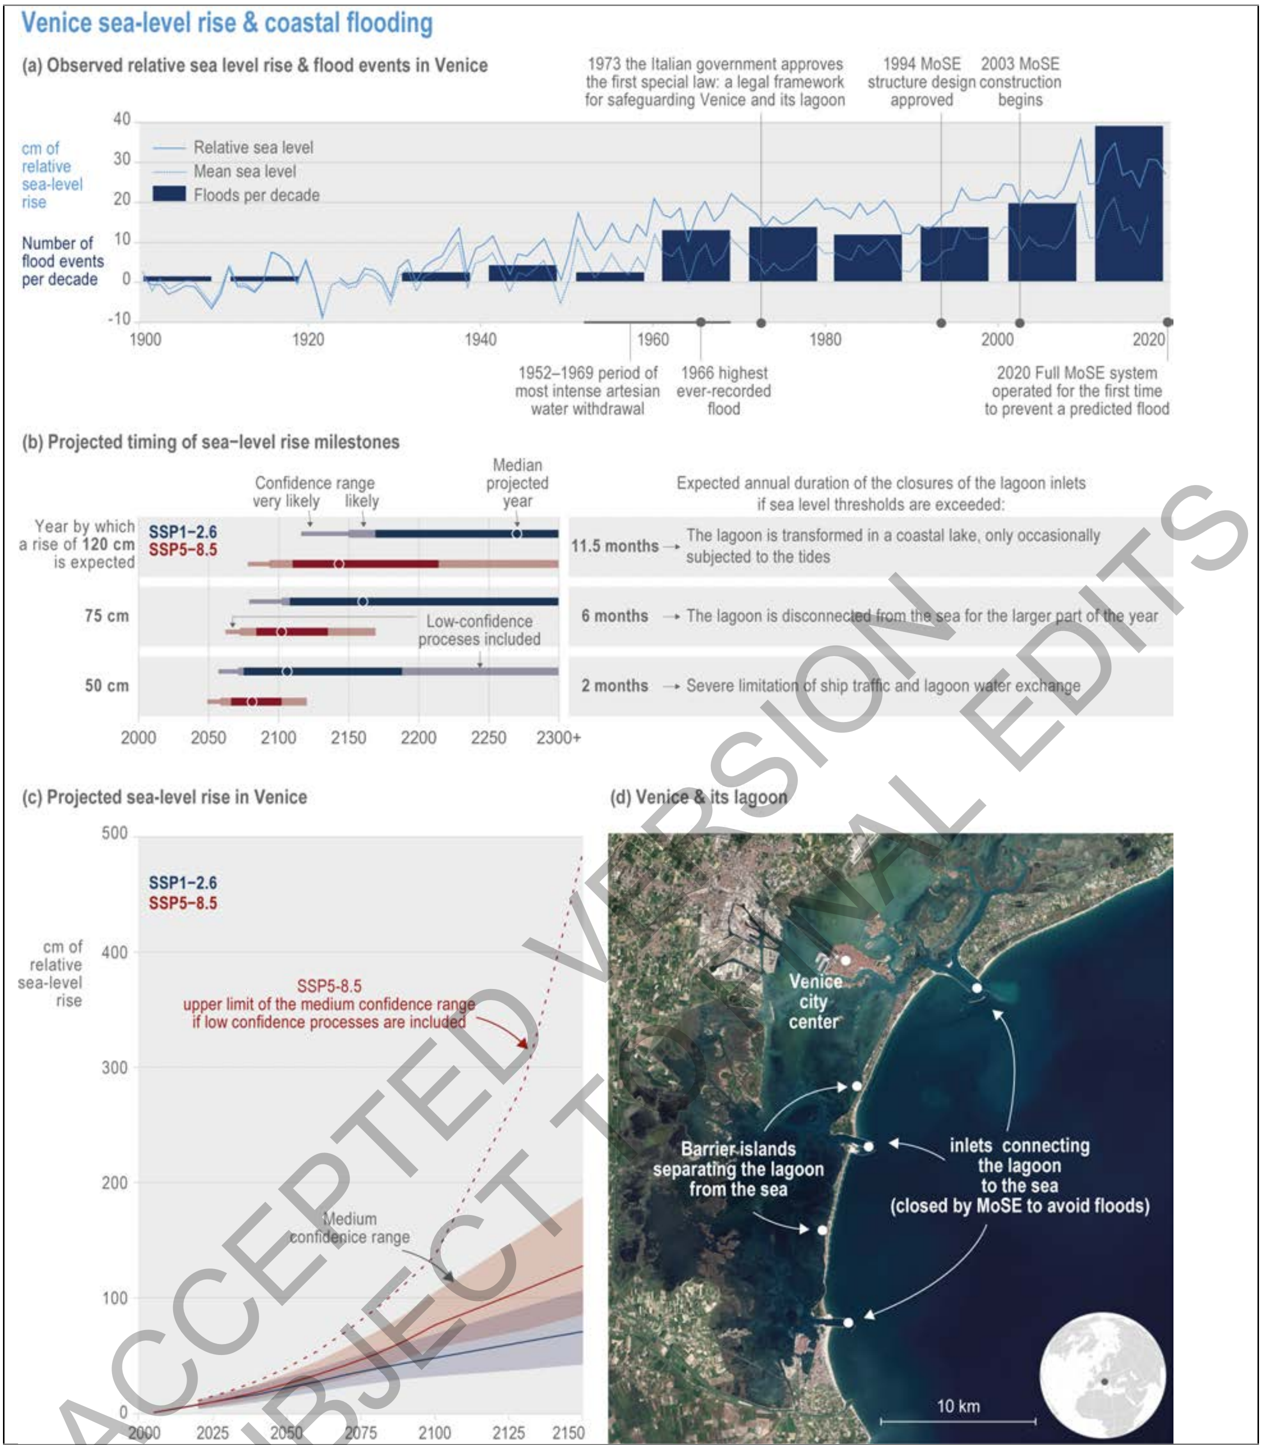

Figure Box 13.1.1: Venice sea level rise and coastal flooding. (a) Evolution of relative and mean sea level in Venice and decadal frequency of floods above the safeguard level in the city centre (Frederikse et al., 2020; Lionello et al., 2021a; Lionello et al., 2021b; Zanchettin et al., 2021). (b) Projected relative sea level rise at the Venetian coast (Fox-Kemper et al., 2021) and (c) timing when critical relative sea level thresholds will be reached depending on scenarios and confidence level (Lionello, 2012; Umgiesser, 2020; Lionello et al., 2021a). Panel d: landsat view of Venice, its lagoon with the three inlets connecting it to the Adriatic Sea.

[END BOX 13.1 HERE]

13.2.1.2 Risks Related to Inland Water

13.2.1.2.1 Riverine and Pluvial Flooding

Precipitation has raised river flood hazards in WCE and UK by 11% per decade from 1960-2010 and decreased in EEU and SEU by 23% per decade (Douville et al., 2021; Ranasinghe et al., 2021). The most recent three decades had the highest number of floods in the past 500 years with increases in summer (Blöschl et al., 2020). Economic flood damages increased strongly, reflecting increasing exposure of people and assets (Visser et al., 2014; Hoegh-Guldberg et al., 2018; Merz et al., 2021).

Projections indicate a continuation of the observed trends of river floods hazards in WCE (*high confidence*) of 10% at 2°C GWL and 18% at 4.4°C GWL and a decrease in NEU and SEU (*medium confidence*) with respectively 5% and 11% in NEU and SEU for a 100-year peak flow, making Europe one of the regions with the largest projected increase in flood risk (Di Sante et al., 2021; Ranasinghe et al., 2021). While there is disagreement on the magnitude of economic losses and people affected, there is *high agreement* on direction of change, particularly in WCE (Alfieri et al., 2018). New research increases confidence in AR5 statements that without adaptation measures, increases in extreme rainfall will substantially increase direct flood damages (e.g., Madsen et al., 2014; Alfieri et al., 2015a; Alfieri et al., 2015b; Blöschl et al., 2017; Dottori et al., 2020; Mentaschi et al., 2020). With low adaptation, damages from river flooding are projected to be 3 times higher at 1.5°C GWL, 4 times at 2°C GWL, and 6 times at 3°C GWL (Alfieri et al., 2018; Dottori et al., 2020). At 2°C GWL, incidence of summer floods is expected to decrease across the whole alpine region, whereas winter and spring floods will increase due to extreme precipitation (Gobiet et al., 2014) and snow melt driven runoff (Coppola et al., 2018).

Pluvial flooding and flash floods due to intense rainfall constitute most flood events in SEU and a substantial risk in other European regions (CCP4, Llasat et al., 2016; Rudd et al., 2020). The majority (56 %) of flood events between 1860-2016 were flash floods (Paprotny et al., 2018a). These had considerable impacts including danger to human lives, e.g. causing total economic damage of USD 1 billion in Copenhagen (Denmark) 2011 (Wójcik et al., 2013), a damage to private households of more than €70 million in Münster (Germany) 2014 (Spekkers et al., 2017), and during the 2021 floods in Belgium, Germany and the Netherlands over 200 deaths, damage to thousands of homes and disrupted water and electricity supply (Kreienkamp et al., 2021). The intensity and frequency of heavy rainfall events is projected to increase (*high confidence*) (Figure 13.3, Ranasinghe et al., 2021). Combined with increasing urbanization, the risk of pluvial flooding is projected to increase (Westra et al., 2014; Rosenzweig et al., 2018; Papalexiou and Montanari, 2019). Small catchments, steep river channels and cities are particularly vulnerable due to large areas of impermeable surfaces where water cannot penetrate (Section 13.6).

13.2.1.2.2 Low Flows and Water Scarcity

The frequency and severity of low flows are projected to increase, making streamflow drought and water scarcity more severe and persistent in SEU and WCE (*medium confidence*) (Figure 13.3, Ranasinghe et al., 2021), but decreases are projected in most of NEU except southern UK (Forzieri et al., 2014; Prudhomme et al., 2014; Schewe et al., 2014; Roudier et al., 2016; Ranasinghe et al., 2021). In EEU, uncertainty about changes in water scarcity pose distinct challenges for adaptation (Greve et al., 2018). At 1.5°C GWL, the number of days with water scarcity (water availability vs water demand) and drought will increase slightly in SEU (Schleussner et al., 2016; Naumann et al., 2018), resulting in 18% of the population exposed to at least moderate water scarcity, increasing to 54% at 2°C GWL (Byers et al., 2018). Moderate water scarcity is emerging in some parts of WCE (Bisselink et al., 2018) increasing to16% of the population under 2°C GWL and SSP2 (Byers et al., 2018). Under 4°C GWL, areas in WCE experience water scarcity, especially in summer and autumn. Future intensive water use can aggravate the situation, in particular in southern Europe (13.5.1 and 13.10.3).

Groundwater abstraction rates reach up to 100 million m³/year across WCE and SEU, and exceed 100 million m³/year in parts of SEU (Wada, 2016). Low recharge rates lead to a depletion of groundwater resources in parts of SEU and WCE (Doll et al., 2014; Wada, 2016; de Graaf et al., 2017), increasing the impacts on water scarcity in SEU. Groundwater pumping and declines in groundwater discharge already threaten environmental flow limits in many European catchments, especially in SEU, extending to almost all basins and sub-basins within the next 30-50 years (de Graaf et al., 2019).

The combined effect of increasing water demand and successive dry climatic conditions further exacerbates groundwater depletion and lowers groundwater levels in SEU but also WCE (Goderniaux et al., 2015).

Declines in groundwater recharge of up to 30% further increase groundwater depletion (Aeschbach-Hertig and Gleeson, 2012) especially in SEU and semi-arid to arid regions (Moutahir et al., 2017). Even in WCE and NEU projected increases in groundwater abstraction will impact groundwater discharge, threatening sustaining environmental flows under dry conditions (de Graaf et al., 2019).

The risks for soil moisture drought are projected to increase in WCE and SEU for all climate scenarios (Grillakis, 2019; Tramblay et al., 2020; Ranasinghe et al., 2021). At 3°C GWL compared to 1.5°C GWL, the drought area will increase by 40% and the population under drought by up to 42%, especially affecting SEU, and to a lesser extent in WCE (Samaniego et al., 2018).

13.2.1.2.3 Water Temperature and Quality

Water temperatures in rivers and lakes have increased over the past century by ~1 to 3°C in major European rivers (CBS, 2014; EEA, 2017b; Woolway et al., 2017). Warming is accelerating for all European river basins (Wanders et al., 2019) increasing by 0.8°C in response to 1.5°C GWL and 1.2°C for 3°C GWL relative to 1971-2000 (van Vliet et al., 2016a) aggravated by declines in summer river flow.

(Ground)water extractions or drainage have caused saltwater intrusions (Rasmussen et al., 2013; Ketabchi et al., 2016). During summer, seawater will also penetrate estuaries further upstream in response to reduced river flow and SLR and result in more frequent closure of water inlets in the downstream part of the rivers in a period when water is most needed (e.g., Haasnoot et al., 2020b) (*high agreement, low evidence*).

13.2.2 Solution Space and Adaptation Options

In recent decades water management in Europe has increasingly shifted towards integrated and adaptive strategies, with most noticeable shifts in WCE (*high confidence*) (e.g., Kreibich et al., 2015; Bubeck et al., 2017). While adaptive strategies are increasingly considered as an approach to strengthen flexibility and implement climate change adaptation actions, given deep uncertainty about the future (Ranger et al., 2013; Klijn et al., 2015; Bloemen et al., 2019; Hall et al., 2019; Pot et al., 2019), more traditional water management approaches still dominate across Europe (OECD, 2013; OECD, 2015; Wiering et al., 2017). Current measures focus on structural flood protection and water resources supply and play an important role to preserve present land use and development patterns. The long-term effectiveness of such measures is increasingly challenged by their reinforcing path-dependency (e.g. flood defence and water supply attract developments which require further protection and supply); this path-dependency limits the solution space and may hamper implementation of transformative measures such as land use change to accommodate the water system *(medium confidence*) (CCP2, Di Baldassarre et al., 2015; Kreibich et al., 2015; Alfieri et al., 2016; Gralepois et al., 2016; Welch et al., 2017; Di Baldassarre et al., 2018; Haer et al., 2020).

Water laws, policies and guidance documents increasingly mainstream climate impacts and adaptation options (Runhaar et al., 2018; Mehryar and Surminski, 2021), though not everywhere. Differences are apparent for example in coastal adaptation where most but not all countries are planning for SLR (Figure 13.5) (McEvoy et al., 2021). Although the planning horizon of 2100 and 1m SLR are most common (adjusted for local conditions), there are significant differences between countries (e.g. the high-end SLR value in 2100 ranges from 0.3 to 3m), which may lead to unequal impacts, over time (McEvoy et al., 2021).

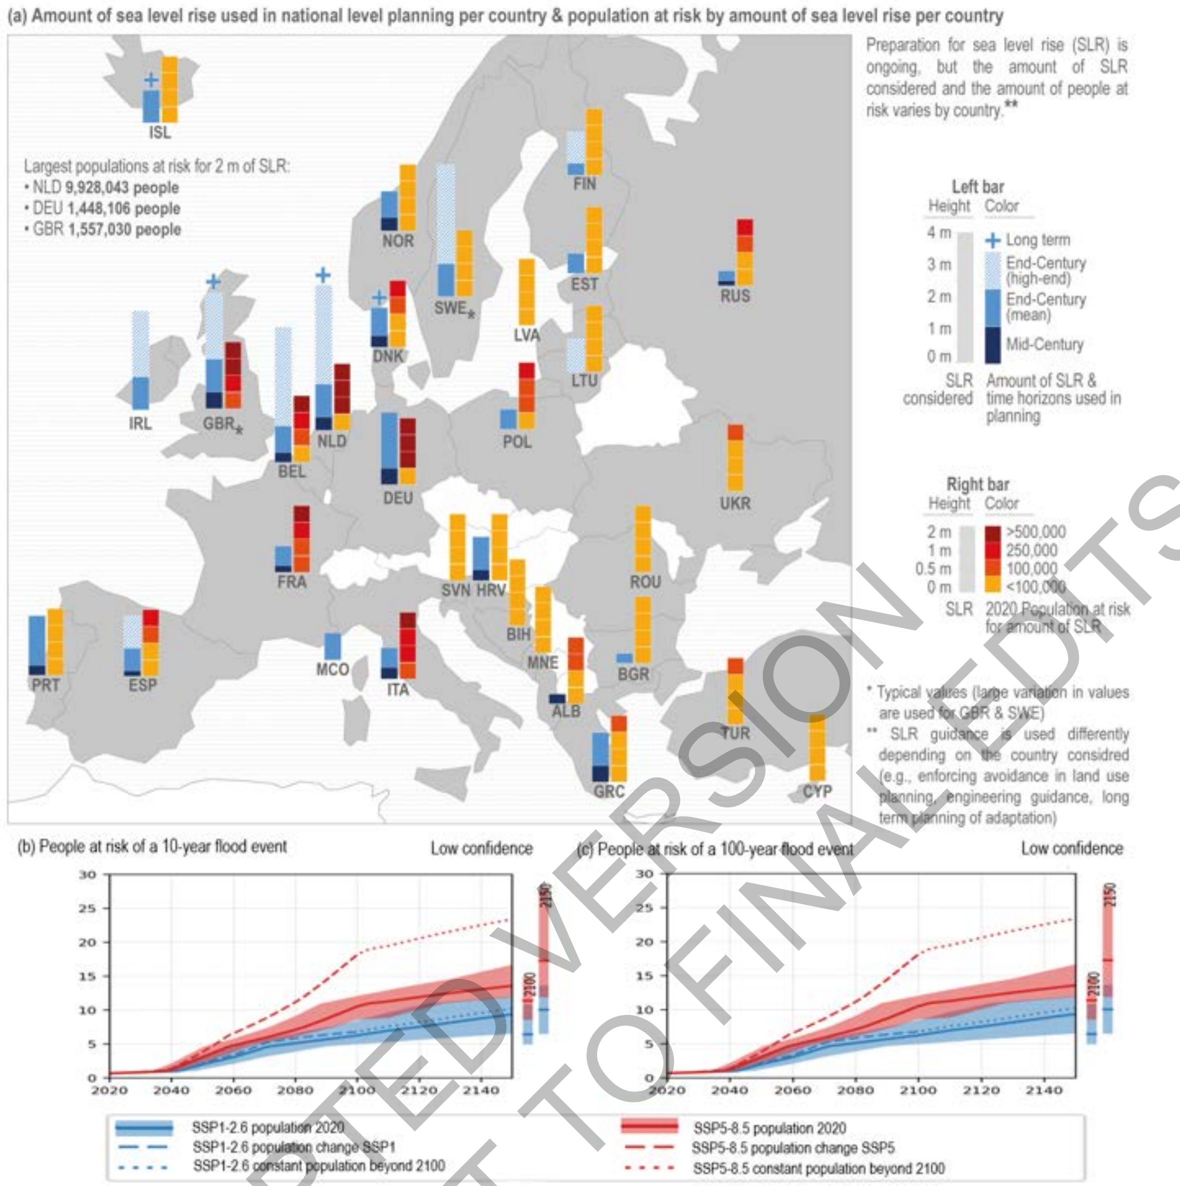

Figure 13.5: Sea level rise (SLR) vulnerability and national planning in Europe. (a) Map of countries in Europe summarizing the amount of SLR each country is planning for, at different time horizons (blue bars) and present population (2020) at risk of a 100-year coastal flood event (orange bars) (Haasnoot et al., 2021b). The amounts of SLR and time horizons reflect national guidance or planning; local or project-based levels may differ (McEvoy et al., 2021). (b) Projected population at risk to a 1 in 10-year coastal flood event under RCP2.6-SSP1 and RCP8.5-SSP5 assuming present protection and population, as well as population change according to respectively, SSP1 and SSP5, based on Merkens (2016); and (c) projected population at risk to 1 in 100-year coastal flood event under RCP2.6-SSP1 and RCP8.5-SSP5, assuming present protection and population, as well as population change according to respectively, SSP1 and SSP5, based on Merkens (2016) (Haasnoot et al., 2021b).

13.2.2.1 Flood Risk Management

Across Europe a range of measures have been implemented to address flood risk (Figure 13.6), with protection as a most used strategy (*high confidence*). Early warning and flood protection have been successful in reducing vulnerability to coastal and riverine flooding (Jongman et al., 2015; Kreibich et al., 2015; Bouwer and Jonkman, 2018). Consequently, fatalities due to river flooding have decreased in Europe, despite similar numbers of people exposed (1990-2010 compared to 1980-1989) (Jongman et al., 2015; Paprotny et al., 2018a).

Coastal flood risk management

Further protection against coastal flooding is considered economically beneficial for densely populated areas (Lincke and Hinkel, 2018; Tiggeloven et al., 2020). At least 83% of flood damages due to coastal flooding could be avoided by elevating dykes along ~23-32% of Europe's coastline by 2100 (RCP4.5-SSP1, RCP8.5-SSP5) (Vousdoukas et al., 2020). Limitations of building flood defences include cost-benefit considerations in rural areas, available land, and social acceptability in densely populated areas (Haasnoot et al., 2018; Hinkel et al., 2018; Meyerhoff et al., 2021).

Nature-based (NbS, e.g. wetlands) and sediment-based (e.g. sand nourishment) solutions are increasingly considered for environmental, economic and/or societal reasons (Cross-Chapter Box NATURAL in Chapter 2, Stive et al., 2013; Pranzini et al., 2015; Pinto et al., 2020; de Schipper et al., 2021). Coastal wetlands can be effective to reduce wave height and form habitats, but their feasibility and effectiveness is limited for densely populated areas with competing land use, runoff of pollution, sediment starved deltas like the Rhine delta (Edmonds et al., 2020) and rapid SLR (Kirwan et al., 2016; Oppenheimer et al., 2019; Haasnoot et al., 2020b). While losses of wetlands could be minor if warming stays below 1.7°C GWL, at high warming or SLR above 0.5m large scale losses of these habitats impact their ecological importance, ecosystem function (Section 13.4, Key Risk 1, 13.10) and their ability to protect coastlines (Roebeling et al., 2013; van der Spek, 2018; Wang et al., 2018; Xi et al., 2021). A combination with structural defences could reduce risk in urbanized coastal regions (*high confidence*). Accommodation through elevated or floating houses have been implemented and proposed locally within cities as part of a hybrid strategy together with protection and as a way of innovative urban development (13.6.2, CCP2, Penning-Rowsell, 2020; Storbjörk and Hjerpe, 2021).

Avoidance through restricting new developments in flood prone areas is applied along the coast of WCE and SEU (Harman et al., 2015; Lincke et al., 2020) and is considered a low-cost alternative to coastal defence at lower SLR. In SEU, an Integrated Coastal Zone Management (ICZM) protocol has been developed which requires a setback zone of 100m from the coast in unprotected areas. Setback zones are projected to reduce impacts considerably in urbanized regions (Lincke et al., 2020). Planned relocation is increasingly considered as a realistic adaptation option in case of extreme SLR (Haasnoot et al., 2021a; Lincke and Hinkel, 2021; Mach and Siders, 2021), e.g UK Shoreline Management Plans (Nicholls et al., 2013; Buser, 2020). Retreat is rarely applied in Europe (*medium confidence*), though it can have larger benefit-cost outcomes than protection, particularly in less populated parts of Europe (Lincke and Hinkel, 2021). Along parts of the coast in the UK (e.g., The Wash), Germany (e.g., Langeoog Island), and the Netherlands (e.g., Westerschelde) retreat has been applied to restore salt marshes and to aid coastal defence (Haasnoot et al., 2019; Kiesel et al., 2020). (Lincke and Hinkel, 2021)

Riverine and pluvial flood risk management

Structural flood protection (e.g. levees) is considered economically beneficial in densely populated areas (Alfieri et al., 2016; Dottori et al., 2020) and could reduce flood damage of ~45% is estimated under 1.5°C GWL and ~70% under 3°C GWL (Dottori et al., 2020).

Providing more room for water through NbS is increasingly considered (Kreibich et al., 2015) as they can reduce risk effectively at lower costs, except in places with limited space or in areas with large protection. Such measures include (forest) restoration for upstream retention, restoration of river channels, and widening riverbeds for natural flood retention (Kreibich et al., 2015; Barth and Döll, 2016; Wyżga et al., 2018). Natural retention areas are estimated to be the most effective option to reduce riverine flood risk across Europe in the 21st century, followed by protection (*low evidence*) (Dottori et al., 2020).

Wet and dry proofing of buildings can be applied at household level. While measures taken at household levels can reduce the risk of flooding, there is often insufficient investment (Bamberg et al., 2017; Aerts et al., 2018) (*medium confidence*). Reasons include low awareness or under-estimation of the risk (Kellens et al., 2013), low perceived efficacy of adaptation measures (van Valkengoed and Steg, 2019), and lack of financial support (Kreibich, 2011). In the long-term, risk reduction measures by governments are projected to outweigh floodproofing at household level, in particular in WCE, while for near-term household adaptation or regionally in SEU this could reduce risk more effectively (Haer et al., 2019). Relocation of households has occurred in response to river flood events, e.g. the 2013 flood events along the Danube river in Austria, with financial compensation playing a crucial role (Mayr et al., 2020; Thaler and Fuchs, 2020; Thaler, 2021).

Urban drainage infrastructure is designed based on historical rainfall intensities, and thus may not have sufficient capacity for increased future intensities (Dale et al., 2018). Adaptation options to pluvial flooding include large retention ponds , local green spaces and green roofs within cities (Zölch et al., 2017; Maragno et al., 2018; Babovic and Mijic, 2019; Ribas et al., 2020).

Effectiveness & feasibility of adaptation options for water-related climate impacts & risk in Europe

Legend	
High = H	1 Physically hampered in highly urbanized regions
Medium = M	2 Low on preventing damage, medium on preventing fatalities
Low = L	3 Availability of sand can hamper feasibility in SEU
No/Limited Evidence	4 Low in SEU, high in NLU, WCE
	5 In SEU, no evidence for other parts of Europe
	6 Medium in SEU & high in WCE/NLU

Figure 13.6: Effectiveness and feasibility of water-related adaptation options to achieve objectives under increasing climate hazards (SM13.1, SM13.9).

Early warning systems, insurance and behaviour change can complement protect and accommodate measures to limit residual risk (*high confidence*). Early warning systems have high monetary benefits (Pappenberger et al., 2015). Behavioural adaptation to flooding relies on recognition of the threat and capacity to respond, both of which are often lacking (Section 13.11.2.2, Bamberg et al., 2017; Haer et al., 2019). Flood risk insurance and compensation systems vary across European countries, ranging from post-disaster payments by governments, compulsory flood insurance, to public-private partnerships where the state acts as reinsurer (Keskitalo et al., 2014; Surminski et al., 2015; Hanger et al., 2018). Risk-based insurance premiums can induce risk averting behaviour but may become unaffordable to poor households and some households in high risk zones (Hudson, 2018; Surminski, 2018). Increasing future flood risks due to both climatic and socioeconomic change could overburden government budgets (*medium confidence*) (Section 13.11.2, Paudel et al., 2015; Mysiak and Perez-Blanco, 2016; Schinko et al., 2017; Mochizuki et al., 2018), result in unavailable or unaffordable insurance for private customers (13.8.3, Hudson et al., 2016; Surminski, 2018), and underfunding and insufficient solvency of insurance companies (Section 13.6.2.5, Lamond and Penning-Rowsell, 2014). Local knowledge about disastrous flood events in the past can be lost across generations, reverting behaviours to avoid settlement in risky areas (Fanta et al., 2019).

Limits to adaptation to extremely high sea level rise scenarios have been identified for coastal defences, such as the Venice MoSE barrier (box 13.1), Thames Barrier in the UK (Ranger et al., 2013) and the Maeslant Barrier in the Netherlands (Kwadijk et al., 2010; Haasnoot et al., 2020b). However, the scale and pace of adaptation required to face high-end SLR scenarios along all coasts of Europe is poorly studied. Given the lead and long lifetime of large critical infrastructure, there is a growing need to look beyond 2100 to support the design of new infrastructure (Cross-Chapter Box SLR in Chapter 3).

13.2.2.2 Water Resources Management

Planning adaptation to water scarcity has centred on increasing availability and supply of fresh water through water storage, diversification of sources and water diversion and transfer (*high confidence*). Reservoirs are costly, have negative environmental impacts, and will not be sufficient under higher warming levels in every place (Papadaskalopoulou et al., 2015a; Di Baldassarre et al., 2018; Garnier and Holman, 2019). Waste water reuse is considered a low-cost and effective measure where wastewater is available (Lavrnic et al., 2017; De Roo et al., 2020), but public acceptance for domestic reuse is presently limited (*high confidence*) (Papadaskalopoulou et al., 2015b; Morote et al., 2019). Increasing desalination capacity is used particularly in SEU but has high energy demands and produces brine waste (Garnier and Holman, 2019; Jones et al., 2019; Morote et al., 2019).

Adaptation measures on the demand side include monitoring (e.g., water meters, early warning systems of drought) and regulating demand, e.g. water restrictions, water pricing, water saving and efficiency measures and land management and cover change (Papadaskalopoulou et al., 2015b; Varela-Ortega et al., 2016; Manouseli et al., 2018; Garnier and Holman, 2019). Prolonged water restrictions and prioritising sectoral supply could result in economic losses e.g. for irrigated agriculture (Section 13.5.2, Wimmer et al., 2014; Salmoral et al., 2019). Economic instruments, such as water pricing, can be effective when combined with incentives for water saving and efficiency (Kayaga and Smout, 2014; Esteve et al., 2018; Crespo et al., 2019). Water saving and efficiency measures, such as leakage repair, education and improved irrigation, could limit conflicts across sectors, but necessitate technological advances and changes of practice together with a willingness to cooperate (Garnier and Holman, 2019; Papadimitriou et al., 2019; Teotónio et al., 2020). Increased irrigation efficiency has reduced water scarcity, particularly in SEU (13.5, De Roo et al., 2020), and occur at farm level in WCE and NEU (Papadaskalopoulou et al., 2015b; van Duinen et al., 2015; Rey et al., 2017), but come with increasing path-dependency on supply and trade-offs which may not be sustainable on the long-term (*high confidence*) (Di Baldassarre et al., 2018).

The assessment of the effectiveness and feasibility of adaptation options shows that a portfolio of supply and demand measures is needed to reduce water scarcity (Key Risk 3, Section 13.10.3), although locally demand-side measures could be sufficient (Kingsborough et al., 2016). Under high warming levels, adaptation to drought and low flows by water saving and efficiency measures may not be sufficient to counteract reduced availability (*medium agreement, low evidence*) (Collet et al., 2015; De Roo et al., 2020). Successful adaptation in the water sector depends on integrating water considerations into sectoral policies (Collet et al., 2015; Papadaskalopoulou et al., 2016). Inclusive and participatory approaches where (local) stakeholders are actively involved in the initiation and execution of water management can enhance problem ownership, quality and democratic legitimacy of processes and decisions, enhance support and accelerate decisions (Edelenbos et al., 2017; Begg, 2018).

13.2.3 Knowledge Gaps

An assessment of the full solution space of adaptation options and pathways under low to high GWLs including the long-term is lacking. A quantification of the effectiveness of measures in reducing risk is limited in the scientific literature. Available assessments consider adaptation by incremental measures. Transformative options, such as land use changes, planned relocation from exposed areas or restricting future development, are rarely considered. While high-end scenarios, describing *low confidence* processes and scenarios beyond 2100 are considered to be useful for risk-averse decision making, in particular coastal adaptation (Hinkel et al., 2019; Haasnoot et al., 2020b), they are rarely considered in practice.

13.3 Terrestrial and Freshwater Ecosystems and their Services

13.3.1 Observed Impacts and Projected Risks

13.3.1.1 Observed Impacts on Terrestrial and Freshwater Ecosystems

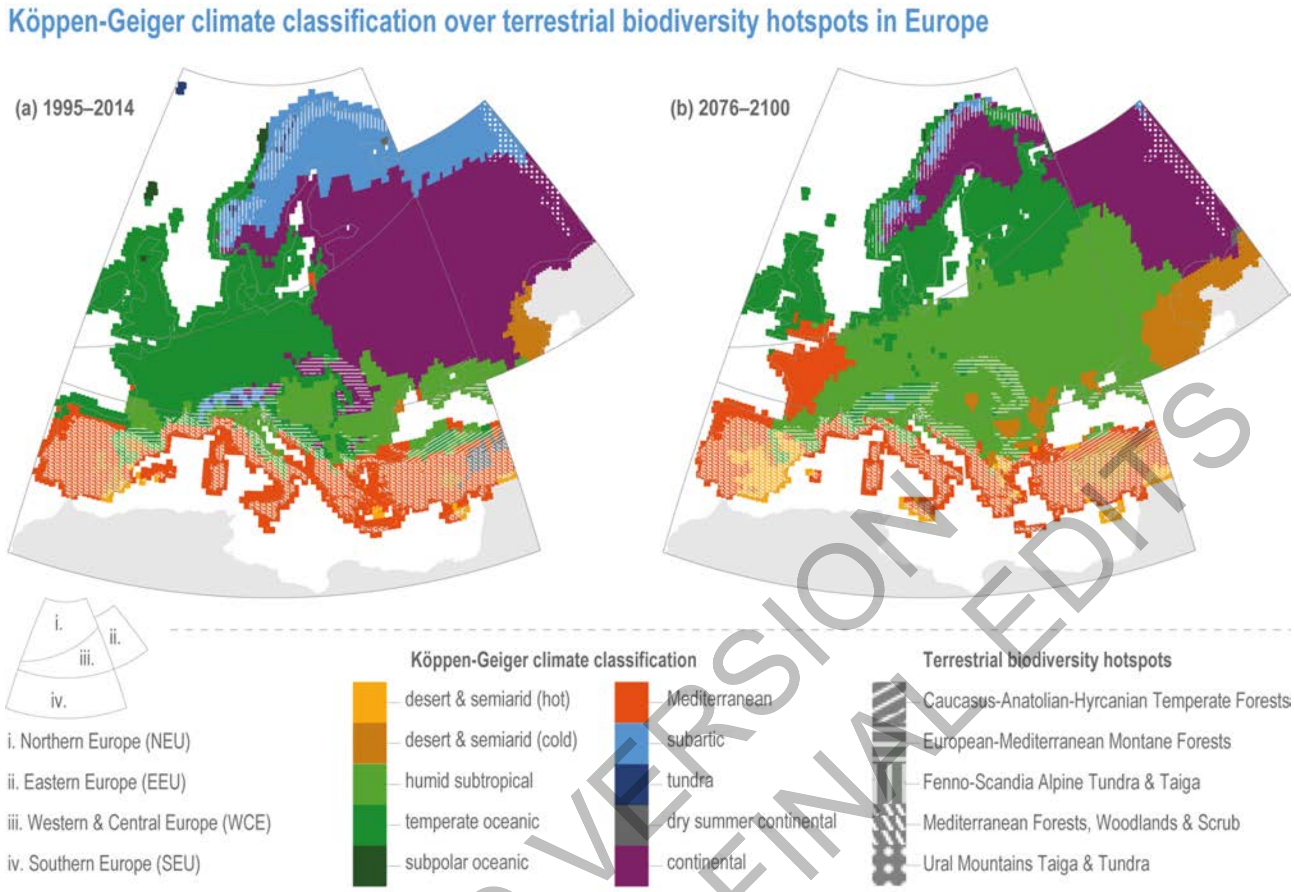

Figure 13.7: Köppen-Geiger climate classification and biodiversity hotspots in Europe. Boundaries of the (a) Northern (NEU), (b) Western-Central (WCE), (c) Southern (SEU), and (d) Eastern (EEU) European regions for 1985-2014 (left) and 2076-2100 (right, A1FI scenario, ~4°C GWL), based on Rubel and Kottek (2010).

European land and freshwater ecosystems (Figure 13.7) are already strongly impacted by a range of anthropogenic drivers (*very high confidence*), particularly habitats at the southern and northern margins, along the coasts, up mountains and in freshwater systems (CCP1). Interacting with climate change are non-climatic hazards, such as habitat loss and fragmentation, over-exploitation, water abstraction, nutrient enrichment, and pollution, all of which reduce resilience of biotas and ecosystems (*very high confidence*). Peatlands in NEU and EEU and other historically important cultural landscapes in Europe are overexploited for forestry, agriculture, and peat mining (Page and Baird, 2016; Tanneberger et al., 2017; Ojanen and Minkkinen, 2020). Inland wetland RAMSAR convention sites in Europe, which constitute 47% of the global sites, have lost area in WCE and gained in SEU from 1980 to 2014 (Xi et al., 2021). Forests in WCE were impacted by the extreme heat and drought event of 2018, with effects lasting into 2019 (Schuldt et al., 2020) and losses in conifer timber sales in Europe (Hlásny et al., 2021).

Extirpation, e.g. local losses of species, have been observed in response to climate change in Europe (*medium confidence*) (Wiens, 2016; EEA, 2017a; Soroye et al., 2020). Strong climate-induced declines have been detected in thermosensitive taxa (Hellmann et al., 2016), including many freshwater groups, insects (Habel et al., 2019; Harris et al., 2019; Seibold et al., 2019; Soroye et al., 2020), amphibians, reptiles (Falaschi et al., 2019), birds (Lehikoinen et al., 2019) and fishes (Myers et al., 2017a; Jarić et al., 2019). The loss of native species, especially specialised taxa, is changing biodiversity; however overall biodiversity could remain stable because losses may be compensated by range shifts of native and the establishment of non-native species (Dornelas et al., 2014; McGill et al., 2015; Hillebrand et al., 2018; Outhwaite et al., 2020).

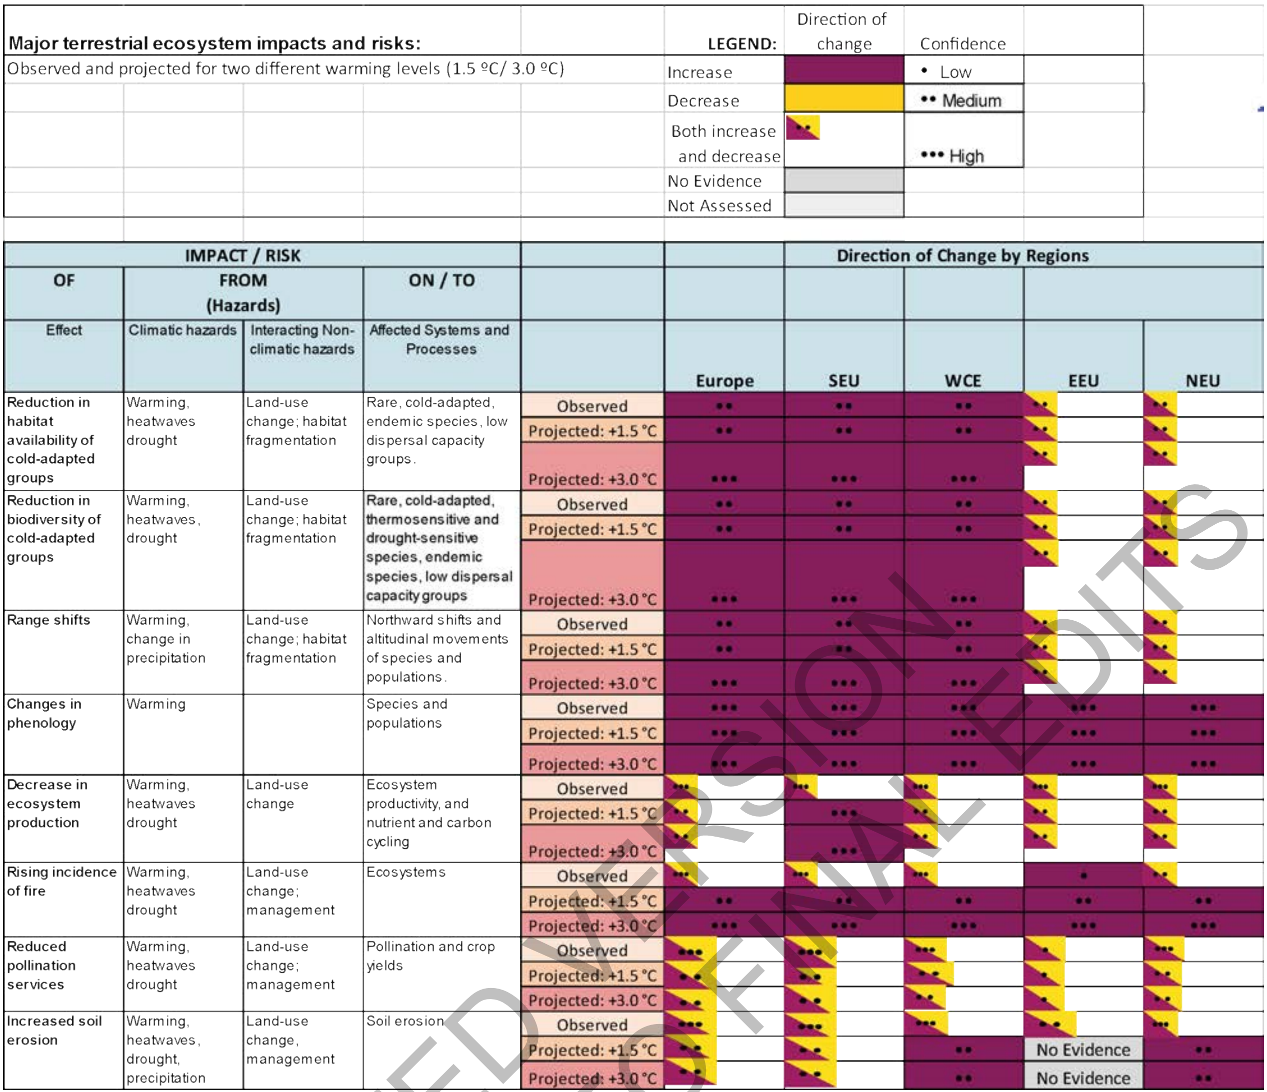

Figure 13.8: Summary of major impacts on and risks for terrestrial and freshwater ecosystems in Europe for 1.5ºC and 3ºC GWL (Table SM13.2).

Range shifts are leading to northward and upward expansions of warm-adapted taxa (*very high confidence*) (Figure 13.8 and Chapter 2). These shifts altered species living in the boreal and alpine tundra (Elmhagen et al., 2015; Post et al., 2019; Mekonnen et al., 2021) and are greening the high Arctic tundra with shrubs and trees (Myers-Smith et al., 2020). Plants display more stable distributions at low than at higher mountain altitudes (Rumpf et al., 2018). Microclimatic variability in some locations can buffer warming impacts (*medium confidence*) (Suggitt et al., 2018; Zellweger et al., 2020; Carnicer et al., 2021). Northward shifts of tree species distributions is documented in North Western Europe (Bryn and Potthoff, 2018; Mamet et al., 2019) but not consistently detected (Cudlín et al., 2017; Vilà-Cabrera et al., 2019).

The timing of many processes, including spring leaf unfolding and autumn senescence and flight dates changed in response to changes in seasonal temperatures, water and light availability (*very high confidence*) (Chapter 2, Szabó et al., 2016; Asse et al., 2018; Peaucelle et al., 2019; Menzel et al., 2020; Rosbakh et al., 2021), resulting e.g. in earlier arrival dates for many birds and butterflies (Karlsson, 2014; Bobretsov et al., 2019; Lehikoinen et al., 2019). Greatest growing season lengthening in plants has been detected in WCE, NEU and EEU, but shortening in parts of SEU driven by later senescence (Garonna et al., 2014), increasing population growth for butterflies and moths (Macgregor et al., 2019) and birds (Halupka and Halupka, 2017), and residence time for migrant birds (Newson et al., 2016).

13.3.1.2 Projected Risks for Terrestrial and Freshwater Ecosystems

Risks for terrestrial ecosystems will increase with warming (*very high confidence*) with high impacts at > 2.4ºC GWL and very high impacts > 3.5ºC GWL (*medium confidence*) (13.10.3.1). Land use changes will increase extirpation and extinction risk (Vermaat et al., 2017) (*very high confidence*). In NEU, biodiversity vulnerability is projected to be lower as new climate and habitat space is becoming available (Warren et al., 2018; Harrison et al., 2019). Warming < 1.5ºC GWL would limit risks to biodiversity, while 4ºC GWL and intensive land use may lead to a loss of suitable climate and habitat space for most species (*low confidence*) (Warren et al., 2018; Harrison et al., 2019).

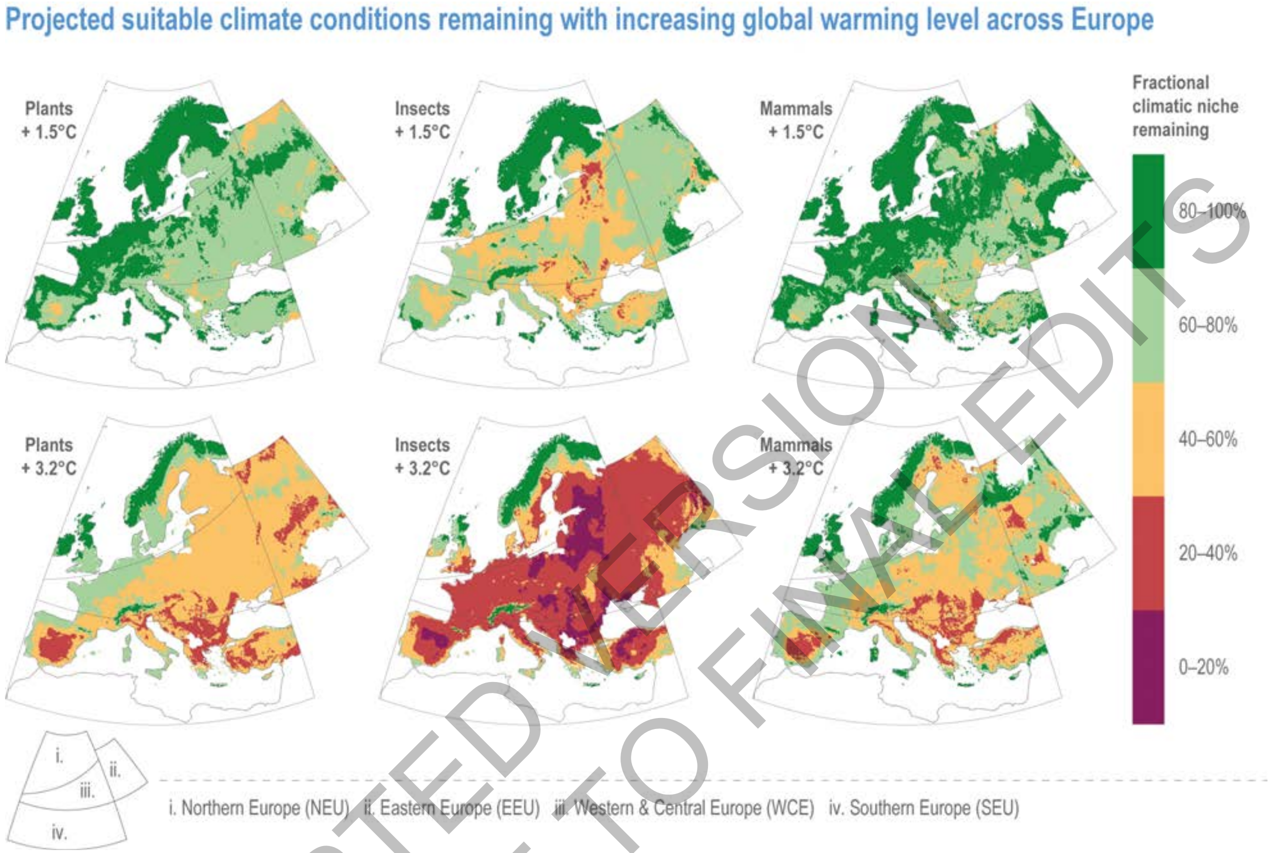

Figure 13.9: Species projected to remain within their suitable climate conditions at increasing levels of climate change. Colour shading represent proportion of species projected to remain within their suitable climates averaged over 21 CMIP5 climate models (Warren et al., 2018). Areas shaded in green retain a large number of species with suitable climate conditions, while those in purple represent areas where climates become unsuitable for more than 80% of the without dispersal (Table SM13.3).

Disruption of habitat connectivity reduces resilience and is projected to impact 30% of lake and river catchments in Europe by 2030, through drought and reduced river flows (Markovic et al., 2017) (*medium evidence*). Average wetland area is not projected to change at 1.7°C GWL across Europe, while for > 4°C GWL expanding sites in NEU are not sufficient to balance losses in SEU and WCE (*high confidence*) (Xi et al., 2021). At 3°C GWL the alpine tundra habitat and its associated species are projected to be lost in the Pyrenees and shrink dramatically in NEU, WCE and EEU (Anisimov et al., 2017; Barredo et al., 2020).

Population range shifts (Figure 13.7, 13.10) are projected to continue (Figure 13.8) (*medium confidence* at 1.5° GWL, *high confidence* at 3.0°C GWL). The largest losses of suitable climatic conditions are projected for plants and insects, with different taxon-specific regions of highest risk, while proportions of species projected to loose suitable climates are lower for other groups (*medium confidence*) (Figure Box 13.1.1, Table SM13.3, Warren et al., 2018). > 1.5°C GWL will lead to a progressive subtropicalisation in SEU, expanding into WCE at > 3°C GWL, a northward shifting of the temperate domain into NEU (Feyen et al., 2020) (*medium confidence*), and an expansion of desert biomes in EEU (Sergienko and Konstantinov, 2016). Changes in distribution are projected for major tree species in all European regions at 1.7°C GWL (Dyderski et al., 2018; Leskinen et al., 2020), with economic implications for managed forests (13.5.1.4). The longer growth season in NEU and WCE will support the establishment of invasive species (CCP1). < 1.5ºC GWL would limit expansion and novel appearances of pests while > 3.4ºC GWL will make large parts of SEU and WCE suitable for pest, e.g. wood beetles (Urvois et al., 2021), and increase economic losses due to lower harvest quality of timber (Toth et al., 2020).

Risks emerging from climate change for phenology are uncertain, given asynchrony between species, taxa and trophic responses (Thackeray et al., 2016; Posledovich et al., 2018; Keogan et al., 2021) and the complexity of phenological events and their cues (Delgado et al., 2020; Ettinger et al., 2020) (*medium confidence*). Spring events may continue to occur earlier (Gaüzère et al., 2016), but reduced chilling may decrease this temporal shift (Wang et al., 2020). Projections for autumn are mixed, with continuing delays (Prislan et al., 2019) or earlier onset of leaf senescence (Wu et al., 2018), but reduced chilling may also decrease these developments (Wang et al., 2020). Advancement, combined with longer autumn growth, may extend the growing season of trees by two days per decade in SEU (Prislan et al., 2019). Warming to > 3°C GWL will impact forest planning in NEU (Caffarra et al., 2014).

13.3.1.3 Observed Impacts and Projected Risks of Wildfires

Fires affect over 400,000 ha every year in the European Union (San-Miguel-Ayanz et al., 2019), with 85% of the area located in SEU (Khabarov et al., 2016; de Rigo et al., 2017; Costa et al., 2020), where 'fire weather' conditions (determined by temperature, precipitation, wind speed and relative humidity) are most pronounced (Figure 13.10). Fire hazard conditions, including heat waves (Boer et al., 2017), have increased throughout Europe from 1980 to 2019 (Figure 13.10), with substantive increases in SEU and WCE (*high confidence*) (Urbieta et al., 2019; Di Giuseppe et al., 2020; Fargeon et al., 2020). Extreme wildfires have been observed in recent years, including 2017 in Portugal, 2018 in Sweden (Krikken et al., 2021) and 2021 in south-eastern Europe. In SEU, WCE and NEU human activities caused more than 90-95% of the fires, while natural ignition accounts for a substantial portion of burnt area in EEU (Wu et al., 2015; Filipchuk et al., 2018).

Except for Portugal, burnt area in SEU has shown a slightly decreasing trend since 1980, with high inter-annual variability (CCP 4, Turco et al., 2016; de Rigo et al., 2017). In SEU, burned terrestrial biomass declined from 2003 to 2019 (Turco et al., 2016), despite increasing fire risks. This trend is parallel to increasing fire management measures implemented (Fernandez-Anez et al., 2021). The slight increase in burned biomass in WCE and NEU is associated with more hazardous landscape configurations and warming in recent decades (Turco et al., 2016; Urbieta et al., 2019).

Projections of wildfire risks are uncertain due to multiple factors, including compound events, fire-vegetation interaction and social factors (Thompson and Calkin, 2011; San-Miguel-Ayanz et al., 2019). Wildfire risks can increase across all regions of Europe at 1.5°C and 3°C GWL (*medium* to *high confidence*) (Figure 13.8). In SEU, the frequency of heat-induced fire-weather is projected to increase by 14% at 2.5°C GWL and rising to 30% at 4.4°C GWL (Turco et al., 2018; Costa et al., 2020; Ruffault et al., 2020). In the European Arctic, the extent and duration of extreme fire seasons will increase because of increasing extreme fire weather, increased lightning activity, and drier vegetation and ground fuel conditions due to prolonged droughts (McCarty et al., 2021). Projections suggest that new fire-prone regions in Europe could emerge, particularly in WCE and NEU where wildfires have been uncommon and fire management capacity is slowly increasing (Wu et al., 2015; Forzieri et al., 2021).

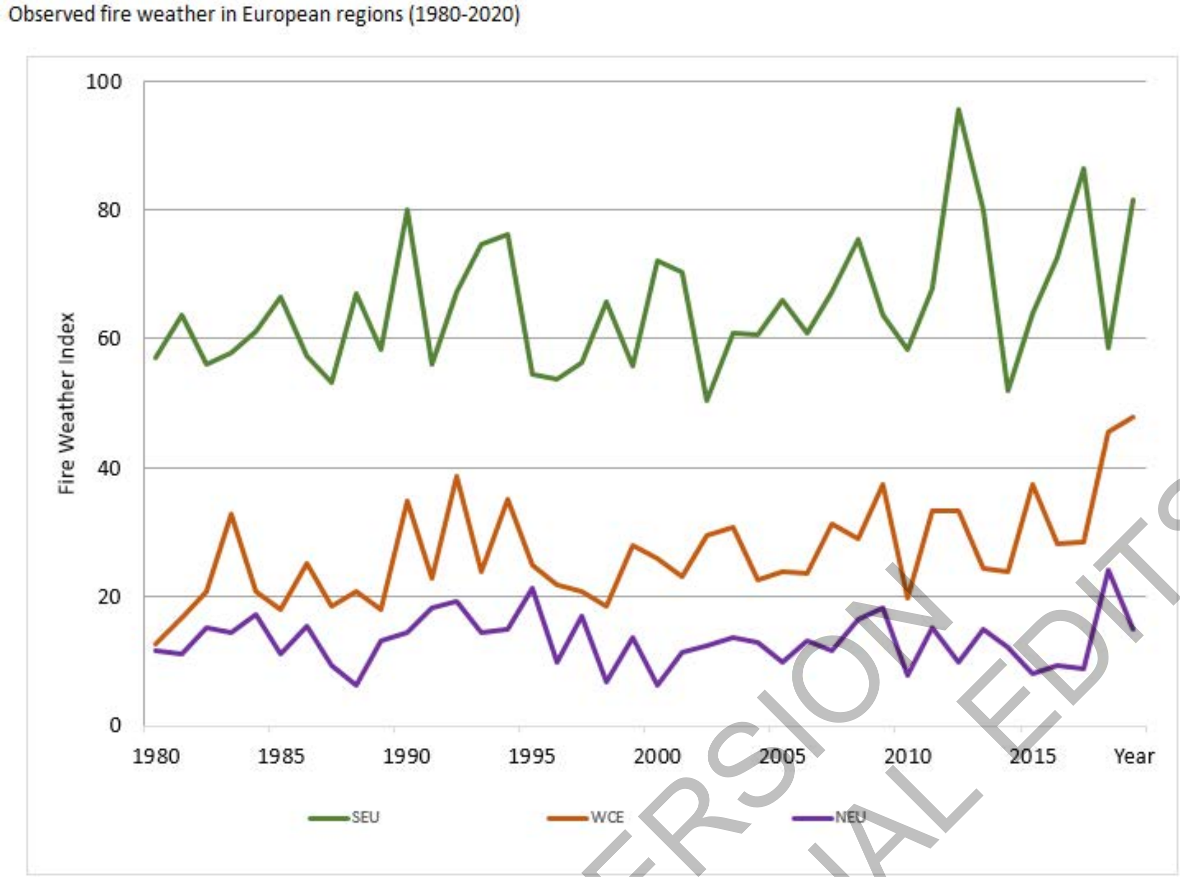

Figure 13.10: Geographical variability and dynamic changes in fire danger in Europe over the last decades. Significant increases in fire hazard at the multidecadal scale and unprecedented years of elevated fire hazard have occurred over the last decade in Southern and Western and Central Europe (SEU, WCE). The environmental conditions required for fires to spread and intensify were evaluated using fire hazard estimates ('Fire Weather Index' (FWI) based on meteorological variables such as temperature, precipitation, wind speed and relative humidity). FWI trends were calculated with the ECMWF ERA-5 FWI reanalysis dataset (Copernicus, 2019; Copernicus, 2020a; Copernicus, 2020b).

13.3.1.4 Observed Impacts and Projected Risks on Ecosystem Functions and Regulating Services

European temperate and boreal forests, wetlands and peatlands hold important carbon stocks (Bukvareva and Zamolodchikov, 2016; Yousefpour et al., 2018). Effects of warming and increasing droughts on soil moisture, respiration and carbon sequestration have been detected across European regions (*high confidence*) (Tab. 13.3, Sanginés de Cárcer et al., 2018; Carnicer et al., 2019; Green et al., 2019; Schuldt et al., 2020). Forest expansion in boreal regions results in net warming (Bright et al., 2017), possibly influencing cloud formation and rainfall patterns (*medium confidence*) (Teuling et al., 2017). These changes are affecting climate, pollination and soil protection services (Table 3.3, Verhagen et al., 2018). If not managed through increased reforestation/revegetation or peatland restoration, future climate change impacts will progressively limit the climate regulation capacity of European terrestrial ecosystems (*medium confidence*) (Figure 13.8), especially in SEU (Peñuelas et al., 2018; Xu et al., 2019). Predominantly positive CO_2 fertilization effects at current warming will change into increasingly negative effects of warming and drought on forests at higher temperatures (*medium confidence*) (Peñuelas et al., 2017; Green et al., 2019; Ito et al., 2020; Wang 2020; Yu et al., 2021). In NEU and EEU, peatlands are projected to shrink with 1.7°C GWL, and become carbon sources at 3°C GWL (Qiu et al., 2020), peat bogs to lose 50% carbon at 2°C GWL, and blanket peatland to shrink or regionally disappear (Gallego-Sala et al., 2010; Ferretto et al., 2019)

Declines in pollinator ranges in response to climate are occurring for many groups in Europe (h*igh confidence*) (Figure Box 13.1.1, Table 13.3, Kerr et al., 2015; Soroye et al., 2020; Zattara and Aizen, 2020), with observed shifts to higher elevations of southern and lower elevation in northern species (Kerr et al., 2015) resulting in higher pollinator richness in NEU (Franzén and Öckinger, 2012). Lags in responses to climate change suggest current impacts on pollination have not been fully realized (IPBES, 2018).

Pollinators are also declining due to lack of suitable habitat, pollution, pesticides, pathogens and competing invasive alien species (Settele et al., 2016; Steele et al., 2019).

Projected climate impacts on pollinators show mixed responses across Europe, but are greater under 3°C GWL (*medium confidence*) (Rasmont et al., 2015). Increasing homogenisation of populations may increase vulnerability to extreme events (Vasiliev and Greenwood, 2021). Geographic changes to the climatic niche of pollinators are similar to insects, with mixed trends, depending on group and location (Figure 13.9, Kaloveloni et al., 2015; Rasmont et al., 2015; Radenković et al., 2017). In NEU, species richness may increase for some groups (Rasmont et al., 2015), with unclear trends for bumblebees (Fourcade et al., 2019; Soroye et al., 2020). Future land use will have important effects on pollinator distribution (Marshall, 2018) as habitat fragmentation in densely populated Europe decreases opportunities for range shifts and micro-climatic buffering (Vasiliev and Greenwood, 2021).

Soil erosion varies across Europe, with higher rates in parts of SEU and WCE, but lower in NEU (*high confidence*) (Table 13.3, Petz et al., 2016; Polce et al., 2016; Borrelli et al., 2020), related to vegetation type and amount of cover, slope and soil type (Panagos et al., 2015a). Short-term, land use change and management may impact soil erosion more than climate (Verhagen et al., 2018). Where conservation agriculture is practised or vegetation cover increasing, erosion is slightly decreasing (Panagos et al., 2015b; Guerra et al., 2016). Reduced soil loss due to reduced spring snow melt has been observed in EEU (Golosov et al., 2018) , while fire exacerbates soil loss, especially in SEU (Borrelli et al., 2016; Borrelli et al., 2017).

Projected increase in rainfall could increase soil erosion, while warming enhances vegetation cover, leading to overall mixed responses (*medium confidence*) (Berberoglu et al., 2020; Ciampalini et al., 2020). In Europe, rainfall erosivity could increase by >81% (Panagos et al., 2017) at 2°C GWL, especially in NEU (Borrelli et al., 2020) where risks can be limited by soil erosion control (Polce et al., 2016). Decreased rainfall projected for parts of SEU could reduce erosion, although increases in rainfall intensity could offset this (Serpa et al., 2015). Soil losses from fire will increase in SEU in response to 2°C GWL (Pastor et al., 2019), especially if combined with extreme rainfall (Morán-Ordóñez et al., 2020). In northern regions, reduced soil losses are projected during spring snowmelt (Svetlitchnyi, 2020).

13.3.2 Solution Space and Adaptation Options

Autonomous species adaptation, via range shifts towards higher latitudes and altitudes and changes in phenology, but extirpation have been documented in all European regions (Figure 13.8) (*very high confidence*). Lowering vulnerability by reducing other anthropogenic impacts (Gillingham et al., 2015), such as land use change, habitat fragmentation (Eigenbrod et al., 2015; Oliver et al., 2017; Wessely et al., 2017), pollution, and deforestation (Chapter 2), enhances adaptation capacity and biodiversity conservation (*high confidence*) (Ockendon et al., 2018). Protected areas, such as the EU Natura 2000 network, have contributed to biodiversity protection (*medium confidence*) (Gaüzère et al., 2016; Sanderson et al., 2016; Santini et al., 2016; Hermoso et al., 2018) but 60% of terrestrial species in these sites could lose suitable climate niches at 4°C GWL (Figure Box 13.1.1, EEA, 2017a).

Most protected areas are static and thus do not take species migration into consideration (*high confidence*) (Gillingham et al., 2015; Heikkinen et al., 2020b). More dynamic areas of protection, such as networks of protected areas with corridors, buffer zones and zoning, can facilitate population shifts (Barredo et al., 2016; Nila et al., 2019; Crick et al., 2020; Keeley et al., 2021) and thereby reduce but not eliminate vulnerability (Wessely et al., 2017; Pavón-Jordán et al., 2020).

Rehabilitation and restoration of land (Prober et al., 2019), particularly abandoned agricultural areas in SEU and NEU (Terres et al., 2015), are long-term strategies to improve regulating services and enhance biodiversity conservation (Morecroft et al., 2019; Campos et al., 2021). Their success will depend on consideration of the future climate niche when restoring peatlands (Bellis et al., 2021) or long-lived species with limited mobility (Hazarika et al., 2021) (*high confidence*). Combination of supporting the resilience of species, increasing functional diversity of habitats, and assisted migration of species at the limit of their adaptive capacity (Park and Talbot, 2018) are needed to protect and restore ecosystems, e.g. forests (Boiffin et al., 2017; Messier et al., 2019). Successful interventions consider habitat and the ecological and evolution interactions of species (Šeho et al., 2019; Diallo et al., 2021) combined with monitoring to assess their effectiveness (Casazza et al., 2021).

Fire management plans and programs are in place in most of SEU, and increasingly developed in the parts of Europe where wildfires are less common (Fernandez-Anez et al., 2021). Capacity to implement and maintain these options remains limited, however (*medium confidence*). The dominant fire management paradigm of fire suppression in some regions of SEU has been questioned, as it contributes to fuel accumulation. Approaches are advocated which combining fire-risk mitigation, prevention, and preparation (Moreira et al., 2020), recovery through post-fire management (Lucas-Borja et al., 2021), diverse fuels treatment (Mirra et al., 2017), including prescribed burning (Fernandes et al., 2013).

Ecosystem-based adaptations (EbA) and nature-based solutions (NbS) that restore or recreate ecosystems, build resilience and produce synergies with adaptation and mitigation in other sectors are increasingly used in Europe (*high confidence*)(Cross-Chapter Box NATURAL in Chapter 2, Berry et al., 2015; Chausson et al., 2020). Planting trees or recreating wetlands can function as part of natural flood management (Dadson et al., 2017; Cooper et al., 2021), whilst urban green infrastructure can reduce flooding (13.2.2) and heat stress and provide recreation opportunities and health benefits (13.6.2.3; Box 13.3) (Kabisch et al., 2016; Choi et al., 2021).

Appropriately implemented ecosystem-based mitigation, such as reforestation with climate-resilient native species (13.3.1.4), peatland and wetland restoration and agroecology (13.5.2), can enhance carbon sequestration or storage (*medium confidence*) (Seddon et al., 2020). Saltmarsh protection or recreation can increase carbon storage capacity, enhance coastal flood protection and provide cultural services (Beaumont et al., 2014; Bindoff et al., 2019). Trade-offs between ecosystem protection, their services and human adaptation and mitigation needs can generate challenges, such as loss of habitats, increased emissions from restored wetlands (Günther et al., 2020) and conflicts between carbon capture services, and provisioning of bioenergy, food, timber and water (Lee et al., 2019; Krause et al., 2020) (*medium confidence*).

The solution space for responding to climate-change risks for terrestrial ecosystem has increased in parts of Europe (*medium confidence*). For example, EbA and NbS figure prominently in the EU Adaptation Strategy (2021a) and climate change adaptation is mainstreamed in the EU Biodiversity Strategy for 2030 (European Comission, 2020), the EU Forest Strategy for 2030 (European Comission, 2021b), the EU Green Infrastructure Strategy (European Comission, 2013a), as well as several national and regional policies. Yet, in the northern parts of EEU and NEU (e.g. Greenland, Iceland, NW Russian Arctic), areas which are often sites of pronounced biodiversity shifts and changes, solutions are lacking or slow in emergence, due to remoteness, lack of resources and sparse populations (Canosa et al., 2020). In the EU, innovative financing schemes such as the Natural Capital Financing Facility are being explored by the European Investment Bank and the European Commission which supports projects delivering on biodiversity and climate adaptation through tailored loans and investments. Multiple EU-level service platforms have been promoted to track climate change impacts on land ecosystems and adaptation (e.g. Climate-Adapt, Copernicus Land and Fire Monitoring Service, Forest Information System of Europe) (13.11.1).

Despite an expanding solution space, widespread implementation and monitoring of natural and planned adaptation across Europe is currently limited, due to high management costs, undervaluation of nature, and conservation laws and regulations that do not consider species shifts under future socioeconomic and climatic changes (*high confidence*) (Kabisch et al., 2016; Prober et al., 2019; Fernandez-Anez et al., 2021). Climate risks are not perceived as urgent due to a continuing perception of high adaptive capacity of ecosystems (Uggla and Lidskog, 2016; Esteve et al., 2018; Vulturius et al., 2018). Limited financial resources prevent widespread implementation of large-scale and connected conservation areas (*high confidence*) (Hermoso et al., 2017; Lee et al., 2019; Krause et al., 2020). Particularly in WCE, competition for land use with other functions, including mitigation options, is a critical barrier to implementation of adaptation. Risks to terrestrial and freshwater ecosystems are rarely integrated into regional and local land use planning, land development plans, and agro-system management (*medium confidence*) (Nila et al., 2019; Heikkinen et al., 2020a) .

13.3.3 Knowledge gaps

Despite growing evidence of climate change impacts and risk, including attributed changes to terrestrial ecosystems (13.10.1), this information is geographically not equally distributed, leaving clear gaps for some processes or regions *(high confidence*). For processes such as wildfire, the Fire Weather Index (13.3.1.3) suggests increasing risks for fires in Europe but robust projections on incidents and magnitudes of wildfire and their impacts on ecosystems and other sectors is currently limited, particularly for NEU, EEU and WCE (*high confidence*).

Many studies consider only individual climate drivers, though new research shows strong interactions between hazards such as warming and drought (13.3.1), as well as non-climatic drivers (Chapter 2). This creates uncertainty about the emergence of extinctions and the magnitudes of impacts for European ecosystems and the services they provide (*high confidence*), such as pollination on food production. RCP-SSP combinations to assess risks are only just emerging (Harrison et al., 2019).

Assessments of the long-term effectiveness of adaptation actions is missing, due to the time lag in determining effectiveness of an action and attributing risk reduction (Morecroft et al., 2019). For example, many landscape restoration actions are discussed but it is unclear which would bring highest benefits and which species should be used for the restoration (Ockendon et al., 2018). Further, adaptation actions will depend on local implementation and benefit from being assessed using cultural and Indigenous knowledge where applicable, but this is hardly studied (*medium confidence*).

13.4 Ocean and Coastal Ecosystems and their Services

13.4.1 Observed Impacts and Projected Risks

13.4.1.1 Observed Impacts

Warming continues to be the key climate hazard for European seas (Figure 13.1). Interacting with other climatic and non-climatic drivers, it has detectable and attributable impacts at a wide range of biological and ecological organisational levels (Figure 13.11).

Major marine ecosystem impacts and risks:

Observed and projected for two different warming levels (1.5 °C/ 3.0 °C)

Figure 13.11: Major impacts and risks for marine and coastal ecosystems in Europe for observed and projected 1.5 °C and 3.0 °C GWL (Table SM13.4).

Particularly habitat loss in shallow coastal waters and at the coasts themselves, and northward distribution shifts of populations and communities are evident across all European marine subregions (Figure 13.11: *high confidence*; Chapter 3). Marine heatwaves have had severe ecological impacts in SEUS (*high confidence*) (CCP 4), threatening sessile benthic biotas and coastal habitats (Munari, 2011; Kersting et al., 2013; Rivetti et al., 2014; Garrabou et al., 2019). Range contractions, extirpations (*medium confidence*) (Smale, 2020) and species redistributions have been observed (*high confidence*) in TEUS (Cottier-Cook et al., 2017) and SEUS (Castellanos-Galindo et al., 2020). Habitat losses, range shifts, species invasions and species thermal preferences altered community compositions (Vasilakopoulos et al., 2017), resulting in the 'subtropicalisation' of TEUS and 'tropicalisation' of SEUS (Chapter 3; CCP 4) and temperature-dependent timing of abundance and reproduction cycles (Hjerne et al., 2019; Polte et al., 2021; Uriarte et al., 2021).

Reductions in growth and reproductive success of calcifying species are not yet unambiguously detected and attributed in European seas (Figure 13.11) (*medium confidence*), as many show resilience (Kroeker et al., 2010; Wall et al., 2015). However, fish population sizes are shrinking (Queirós et al., 2018; Ikpewe et al., 2021), and growth, reproduction and recruitment are negatively impacted (Lindegren et al., 2018; Goldberg et al., 2019; Hidalgo et al., 2019; Vieira et al., 2019; Denechaud et al., 2020; Maynou et al., 2020; Polte et al., 2021), though positive effects also occur (Sguotti et al., 2019; Tanner et al., 2019). Biodiversity changes depend on region, habitat, and taxon (Figure 13.11) (*medium confidence*) overall resulting in the redistribution of biodiversity in Europe (García Molinos et al., 2016), and biodiversity declines in some subregions (*high confidence*) (IPBES, 2018).

Biological and ecological impacts have cascading effects for marine ecosystem functioning (Chivers et al., 2017; Baird et al., 2019) and biogeochemical cycling (Huete-Stauffer et al., 2011; Munari, 2011; Kersting et al., 2013; Rivetti et al., 2014; Garrabou et al., 2019). In TEUS, increased water-column stratification (Section 13.1) and decreasing eutrophication, result in reduced primary production (*high confidence*) (Figure 13.11, Capuzzo et al., 2018) and productivity at higher trophic levels (Free et al., 2019) (*high confidence*), while in NEUS sea-ice decline resulted in primary production increase by 40-60% (Figure 13.11) (*high confidence*) (Arrigo and van Dijken, 2015; Borsheim, 2017; Lewis et al., 2020). Climate-related deoxygenation impacts are small in most European waters (Figure 13.11) (*medium confidence*), expect for semi-enclosed seas such as the Baltic and Black Seas (Frolov et al., 2014; Jacob et al., 2014; Reusch et al., 2018). Here warming and eutrophication altered ecosystem functioning (*high confidence*), reduced potential fish yield, increased harmful algal blooms (Alekseev et al., 2014; Carstensen et al., 2014; Berdalet et al., 2017; Daskalov et al., 2017; Riebesell et al., 2018; Stanev et al., 2018), and the risks of *Vibrio* pathogens and vibriosis (Section 13.7.1, Baker-Austin et al., 2017; Semenza et al., 2017). Across all European seas there is only *low confidence* of a consistent change in provisioning ecosystem services (e.g., fishing yields, Section 13.5), because of interregional variability, but *high confidence* in the decrease in regulating services and coastal protection because of cascading effects of ecosystem impacts (Figure 13.11).

13.4.1.2 Projected Risks

Risks to marine and coastal European ecosystems are *very likely* to intensify (Figure 13.11) in response to projected further warming. Since the capacity of natural systems for autonomous adaptation is limited (Thomsen et al., 2017; Miller et al., 2018; Bindoff et al., 2019) (*medium confidence*), pronounced changes in community composition and biodiversity patterns are projected by 2100 for TEUS and the eastern Mediterranean Sea (SEUS) for> 3°C GWL (García Molinos et al., 2016), challenging conservation efforts (Corrales et al., 2018; Cramer et al., 2018; Kim et al., 2019). At 1.5°C GWL, particularly in winter, Mediterranean coastal fish communities are projected to lose ~10% of species, increasing to ~60% at 4°C GWL (Dahlke et al., 2020), exacerbating regime shifts linked to overexploitation (Clark et al., 2020) (*medium confidence*). Warming at this level will threaten many species currently living in Marine Protected Areas (MPA) in TEUS and NEUS (Bruno et al., 2018). Increasing marine heatwaves (MWH), particularly in SEUS at 4°C GWL (Darmaraki et al., 2019a), elevate risks for species (Galli et al., 2017), coastal biodiversity, and ecosystem functions, goods and services (Smale et al., 2019). However, MWH-related risk levels differ among biotas (Pansch et al., 2018) and across European seas (Smale et al., 2015).

Marine primary production is projected to further decrease by 2100 in most European seas between 0.3% at 1.5°C GWL to 2.7% at 4°C GWL (Figure 13.11) (*high confidence*), mainly caused by stratification-driven reductions in nutrient availability, impacting food webs (Doney et al., 2012; Laufkoetter et al., 2015; Wakelin et al., 2015; Salihoglu et al., 2017; Holt et al., 2018; Bryndum-Buchholz et al., 2019; Carozza et al., 2019; Kwiatkowski et al., 2019). In the Barents Sea, however, largely stable primary production is projected under all scenarios in response to sea-ice decline (Slagstad et al., 2011) and in the eastern Mediterranean due to reduced stratification (Macias et al., 2015; Moullec et al., 2019). These changes in productivity are projected to increase of fish and macroinvertebrate biomass between 5 and 22% (Moullec et al., 2019). Decreasing net primary production will impact higher trophic levels (Section 13.5.1), e.g., in TEUS (Holt et al., 2016; Holt et al., 2018). Marine animal biomass is projected to *likely* decline in most European waters, with decreases < 10% under all scenarios until the 2030s but losses growing to 25% at 2°C GWL and 50% at 4°C GWL in coastal waters of the NE Atlantic (Lotze et al., 2019; Bryndum-Buchholz et al., 2020).

Ocean acidification and its biological and ecological risks are projected to rise in European waters by impeding growth and reproductive success of vulnerable calcifying organisms (Figure 13.11) (*medium confidence*). Coralline algae are projected to reduce skeletal performance at 3°C GWL, with negative consequences for habitat formation (Ragazzola et al., 2016) (*medium confidence*). Regionally (Brodie et al., 2014), differences in species-specific vulnerability will result in community shifts from calcifying macroalgae (Ragazzola et al., 2013) (*medium confidence*) to non-calcifying macroalgae (Gordillo et al., 2016) *(high confidence*). Experimental studies demonstrated high resilience of some important habitat formers, such as the deep-water coral Lophelia pertusa (Wall et al., 2015; Morato et al., 2020), and habitat engineers, such as Mediterranean limpets (Langer et al., 2014), . facilitated by energy reallocation. However, if not supported by sufficient food availability (Thomsen et al., 2013; Clements and Darrow, 2018), such energy reallocation will negatively impact growth or reproduction (*medium confidence*) (Büscher et al., 2017). (Thomsen et al., 2013)This suggests that acidification risks will be amplified by increased stratification and reduced primary production (*medium confidence*). The emergence of harmful algal blooms and pathogens at higher GWLs is unclear across all European seas (Figure 13.11) (*low confidence*).

Risks to marine biotas and ecosystems in European seas are projected to impact important ecosystem services (Figure 13.11). Elevated CO_2 levels predicted at 4°C GWL will affect the C/N ratio of organic-matter export and, hence, the efficiency of the biological pump (*low confidence*), depending on the shifts in plankton composition and, hence, food-web structure (Taucher et al., 2020). Atlantic herring (*Clupea harengus*) will benefit with enhanced larval growth and survival from indirect food-web effects (Sswat et al., 2018a), whereas Atlantic cod (*Gadus morhua*) will face overall negative impacts (*medium confidence*) (Section 13.5, Stiasny et al., 2018; Stiasny et al., 2019). Anoxic dead zones in the Black (Altieri and Gedan, 2015) and the Baltic (Jokinen et al., 2018; Reusch et al., 2018) Seas are projected to increase, e.g., by 5% in the Baltic Sea at 4°C GWL (Saraiva et al., 2019). Europe's coastal vegetated 'blue-carbon' ecosystems (subtidal seagrass meadows and intertidal salt marshes) are highly vulnerable (Spencer et al., 2016; Schuerch et al., 2018; Spivak et al., 2019), particularly in microtidal areas such as the Baltic and Mediterranean coast. Losses are projected for *Posidonia oceanica* seagrass habitats in the Mediterranean by of up to 75% at 2.5°C GWL (*low confidence*) (Chapter 3). The Wadden Sea, the world's largest system of intertidal flats, is projected to reduce in surface area and height, as the sediment transport capacity limits the possibility of growth with rapidly rising sea levels (Wang et al., 2018; Jiang et al., 2020). For the Dutch Wadden Sea, the critical rate of 6 to 10 mm yr^{-1}, at which intertidal flats will start to 'drown', will be reached by 2030 at 1.5°C GWL (*medium confidence*), or even earlier through subsidence due to human activities (van der Spek, 2018). European coastal zones provided a total of €494 billion of ecosystem services in 2018, and 4.2 to 5.1% of this value will be lost due to coastal erosion by 2100 at 2.5°C and 4.6°C GWL, respectively (*medium confidence*) (Paprotny et al., 2021).

13.4.2 Solution Space and Adaptation Options

Human adaptation options for marine systems encompass socio-institutional adaptation, technology, and measures supporting autonomous adaptation (Chapter 3). Integrated Coastal Zone Management (ICZM) and Marine Spatial Planning (MSP) are frameworks for addressing climate-change adaptation needs, as well as operationalizing and enforcing marine conservation. However, ICZM and MSP do commonly not explicitly take climate-change adaptation into consideration (Elliott et al., 2015), Transboundary ICZM and/or MSP (Gormley et al., 2015) will become even more important with the projected acceleration of range extensions and ecological regime shifts due to climate change (IPCC, 2019).

Many climate-change adaptation governance and implementation measures are embedded in international strategies, such as HELCOM (Baltic Marine Environment Protection Commission (HELCOM) (Backer et al., 2010), OSPAR (Convention for the Protection of the Marine Environment of the North-East Atlantic) (OSPAR, 2009), and the Marine Strategy Framework Directive (MFSD) and European Water Framework Directive (EWFD) of the European Union. In the Russian Arctic, mainly the Barents Sea, conservation priority areas (CPA) have been identified as Ecologically and Biologically Significant Areas (EBSA) (Solovyev et al., 2017). However, plans are generally at a relatively early stage (Miller et al., 2018), and assessments of the effectiveness of these policy frameworks to accelerate climate-change adaptation are ongoing (Haasnoot et al., 2020a).

'Green' adaptations, either 'Ecosystem based Adaptations' or 'Nature based Solutions, are part of adaptive management strategies (European Comission, 2011) that facilitate coastal flood protection (Section 13.2.2; Chapter 3; CCC SLR) and generate benefits beyond habitat creation (*medium confidence*), e.g., from avoided expenditures for flood defence infrastructure and avoided loss of the built assets (Gedan et al., 2010). Marine Protected Areas (MPAs) have been identified as adaptation options for natural areas, including permitted and non-permitted uses (Chapter 3, Selig et al., 2014; Hopkins et al., 2016a; Roberts et al., 2017). The extent of MPAs has been increasing in Europe, albeit with strong regional variations (Figure 13.12). MPAs provide protection from local stressors, such as commercial exploitation, and enhance the resilience of marine and coastal ecosystems and thus lessen the impacts of climate change (*medium confidence*) (Narayan et al., 2016; Roberts et al., 2017). However, climate change risk reduction is only a limited MPA objective (Hopkins et al., 2016b; Rilov et al., 2019). The implementation of the legal frameworks, such as the EC Habitats Directive and EC Birds Directive, allows for enabling adaptation (Verschuuren, 2015) as does the incorporation of climate considerations in management of Natura 2000 sites (European Comission, 2013b).

There is evidence that better international cooperation is required to increase effectiveness of the MSFD (Cavallo et al., 2019), and the Good Environmental Status is currently not effectively monitored (Machado et al., 2019).

The greatest benefits are obtained from large, long established, no-take MPAs (Edgar et al., 2014). Yet most MPAs in Europe are partially protected or multi-use areas, and existing no-take areas tend to be very small (< 50 km^2). No take areas are accounting in total for less than 0.4% of the area European waters (Figure 13.12) and are often nested within multi-use MPAs. In some partially protected MPAs, local stressors, such as fishing, are higher than adjacent unprotected areas (*medium confidence*) (Zupan et al., 2018a; Mazaris et al., 2019). Despite evidence for climate mitigation benefits of no-take zones (Roberts et al., 2017), the efficacy of partial protected MPAs is debated and dependent on local management (Zupan et al., 2018b). MPAs of all types require effective management to contribute to mitigating climate change impacts, including effective monitoring and enforcement (Watson et al., 2014), yet the management effectiveness of European MPAs has repeatedly been called into question (Batista and Cabral, 2016; Amengual and Alvarez-Berastegui, 2018; Fraschetti et al., 2018; Rilov et al., 2019). Many MPAs lack management plans, and insufficient resources are frequently an issue (Álvarez-Fernández et al., 2017; Schéré et al., 2020). Thus, whilst substantial in potential, the current capacity of the European MPA network to reduce climate change impacts is limited (Jones et al., 2016; Claudet et al., 2020).

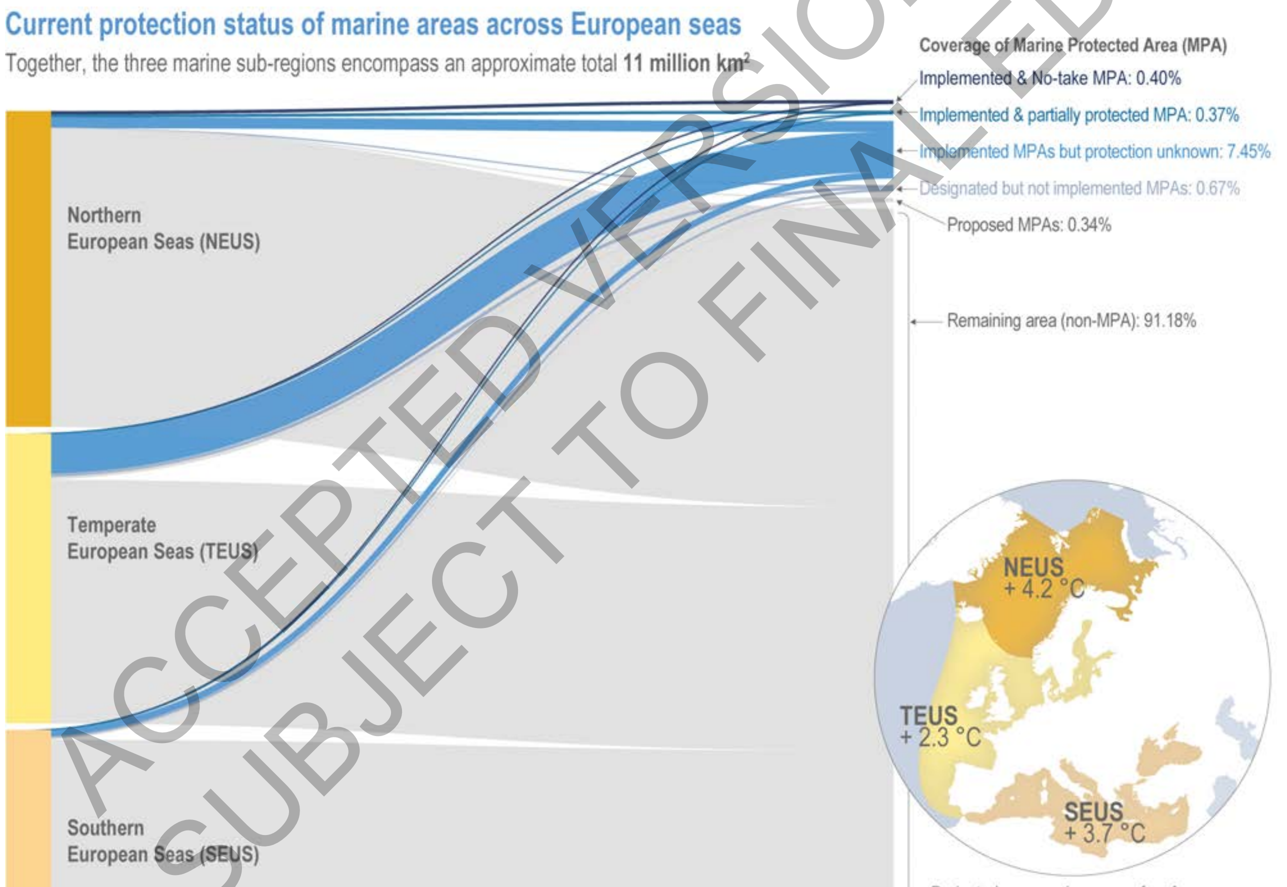

Figure 13.12: Marine Protected Areas (MPA) in European seas. Proportions of designated and proposed MPAs in the total areas of northern (NEUS), temperate (TEUS) and southern (SEUS) European seas, as well as the shares of no-take, partial, unimplemented and unknown protection levels of designated MPAs (Marine Conservation Institute, 2021). Moreover, the average increase of surface-sea temperatures (SST) at 4.0°C GWL by 2100 in NEUS, TEUS and SEUS is indicated.

Conservation approaches (MPAs, climate refugia), habitat restoration efforts (Bekkby et al., 2020), and further ecosystem-based management policies do support alleviation of or adaptation to climate-change impacts (*medium confidence*) but are themselves impacted by climate change (Chapter 3). Moreover, the interaction of adaptation and mitigation measures poses risks to marine systems. Many coastal regions of the North Sea, especially in the south, are particularly susceptible to rising sea levels because of the strong tidal regime and the effects of storm surges (Figure 13.3). Hard measures to protect human infrastructure against sea level rise (Section 13.2) will lead to loss of coastal habitats, with negative impacts on marine biodiversity (Cross-Chapter Box SLR in Chapter 3, Airoldi and Beck, 2007; Cooper et al., 2016). While rising sea levels will also directly threaten intertidal and beach ecosystems, coastal wetlands will benefit (*medium confidence*), in case lateral accommodation space and the opportunity for systems to migrate landwards and upwards is provided, enhancing their ability to capture and store carbon (Rogers et al., 2019) (WGIII AR6 Chapter 4). In general, European coastal blue-carbon ecosystems, e.g. seagrass meadows, kelp forests, tidal marshes (Bekkby et al., 2020) are potentially effective as carbon sinks in climate mitigation, akin to reforestration efforts on land (section 13.3). However, their expansion has the potential to interfere with other ecosystem services (Cadier et al., 2020) and biodiversity conservation (Howard et al., 2017; Chausson et al., 2020). The 'Blue Growth' strategy of the European Commission with the aim to increase offshore activities (European Comission, 2012) will increase the pressures on the marine environments (*medium confidence*). Large-scale offshore wind-park infrastructure is currently developed in European seas, mostly in the North Sea (WindEuropeBusinessIntelligence, 2019), as a major component of climate-change mitigation efforts (WGIII AR6 Chapter 6). The introduction of novel hard-substrate intertidal habitats has and will have profound ecological ramifications for marine systems, including hydrodynamic changes, stepping-stones for non-native species, noise and vibration, and changes of the food web (Lindeboom et al., 2011; De Mesel et al., 2015; Gill et al., 2018; Dannheim et al., 2019) (*high confidence*).

13.4.3 Knowledge Gaps

Major knowledge gaps are uncertainties and shortcomings in our understanding of combined, cascading and interacting impacts of climatic and non-climatic pressures on European marine and coastal socio-ecological systems (Korpinen et al., 2021). Further observational, experimental, and modelling work will enhance the insight into multiple drivers, processes and their interactions, strengthen the confidence of risk projections and provide a foundation for future adaptation actions.

There is limited knowledge about the connectivity among populations, species, and ecosystems which would provide new recruits, enable gene flow in Marine Protected Areas (MPA) networks (Dubois et al., 2016; Sahyoun et al., 2016), and facilitate assisted migration. MPAs cover a wide range of protection status with *limited evidence* which level of protection and connectivity is needed to achieve adaptations goals in response to future warming.

Although European seas and coasts are comparatively well-studied on a global scale, the spatial and temporal resolution and coverage of open-access data is still limited in many regions, particularly in eastern Europe. The detection and attribution of ongoing or emerging environmental and biological changes is therefore limited. Some efforts are in place, such as the six 'Sea-basin Checkpoints' (North Sea, Mediterranean Sea, Arctic, Atlantic, Baltic, Black Sea) that were established since 2013 under The European Marine Observation and Data Network, but high quality observations of key ocean characteristics at the level of regional sea-basins are still too scarce to support decision-making for marine adaptation (Míguez et al., 2019).

13.5 Food, Fibre, and Other Ecosystem Products

13.5.1 Observed Impacts and Projected Risks

13.5.1.1 Crop Production

Agriculture is the primary user of land in Europe. In 2013, Europe provided 28% of cereals, 59% of sugar beet and 60% of wine produced globally, as well as being part of a globalized food system with a third of the commodities produced and consumed in Europe traded internationally (FAOSTAT, 2019).

Observed climate change has led to a northward movement of agro-climatic zones in Europe and earlier onset of the growing season (Ceglar et al., 2019) (*high confidence*). Warming and precipitation changes since 1990 explain continent-wide reductions in yield of wheat and barley and increases in maize and sugar beet (*high confidence*) (Fontana et al., 2015; Moore and Lobell, 2015; Ray et al., 2015; Ceglar et al., 2017). Heat stress has increased in southern Europe in spring, in summer throughout central and southern Europe, and recently expanded into the southern boreal zone (Fontana et al., 2015; Ceglar et al., 2019). Drought, excessive rain, and the compound hazards of drought and heat (13.2.1, 13.3.1, 13.10.2) increased costs and cause economic losses in forest productivity (Schuldt et al., 2020) and annual and permanent crops and livestock farming (Stahl et al., 2016), including losses in wheat production in the EU (van der Velde et al., 2018) and EEU (Ivanov et al., 2016; Loboda et al., 2017) (*high confidence*), with the severity of impacts from extreme heat and drought tripling over last 50 years (Brás et al., 2021). Meteorological extremes due to compound effects of cold winters, excessive autumn and spring precipitation, and summer drought caused production losses (up to 30% relative to trend expectations) in 2012, 2016, 2018 (Ben-Ari et al., 2018; van der Velde et al., 2018; Zscheischler et al., 2018; Toreti et al., 2019b) that were exceptional compared to recent decades (Webber et al., 2020). Regionally, warming caused increases in yields of field grown fruiting vegetables, decreases in root vegetables, tomatoes and cucumbers (Potopová et al., 2017) and earlier flowering of olive trees (Garcia-Mozo et al., 2015) (*high confidence*). Delayed harvest due to both wet conditions and earlier harvests in central Europe in response to warming impacted wine quality (Cook and Wolkovich, 2016; van Leeuwen and Darriet, 2016; Di Lena et al., 2019).

Evidence for growing regional differences of projected climate risks is increasing since AR5 (*high confidence*). While there is high agreement of the direction of change, the absolute yield losses are uncertain due to differences in model parameterization and whether adaptation options are represented (*high confidence*) (Donatelli et al., 2015; Moore and Lobell, 2015; Knox et al., 2016; Webber et al., 2018). At 1.5°C GWL, compound events which led to recent large wheat losses are projected to become 12% more frequent (Ben-Ari et al., 2018). Growing regions will shift northward or expand for melons (Bisbis et al., 2019), tomatoes and grapevines reaching NEU and EEU in 2050 under 1.5°C GWL (Hannah et al., 2013; Litskas et al., 2019) (*high confidence*), while warming would increase yields of onions, Chinese cabbage and French beans (Bisbis et al., 2019) (*medium confidence*). In response to 2°C GWL, agro-climatic zones in Europe are expected to move northward 25-135 km/decade, fastest in EEU (Ceglar et al., 2019). Negative impacts of warming and drought are counterbalanced by CO_2 fertilization for crops such as winter wheat (*medium confidence, medium agreement*), resulting in some regional yield increases with climate change (Zhao et al., 2017; Webber et al., 2018).

Reductions in agricultural yields will be higher in the south at 4°C GWL, with lower losses or gains in the north (Figure 13.5, Trnka et al., 2014; Webber et al., 2016; Szewczyk et al., 2018) (*high confidence*). Largest impacts of warming are projected for maize in SEU (Deryng et al., 2014; Knox et al., 2016) (*high confidence*) with yield losses across Europe of 10-25% at 1.5-2°C GWL and 50-100% at 4°C GWL (Deryng et al., 2014; Webber et al., 2018; Feyen et al., 2020).

Use of longer season varieties can compensate for heat stress on maize in WCE and lead to yield increases for Northern Europe, but not SEU for 4°C GWL (Siebert et al., 2017; Ceglar et al., 2019) (*medium confidence*). Irrigation can reduces projected heat and drought stress, e.g., for wheat and maize (Ruiz-Ramos et al., 2018; Feyen et al., 2020), but use is limited by water availability (13.2.1; KR3). The advantages of a longer growing season in NEU and EEU are outbalanced by the increased risk of early spring and summer heat waves (Ceglar et al., 2019).

Warming causes range expansion and alters host pathogen association of pests, diseases and weeds affecting health for European crops (Caffarra et al., 2012; Pushnya and Shirinyan, 2015; Latchininsky, 2017) *(high confidence*) with high risk for contamination of cereals (Moretti et al., 2019). Regionally predicted reduction in rainfall (13.1) can lead to carryover of herbicides (Karkanis et al., 2018).

Net yield losses will reduce economic output in the EU from agriculture, reaching a reduction of 7% for the EU and UK combined, and 10% in SEU at 4°C GWL (Naumann et al., 2021). Farmland values are projected to decrease by 5-9% per degree of warming in SEU (Van Passel et al., 2017). Increased heat and drought stress and reduced irrigation water availability will decreased profitability and cause abandonment of farmland in SEU (Holman et al., 2017) (*limited evidence, low confidence*).

13.5.1.2 Livestock Production

Heat and humidity affect livestock directly exposed in open barns and outdoors, such as dairy cows and goats (Gauly et al., 2013; Bernabucci et al., 2014; Silanikove and Koluman, 2015), and cold adapted husbandry (Box 13.2, Section 13.8.3) (*high confidence*). Heat impacts animal health (Sanker et al., 2013; Lambertz et al., 2014), nutrition, behaviour and welfare (Heinicke et al., 2019), performance and product quality (Gauly and Ammer, 2020). Climate change also impacts grassland production, fodder composition and quality, particularly in SEU (Dumont et al., 2015) and EEU (Bezuglova et al., 2020), as well as altering the prevalence, distribution and load of pathogens and their vectors (2.4.2.7.3) (Morgan et al., 2013; Charlier et al., 2016) (*high confidence*). Projected impacts on poultry and pigs are low due to temperature control in large parts of Europe, but greater in SEU where open systems prevail (Chapter 5).

Warming increases the pasture growing season and farming period in NEU and at higher altitudes (Fuhrer et al., 2014), while longer drought periods and thunderstorms can influence abandonment of remote Alpine pastures, reducing cultural and landscape ecosystem services and losing traditional farming practices (Herzog and Seidl, 2018) (*high confidence*) (Section 13.8.3). At 2-4°C GWL grassland biomass production for forage-fed animals will increase in NEU and the northern Alps, while forage production will decrease in SEU and the southern Alps due to heat and water scarcity (Gauly et al., 2013; Jäger et al., 2020), causing regional reductions of cow milk production in WCE and SEU (Silanikove and Koluman, 2015) (*high confidence*).

13.5.1.3 Aquatic Food Production

Seafood production in Europe provides jobs for >250,000 people, predominantly in SEU (Carvalho et al., 2017). Marine fisheries contribute 80% to European aquatic food production, while marine aquaculture provides 18% and freshwater production 3% (Blanchet et al., 2019). The Russian Federation provides 1/4 of seafood production in Europe (FAOSTAT, 2019).

Climate change has impacted European marine food production (*high confidence*). However, extraction is still the major impact on commercially important fish stocks in Europe (Mullon et al., 2016), with 69% of stocks overfished and 51% outside safe biological limits (Froese et al., 2018). The North Sea, the Iberian coastal Sea and Celtic Sea-Biscay Shelf are globally among the areas most negatively affected by warming with losses of 15-35% in maximum sustainable yields (MSY) during the last decades (Free et al., 2019). Warming caused ongoing northward movement and range expansion of Northeast Atlantic fish stocks (13.4, Baudron et al., 2020). In the North Sea, cuttlefish (van der Kooij et al., 2016; Oesterwind et al., 2020) and tuna (Bennema, 2018; Faillettaz et al., 2019) became new target species (*medium confidence*). In SEU, warm-water species increasingly dominate fisheries landings (Fortibuoni et al., 2015; Teixeira et al., 2016; Vasilakopoulos et al., 2017).

European countries are assessed to be globally among the least vulnerable to the impacts of climate change on fisheries-related food security risks (*high confidence*) due to low levels of exposure to climate hazards, low dependency of economies on fisheries and a high adaptive capacity (Barange et al., 2014; Ding et al., 2017). European freshwater production is suggested to be less vulnerable than marine sectors and marine production vulnerability increases with latitude (Blanchet et al., 2019). In the aquaculture sector Norway is highly vulnerable due to high sensitivity of salmon farming to warming and high per-capita production (Handisyde et al., 2017). In the fisheries sector, vulnerability for fishing communities is highest in SEU and UK (Figure 13.9A , Handisyde et al., 2017; Payne et al., 2021), while for aquaculture sectors it is highest in SEU and some NEU and WCE countries (Figure 13.9B, 2020).

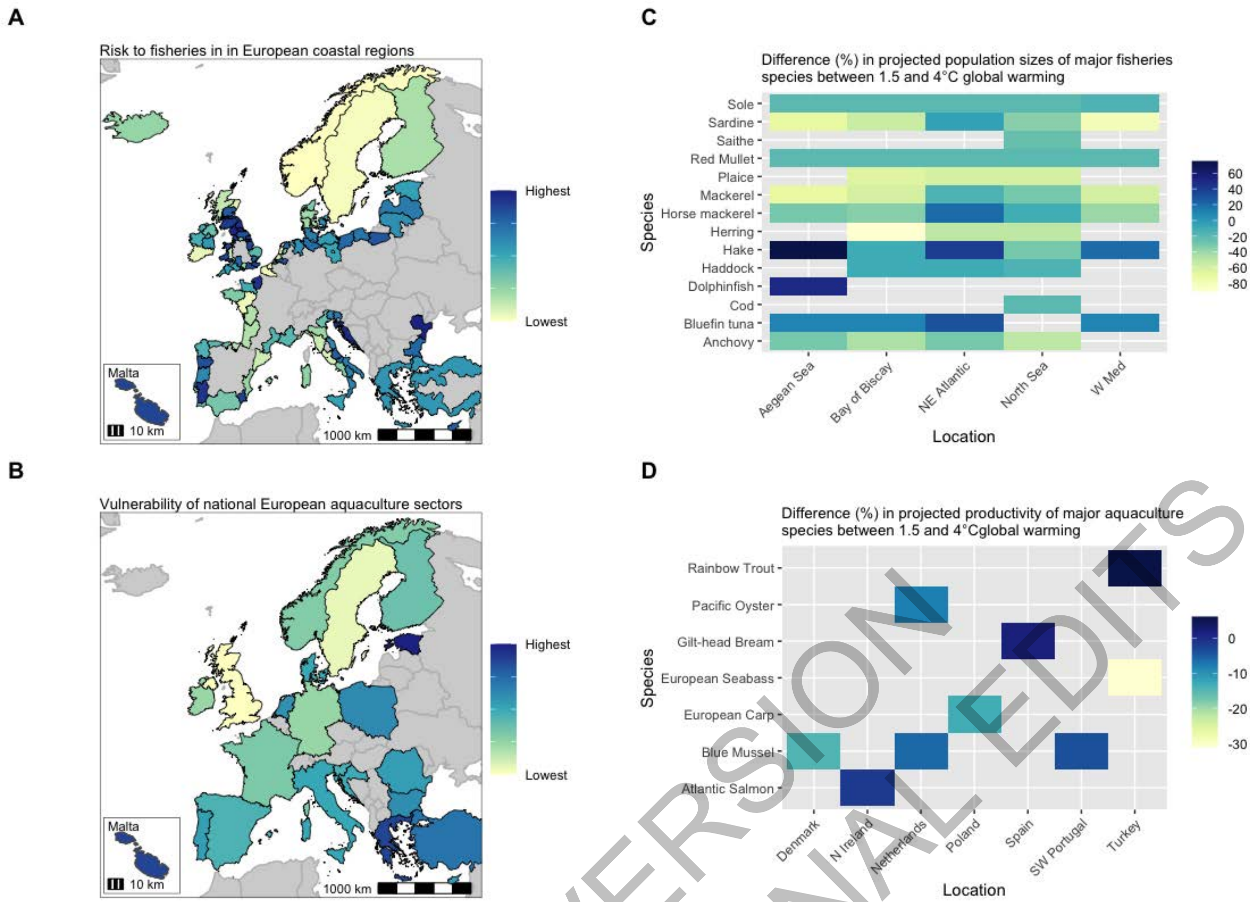

Figure 13.13: Future vulnerability and risks for aquatic food production. (a) Vulnerability for fisheries in 105 coastal regions across 26 countries based on biological traits and physiological metrics of 556 resource populations (Payne et al., 2021); (b) Vulnerability of major aquaculture species in European countries on physiological attributes, farming methods and economic output (Peck et al., 2020); (c-d) Differences (%) between projected changes for 1.5°C and 4°C global warming (Peck et al., 2020), with (c) changes in abundance of major fish species by region, and (d) changes in productivity of major aquaculture species by country.

Future vulnerabilities, risks and opportunities are projected to strongly vary regionally and between major fisheries and aquaculture species (Peck et al., 2020) (Figure 13.13 c,d). Assuming MSY-management, projections suggest reduced abundance of most commercial fish stocks in European waters of 35% (up to 90% for individual stocks) between 1.5°C and 4.0°C GWL (Peck et al., 2020; Payne et al., 2021) (*medium confidence*) (Figure 13.13). In response to 4°C GWL, higher trophic level biomass is projected to increase in the SEUS mainly due to increases of small pelagic and thermophilic, often exotic species (Moullec et al., 2019).

Ocean acidification (Section 13.4, Chapter 4) will develop into a major risk for marine food production in Europe under 4°C GWL (*high confidence*), affecting recruitment of important European fish stocks such as those of cod in the Western Baltic and Barents Sea by 8 and 24%, respectively (Sswat et al., 2018b; Stiasny et al., 2018; Voss et al., 2019). Acidification is also projected to negatively affect marine shellfish production and aquaculture in Europe with 4°C GWL (*medium confidence*) (Fernandes et al., 2017; Narita and Rehdanz, 2017; Mangi et al., 2018).

13.5.1.4 Forestry and Forest Products

Climate change is altering the structure and function of European forests via changes in temperature, precipitation and atmospheric CO_2 as well as through interaction with pests and fire (13.3.1) (Moreno et al., 2018; Morin et al., 2018; Senf et al., 2018; Orlova-Bienkowskaja et al., 2020) (*high confidence*). Species-specific responses of trees to drier summers (Vitali et al., 2018) shape regional variability in European forest productivity in response to water and nutrient availability, heat wave and evaporative demand (Reyer et al., 2014; Kellomäki et al., 2018). While warming and extended growing seasons have positive impacts on forest growth in cold areas in WCE and NEU (Pretzsch et al., 2014; Matskovsky et al., 2020), EEU (Tei et al., 2017) and higher altitude (Sedmáková et al., 2019), drought stress across Europe has been increasing (Primicia et al., 2015; Marqués et al., 2018; Ruiz-Pérez and Vico, 2020) (*high confidence*). Combined with land-use, climate change has increased large scale forest mortality since the 1980s (Senf et al., 2018). Extreme events such as the 2018 drought in WCE caused widespread leaf shedding and mortality of trees (Buras et al., 2020) with carryovers into 2019 (Schuldt et al., 2020) and bark beetle outbreaks (Netherer et al., 2019) resulting in felling and cuttings of more than 1 Million ha of spruce forest and disrupting timber markets (Mauser, 2021).

In response to 3°C GWL, forest productivity is projected to increase in NEU and altitudes, show mix trends in WCE and decreases in SEU (Reyer et al., 2014) (*medium confidence*). This trend is driven by increases in productivity of pine and spruce and decreases of beech and oak and excludes disturbances and management options (Reyer et al., 2014). Water stress exacerbates the incidence from and effects of fire and other natural disturbances (13.3.1), resulting in forest productivity declines or cancelling out productivity gains from CO_2 (Seidl et al., 2014; Reyer et al., 2017) (*high confidence*). In response to 1.7 °C GLW, managed forest and unmanaged woodland areas are projected to decrease only minimally, while at >2.5°C GLW declines increasing for managed forest and unmanaged woodland area increases (Harrison et al., 2019). Reducing warming from 4°C GLW to below 1.7 °C GLW would reduce the Europe wide impacts on managed forest by 34% (Harrison et al., 2019).

13.5.2 Solution Space and Adaptation Options

The solution space for climate change adaption for food and timber includes production related options (13.5.2.1 - 13.5.2.3) and market-based changes to consumer demand and trade (13.5.2.4). The assessment of effectiveness and feasibility of options in the food system is summarised in Figure 13.14.

Effectiveness & feasibility of adaptation options for food system to climate impacts & risk in Europe

Impact Type	Adaptation Option	Effectiveness	Feasibility						Confidence	
			Economic	*Technological*	*Institutional*	*Socio-cultural*	*Ecological*	*Geophysical*	*Evidence*	*Agreement*

Figure 13.14: Effectiveness and feasibility of the main adaptation options for food systems in Europe. (SM13.9 and Table SM13.5).

13.5.2.1 Crops and Livestock

Farm management adaptations options to climate change include changing sowing and harvest dates, changes in cultivars, irrigation and selecting alternative crops (Figure 13.14, 13.15) (Donatelli et al., 2015). Irrigation is effective at reducing yield loss from heat stress and drought, e.g., for wheat and maize (Figure 13.14, 13.15), but increases demand for water withdrawals (Siebert et al., 2017; Ruiz-Ramos et al., 2018; Feyen et al., 2020). Where sufficient water and infrastructure is available, irrigation of wheat reverses yield losses across Europe at 2°C GWL to become gains, while yield losses in maize in SEU are reduced from up to 80% to 11% (Feyen et al., 2020). Extensive droughts during the last two decades caused many irrigated systems in southern Europe to cease production (Stahl et al., 2016) indicating limited adaptive capacity to heat and drought (*medium confidence*). Water management for food production on land is becoming increasingly complex due to the need to satisfy other social and environmental water demands (KR3, 13.10) and is limited by costs and institutional coordination (Iglesias and Garrote, 2015). Agricultural water management adaptation practices include irrigation, reallocating of water to other crops, improving use efficiency, and soil water conservation practices (Iglesias and Garrote, 2015). In-season forecasts of climate impacts on yield have successfully been used in the 2018 drought for European wheat (van der Velde et al., 2018).

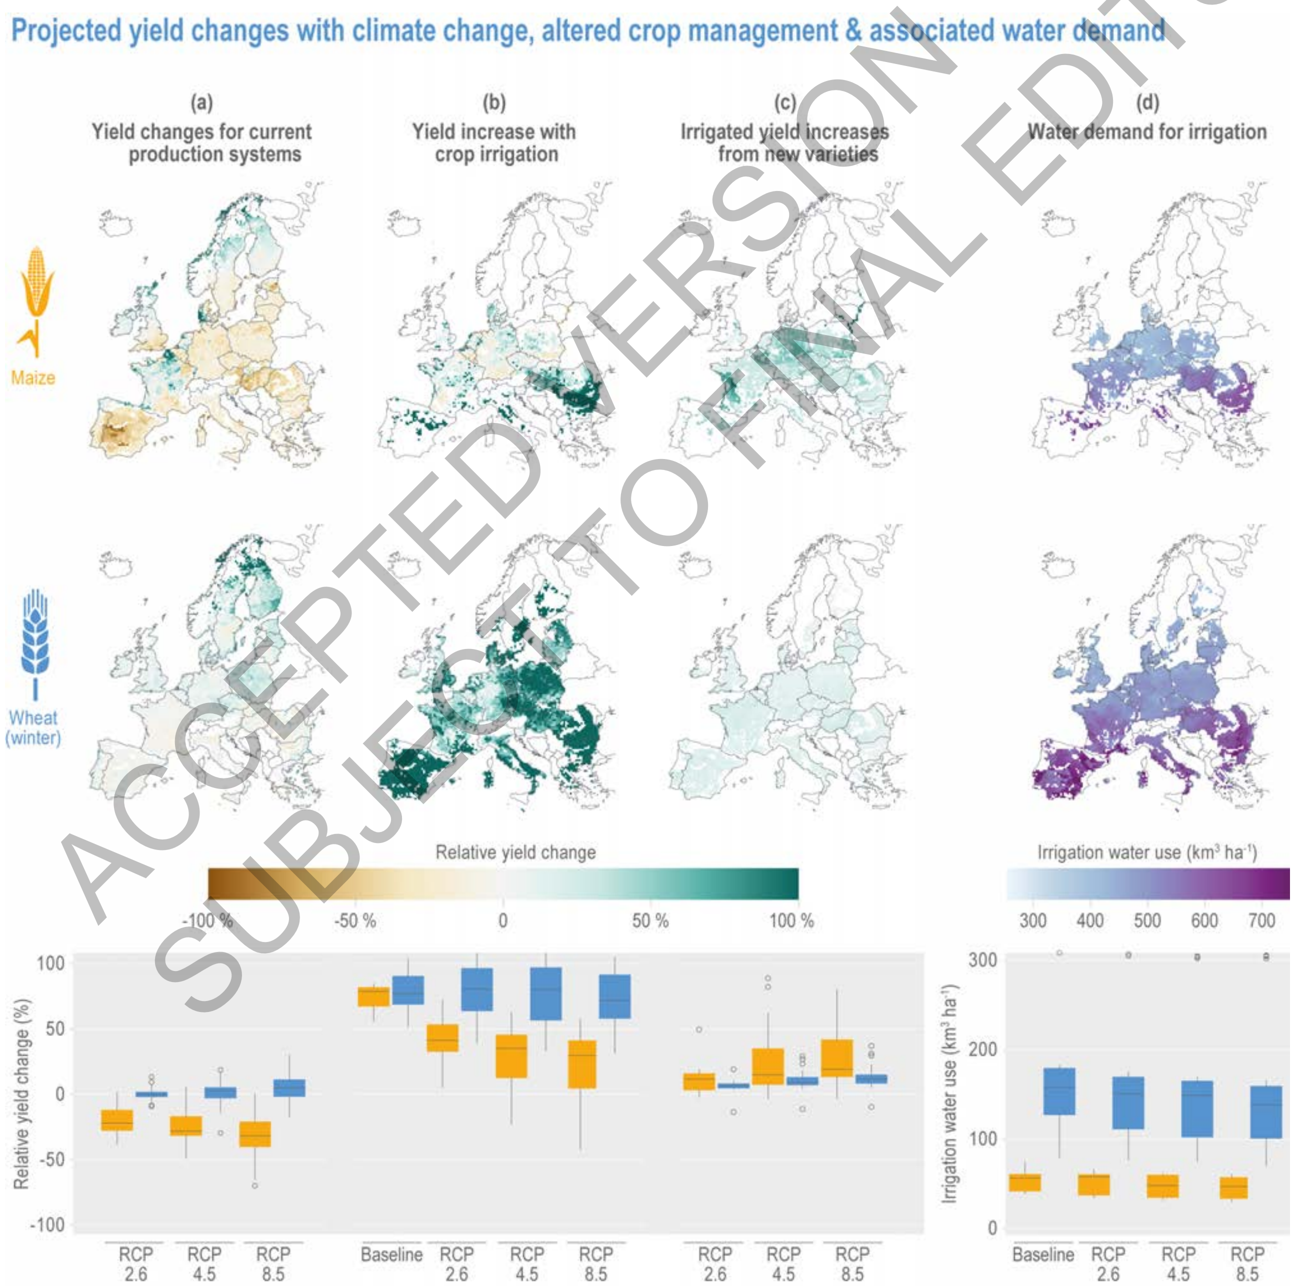

Figure 13.15: Projected yield changes with climate change for 1.5 °C GWL (RCP 2.6), 1.7 °C (RCP4.5) and 2°C GWL (RCP8.5) and altered crop management, and associated water demand, showing: (a) relative yield changes under climate change and elevated CO_2 for current production systems, i.e. rainfed and irrigated simulations weighted by

current share of rainfed and irrigated areas; (b) yield increase if current predominantly rainfed areas are full irrigated; (c) additional yield increases for irrigated production systems if new varieties used to avoid losses associated with faster development and earlier maturity under climate change; and, (d) water demand for irrigated systems with current varieties in currently rainfed areas (Webber et al., 2018). Relative yield changes to a period centred on 2055 to a baseline period centred on 1995. Boxplots are Europe aggregate results considering current production areas (a) or current rainfed areas (b, c) with boxplots showing uncertainty across crop models and GCMs. The maps are for the crop model median for RCP 4.5 (1.7°C GWL) with GFDL-CM3.

Changes to cultivars and sowing dates can reduce yield losses (Figure 13.15), but are insufficient to fully ameliorate losses projected >3℃ GWL, with an increase of risk from north to south and for crops growing later in the season such as maize and wheat (*high confidence*) (Ruiz-Ramos et al., 2018; Feyen et al., 2020). Adaptations for early maturing reduce yield loss by moving the cycle towards a cooler part of year, and also constrains the increases in irrigation water demands, but reduce the period for photosynthesis and grain filling (*high confidence*) (Ruiz-Ramos et al., 2018; Holzkämper, 2020). Crop breeding for drought and heat tolerance can improve sustainability of agricultural production under future climate (Costa et al., 2019), particularly in SEU where drought tolerant varieties provide 30% higher yields than drought-sensitive varieties at 3°C GWL (Senapati et al., 2019). Soil management practices, such as crop residue retention or improved crop rotations, generally undertaken as a mitigation option to increase soil carbon sequestration, are not commonly evaluated for adaptation in European agriculture (Hamidov et al., 2018).

Adaptation practices for livestock systems on European farms commonly focus on controlling cooling, shade provision and management of feeding times (Gauly et al., 2013). These options are used in indoors reared species (Gauly et al., 2013), but limited in mountain pastures (Deléglise et al., 2019) (*high confidence)*. Response options to insufficient amount and quality of fodder include changing feeding strategies (Kaufman et al., 2017; Ammer et al., 2018), feed additives (Ghizzi et al., 2018), relocating livestock linked to improved pasture management, organic farming (Rojas-Downing et al., 2017; EEA, 2019c), importing fodder and reducing stock (Toreti et al., 2019b). Dairy systems that maximize the use of grazed pasture are considered more environmentally sustainable, but are not fully supported by policy and markets (Hennessy et al., 2020) (*medium confidence*). Genetic adaptation of crops, pasture and animals could be a long-term adaptation strategy (Anzures-Olvera et al., 2019; Deléglise et al., 2019). Control strategies for pathogens and vectors include indoor or outdoor rearing and applying new diagnostic tools or drugs (Bett et al., 2017; Vercruysse et al., 2018), and regulations to ensure safe trade and reduce risks of introducing or spreading pests (European Comission, 2016).

Agro-ecological systems provide adaptation options that rely on ecological process (e.g., soil organic matter recycling and functional diversification) to lower inputs without impacting productivity (Cross-Chapter Box NATURAL in Chapter 2 , Aguilera et al., 2020). High frequency rotational grazing and mixed livestock systems are agro-ecological strategies to control pathogens (Aguilera et al., 2020). Agroforestry, integrating trees with crops (silvoarable), livestock (silvopasture), or both (agrosilvopasture) can enhance resilience to climate change (Chapter 5), but implementation in Europe needs improved training programs and policy support (Hernández-Morcillo et al., 2018) (*high confidence*).

Technological innovations including “smart farming” and knowledge training can strengthen farmers’ responses to climate impacts (Deléglise et al., 2019; Kernecker et al., 2019), although strong belief in “technosalvation” by farmers (Ricart et al., 2019) can reduce the solution space and timing of adaptation options. Agricultural policy, market prices, new technology and socio-economic factors play a more important role in short-term farm-level investment decisions than climate change impacts (Juhola et al., 2016; Hamidov et al., 2018) (*high confidence*).

Effective policy guidance is needed to increase the climate-resilience of agriculture (Spinoni et al., 2018; Toreti et al., 2019b). Financial measures include simplifying procedures for obtaining subsidies and insurance premiums and interest rates that incentivise adoption of climate friendly agricultural methods (Garrote et al., 2015; Iglesias and Garrote, 2015; Zakharov and Sharipova, 2017; Hamidov et al., 2018; Wiréhn, 2018). The EU’s Common Agricultural Policy has increasingly focused on environmental outcomes (AllianceEnvironnement, 2018) but does not sufficiently provide for adaptation measures (Leventon et al., 2017; Pe'er et al., 2020). Limits to European farm-level adaptation include lack of resources for investment, political urgency to adapt, institutional capacity, access to adaptation knowledge and information from other countries (EEA, 2019c).

13.5.2.2 Aquatic Food

Climate-resilient fish production in Europe is the goal of the European Union's Common Fisheries Policy (CFP) rebuilding fish stocks to maximum sustainable yield (MSY) levels, but success has been variable (Froese et al., 2018; Stecf, 2019). Adaptation is largely ignored in related EU policy frameworks such as the CFP, the Marine Strategy Framework Directive, and the "Strategic guidelines for the sustainable development of EU aquaculture." (Pham et al., 2021). A major governance challenge for adaptation will be the redistribution of the fixed allocation scheme for total allowable catches (Harte et al., 2019; Baudron et al., 2020). Inflexible and non-adaptive allocation schemes can result in conflicts among European countries (*medium confidence*), as demonstrated by the case of the North East Atlantic mackerel (Spijkers and Boonstra, 2017).

The development of adaptation strategies for seafood production since the Paris Agreement is insufficient in Europe (*high confidence*) (Kalikoski et al., 2018; Pham et al., 2021). Concrete plans for adaptation planning towards climate-ready fisheries and aquaculture are lacking in all parts of Europe (European Comission, 2018), especially accounting for the expected reduced landings of traditional target species and in preparation for a new portfolio of resource species (Blanchet et al., 2019).

Recent scientific progress towards adaptation in European fisheries and aquaculture include conceptual guidance and demonstration cases on climate adaptation planning (Pham et al., 2021) and climate vulnerability assessments (Blanchet et al., 2019; Peck et al., 2020; Payne et al., 2021). Socio-political scenarios for European aquatic resources have been developed and have the potential to inform adaptation planning by European fisheries and aquaculture sectors (Kreiss et al., 2020; Hamon et al., 2021; Pinnegar et al., 2021).

13.5.2.3 Forests

Forest management has been adopted as a frequent strategy to cope with drought, reduce fire risk, and maintain biodiverse landscapes and rural jobs (Hlásny et al., 2014; Fernández-Manjarrés et al., 2018). Successful adaptation strategies include altering the tree species composition to enhance the resilience of European forests (Schelhaas et al., 2015; Zubizarreta-Gerendiain et al., 2017; Pukkala, 2018) (*high confidence*). Greater diversity of tree species reduces vulnerability to pests and pathogens (Felton et al., 2016) and increases resistance to natural disturbances (Jactel et al., 2017; Pukkala, 2018; Pardos et al., 2021) (*high confidence*). Depending on forest successional history (Sheil and Bongers, 2020), tree composition change can increase carbon sequestration (Liang et al., 2016), biodiversity and water quality (Felton et al., 2016) (*high confidence*). Conservation areas can also help climate change adaptation by keeping the forest cover intact, creating favourable microclimates and protecting biodiversity (Jantke et al., 2016) (*low confidence*).

Reforestation reduces warming rates (Zellweger et al., 2020) and extremely warm days (Sonntag et al., 2016) inside forests reducing natural disturbances and fires (*high confidence*). Active management approaches can limit the impact of fires (13.3.1) on forest productivity, including fuel reduction management, prescribed burning, changing from conifers to deciduous, less flammable species, and recreating mixed forests (Feyen et al., 2020) and agroforestry (Damianidis et al., 2020).

13.5.2.4 Demand and Trade

An increasing globalized food system makes European nations sensitive to supply chain disturbances in other parts of the world, but also provides capacity to adapt to production shifts within Europe through changes in international trade (Section 13.9.1) (Alexander et al., 2018; Challinor et al., 2018; Ercin et al., 2021). Consumer demand for food and timber products can adapt to productivity changes and be mediated by price (e.g., in response to production changes or policies on food related taxation), reflect changes in preferences (e.g., towards plant-based foods motivated by environmental, ethical or health concerns), or reductions in food waste (Alexander et al., 2019; Willett et al., 2019) (*high confidence*). Although mitigation potentials of dietary changes have received increasing attention, evidence is lacking on potential for adaptation through changes in European food consumption and trade, despite these socio-economic factors being a strong driver for change (Harrison et al., 2019, Kebede, 2021, Integrated assessment of the food-water-land-ecosystems nexus in Europe: Implications for sustainability) (*medium confidence*). Calls are increasing across Europe for sustainable and resilient agri-food systems acknowledging interdependencies between producers and consumers to deliver healthy, safe and nutritional foods and services (Venghaus and Hake, 2018) (Section 13.7).

13.5.3 Knowledge Gaps

Aggregated projections of impacts, especially of combined hazards, are still rare despite many physiological papers on species specific response to warming in all food sectors (*high confidence*). This is specifically true for scenarios that consider land use change and population growth, though Agri SSPs are currently being developed (Mitter et al., 2019). Effectiveness of adaptation options is predominantly qualitatively mentioned but not assessed and effectiveness of combinations of measures is rarely assessed (Ewert et al., 2015; Holman et al., 2018; Müller et al., 2020) (*high confidence)*. Effective adaptation planning would be supported by better modelling and scenario development including improved coupled nature-human interactions, e.g., with more realistic representation of behaviours beyond economic rationality and 'bottom-up' autonomous farmer adaptations, as well as greater stakeholder involvement.

Coverage of impacts and adaptation options in Europe are biased towards the EU28 and have gaps within the eastern part of WCE and EEU, despite dramatic changes in land use over the recent decades in Russia and Ukraine (*high confidence*) which have the potential to increase production and export of agricultural products, especially wheat, meat and milk (Swinnen et al., 2017).

A bias towards modelling of cereals, specifically wheat and maize, results in gaps in knowledge for fruit and vegetables, especially for temperate regions in Europe (Bisbis et al., 2019). The assessment of irrigation needs and the impact of CO_2 and O_3 tend to focus on individual species and processes hindering upscaling to multiple stressors and mixed production (Challinor et al., 2016; Webber et al., 2016) (*high confidence*).

There is a lack of actionable adaptation strategies for European fisheries and aquaculture. Knowledge gaps include adaptive capacities of local fishing communities to a new mix of target species and the consumer acceptance of the product. Increased knowledge on the effects on freshwater fisheries and their resources is also needed.

13.6 Cities, Settlements and Key Infrastructure

Urban areas in Europe offer home to 547 million inhabitants, corresponding to 74% of the total European population (UN/DESA, 2018). In the EU-28, 39% of the total population lives in metropolitan regions (i.e., areas with at least one million inhabitants) where 47% of the total GDP is generated (Eurostat, 2016). Apart from urban settlements, this section also covers energy and transport systems, as well as tourism, industrial and business sectors which are key for livelihood, economic prosperity and well-being of residents.

13.6.1 Observed Impacts and Projected Risks

13.6.1.1 Energy Systems

The energy sector in Europe already faces impacts from climate extremes (*high confidence*). Significant reductions and interruptions of power supply have been observed during exceptionally dry and/or hot years of the recent 20-year period, e.g. in France, Germany, Switzerland and UK during the extremely hot summer of 2018 which led to water cooling constraints on power plants (van Vliet et al., 2016b; Abi-Samra, 2017; Vogel et al., 2019). Heating degree days decreased and cooling degree days increased during 1951-2014, with clearer trends after 1980 (De Rosa et al., 2015; Spinoni et al., 2015; EEA, 2017b). Projected climate risks for energy supply are summarized in Figure 13.16.

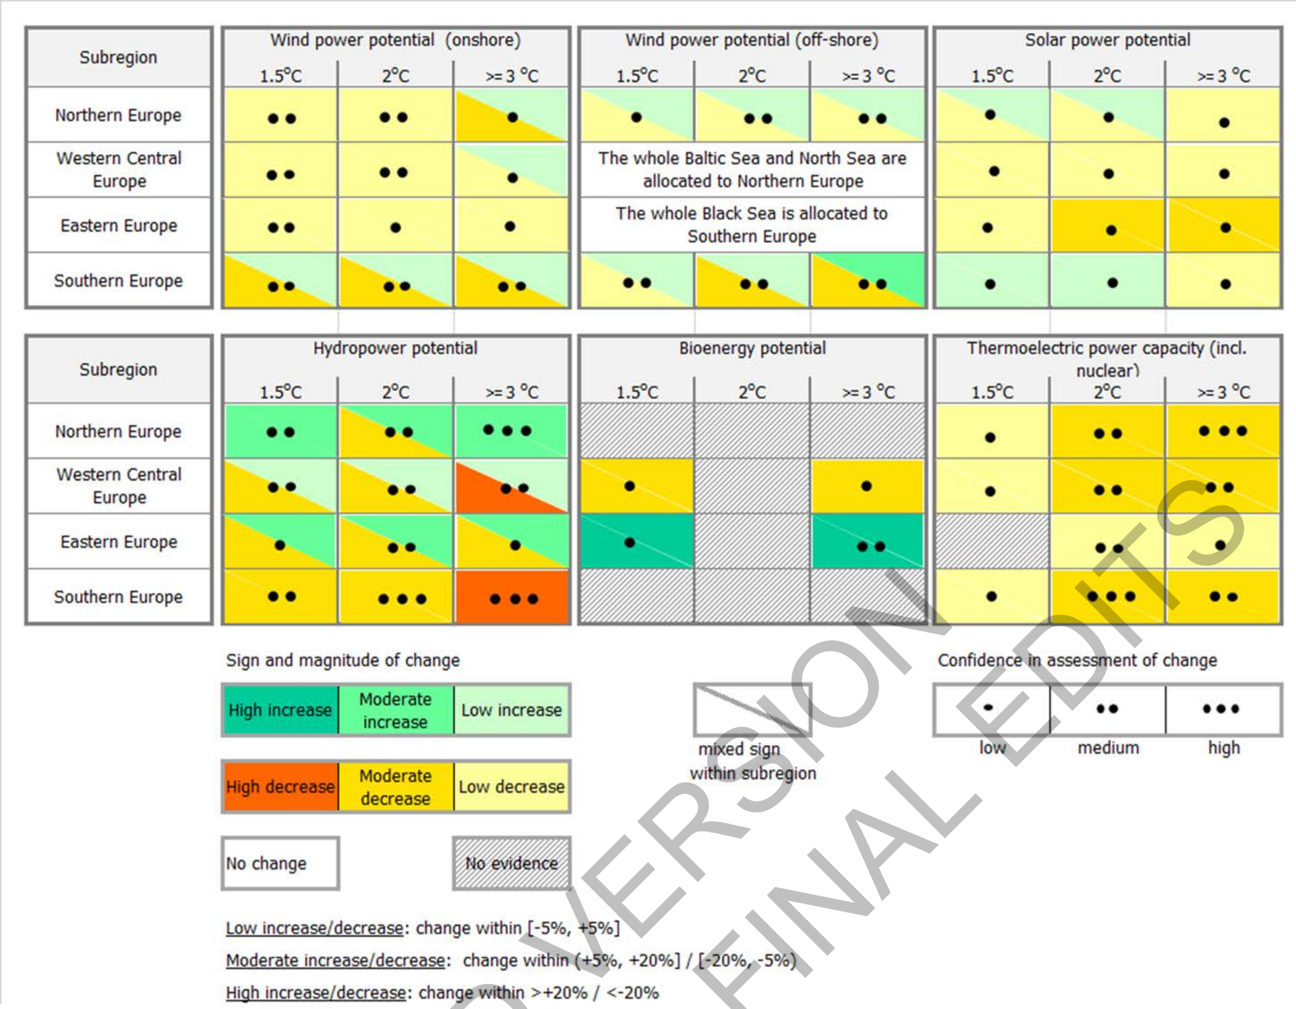

Figure 13.16: Projected climate change risks for energy supply in Europe for major sources and under 1.5 °C, 2 °C and >3 °C GWL (Tables SM13.5.6-13).

New studies reinforce the findings of AR5 on risks for thermoelectric power and regional differences between NEU and SEU regarding risks for hydropower (Figure 13.16). In NEU and EEU, extremely high water inflows to dams are projected to increase flooding risks for plant and nearby settlements (Chernet Haregewoin et al., 2014; Porfiriev et al., 2017), while increasing temperatures could reduce the efficiency of steam and gas turbines (Porfiriev et al., 2017; Cronin et al., 2018; Klimenko et al., 2018a). Water scarcity may limit onshore carbon capture and storage in some regions (Byers et al., 2016; Murrant et al., 2017; EEA, 2019a).

Reduced surface wind speeds during 1979-2016 (Frolov et al., 2014; Perevedentsev and Aukhadeev, 2014; Tian et al., 2019) support projected trends in decreasing onshore wind energy potential. Seasonal changes may result in reductions in many areas in summer (by 8-30% in Southern Europe) and increases in most of NEU during winter. Increasing probabilities and persistence of high winds over the Aegean and Baltic Seas (Weber et al., 2018a) could create new opportunities for offshore wind. The future configuration of the wind fleet will affect the spatial and temporal variability of wind power production (Tobin et al., 2016). Total backup energy needs in Europe could increase by 4-7% by 2100 (Wohland et al., 2017) with potentially larger seasonal changes (Weber et al., 2018b).

There is *low evidence* and *limited agreement* on projections of solar power potential due to differences in the integration of aerosols and the estimated cloud cover between climate models (Bartok et al., 2017; Boé et al., 2020; Gutiérrez et al., 2020). Studies on climate risks for bioenergy are also limited.

Energy demand is projected to display regional differences in response to global warming beyond 2ºC GWL, with a the significant southwest-to-northeast decrease of heating degree days by 2100 (particularly in northern Scandinavia and Russia), and a smaller north-to-south increase of cooling degree days (Porfiriev et al., 2017; Spinoni et al., 2018; Coppola et al., 2021). Under present population numbers, total energy demand would decrease in almost all Europe, whereas it could increase in some countries (e.g. UK, Spain, Norway) when considering Eurostat's population projections (Klimenko et al., 2018b; Spinoni et al., 2018).There is *medium confidence* that peak load will increase in SEU and decrease in NEU (Damm et al., 2017; Wenz et al., 2017; Bird et al., 2019). Beyond 2ºC GWL, a shift of peak load from winter to summer in many countries is possible (Wenz et al., 2017). Together with water-cooling constraints for thermal power, this change in load may challenge the stability of electricity networks during heatwaves (EEA, 2019a). Technological factors, increased electricity use and adaptation influence significantly the temperature sensitivity of electricity demand and consequently risks (Damm et al., 2017; Wenz et al., 2017; Cassarino et al., 2018; Figueiredo et al., 2020). Potential power curtailments or outages during climatic extremes may increase electricity prices (Pechan and Eisenack, 2014; Steinhäuser and Eisenack, 2020).

13.6.1.2 Transport

Heatwaves in 2015 and 2018 in parts of WCE and NEU caused road melting, railway asset failures, and speed restrictions to reduce the likelihood of track buckling (Ferranti et al., 2018; Vogel et al., 2019). Recent studies on projected risks focus mainly on infrastructure and much less on transport flows and disruptions.

Sea level rise (section 13.2) may disrupt port operations and surrounding areas, mainly in parts of NEU and WCE (Christodoulou et al., 2018), while changes of waves agitation could increase non-operability hours of some Mediterranean ports beyond 2°C GWL (Sierra et al., 2016; Camus et al., 2019; Izaguirre et al., 2021). Low water level days at some critical locations for inland navigation at the Rhine river are projected to increase beyond 2ºC GWL, while decreases at the Danube river are possible (van Slobbe et al., 2016; Christodoulou et al., 2020).

Risks of rutting and blow-ups of roads (particularly in low altitudes) due to high summer temperatures are expected to increase in WCE and EEU at 3ºC GWL (*medium confidence*) (Frolov et al., 2014; Matulla et al., 2018; Yakubovich and Yakubovich, 2018). In EEU and northern Scandinavia, the higher number of freezing-thawing cycles of construction materials will increase risks for roads (Frolov et al., 2014; Yakubovich and Yakubovich, 2018; Nilsen et al., 2021) while warming beyond 2ºC GWL could significantly reduce road maintenance costs in NEU (Lorentzen, 2020), but limiting off-road overland transport in north-western Russia (Gädeke et al., 2021). Beyond 3ºC GWL, more frequent hourly precipitation extremes are projected over WCE and NEU in summer (e.g. 2-fold and 10-fold increase for events exceeding the present-day 99.99th percentile in Germany and UK) but more widely across Europe in autumn and winter (increase higher than 10-fold for 99.99th percentile events in southern Europe in autumn (Chan et al., 2020), potentially severely damaging roads as happened in Mandra, Greece in 2017 (Diakakis et al., 2020). Landslide risks in WCE and SEU could increase beyond a 2ºC GWL, threatening road networks (Schlogl and Matulla, 2018; Rianna et al., 2020).

Current flood risk for railways could double or triple at 1.5-3°C GWL, particularly in WCE, increasing public expenditure for rail transport in Europe by €1.22 billion annually under 3°C GWL and no adaptation (Bubeck et al., 2019). Thermal discomfort in urban underground railways is expected to increase, even at a high level of saloon cooling (Jenkins et al., 2014a).

The number of airports vulnerable to inundation from sea level rise and storm surges may double between 2030 and 2080 without adaptation, especially close to the North Sea and Mediterranean coasts (Christodoulou and Demirel, 2018). Rising temperatures reducing lift generation could impose weight restrictions for large aircraft at 2ºC GWL and beyond in airports of France, UK and Spain (Coffel et al., 2017). There is a lack of studies quantifying the effect of future extreme events on flight arrivals at and departures from European airports.

13.6.1.3 Business and Industry

European industrial and service sectors contribute 85% to Gross Value Added in EU-28 (Eurostat, 2020); while their direct exposure and vulnerability is smaller compared to sectors directly reliant on weather, they are directly and indirectly affected by heat, flooding, water scarcity and drought (Weinhofer and Busch, 2013; Gasbarro and Pinkse, 2016; Meinel and Schule, 2018; Schiemann and Sakhel, 2018; TEG, 2019). Heat reduces the productivity of labour particularly in construction, agriculture and manufacturing (García-León et al., 2021; Schleypen et al., 2021) (section 13.7.1). Direct losses from floods in Europe are highest for manufacturing, utilities, transportation; indirect losses arise e.g. for manufacturing, construction, and banking and insurance (Koks et al., 2019a; Sieg et al., 2019; Mendoza-Tinoco et al., 2020). Drought and water scarcity directly affect European industries in the sectors of pulp and paper, chemical and plastic manufacturing and food and beverages (Gasbarro et al., 2019; Teotónio et al., 2020); additionally, drought may indirectly affect sectors relying on shipping, hydropower, or public water supply (Naumann et al., 2021). The European financial and insurance sector is affected by climate change impacts via their customers and financial markets (Bank of England, 2015; Georgopoulou et al., 2015; Battiston et al., 2017; TCFD, 2017; Bank of England, 2019; de Bruin et al., 2020; Monasterolo, 2020).

The vulnerability to climate hazards varies by European region, type of risk, sector and business characteristics (Gasbarro et al., 2016; Forzieri et al., 2018; ECB, 2021a; Kouloukoui et al., 2021). Current damages are mainly related to river floods and storms, but heat and drought will become major drivers in the future (*medium confidence*); until 2050, the probability of default of firms located in particularly exposed locations may increase to up to four times of that of an average firm in all sectors (ECB, 2021a).

Many European sectors are exposed to multiple and cross-cutting risks (Gasbarro et al., 2019; Schleypen et al., 2021). Indirect effects via supply chains, transport and electricity networks can be as high as or substantially higher than direct effects (*medium confidence*) (Koks et al., 2019a; Koks et al., 2019b; Knittel et al., 2020).

13.6.1.4 Tourism

Snow cover duration and snow depth in the Alps decreased since the 1960s (Klein et al., 2016; Schöner et al., 2019; Matiu et al., 2021). Despite snowmaking, the number of skiers to French resorts at low elevations during the extraordinary warm/dry winters of 2006/2007 and 2010/2011 was 12-26% lower (Falk and Vanat, 2016).

Due to reduced snow availability and hotter summers, damages are projected for the European tourism industry, with larger losses in SEU (*high confidence*) and some smaller gains in the rest of Europe (*medium confidence*) (Ciscar et al., 2014; Roson and Sartori, 2016; Dellink et al., 2019).

At 2°C GWL, the operation of low altitude resorts without snowmaking will *likely* be discontinued, while beyond 3°C GWL snowmaking will be a necessary but not always sufficient for most resorts in many European mountains and parts of NEU (Pons et al., 2015; Joly and Ungureanu, 2018; Scott et al., 2019; Spandre et al., 2019). Expanding snowmaking is capital-intensive and will strongly increase water and energy consumption, particularly at 3°C GWL and beyond (Spandre et al., 2019; Morin et al., 2021), adversely affecting the financial stability of small resorts (Pons et al., 2015; Falk and Vanat, 2016; Spandre et al., 2016; Joly and Ungureanu, 2018; Moreno-Gené et al., 2018; Steiger and Scott, 2020). Permafrost degradation due to rising temperatures is expected to create stability risks for ropeway transport infrastructure at high-altitude Alpine areas (Duvillard et al., 2019).

Climatic conditions from May to October at 1.5-2°C GWL are projected to become more favourable for summer tourism in NEU and parts of WCE and EEU, while there is *medium confidence* on opposite trends for SEU from June to August (Grillakis et al., 2016; Scott et al., 2016; Jacob et al., 2018; Koutroulis et al., 2018). The amenity of European beaches may decrease as a result of sea level rise amplifying coastal erosion and inundation risks, although less in NEU (Ebert et al., 2016; Toimil et al., 2018; Lopez-Doriga et al., 2019) (Section 13.2 and Ranasinghe et al., 2021 Section 12.4.5).

13.6.1.5 Built Environment, Settlements and Communities

Expected shift of European residents to large cities and coastal areas will increase assets at risk (Section 13.2). The share of urban population in Europe is projected to increase from 74% in 2015 to 84% in 2050, corresponding to 77 million new urban residents (UN/DESA, 2018), with most of this increase in SEU and WCE (particularly in Turkey and France). In the EU-28, urban residents in 2100 may increase by about 30 million under SSP1 and SSP5, and decrease by 90-110 million under SSP3 and SSP4 (Terama et al., 2019).

About 32% of 571 European cities in the GISCO Urban Audit 2014 dataset show a medium to high or relatively high vulnerability against heatwaves, drought and floods (Tapia et al., 2017). Under current vulnerabilities, future climate hazards will augment climate risks for several cities, particularly beyond 3°C GWL (Figure 13.17). In many NEU cities, a high increase in pluvial flooding risk by the end of the century is possible, while in WCE cities may face a high increase in pluvial flooding risks, moderate to very high increase in extreme heat risk, and to some extent moderate to high increase in drought risk. Many SEU cities could face a high to very high increase in risks from extreme heat and meteorological drought.

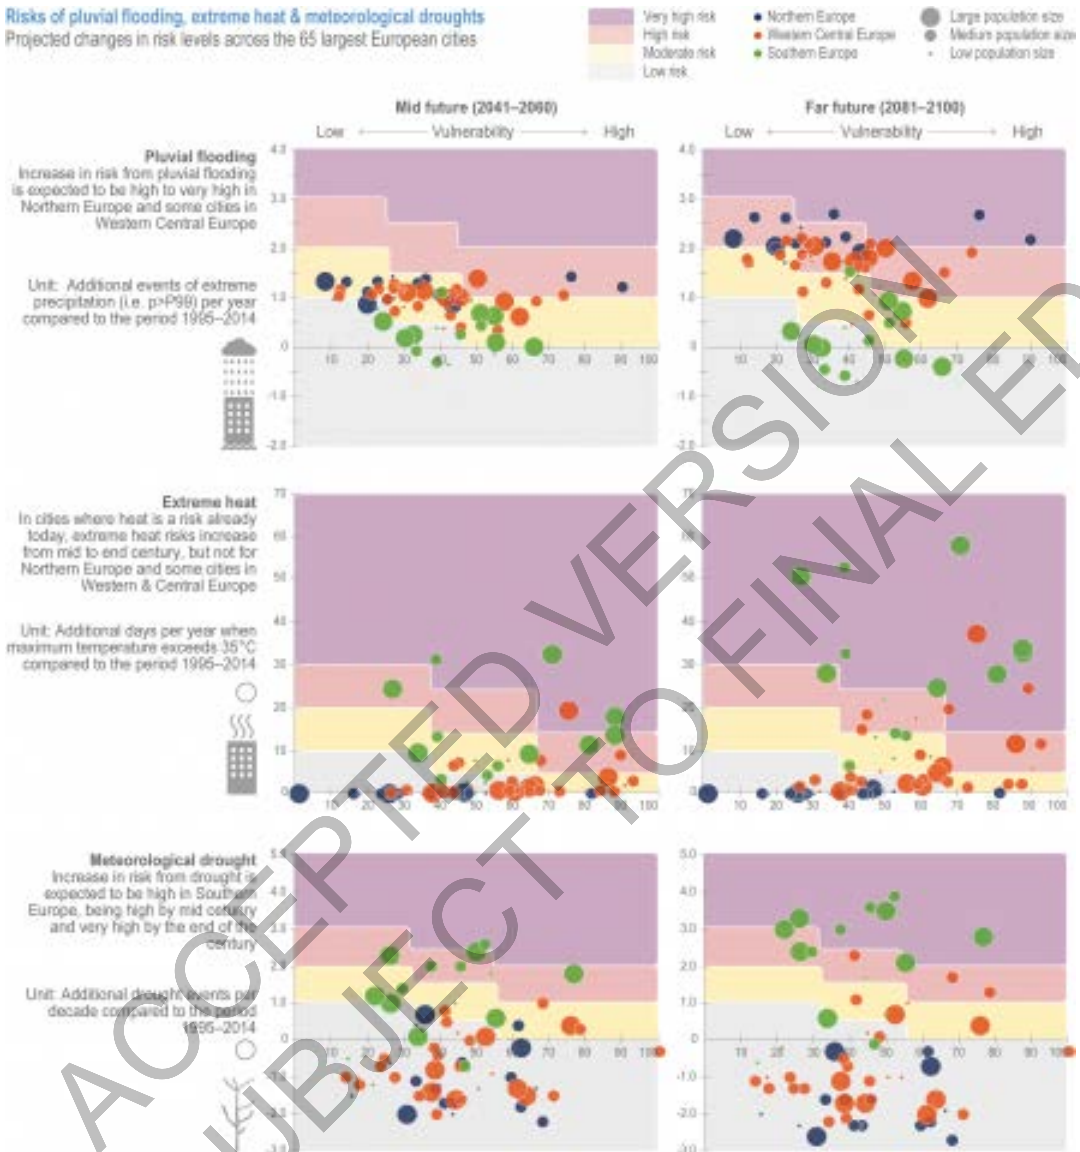

Figure 13.17: Projected changes in pluvial flooding, extreme heat and meteorological drought risks for the 65 largest cities in EU-28 plus Norway and Switzerland for 2.5°C GWL and 4.4°C GWL compared with the baseline (1995-2014) (Tapia et al., 2017). Exposure is expressed in terms of current population. Values of climatic impact-drivers are derived from the Euro-CORDEX regional climate model ensemble.

13.6.1.5.1. Risks from coastal, river and pluvial flooding

New studies increase confidence in AR5 statements that flood damages will increase in coastal areas due to sea level rise and changing social and economic conditions (section 13.2.1.1). Except for areas affected by land uplift, it is projected that further adaptation will be required to maintain risks at the present level for most coastal cities and settlements (Haasnoot et al., 2013; Ranger et al., 2013; Malinin et al., 2018; Hinkel et al., 2019; Umgiesser, 2020).

In many cities, the sewer system is older than 40 years, potentially reducing their capacity to deal with more intense pluvial flooding (EEA, 2020c). Apart from climate change, urbanization is an important driver for increases in flooding risks as it results in growth of impervious surfaces. Flash floods are particularly challenging, causing the overburdening of drainage systems (Dale et al., 2018), urban transport disruptions, and health and pollution impacts due to untreated sewage discharges (Kourtis and Tsihrintzis, 2021).

More than 25% of the population in nearly 13% of the EU-cities lives within potential river floodplains. In many of these, e.g. 50% of UK cities, a significant increase of the 10-year high river flow is possible beyond 2°C GWL under a high-impact scenario (i.e. 90th percentile of projections) (Guerreiro et al., 2018; EEA, 2020c).

13.6.1.5.2 Risks from heatwaves, cold waves and drought

Heatwave days and number of long heatwaves increased in most capitals from 1998-2015 compared to 1980-1997 (Morabito et al., 2017; Seneviratne et al., 2021). In the summer of 2018, many cities suffered from heatwaves attributed to climate change (Vogel et al., 2019; Undorf et al., 2020). As a result, indoor overheating and reduced outdoor thermal comfort, often coupled with urban heat island (UHI) effect, have already impacted European cities (Di Napoli et al., 2018; EEA, 2020c) (see also Section 13.7.1).

Heatwaves are *likely* to become a major threat not only for SEU but also for WCE and EEU cities (Russo et al., 2015; Guerreiro et al., 2018; Lorencova et al., 2018; Smid et al., 2019).At 2ºC GWL and SSP3, half of1.1 the European population will be under very high risk of heat stress in summer (Rohat et al., 2019). The UHI effect will further increase urban temperatures (Estrada et al., 2017). In many cities, hospitals and social housing tend to be located within the intense UHI, thus increasing exposure to vulnerable groups (EEA, 2020c). There is *high confidence* that overheating during summer in buildings with insufficient ventilation and/or solar protection will increase strongly , with thermal comfort hours potentially decreasing by 74% in locations of southern Europe at 3ºC GWL (Jenkins et al., 2014a; Hamdy et al., 2017; Heracleous and Michael, 2018; Dino and Meral Akgül, 2019; Shen et al., 2020). Highly insulated buildings, following present building standards, will be vulnerable to overheating, particularly under high GWL levels, unless adequate adaptation measures are applied (Williams et al., 2013; Virk et al., 2014; Mulville and Stravoravdis, 2016; Fosas et al., 2018; Ibrahim and Pelsmakers, 2018; Salem et al., 2019; Tian et al., 2020). Cities in NEU and WCE are more vulnerable due to limited solar shading and fewer air conditioning installations (Ward et al., 2016; Thomson et al., 2019). Cooling energy demand in SEU buildings has been projected to increase by 81-104% by 2035 and by 91-244% after 2065 compared to 1961-1990 depending on GWL (Cellura et al., 2018). Increases of 31-73% by 2050 and by 165-323% by 2100 compared to 1996-2005 were estimated for buildings in NEU (Dodoo and Gustavsson, 2016) with risks modified by adaptation (Viguié et al., 2020) (see section 13.6.2). Cold waves beyond 3ºC GWL will not represent an effective threat for European cities at the end of the century, and only a marginal hazard under 2ºC GWL (Smid et al., 2019).

At 2ºC GWL and beyond, cities in SEU and large parts of WCE would exceed the historical maximum 12-month Drought Severity Index of the past 50-years (on drought risks see Section 13.2) and 30% will have at least 30% probability of exceeding this maximum every month (Guerreiro et al., 2018). This could adversely affect the operation of municipal water services (Kingsborough et al., 2016). For example, under 2ºC GWL, the reservoir storage volume is predicted to decrease for all of England and Wales catchments, resulting in a probability of years with water use restrictions doubling by 2050 and quadrupling by 2100 compared to 1975-2004 (Dobson et al., 2020). The combination of high temperatures, drought, and extreme winds, potentially coupled with insufficient preparedness and adaptation, may amplify the damage of wildfires in peri-urban environments (13.3.1.3). High fuel load combined with proximity of the built environment to wildland highly increases fire risks (EEA, 2020c).

Extreme heat and drought causes shrinking and swelling of clays, threatening the stability of small houses in peri-urban environments (Pritchard et al., 2015), with damage costs of € 0.9-1 billion during the 2003 heatwave (Corti et al., 2011). In WCE and SEU, mean annual damage costs could increase by 50% for 2°C GWL, and by a factor of 2 for 3°C GWL (Naumann et al., 2021).

13.6.1.5.3 Risks from thaw of permafrost and mudflows

Increasing temperatures in NEU and the Alps lead to accelerated degradation of permafrost, negatively affecting the stability of infrastructures (Stoffel et al., 2014; Beniston et al., 2018; Duvillard et al., 2019). In the Caucasus, glacial mudflows due to permafrost degradation and modern tectonic processes pose a significant danger to the infrastructure (Vaskov, 2016). In the last 30 years, the permafrost temperature in the European part of the Russian Arctic has increased by 0.5-2.0°C, resulting to damages of buildings, roads and pipelines and to significant expenditure for stabilizing soils (Porfiriev et al., 2017; Konnova and Lvova, 2019). Beyond 3ºC GWL, the bearing capacity for infrastructure in the permafrost region of the European Russia could decrease by 32-75% by mid-century and by 95% by 2100, potentially affecting settlements in northern EEU (Shiklomanov et al., 2017; Streletskiy et al., 2019). Increasing number of cycles of freezing and thawing, observed in EEU, led to accelerated aging of building envelopes (Frolov et al., 2014) (13.8.1.4). Permafrost degradation due to higher temperatures could increase the potential of debris flow detachment in Alpine locations (13.6.1.4, Damm and Felderer, 2013).

Increased precipitation falling on local topography can increase landslide and mudflow risks, as seen in settlements at the Caucasus mountainous region (Marchenko et al., 2017; Efremov and Shulyakov, 2018; Kerimov et al., 2020). At the Umbria region in Italy, landslide events could increase by 16-53% under 2ºC GWL and by 24-107% beyond 3ºC GWL, mostly during winter (Ciabatta et al., 2016). Risks from shallow landslides are expected to increase in the Alps and Carpathians if no adequate risk mitigation measures are in place (CCP5.3.2, Gariano and Guzzetti, 2016).

13.6.2 Solution Space and Adaptation Options

Monetary assessments of future damages from climate extremes on critical infrastructures show a sevenfold escalating figures by 2080s (Figure 13.18) compared to the baseline (Forzieri et al., 2018), highlighting the need for adaptation.

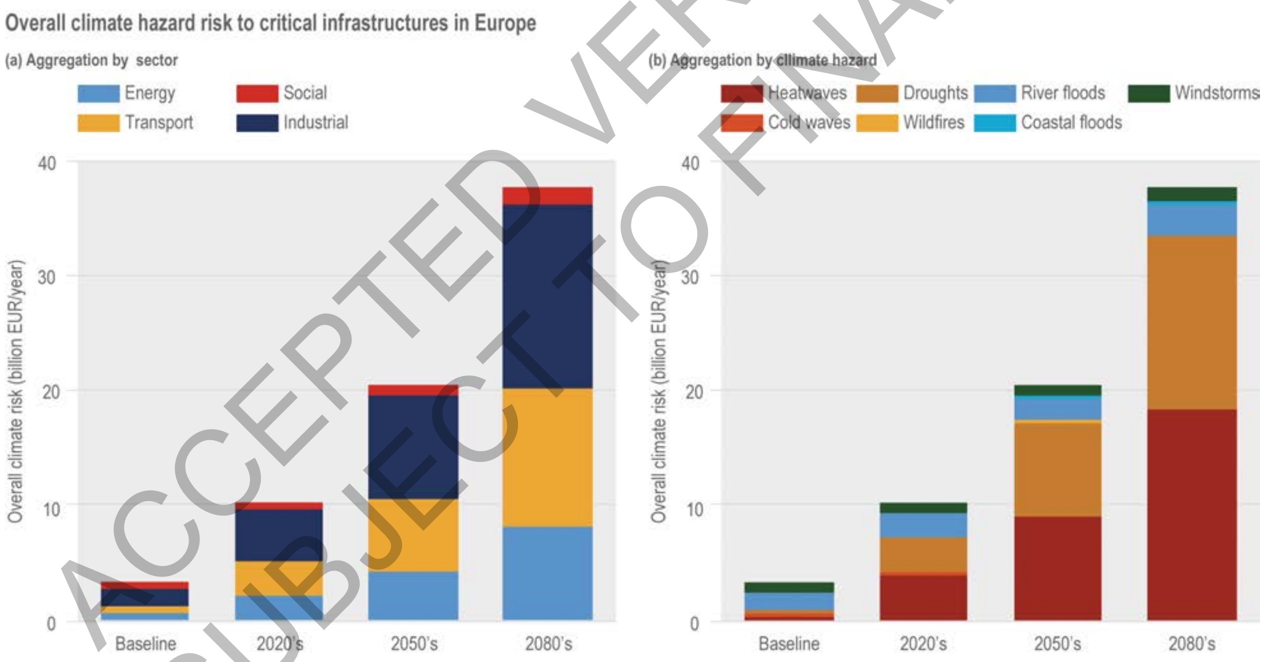

Figure 13.18: Climate risks to critical infrastructures, aggregated at European (EU+) level under the SRES A1B scenario (Forzieri et al., 2018). Baseline: 1981-2010. 2020s: 2011–2040. 2050s: 2041–2070. 2080s: 2071–2100.

13.6.2.1 Current Status of Adaptation

There is new evidence on increasing adaptation planning in cities, settlements, and key infrastructure, but less on implemented adaptation (Table 13.1; Box 13.3; Figure 13.36), adaptation by private actors and by cities against sea level rise (Chapter 16; CCP2).

Table 13.1: Present status of planned and implemented adaptation in cities, energy sector, tourism sector, transport and industry in Europe

	General commitments / Adaptation Plans	Implemented adaptation actions
Cities	• Increasing number of cities acknowledging the critical role of adaptation in building resilience to climate change. • Of 9609 European municipalities in the Covenant of Mayors for Climate & Energy (CoM), 2221 reported on adaptation through the CoM platform, 429 provided some information on adaptation goals, risk and vulnerability assessments/action plans, and 230-290 reported adaptation goals and funds for adaptation. Extreme heat, droughts and forest fires are the most often reported hazards. • Most urban adaptation plans include ecosystem-based measures (but often with insufficient baseline information and lack of convincing implementation actions). • Adaptation to risks from climate extremes (mostly flooding) is often addressed through municipal emergency plans.	• Large cities are in the process of implementation (e.g., Helsinki, Copenhagen, Rotterdam, Barcelona, Madrid, London, Moscow). • Many cities have implemented measures potentially supporting adaptation but not labelled as such. • Current climate policies implemented at city-scale are primarily addressing mitigation and, to a lesser extent adaptation. • Increasing use of Nature-based Solutions (NbS) and ecosystem-based adaptation (EbA) to address urban heating and the discontinuity of the urban water cycle due to surface sealing and limited infiltration. • Strategic, tactical, and emergency measures applied for drought management (e.g., London, Istanbul)
Energy	• 29 countries (in place in 14 and in progress in 15). • Few countries have considered specific adaptation actions (mostly preparatory) in their national or energy-specific risk assessments.	• 11 countries (actions implemented in 5 and in progress in 6)
		• Measures undertaken by some distribution system operators (DSOs) and energy companies, focusing on adaptation of transmission lines, water cooling, dams for avoiding flooding during intense precipitation events, actions to avoid flooding and to secure fuel supply.
Tourism	• Consideration of tourism in national adaptation strategies is limited, and national tourism strategies rarely mention adaptation. • Tourism operators do not consider longer term adaptation strategies to be relevant. • Legally binding consideration of climate change when constructing new tourism units (e.g., the 2016 French Mountain Act).	• 18-67% of ski slopes (67% in Austria, 39% in Switzerland, 18% in Bavaria-Germany, 20% in French Alps, and 45% in Spain apply snowmaking. • Resorts offering nocturnal skiing (e.g., Spain) and other snow-based activities. Transformation to all-year mountain resorts (e.g., 70% of Spanish ski resorts).
		• Some diversification of tourism products offered in Mediterranean coastal destinations. • Implementation of water saving measures, primarily for cost reduction.
Transport	• Only 10 countries have started coordination activities or identified adaptation measures. • An integrated, trans-modal approach to adaptation is lacking. • Few countries are mainstreaming of adaptation within transport planning and decision-making (e.g., the 'Low-water Rhine' action plan and in Germany).	• Only in 5 countries. • Majority of actions are preparatory. • Actions mostly focus on infrastructure and much less on services, although the latter have started gaining ground (e.g., operational forecasts for water levels in rivers). • Transport modes often compete for public funds, and political priorities for specific modes often influence adaptation
	• Some action is undertaken in the public and private sector, e.g., revised manuals/guidelines/ protocols to consider climate change impacts and extreme events (e.g., Deutsche Bahn, Norwegian Public Roads Administration).	• Some public and private actors are moving faster: new railway drainage standards (Network Rail/ UK), prediction of adverse weather events (Spanish rail service operator), measures against coastal flooding (Copenhagen Metro), measures for sea level rise (Rotterdam port and France).
Industry and business	• Recommendation of the High Level Expert Group on Sustainable Finance ((HLEG) that the European Commission endorses and implements the guidelines provided by the Task force on Climate-Related Financial Disclosure in 2019.	• 50 of European large listed companies publicly disclosed their climate risks in 2020; yet only a small share provided specifics on sectoral risks, how risks differ over time and by different climate scenarios • Large national/multinational companies, and companies regulated by mitigation policy are first movers in corporate adaptation, while small and medium-sized enterprises often lack knowledge and resources to address risks and adaptation options. • Development of different tools (stress testing, scenario analysis, value at risk) by climate service providers, insurance companies and central banks

Legend: Well-established adaptation | Advancing adaptation | Low adaptation

Although urban adaptation is underway, many small, economically weak (i.e. with low GDP/capita) or cities facing high climate change risks lack adaptation planning (Reckien et al., 2015; EEA, 2016). While almost all large municipalities in NEU and WCE report implemented actions at least in one sector, this is not the case for 39% of municipalities in SEU (Aguiar et al., 2018). In the UK, the legal requirement to develop urban adaptation plans has been a significant driver for their widespread adoption (Reckien et al., 2015). The availability of and access to funding for adaptation is also crucial for plan development (section 13.11.1). Network membership (e.g., ICLEI, C40, Covenant of Mayors for Climate & Energy) is an important driver for city planning and transfer of best practices (Heikkinen et al., 2020a). Stakeholder engagement is key for successful adaptation (Bertoldi et al., 2020)(see Chapter 17).

Only 29% of local adaptation plans are mainstreamed in cities, which could reduce the effectiveness of implementing adaptation (Reckien et al., 2019) (13.11.1.2). Although large municipalities usually fund the implementation of their adaptation plans, smaller and less populated municipalities (particularly in SEU and EEU) often depend on intergovernmental, international and national funding.

13.6.2.2 Adaptation Options as a Function of Impacts

Examples of adaptation options in Europe are presented in Figure 13.19.

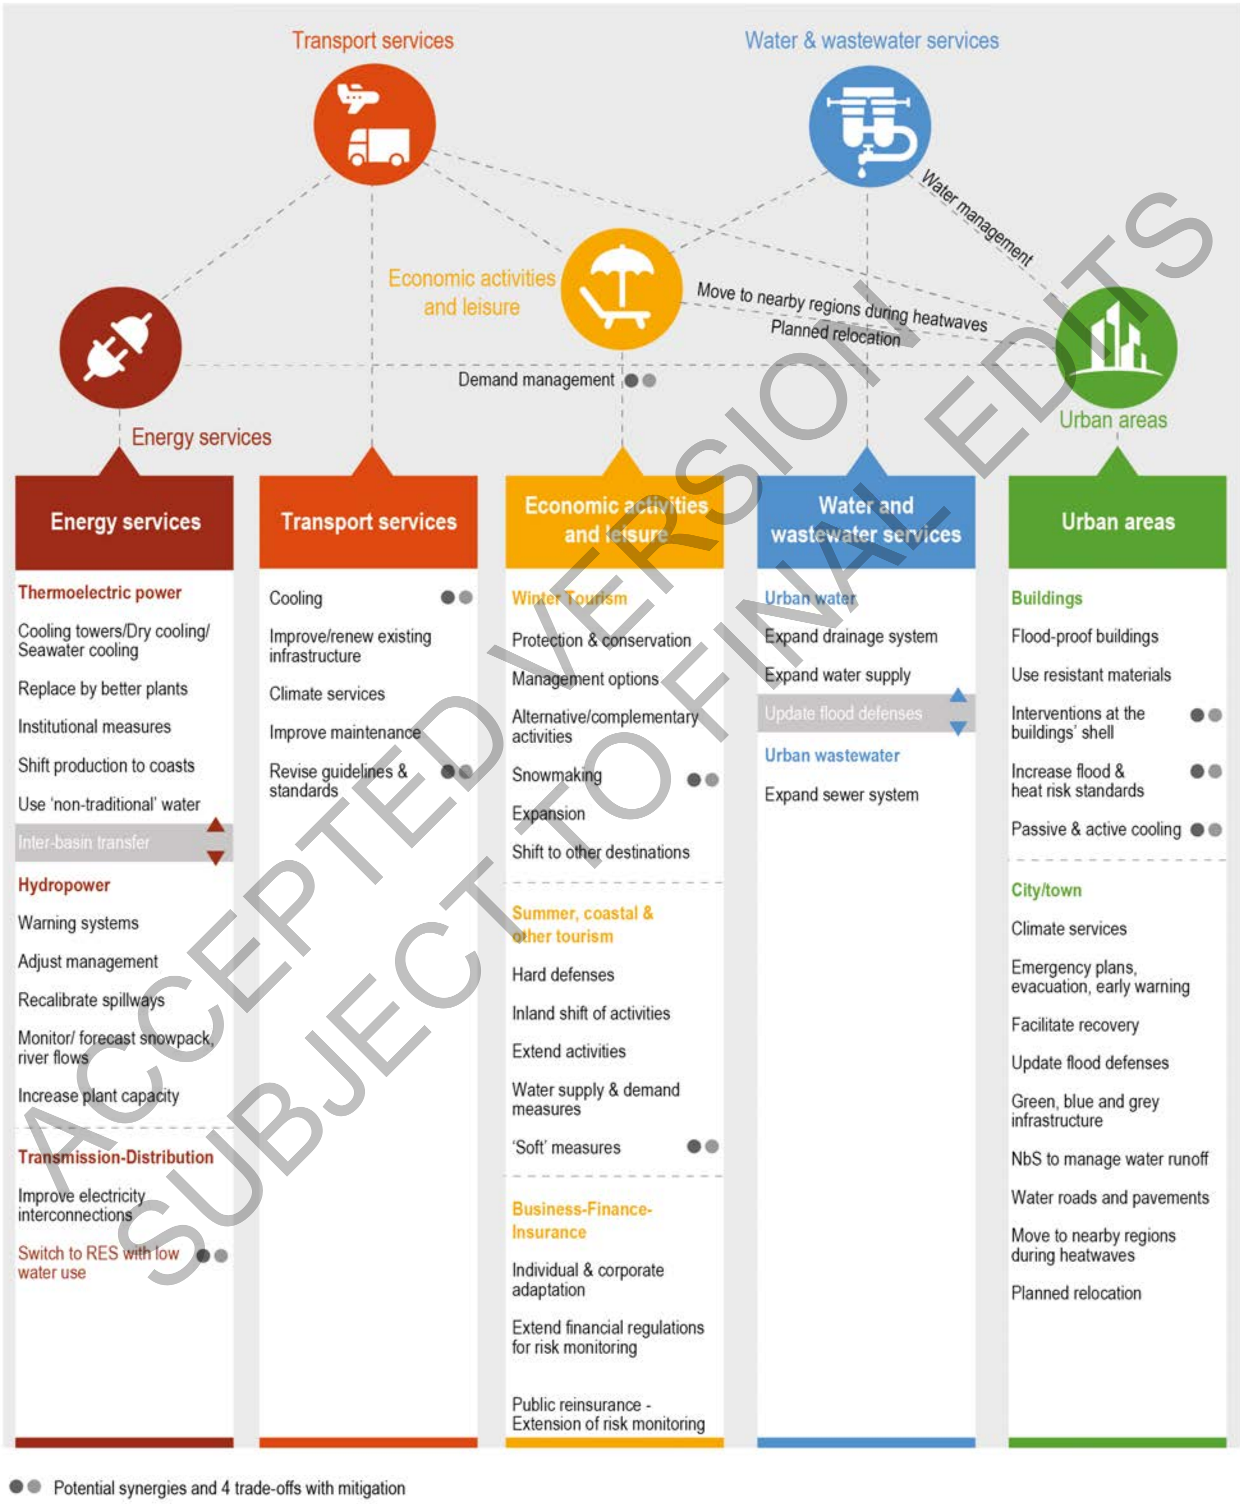

Figure 13.19: Adaptation options in cities, settlements, and key infrastructure in Europe (Table SM13.7).

Nature-based solutions (NbS) and ecosystem-based adaptation (EbA) such as green spaces, ponds, wetlands and green roofs for urban stormwater management and vegetation for heat mitigation represent an emerging adaptation option in cities. Combined with traditional water infrastructure, they can contribute to managing urban flood events (Kourtis and Tsihrintzis, 2021), playing a role in mitigating flood peaks (Pour et al., 2020) and protecting critical urban infrastructure (Ossa-Moreno et al., 2017). For example, in the Augustenborg district of Malmö, Sweden, using nature to manage stormwater runoff resulted in capturing an estimated 90% of runoff from impervious surfaces and reduced the total annual runoff volume from the district by about 20% compared to the conventional system (EEA, 2020c). Urban greening is associated with lower ambient air temperature and relatively higher thermal comfort during warm periods (Bowler et al., 2010; Oliveira et al., 2011; Cohen et al., 2012; Cameron et al., 2014). The scale and relative degree of management or integration of approaches drawing on nature with ‘engineered’ solutions affect their vulnerability to climate change. Small-scale urban NbS are relatively less vulnerable due to increased capacity for intervention, while the relatively greater contact between stakeholders and urban NbS (compared with larger-scale, rural approaches) provides greater opportunity for human intervention to ensure the survival of urban vegetation during droughts or heatwaves.

When selecting and combining adaptation options, challenges remain on how to address uncertainties of climate projections and climatic extremes (Fowler et al., 2021) and to translate scientific input into practical guidance for adaptation (Dale, 2021) (Section 13.11.1.3).

An assessment of the feasibility and effectiveness of main adaptation options, based on literature, is presented in Figure 13.20; for adaptation to flood risk, see Figure 13.6.

Effectiveness & feasibility of main adaptation options to climate impacts & risk for cities, settlements & key infrastructure in Europe

Impact types	Adaptation options	Effectiveness	Feasibility: Economic	Technological	Institutional	Socio-cultural	Ecological	Geophysical	Confidence: Evidence	Agreement
Reduction of thermal comfort due to increasing temperatures & extreme heat	Interventions in the building shell	M	M	L	M	L	NL	M	M	M

No/Limited Evidence = NL

Figure 13.20: Effectiveness and feasibility of main adaptation options for cities, settlements and key infrastructure in Europe (SM13.9 and Table SM13.8).

There are gaps of knowledge on the social, environmental and geophysical dimension of feasibility for many options and a holistic assessment of different options is largely lacking. This latter could reveal unintended impacts from and synergies or trade-offs between options, as in water and wastewater services (Dobson and Mijic, 2020).

13.6.2.3 Adaptation Limits, Residual Risks, Incremental and Transformative Adaptation

Adaptation in cities, settlements and key infrastructure in Europe faces technical, environmental, economic and social limits (Figure 13.21).

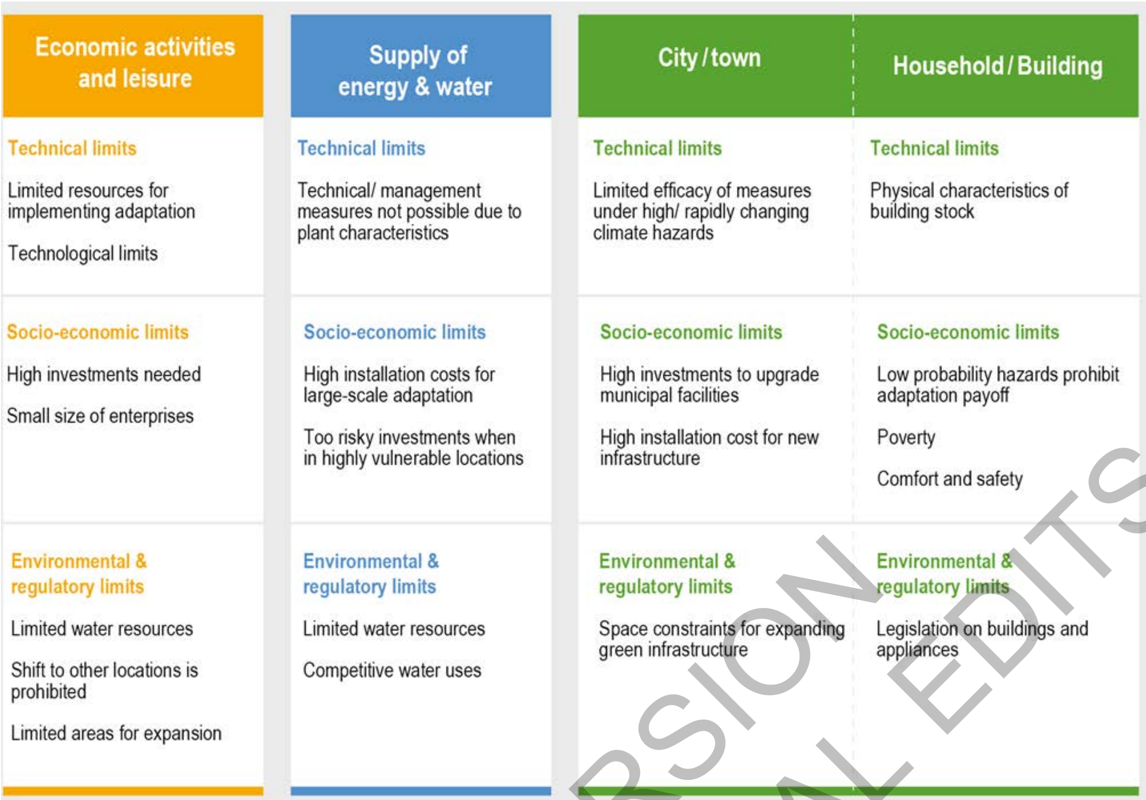

Figure 13.21: Indicative adaptation limits in cities, settlements and key infrastructure in Europe (Table SM13.16).

Adaptation options for many sectors will not be sufficient to remove residual risks, e.g. regarding overheating in buildings under high GWL, (Tillson et al., 2013; Virk et al., 2014; Dodoo and Gustavsson, 2016; Mulville and Stravoravdis, 2016; Hamdy et al., 2017; Heracleous and Michael, 2018; Dino and Meral Akgül, 2019); snowmaking beyond 3°C GWL (Scott et al., 2019; Steiger et al., 2020; Steiger and Scott, 2020); hydropower (Gaudard et al., 2013; Ranzani et al., 2018); electricity transmission and demand (Bollinger and Dijkema, 2016; EEA, 2019a; Palkowski et al., 2019); urban subways (Jenkins et al., 2014a); and flood mitigation in cities (Skougaard Kaspersen et al., 2017; Umgiesser, 2020). Some adaptation actions in a sector may also have side-effects on others, increasing their vulnerability (Pranzini et al., 2015) (sections 13.2.2 and 13.2.3).

Examples of transformative adaptation in urban areas are observed (e.g., the Benthemplein water square, the Floating Pavilion in Rotterdam and the Hafencity flood proofing in Hamburg), but they often remain policy experiments and prove challenging to upscale (Jacob, 2015; Restemeyer et al., 2015; Restemeyer et al., 2018; Holscher et al., 2019). The active involvement of local stakeholders, public administration and political leaders are drivers for community transformation, whereas lack of local resources and/or capacities are frequently reported barriers to change (Fünfgeld et al., 2019; Thaler et al., 2019).

13.6.2.4 Governance and Insurance

Urban adaptation plans can enhance resilience and their development is mandatory in the UK, France, and Denmark (Reckien et al., 2019). There is *medium confidence* that the development of urban adaptation planning is much more influenced by a city's population size, present adaptive capacity and GDP per capita than by anticipated climate risks (Reckien et al., 2018). A high organizational capacity in a municipality may not be a necessary condition for forward-looking investment decisions on urban water infrastructure, although enablers differ for small versus medium-to-large municipalities (Pot et al., 2019). There is large in-country variation in policy mixes utilized by local governments for supporting adaptation (Lesnikowski et al., 2019). In early adapter cities (e.g., Rotterdam), adaptation is institutionally embedded in climate, resilience and sustainability-related actions and collaboration between city departments, government levels, businesses, and rest stakeholders (Holscher et al., 2019). In most other cities however, adaptation planners rarely consider collaborations with citizens and there are difficulties in departmental coordination and upscaling from pilot projects (Brink and Wamsler, 2018).

The level and type of collaboration between the public and private sector in managing climate risks varies across Europe (Wiering et al., 2017; Alkhani, 2020). For example, in flood management (also section 13.2), the private sector involvement in Rotterdam is much more pronounced and there are joint public–private responsibilities throughout most of the policy process due to the large share of private ownership of land and real estate (Mees et al., 2014).

In large infrastructure networks, the lack of a leading and powerful institutional body, with sufficient research resources targeted to climate change risk assessment, may limit adaptive capacity, as for example in railways (Rotter et al., 2016).

The European insurance industry has developed tailored products for specific climate risks threatening cities, settlements and key infrastructure, such as risk-based flood insurance for homeowners and companies (section 13.2.3). The European insurance industry is developing new services (such as risk analysis and catastrophe modelling embedding climate change, early warning and post-event recovery recommendations) and it has recently started to play a role as communicator of future risks and as institutional investor with the aim of risk reduction (Jones and Phillips, 2016; Marchal et al., 2019).

13.6.2.5 Links between Adaptation and Mitigation

Evidence from transport in Europe shows that adaptation actions do not consider enough long-term transition paths embedded in mitigation, while mitigation strategies are often not assessed under future climate scenarios (Aparicio, 2017). Without rapid decarbonization of electricity supply, greenhouse gas emissions will increase due to the increased use of air-conditioning installations in cities. This trade-off can be reduced to some extent through use of more efficient cooling technologies (IEA, 2018) and complementary adaptation measures such as large-scale urban greening, building policies and behavioural changes in air conditioning use (Viguié et al., 2020; Sharifi, 2021; Viguié et al., 2021). Greenhouse gas emissions from transport may increase due to the temporary relocation of city residents to cooler locations during heatwaves (Juschten et al., 2019), and from increased energy use for snowmaking in European ski resorts (Scott et al., 2019).

13.6.3 Knowledge Gaps

A key knowledge gap is the lack of a quantitative European-wide integrated assessment of future climate change risks on water and energy, including different socio-economic futures. Models capable of representing integrated policies for energy and water are lacking (Khan et al., 2016) including quantitative modelling of impacts on energy transmission and coastal energy infrastructure (Cronin et al., 2018). These lacks are especially pertinent when combined with the small number of studies considering SSP population projections, and adaptation tipping points. The limited social vulnerability assessments, mapping, and validation (Rufat et al., 2019) contribute further to these knowledge gaps.

While compound, concurrent, and consecutive climate extremes become more frequent, there is limited knowledge on sectoral risks or on cascading risks for through transport, telecommunications, water, and banking and finance. While heat is well studies, studies on risks for cities and key infrastructure from hailstorms and lightning are missing.

Empirical data on the damage of transport infrastructure (e.g., railways) covering different European countries is not systematically collected and indirect economic effects of interruptions of transport networks are not well studied (Bubeck et al., 2019). These deficits result in uncertainties associated with impacts of climate change on transport flows and indirect impacts (delays, economic losses).

There is limited knowledge on interactions created by synchronous adaptation in ski tourism supply and demand, and models are not yet including individual snowmaking capacity and a higher time resolution (Steiger et al., 2019). Furthermore, there is no European-wide assessment of coastal flooding risks on tourism.

Many studies lack consideration of market characteristics (e.g., competitors) in their risk assessment which would be improved by location- and sector-specific knowledge on climate risks for firm assets, operations, business, industry, finance and insurance needed to inform adaptation actions (de Bruin et al., 2020; Feridun and Güngör, 2020; Monasterolo, 2020).

13.7 Health, Wellbeing and the Changing Structure of Communities

13.7.1 Observed Impacts and Projected Risks

13.7.1.1 Mortality due to Heat and Other Extreme Events

Attribution studies show that human-induced climate change is increasing the frequency and intensity of heat waves and has already impacted human health in Europe (Section 13.10.1, Vicedo-Cabrera et al., 2021); for example the 2010 heatwave in EEU resulted in 55,000 heat-related deaths (Barriopedro et al., 2011; Russo et al., 2015); the 2018 heatwave in NEU (Ebi et al., 2021) and the 2019 heatwave in WCE and NEU both had significant health impacts (Cross-Chapter Box DISASTER in Chapter 4, Vautard et al., 2020; Watts et al., 2021). Elderly, children, (pregnant) women, socially isolated people and those with low physical fitness are particularly exposed and vulnerable to heat-related risks, as are those people suffering from pre-existing medical conditions, including cardiovascular disease, kidney disorders, diabetes and respiratory diseases (de'Donato et al., 2015; Sheridan and Allen, 2018; Naik et al., 2021). An aging population in Europe is increasing the pool of vulnerable individuals, resulting in higher risk of heat-related mortality (Montero et al., 2012; Carmona et al., 2016b; WHO, 2018b; Watts et al., 2021).

1.5°C GWL warming could result in 30,000 annual deaths due to extreme heat, with up to three-fold the number under 3°C GWL (*high confidence*) (Roldán et al., 2015; Forzieri et al., 2017; Kendrovski et al., 2017; Naumann et al., 2020). The risk of heat stress, including mortality and discomfort, is dependent on socioeconomic development (Rohat et al., 2019; Ebi et al., 2021) (Figure 13.22). Heat stress risks will be lower under SSP1 than SSP3 or SSP4 scenarios (*high confidence*) (Hunt et al., 2017; Rohat et al., 2019; Wang et al., 2020; Ebi et al., 2021). The incidence of heat-related mortality and morbidity will be highest in SEU, where their magnitude is also expected to increase more rapidly (Forzieri et al., 2017; Gasparrini et al., 2017; Guo et al., 2018; Díaz et al., 2019; Vicedo-Cabrera et al., 2021). WCE, NEU, SEU will experience accelerating negative consequences beyond 1.5°C GWL, particularly under SSP3 and SSP4 due to higher vulnerability compared with SSP1 (Figure 13.22, Rohat et al., 2019). The number of heat-related respiratory hospital admissions is projected to increase from 11,000 (1981-2010) to 26,000 annually (2021-2050), particularly in SEU mainly due to a relative increase in the number of extremely hot days (Åström et al., 2013). Cold spells are projected to decrease across Europe, particularly in southern Europe, but do not compensate for the additional heat related deaths projected (Lhotka and Kysely, 2015; Carmona et al., 2016a; Martinez et al., 2018).

74% of Europeans live in urban areas (section 13.6), where the effect of heat waves on human health is exacerbated by microclimates due to buildings and infrastructure, heat island effects, and air pollution (WHO, 2018a; Smid et al., 2019). In large European cities, stabilizing climate warming at 1.5°C GWL would decrease premature deaths by 15–22% in summer compared with stabilization at 2°C GWL (Mitchell et al., 2018) (*high confidence*).

Although there is *very high confidence* that risk consequences will inevitably be more pervasive and widespread in a warmer Europe, evidence of higher heat tolerance is also emerging across most European regions (Todd and Valleron, 2015; Åström Daniel et al., 2016 Sweden, 1901–2009; Follos et al., 2020). Future projections of mortality rates in Europe under the assumption of complete acclimatization suggest constant or even decreasing rates of mortality in spite of global warming (Åström et al., 2017; Guo et al., 2018; Díaz et al., 2019). However, there are large uncertainties in the ability to adapt to future heat extremes which might fall outside of historical ranges (Vanos et al., 2020).

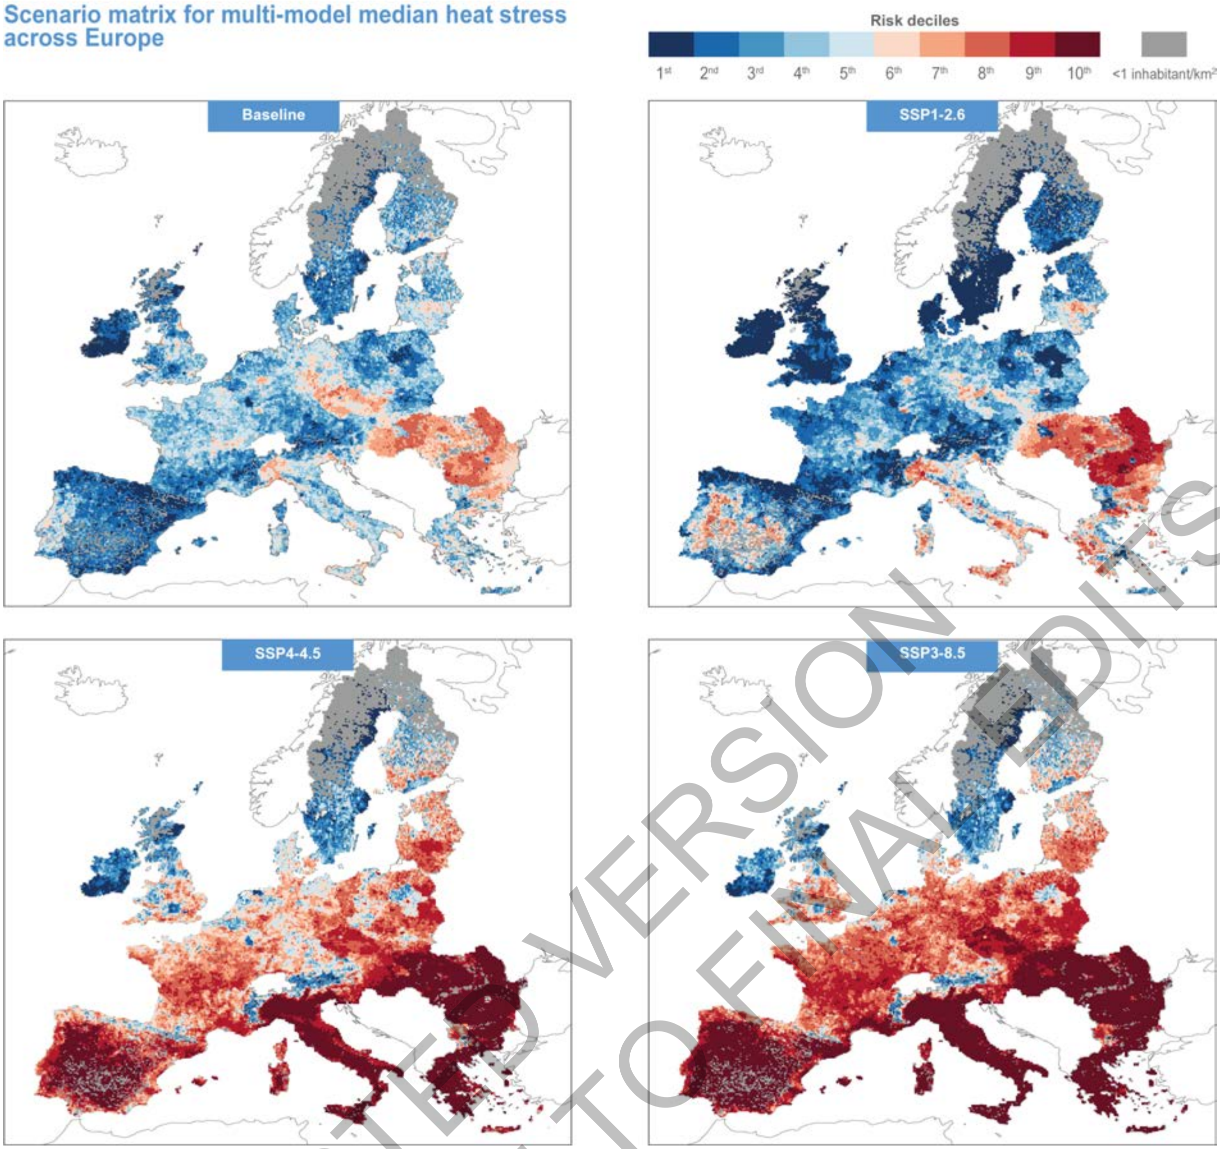

Figure 13.22: Scenario matrix for multi-model median heat stress risks for the baseline 1986-2005, and different SSP-RCP combinations for the period 2040-2060. SSPs are extended SSPs for Europe (EU28+). Heat stress risk is calculated by geometric aggregation of the hazard (heat wave days), population vulnerability and exposure. Risk values are normalised using a z-score rescaling with a factor 10-shift. Details of the methodology are provided in Rohat et al. (2019).

Other extreme events already result in major health risks across Europe. Between 2000 and 2014, for example, floods in Russia killed approximately 420 people, mainly older women (Belyakova et al., 2018). Fatalities associated with coastal and riverine flooding (13.2.2), wildfires (13.3.4), and windstorms could rise substantially by 2100 (Forzieri et al., 2017; Feyen et al., 2020). Lifetime exposure to extreme weather events for children born in 2020 will be about 50% larger at 3.5°C compared to 1.5°C GWL (Thiery et al., 2021).

13.7.1.2 Air Quality

Air pollution is already one of the biggest public health concerns in Europe; in 2016, roughly 412,000 people died prematurely due to long-term exposure to ambient PM2.5, 71,000 due to NO_2, and more than 15,000 premature mortalities occurred due to near surface ozone (EEA, 2019b; Lelieveld et al., 2019). Impacts of air pollution determined by air quality policies, changes to temperature, humidity, and precipitation (Naik et al., 2021). Climate change could increase air pollution health effects, with the size of the effect differing across European regions and pollutants (Jacob and Winner, 2009; Orru et al., 2017; Tarin-Carrasco et al., 2021) (*medium confidence*). Increases in temperature and changes in precipitation will impact future air quality due to increased risk of wildfires and related air pollution episodes. Data on the health impacts of wildfires in

Europe is currently limited (Section 13.3.1.4), but examples such as the 2017 fires suggest that more than 100 people died prematurely in Portugal alone as a result of poor air-quality (Oliveira et al., 2020).

At 2.5°C GWL, mortalities due to exposure to PM2.5 are projected to increase by up to 73% in Europe (*medium confidence*) (Silva et al., 2017; Lelieveld et al., 2019; Tarin-Carrasco et al., 2021). At 2°C GWL, annual premature mortalities due to exposure to near-surface ozone are projected to increase up to 11% in Western Central and Southern Europe and to decrease up to 9% in Northern Europe (under RCP4.5) (Orru et al., 2019) (*medium confidence*). Projected increase in wildfires and reduced air quality is expected to increase respiratory morbidity and mortality, especially in SEU (Slezakova et al., 2013; de Rigo et al., 2017). Constant or lower emissions combined with stricter regulations and new policy initiatives, might improve air quality in coming decades (*medium agreement, low evidence*). Aging population in Europe augments the future air quality mortality burden by 3-13% in 2050 (Geels et al., 2015; Orru et al., 2019). Beside ambient air quality, projected increases in flood risk and heavy rainfall could decrease indoor air quality (13.6.1.5.2) due to dampness and mould, leading to increased negative health impacts, including allergies, asthma and rhinitis (EASAC, 2019; EEA, 2019b).

13.7.1.3 Climate Sensitive Infectious Diseases

Figure 13.23 summarizes the observed and projected changes in climatic suitability and assesses the risk for selected climate-sensitive infectious diseases in Europe.

Among the tick-borne diseases, Lyme disease is the most prevalent disease in Europe. There has been a temperature-dependent range expansion of ticks that is projected to expand further north in Sweden, Norway and the Russian Arctic. (Jaenson et al., 2012; Jore et al., 2014; Tokarevich et al., 2017; Waits et al., 2018) and to higher elevations in Austria and the Czech Republic (Daniel et al., 2003; Heinz et al., 2015) (*medium confidence).* A potential habitat expansion of these ticks of 3.8% across Europe, relative to 1990-2010, is projected for 2°C GWL (Porretta et al., 2013; Boeckmann and Joyner, 2014). In contrast, there are projected habitat contractions for these ticks in SEU due to unfavourable climatic conditions (Semenza and Suk, 2018).

The Asian tiger mosquito (*Aedes albopictus*) is present in many European countries and can transmit Dengue, Chikungunya and Zika (Liu-Helmersson et al., 2016; Tjaden et al., 2017; Messina et al., 2019). There is a moderate climatic suitability projected for chikungunya transmission, notably across France, Spain, and Germany but also contractions, particularly in Italy. Europe experienced an exceptionally early and intense transmission season of West Nile virus in 2018, with elevated spring temperature abnormalities (Haussig et al., 2018; Marini et al., 2020). Projections for Europe show West Nile virus risk to expand; by 2025 the risk is projected to increase in SEU and south and eastern parts of WCE (*medium confidence*) (Semenza et al., 2016). Although climatic suitability for malaria transmission in Europe is increasing and will lead to a northward spread of the occurrences of *Anopheles* vectors, the risk from malaria to human health in Europe remains low due to economic and social development and access to health care (*medium confidence*) (Sudre et al., 2013; Hertig, 2019).

Water-borne diseases are also associated with changes in climate such as heavy precipitation events (Semenza, 2020). Warming has been linked with elevated incidence of campylobacteriosis outbreaks in different European countries (Yun et al., 2016; Lake et al., 2019). Marine bacteria such as vibrio thrive under elevated sea surface temperature and low salinity such as the Baltic Sea. Under further warming, the number of months with risk of Vibrio transmission increases and the seasonal transmission window expands, thereby increasing the risk to human health in the future (*high confidence*) (Baker-Austin et al., 2017; Semenza et al., 2017).

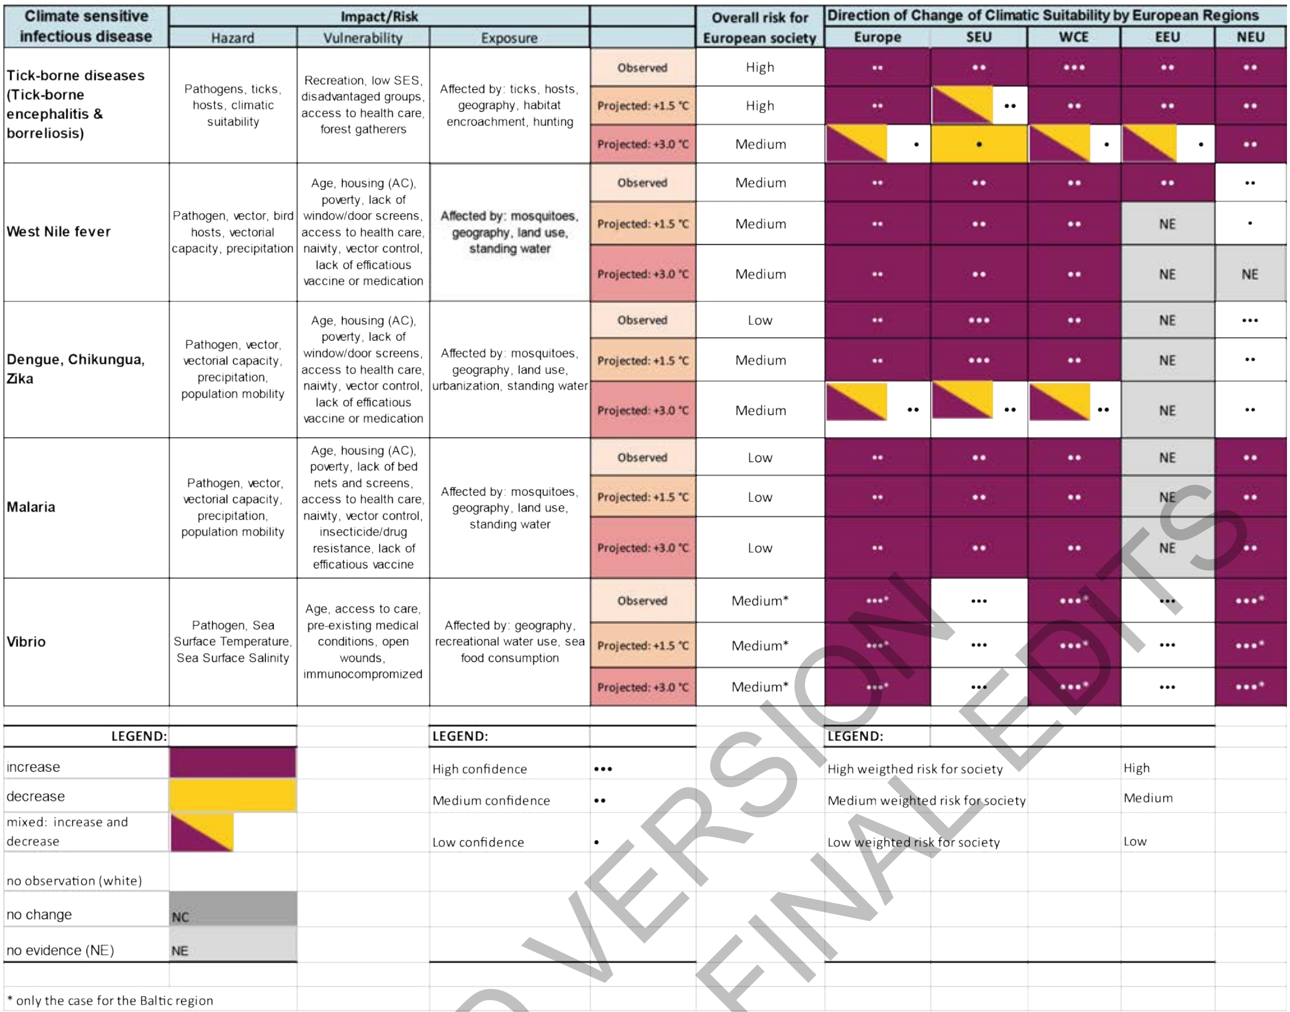

Figure 13.23: Assessment of climate sensitive infectious diseases. The assessment considers the main drivers of hazard (climatic impact drivers, pathogens and vectors), vulnerability (lack of safeguards and a predisposition to these hazards) and exposure (humans to be affected by these pathogens and vectors), the direction of change of climatic suitability (i.e. temperature, precipitation, relative humidity, extreme weather events) of observed changes and at 1.5°C and 3°C GWL, and assesses the overall infectious disease risks across Europe (Chapter 7.3 and 7.4, Lindgren et al., 2012; Semenza and Paz, 2021). The assessment does not consider incidence of disease infections through autochthonous transmission. (Table SM13.18).

13.7.1.4. Allergies and Pollen

The main drivers of allergies are predominantly non-climatic (e.g. increased urbanization, adoption of westernized lifestyles, social and genetic factor) but climate change strongly contributes to the spread of some allergenic plants, thus exacerbating existing and causing new allergies to humans across Europe (*high confidence*) (D'Amato et al., 2016; EASAC, 2019). The prevalence of hay fever (*allergic rhinitis*), for example, is between 4% and 30% among European adults (Pawankar et al., 2013). The invasive common ragweed is a key species already causing major allergy in late summers (including hay fever and asthma), particularly in Hungary, Romania and parts of Russia (Ambelas Skjøth et al., 2019). Across Europe, sensitization to ragweed is expected to increase from 33 million people in 1986–2005 to 77 million people at 2°C GWL (Lake et al., 2017).

Warming will result in an earlier start of the pollen season and extending it, but this differs across regions, species, traits and flowering periods (Ziello et al., 2012; Bock et al., 2014; EASAC, 2019; Revich et al., 2019). For instance in different parts of WCE and NEU, the start of the birch season flowering has been shifted and extended up to two weeks earlier during recent decades (Biedermann et al., 2019). Airborne pollen concentrations are projected to increase across Europe (Ziello et al., 2012). In south-eastern Europe, where pollen already has a substantive impact, the pollen count could increase more than 3 to 3.5 times at

2.5°C GWL and can become a more widespread health problem across Europe, particularly where it is currently uncommon (*medium agreement, low evidence*) (Lake et al., 2017).

13.7.1.5. Labour Productivity and Occupational Health

Extreme heat and cold waves have been linked to an increased risk of occupational injuries (Martinez-Solanas et al., 2018) and changes in labour productivity (Orlov et al., 2019; García-León et al., 2021) while evidence on the consequences of other extreme events is lacking. The sectors with a high percentage of high intensity outdoor work in Europe, mainly agriculture and construction, have the highest risk of increased injury and labour productivity losses, but also manufacturing and service sectors can be affected when air conditioning is not available (Gosling et al., 2018; Szewczyk et al., 2018; Dellink et al., 2019; Orlov et al., 2019) (13.6.1.3). The heatwaves of August 2003, July 2010 and July 2015 concentrated in SEU and led to reductions in monthly worker productivity of on average 3-3.5% in SEU, ranging up to 8-9% in Cyprus (2003, 2010) and in Italy (2015) (Orlov et al., 2019); in contrast, the heatwave of 2018 centred on NEU, but also led to pronounced productivity reductions in WCE and SEU (García-León et al., 2021); each of these major European heatwaves led to considerable economic losses in agriculture and construction (*high confidence*) and reduced GDP in Europe (except EEU) by 0.3-0.5% (García-León et al., 2021). At 2.5°C GWL and beyond, GDP losses are projected to increase fivefold compared to 1981-2010, ranging from 2-3.5% in SEU, to 0.5-1.5% in WCE, and below 0.5% in NEU and EEU (Roson and Sartori, 2016; Takakura et al., 2017; Szewczyk et al., 2018; Dellink et al., 2019; García-León et al., 2021) (13.10.3).

13.7.1.6. Food Quality and Nutrition

There is growing evidence that climate change will negatively affect food quality (diversity of food, nutrient density, and food safety) and food access, although the risks for European citizens are significantly lower compared to other regions (Fanzo et al., 2018; IFPRI, 2018). Projected changes in crop and livestock production (13.5.1), particularly reduced access to fruits and vegetables and foods with lower nutritional quality, will impact already vulnerable groups (Swinburn et al., 2019). The effects of climate change on food quality and access varies by income, livelihood, and nutrient requirements, with low income and more vulnerable societal groups in Europe most affected (IFPRI, 2018). Spikes in food prices due to changing growing conditions in Europe (13.5.1), increased competition for land (e.g., land-based climate change mitigation), and feedbacks from international markets, are expected to decrease access to affordable and nutritious food for European citizens (13.9.1) (EASAC, 2019; Loopstra, 2020). Reduced access to healthy and varied food could contribute to overweight and obesity which is a growing health concern across European countries (Springmann et al., 2016). Increased rates of obesity and diabetes further exacerbate risks from heat-related events (EASAC, 2019).

13.7.1.7. Mental Health and Wellbeing

Extreme weather events can trigger post-traumatic stress disorder (PTSD), anxiety and depression; this is well-documented for flooding in Europe (*high confidence*), but less for other extreme weather events. For example, in the UK, flooded residents suffered stress and identity loss from the flood event itself, but also from subsequent disputes with insurance and construction companies (Carroll et al., 2009; Greene et al., 2015). Residents displaced from their homes for at least one year due to 2013-2014 floods in England were significantly more *likely* to experience PTSD, depression and anxiety, with stronger effects in the absence of advance warning (Munro et al., 2017; Waite et al., 2017). There is emerging evidence across Europe that young people may be experiencing anxiety about climate change, though it is unclear how widespread or severe this is (Hickman, 2019). In northern Italy, the number of daily emergency psychiatric visits and mean daily air temperature has been linked (Cervellin et al., 2014).

13.7.2 Solution Space and Adaptation Options

Adaptation to health impacts has generally received less attention compared to other climate impacts across Europe (EASAC, 2019). Progress on health adaptation can be observed. Between 2012 and 2017, at least 20 European countries instituted new governance mechanisms, such as interdepartmental coordinating bodies for health adaptation and adopted health adaptation plans (Kendrovski and Schmoll, 2019). Progress on city level health adaptation is generally limited (Araos et al., 2015) , with most activities occurring in SEU (Paz et al., 2016) *(high agreement, medium evidence)*.

Figure 13.24 presents the assessment of the feasibility and effectiveness of key heat-related health adaptation actions. It shows that substantial social-cultural and institutional barriers complicate widespread implementation of measures; studies on the implementation of new blue-green spaces in existing urban structures in, for example Sweden (Wihlborg et al., 2019), UK (Carter et al., 2018), the Netherlands (Aalbers et al., 2019), point to important feasibility challenges (e.g., access to financial resources, societal opposition, competition for space) (*high confidence*). Lower perception of health risks has been observed amongst vulnerable groups which, in conjunction with perceived high costs of protective measures, act as barriers to implementing health adaptation plans (van Loenhout et al., 2016; Macintyre et al., 2018; Martinez et al., 2019). Key barriers to mental health adaptation actions include lack of funding, coordination, surveillance, and training (e.g., psychological first aid) (Hayes and Poland, 2018). Existing health measures, such as monitoring and early warning systems, play an important role in detecting and communicating emerging climate risks and weather extremes (Confalonieri et al., 2015; Casanueva et al., 2019; Linares et al., 2020)} (*high confidence*). Stricter enforcement of existing health regulation and policy can have a positive effect in reducing risks (Berry et al., 2018).

Effectiveness & feasibility of main adaptation options to reduce heat related impacts & risks to human health in Europe

Impact Type	Adaptation Option	Effectiveness	Feasibility						Confidence	
			Economic	*Technological*	*Institutional*	*Socio-cultural*	*Ecological*	*Geophysical*	*Evidence*	*Agreement*
Mortality, morbidity, exposure, stress from heat	Behavior change measures	M	NL	NL	H	H	NL	NL	M	L
	Natural cooling	L	NL	M	NL	M	NL	NL	H	L
	Building interventions	M	M	M	NL	M	NL	H	H	L
	Green infrastructures	M	M	M	M	M	H	M	M	H
	Heat proof land management	H	NL	M	M	H	H	M	M	M
	Heat health action plans	H	NL	M	H	H	NL	NL	H	H
	Bundle of options	H	H	NL	NL	NL	NL	H	M	L

Legend
High = H
Medium = M
Low = L
No/Limited Evidence = NL

Figure 13.24: Effectiveness and feasibility of the main adaptation options to reduce heat related impacts and risks to human health in Europe. (SM13.9 and Table SM13.19).

The effectiveness of most options in reducing climate induced health risks is determined by many co-founding factors, including the extent of the risk, existing socio-political structure and culture, and other adaptation options in place (*high agreement, medium evidence*). Successful examples include the implementation of heat wave plans (Schifano et al., 2012; van Loenhout and Guha-Sapir, 2016; De'Donato et al., 2018), improvements in health services, and infrastructure of homes (Vandentorren et al., 2006) (Section 13.10.2.1). A study of nine European cities, for example, showed lower numbers of heat-related deaths in Southern European cities, and attributed this to the implementation of heat prevention plans, a greater level of individual and household adaptation, and growing awareness of citizens about exposure to heat (de'Donato et al., 2015). Long-term national prevention programs in Northern Europe have been shown to reduce temperature-related suicide (Helama et al., 2013). Physical fitness of individuals may increase resilience to extreme heat (Schuster et al., 2017). Combining multiple types of adaptation options into a consistent policy portfolio may have an amplifying effect in reducing risks, particularly at higher GWL (Lesnikowski et al., 2019) (*medium confidence*) (Chapter 7).

Health adaptation actions have demonstrable synergies and trade-offs (Cross-Chapter Box HEALTH in Chapter 7). For example, increasing green-blue spaces in Europe's densely populated areas can be effective in improving micro-climates, reducing the impact of heat waves, improving air quality, and improving mental health by increasing access to fresh air and green (restorative) environment (Gascon et al., 2015; Kondo et al., 2018; Kumar et al., 2019). Health adaptations can also have negative trade-offs, be inconsistent with mitigation ambitions, and could lead to maladaptation. Green-blue spaces, for example, may create new nesting grounds for carriers of vector-borne diseases, increase pollen and allergies (Kabisch et al., 2016), enlarge freshwater use for irrigation (Reyes-Paecke et al., 2019), and could raise climate equity and justice issues such as green gentrification (Yazar et al., 2019). Similarly, air conditioning and cooling devices are considered highly effective but have low economic and social feasibility and negative trade-offs due to increasing energy consumption, raising energy costs which is particularly challenging for the poor (Section 13.8.1.1), enhancing the heat island effect, and increasing noise pollution (Fernandez Milan and Creutzig, 2015; Hunt et al., 2017; Macintyre et al., 2018).

The solution space for implementing health adaptation options is slowly expanding in Europe. Health adaptation can build on, and integrate into, established health system infrastructures but these differ significantly across Europe, as do existing capacities to deal with climate-related extreme events (Austin et al., 2016; Austin et al., 2018; Orru et al., 2018; Watts et al., 2018; Austin et al., 2019; Martinez et al., 2019). Despite some progress, limited mainstreaming of climate change is observed, particularly due to low societal pressure to change, confidence in existing health systems, and lack of awareness of links between human health and climate change (*medium confidence*) (Austin et al., 2016; WHO, 2018b; Watts et al., 2021). Coordination of health adaptation actions across scales and between public sectors is needed to ensure timely and effective responses for a diversity of health impacts *(high confidence)* (Austin et al., 2018; Ebi et al., 2018). Key enabling conditions to extend the solution space include increasing the role for national and regional governments in facilitating knowledge sharing across scales, allocating dedicated financial resources, and creating dedicated knowledge and policy programs on climate and health (Wolf et al., 2014; Akin et al., 2015; Curtis et al., 2017). Investing in public healthcare systems more broadly increases their capacity to respond to climate-related extreme events and will ensure wider societal benefits as the COVID-19 pandemic has demonstrated (Cross-Chapter Box COVID in Chapter 7).

Despite a range of options available, there are limits to how much adaptation can take place and residual risks remain. These are predominantly discussed in the context of excess mortality and morbidity to heat extremes (Hanna and Tait, 2015; Martinez et al., 2019). Future heat waves are expected to stretch existing adaptation interventions well beyond levels observed in response to the observed events of 2003 and 2010 (Hanna and Tait, 2015), see Section 13.10.2.1.

13.7.3 Knowledge Gaps

Literature on the link between public health, climate impacts, vulnerability and adaptation is skewed across Europe, with most studies focusing on region-specific impacts (e.g., flood injuries in WCE, heatwaves in SEU). In general, attributing health impacts to climate change remains challenging, particularly for mental health and wellbeing, (mal)nutrition and food quality, and climate sensitive infectious diseases, where other socio-economic determinants play an important role. The connection between climate change and health risks under different socio-economic development pathways is hardly studied comprehensively for Europe, with some exceptions for extreme events. However, these interactions seem to play an important role in better understanding projected risks and inform choices on adaptation planning.

Some climate-related health issues are emerging but evidence is too limited for a robust assessment, for example the links between climate change and violence in Europe (Fountoulakis et al., 2016; Mares and Moffett, 2016; Sanz-Barbero et al., 2018; Koubi, 2019).

The solution space for public health adaptation in Europe, and the effectiveness of levers for interventions, are hardly assessed. Although health adaptations are documented, these are particularly around mortality and injuries due to extreme events (predominantly floods (13.2.1) and heat waves (13.7.1.1). There are very few studies assessing the barriers and enablers of health adaptations, nor systematic assessment of the effectiveness of (portfolio of) options. Limited insights into what works and where hamper upscaling these insights across Europe and constrains the ability to evaluate whether investments in health adaptation have actually reduced risks.

13.8 Vulnerable Livelihoods and Social Inequality

This section addresses social consequences of climate change for Europe, by looking into consequences for poor households and minority groups; migration and displacement of people; livelihoods particularly vulnerable to climate change (indigenous and traditional communities); and cultural heritage.

13.8.1 Observed Impacts and Projected Risks

13.8.1.1 Poverty and Social Inequality

While climate change is not the main driver of social inequality in Europe, poor households and marginalized groups in Europe are affected more strongly than other social groups by flooding, heat and drought and risks to spreading diseases (*medium confidence*).

Urban poor and ethnic minorities often settle in more vulnerable settlement zones, and are therefore impacted more by flooding (*medium confidence*) (Medd et al., 2015; Župarić-Iljić, 2017; Efendić, 2018; Fielding, 2018; Winsemius et al., 2018; Puđak, 2019; Inuit Circumpolar Council, 2020). Yet, in some western European residential waterside developments this pattern is reversed by flooding impacting high income residents more strongly (Walker and Burningham, 2011).

The health of the poor is disproportionately affected e.g. during heat waves in the Mediterranean (Jouzel and Michelot, 2016). Women, those with disabilities and the elderly are disproportionately affected by heat (Section 13.7.1). Floods in the Western Balkans in 2014 resulted in heavy metal pollution of water and land threatening the health condition of the poorer rural population (Filijović and Đorđević, 2014). Access to water and sanitation is less available to poorer households and marginalized groups in Europe (Ezbakhe et al., 2019; Anthonj et al., 2020) which could be intensified by increasing water scarcity in parts of Europe under future climate change (Section 13.10.3).

Food self-provisioning is a widespread practice in many parts of Europe (Aleynikov et al., 2014; Corcoran, 2014; Church et al., 2015; Mustonen and Huusari, 2020), reaching over half of German rural areas (Vávra et al., 2018). While it strengthens resilience for disadvantaged households (Church et al., 2015; Boost and Meier, 2017; Promberger, 2017; Vávra et al., 2018; Ančić et al., 2019; Pungas, 2019) and renews their local knowledge, it can become at risk in regions with projected crop yield reductions (*high confidence*) (Hallegatte et al., 2016; Quiroga and Suárez, 2016; Myers et al., 2017b; Inuit Circumpolar Council, 2020), and after extreme weather events (Filijović and Đorđević, 2014).

Energy poor households often live in thermally inefficient homes and cannot afford air conditioning to adapt to overheating in summer (Sanchez-Guevara et al., 2019; Thomson et al., 2019). While energy poverty is much more prevalent in southern and eastern Europe (Bouzarovski and Petrova, 2015; Pye et al., 2015; Atsalis et al., 2016; Monge-Barrio and Sánchez-Ostiz Gutiérrez, 2018), climate change will also exacerbate energy poverty in European regions where heating was so far the major share of energy costs (*medium confidence*) (Sanchez-Guevara et al., 2019; Randazzo et al., 2020).

13.8.1.2 Migration and Displacement of People

Most migration and displacement due to climate change is taking place within national borders and single regions (Cross-Chapter Box MIGRATE in Chapter 7). There is *low confidence* in climate change contributing to migration from outside Europe into Europe (Gemenne, 2011; Topilin, 2016; Gemenne and Blocher, 2017; Selby et al., 2017). Some economic models project that asylum applications to the EU might increase by a third at 2.5°C GWL and more than double beyond 4°C GWL by end of the century (Missirian and Schlenker, 2017), but empirical evidence shows that applications might decrease due to growing economic and legal barriers in the capacity of populations to emigrate from Africa or other regions (Kelley et al., 2015; Zickgraf, 2018; Borderon et al., 2019).

Migration of people within Europe is predominantly triggered by economic disparities among European countries (Fischer and Pfaffermayr, 2018). There is *limited* and *inconclusive* evidence for climate-driven impacts on these movements (Hoffmann et al., 2020). Small scale climate-induced displacement within Europe occurs in the aftermath of flood and drought disasters and over short distances (Cattaneo et al., 2019). The unequal distribution of future climate risks (13.1) and adaptive capacity across European regions may increase pressure for internal migration (Williges et al., 2017; Forzieri et al., 2018). For instance, projected sea level rise (13.2.1, Cross-Chapter Box SLR in Chapter 3) may result in planned relocation of coastal settlements and inland migration in the UK, the Netherlands and the northern Mediterranean (Mulligan et al., 2014; Antonioli et al., 2017). The number of people living in areas at risk in Europe is projected to increase with future SSPs increasing exposure (Merkens et al., 2016; Byers et al., 2018; Harrison et al., 2019).

13.8.1.3 Loss and Damage to Vulnerable Livelihoods in Europe

A number of livelihoods maintaining unique cultures in Europe is particularly vulnerable to climate change (Table 13.2): indigenous communities in the European polar region because of their dependence on cryosphere ecosystems *(high confidence*) (CCP Polar, Hayashi, 2017; Huntington et al., 2017; Hock et al., 2019; Meredith et al., 2019; Inuit Circumpolar Council, 2020; Douville et al., 2021; Fox-Kemper et al., 2021) and communities dependent on small-scale fisheries, traditional farming and unique cultural landscapes (*medium confidence*) (Kovats et al., 2014; Ruiz-Díaz et al., 2020).

For Sámi reindeer herding impacts cascade due to a lack of access to key ecosystems, lakes and rivers thereby threatening traditional livelihoods, food security, cultural heritage (e.g. burial grounds, seasonal dwellings and routes), mental health (Box 13.2 and Figure 13.13, Feodoroff, 2021), and growing costs for example as a result of the need for artificial feeding of reindeer.

Table 13.2: Examples of losses and damages to vulnerable livelihoods in Europe, differentiating for different categories of non-economic loss and damage. (Table SM13.20.).

	Human life		Communal and production sites and intrinsic value
	Sense of place		Agency and identity
	Cultural artefacts		Psychological and emotional distress
	Biodiversity and ecosystems		

Climate hazard	Change in exposure and vulnerability	Observed impact / projected risk
Loss of livelihood, culture, health and wellbeing of the Sámi and the Nenets. 		
Decrease and alterations in snow and ice sheet, unstable winter weather, especially in the form of rain-on-snow events; increased precipitation and thawing permafrost, in tundra; unstable loss/flux of marine ice cover.	Land-use change (e.g. expansion of renewable energy) resulting in pasture loss and disconnection of ecosystems.	Loss of livelihood (e.g. reindeer herding), loss of food security (cold dependent species), culture, health (impact on safety; psychological impacts from stress to reindeer and Indigenous way of life), and cultural and linguistic wellbeing; release of anthrax from permafrost soils in the Nenets area.
Loss of key species in high-Arctic freshwater habitats, proliferation of introduced species and disruption of local food systems in Greenland, Finland, Sweden, NW Russia and Scotland. 		
Warmer water temperatures in high-Arctic freshwater habitats (13.3.1) increase productivity in oligotrophic systems and eventually	Introduced Pacific Pink Salmon has expanded in range since 1970s, affecting endemic species through competition and reducing their	Shifts in freshwater aquatic habitats and loss of endemic cold-dependent fish, such as Arctic Char and Arctic Salmon, cause disruptions to local

lead to loss of oxygen in water; warming temperatures and changes to ice cover and cryosphere lead to access issues to freshwater fisheries.	abundance. Increased nutrient loading of rivers and rapid expansion of algae increase the risks for cold-dependent fish.	food supply, and local extinctions threatens livelihood safety and cultural well-being.
Warmer winters lead to loss of income from ice fishing and cultural heritage in Finland.		
The start of ice cover on lakes, e.g. lake Puruvesi (Finland), has changed from November to February; ice breakup occurs much earlier in the year.	The quality of the water in the lakes used for fishing depend on ice cover during most of the year, and the season of open water is now much longer, increasing nutrient flow and loss of water quality in these lakes.	Lack of winter ice combined with delayed freeze up and earlier ice breakup reduce fish harvest for important species by up to 50% and impacts local safety, ecosystems, oral history maintenance and the local economy.
Changes to marine food web results in loss of Indigenous knowledge and food insecurity in Greenland.		
Warmer ocean waters moving further north (so-called "atlantification" of Greenland waters); higher temperatures removing sea ice	Traditional practices and knowledge based on sea ice uses and hunting are being lost; species are being replaced with southern fish.	Loss of Indigenous knowledge of how to deal with and use sea ice regarding species and navigation, loss of access to seals and walruses, food insecurity.
Reduced yields on managed alpine grasslands decreases the self-sufficiency of pastoral livestock farming in the Austrian, French and Swiss Alps		
Increase in heat, precipitation variability and agricultural as well as hydrological drought; less snow on the ground, increase in glacier melt, landslides susceptibility and erosion	Land-use change resulting in natural reforestation of abandoned pastoral land; shifts in alpine plant communities; more intensive cultivation of grasslands; change in agricultural markets and support policy.	Abandonment of summer pastures and farms, with negative consequences for farming income, tourism, cultural and aesthetic values.
Reduced yields on semi-natural grasslands, compromising livestock feeding in winter, and ultimately decreasing viability of pastoralism in the Spanish Pyrenees		
Higher temperatures and more variable precipitation, less snow, change in seasonality and drought	Demographic change, change in policy and market conditions, simplification of pastoral practices and agroecosystems, land abandonment or afforestation of marginal pastoral lands and intensification of more favourable lands in the lowlands, troublesome coexistence with tourism and nature conservation initiatives	Decreasing viability of pastoralism, concentration of pastoral production on most profitable locations for intensive rearing of livestock with abandonment of the rest of the land; pastoral land encroachment both by shrubs and other activities; grassland degradation; biodiversity loss
Retreating glaciers and changes in the landscape lead to loss of identity, culture and self-reliance in the Italian Alps (Alto Adige)		

Glacier volume loss from increasing temperatures	Vulnerability is mainly driven by reliance on tourism	Loss of sense of community through shared memories, and history. Sadness caused by the loss of what feels like "home". Loss of well-being due to uncertainty and fear of the future.
Drought results in a reduction of provisioning (water) and regulating services (protection against floods) in Western and Eastern Alps, Iberian Mountains, Dinaric Mountains		
Increase in drought, particularly under high-end GWL	Forest management strategies, including that of natural forests, can enhance or reduce vulnerability.	Critical importance of alpine natural forests and meadows for regulating services; Negative impacts of climate change are found mainly at low elevations and for specific species (Norway spruce); decrease in soil moisture due to abandonment of pastoralism result in reduced water provision for downstream water users
Increase of sea temperature leads to shifts in distribution of cold water species, reducing productivity at lower latitudes. Artisanal fisheries in Southern European coastal areas (Mediterranean) that rely on local, nearshore stocks can have difficulties to adapt		
Increase in sea temperature	Substitution of artisanal fisheries by industrial fisheries; less support by governments, shift in employment (e.g. tourism) which do not match the skill sets, education or desires of small-scale fishers; national quotas system leads to prices to high buy or lease quotas and immense amount of bureaucracy and regulations	Due to their low investment capacity and boat size, fishers are limited in their movement to other fishing places when local fish stocks decline. Increasing sea temperatures are increasing the threat of invasive species in coastal ecosystems.

[START BOX 13.2 HERE]

Box 13.2: Sámi Reindeer Herding in Sweden

Reindeer (*Rangifer tarandus*) are keystone species in northern landscapes (Vors and Boyce, 2009). Reindeer herding is a traditional, semi-nomadic livelihood of the Sámi. Reindeer migrate between seasonal pastures that cover 55% of Sweden and are simultaneously used for multiple other purposes (Sandström et al., 2016). Reindeer herding is recognized as an indigenous right, protected by the UN Declaration on the Rights of Indigenous Peoples, several UN conventions and through Swedish national legislation.

Temperatures in Arctic and sub-Arctic regions have increased on average by 2°C over the last 30 years (*very high confidence*) (Ranasinghe et al., 2021). Future warming is expected to further increase winter precipitation (*high confidence*) (Ranasinghe et al., 2021) and rain-on-snow events, creating a hard ice crust on the snow after refreezing (Bokhorst et al., 2016; Rasmus et al., 2018).

The documented and projected impacts on reindeer are complex and varied. Warming and CO_2 increase result in higher plant productivity (Section 13.3), changes in plant community composition, and higher parasite harassment; unstable ice conditions affect migration; extreme weather conditions during critical winter months, more frequent forest fires and changes in plant community composition reduce pasture quality (*medium confidence*) (Mallory and Boyce, 2018) (Figure Box 13.2.1). High snow depth and rain-on-snow events impede reindeer access to ground lichen in winter and delay spring green-up during critical calving period; both cause malnutrition and negative impacts on reindeer health, mortality and reproductive success (*medium confidence*) (Hansen et al., 2014; Forbes et al., 2016; Mallory and Boyce, 2018). Lower slaughter weights and increased mortality reduce the income of herders (*high confidence*) (Tyler et al., 2007; Helle and Kojola, 2008).

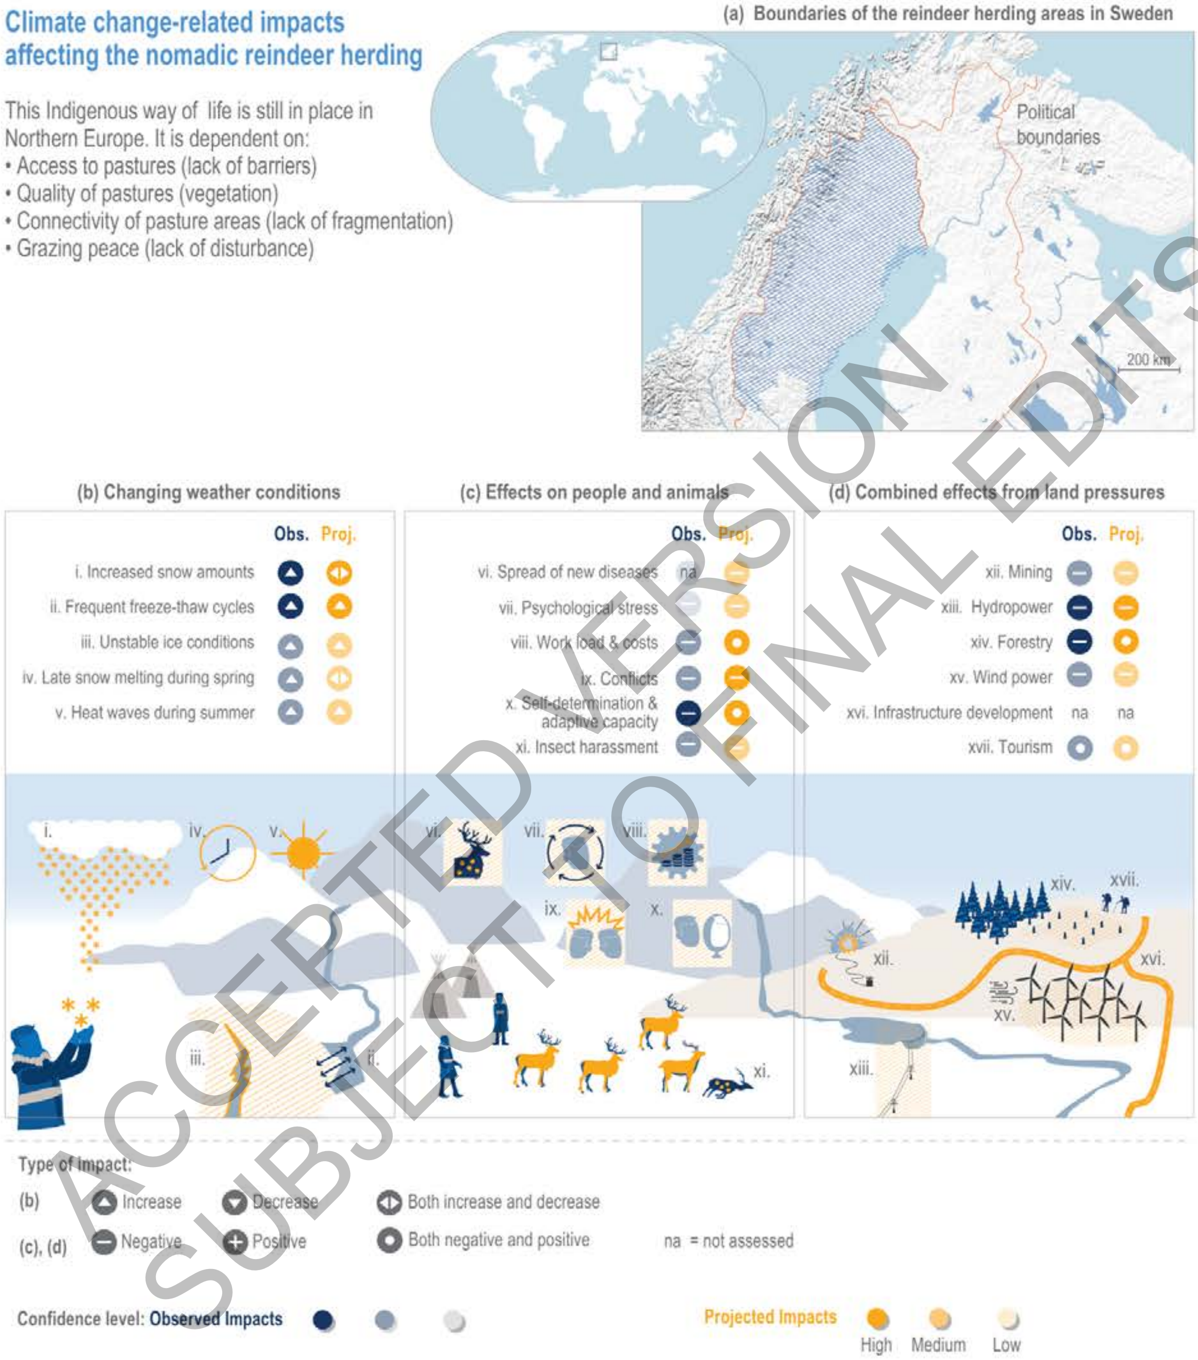

Figure Box 13.2.1: Cumulative impacts of climate and land use change on reindeer herding as a traditional, semi-nomadic Sámi livelihood (Table SM13.21).

Reindeer herders already autonomously adapts to changing conditions through flexible use of pastures and supplementary feeding (*high confidence*), reducing and thereby hiding some of the negative impacts of climate change (Uboni et al., 2016). However, adaptive herding practices have themselves added significant burden through increased workload, costs and stress (*high confidence*) (Furberg et al., 2011; Löf, 2013;

Rosqvist et al., 2021). Supplementary feeding increases risk for infectious diseases and implies culturally undesirable herding practices (*low confidence*) (Lawrence and Kløcker Larsen, 2019; Tryland et al., 2019).

Rapid land use change reduces the ability to adapt (*high confidence*) (Tyler, 2010; Löf, 2013). National and EU policies expand land uses for mining, wind energy and bioeconomy in the area, causing loss, fragmentation and degradation of pastures, and increasing human disturbance to animals *(medium confidence)* (Kivinen et al., 2012; Skarin and Åhman, 2014; Kivinen, 2015; Skarin et al., 2015; Sandström et al., 2016; Beland Lindahl et al., 2017; Österlin and Raitio, 2020). The cumulative impacts of these land-uses on pastures are not adequately assessed or recognized in land use planning (Kløcker Larsen et al., 2017; Kløcker Larsen et al., 2018). Herding communities face strong barriers to protecting their rights and halting further degradation of pastures (*medium confidence*) (Allard, 2018; Kløcker Larsen and Raitio, 2019; Raitio et al., 2020). Attempts by herding communities to stop mining projects have led to conflicts with other actors, including racist hate speech (Persson et al., 2017; Beland Lindahl et al., 2018). Combined with land use conflicts, climate impacts cause reduced psycho-social health and increase suicidal thoughts among herders *(low confidence)* (Kaiser et al., 2010; Furberg et al., 2011).

Reindeer herding is significantly affected by climate change directly and indirectly (Figure Box 13.2.1) (Pape and Löffler, 2012; Andersson et al., 2015). The cumulative effects of land use and climate change have already increased vulnerability and reduced the adaptive capacity of reindeer herding to the extent that its long-term sustainability is threatened (*medium confidence*) (Löf, 2013; Horstkotte et al., 2014; Kløcker Larsen et al., 2017).

Maintaining and improving the solution space to adapt reindeer herding is crucial for reducing existing impacts and projected risks of climate and land use change (Andersson et al., 2015; Turunen et al., 2016; AMAP, 2017; Hausner et al., 2020). Lack of control over land use is the biggest and most urgent threat to the adaptive capacity of reindeer herding and the right of Sámi to their culture (*high confidence*) (Pape and Löffler, 2012; Andersson et al., 2015; Kløcker Larsen and Raitio, 2019).

[END BOX 13.2 HERE]

13.8.1.4 Cultural and Natural Heritage

Climate change poses a serious threat to preservation of cultural heritage in Europe, both tangible and intangible (*high confidence*) (Haugen and Mattsson, 2011; Daire et al., 2012; Dupont and Van Eetvelde, 2013; Macalister, 2015; Phillips, 2015; Fatorić and Seekamp, 2017; Graham et al., 2017; Carroll and Aarrevaara, 2018; Sesana et al., 2018; Iosub et al., 2019; Daly et al., 2020). At higher GWL, building exteriors and valuable indoor collections become at risk (Leissner et al., 2015). Coastal heritage such along the North Sea and Mediterranean are under water-related threats (Reimann et al., 2018b; Walsh, 2018; Harkin et al., 2020) (Box 13.1 Venice; WGII AR6 CCP4).

Disappearing cultural heritage can reduce incomes due to loss of tourism (Hall et al., 2016), as exemplified by glacier retreat e.g. in the Swiss Alps and Greenland (Bjorst and Ren, 2015; Bosson et al., 2019) (CCP5.3.2.4). Glacier retreat can create a sense of discomfort, loss of sense of place, displacement and anxiety in people (Section 13.7) (Albrecht et al., 2007; Brugger et al., 2013; Allison, 2015; Jurt et al., 2015). Intangible cultural heritage, such as place names, and lost traditional practices can also be affected (Mustonen, 2018; Dastgerdi et al., 2019).

13.8.2 Solution Space and Adaptation Options

As climate change is interacting with many other drivers of poverty, improving the social position of the currently poor may increase their climate resilience (*low confidence*) (Hallegatte and Rozenberg, 2017; Fronzek et al., 2019). Some adaptation actions have the potential to alleviate poverty (Section 13.11.3), but adaptation can also increase social inequalities, e.g. when practices of disaster recovery focus on high visibility areas and not on low-income neighbourhoods or marginalized spaces (D'Alisa and Kallis, 2016). Risk communication and management reliant on new information technologies can exclude elderly and populations with lower educational attainment (Kešetović et al., 2017).

Unlike migration within the European Union, migration from outside Europe to Europe is heavily constrained by restrictive migration and asylum policies (Fielding, 2011; Mulligan et al., 2014), eventually leaving people to stay in more exposed and risk-prone regions (Benveniste et al., 2020). To reduce vulnerability in these regions, Europe can contribute to adaptation and development in regions outside Europe (section 13.9.4).

Indigenous and local knowledge, embedded e.g. in fishermen, farmers and navigators, can be a vehicle for detecting, monitoring and observing impacts (Arctic Council, 2013; Brattland and Mustonen, 2018; Madine et al., 2018; Meredith et al., 2019) (section 13.11.1.3). Regarding risks to northern traditional livelihoods and indigenous communities, small-scale adaptation is taking place, for example by ecological restoration of habitats (section 13.3) (Mustonen and Kontkanen, 2019). However, limited access to resources outside the jurisdictions of the communities limits the scope of community-based adaptation (Arctic Council, 2013; Mustonen et al., 2018; Meredith et al., 2019).

European cultural heritage in general and world heritage sites specifically lack adaptation strategies to preserve key cultural assets (Haugen and Mattsson, 2011; Howard, 2013; Heathcote et al., 2017; Reimann et al., 2018b; Harkin et al., 2020). Key reasons are the underdeveloped adaptation actions available, resources for implementing them, and absence of overarching policy guidance (Phillips, 2015; Fernandes et al., 2017; Sesana et al., 2018; Daly et al., 2020) (Sesana et al., 2018; Fatorić and Biesbroek, 2020; Sesana et al., 2020).

13.8.3 Knowledge Gaps

There is limited understanding of how different social groups are affected by the four European key risks under future climate change (13.11.2), and by adaptation to them. Similarly, the interaction of multiple risks across sectors and how this interaction results in displacement, migration, or immobility of people both within and from outside Europe is insufficiently understood. For indigenous and traditional livelihoods in Europe, the understanding of how risks will change at different warming levels is very limited, due to complex interactions with socio-economic and political change. For European cultural heritage, there is also a lack of tailored knowledge and understanding of the impacts and how to translate these into adaptation measures.

13.9 Interregional Impacts, Risks and Adaptation

This section addresses interregional risks between Europe and other parts of the world. Global risk pathways affecting sectors and supply chains relevant for European economies and societies involve (1) ecosystems, (2) people (e.g., through migration), (3) financial flows, and (4) trade, and these pathways ultimately impact security, health, wellbeing and food supply (Yokohata et al., 2019) (Cross-Chapter Box INTEREG in Chapter 16).

13.9.1 Consequences of Climate-change Driven Impacts, Risks and Adaptation Emerging in Other Parts of the World for Europe

Recent literature (Wenz and Levermann, 2016; Hedlund et al., 2018; Benzie et al., 2019) strengthens the confidence in the AR5 statement that "with increasing globalization, the impacts of climate change outside the European region are *likely* to have implications for countries within the region" (Kovats et al., 2014). The exposure of European countries to trans-European climate impact and risk pathways varies depending on their territorial settings, national policies and position in the global supply chain (*high confidence*) (Berry et al., 2015; Hedlund et al., 2018; Benzie et al., 2019). There is *limited evidence* that Europe is more exposed to interregional risks than North America, and less than Africa and Asia (Hedlund et al., 2018). The social and governance context in Europe make the region less vulnerable to conflicts driven by climate change than other regions, at least up to 2°C GWL (Buhaug et al., 2014; Mach et al., 2019; Ide et al., 2020).

Climate risks in other parts of the world can be transmitted to European economies via trade networks (Figure 13.25). European agricultural imports exert a high water footprint in originating countries already today (Dolganova et al., 2019; Ercin et al., 2019), and some crop imports such as tropical fruits are highly vulnerable to future climate change (Brás et al., 2019). Simultaneous breadbasket failures, and trade restrictions increase risks to food supply (*medium confidence*) (Fellmann et al., 2014; d'Amour et al., 2016; Gaupp et al., 2017; Gaupp et al., 2020). There is *high confidence* that the European economy could be negatively affected by supply chain disruptions due to flooding destroying facilities, heatwaves and malaria reducing productivity in labour intensive industries and regions (13.7.1), and sea level rise affecting ports and cities along coastlines (13.6.1.2) (Nicholls and Kebede, 2012; Challinor, 2016; Wenz and Levermann, 2016; Hedlund et al., 2018; Koks, 2018; Szewczyk et al., 2018; Willner et al., 2018; Knittel et al., 2020; Kulmer et al., 2020; Carter et al., 2021).

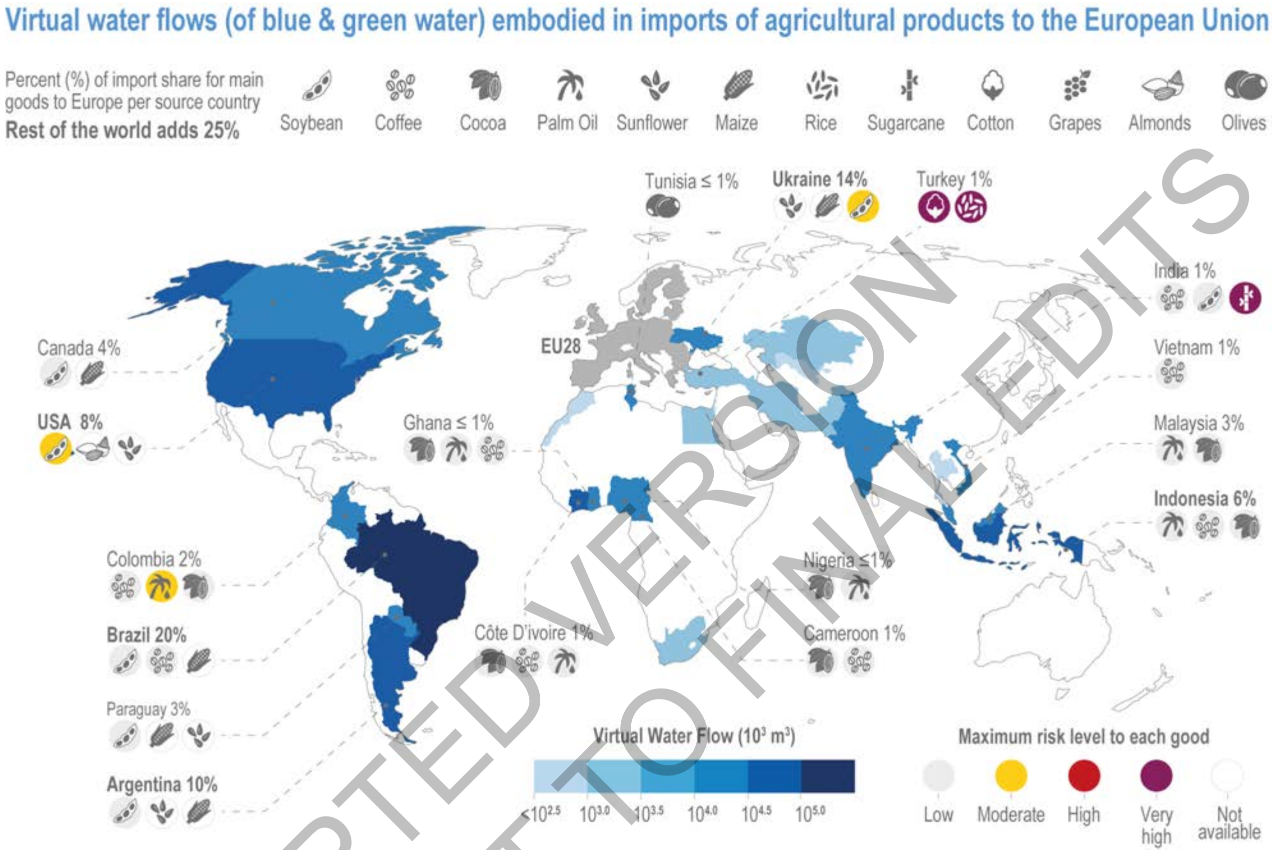

Figure 13.25: Trans-European climate risks in trade: virtual water flows embodied in agricultural imports to Europe in 2018 and the vulnerability to climate change of the most important crops in the originating countries (Dolganova et al., 2019; Ercin et al., 2019).

13.9.2 Interregional Consequences of Climate Risks and Adaptation Emerging from Europe

New literature since AR5 suggests that climate risks in Europe can propagate worldwide in response to 3°C GWL (*medium confidence*). Key concerns include climate impacts on European agriculture threatening global food security (Berry et al., 2017; van der Velde et al., 2018) (Section 13.5.1) and the European demand limiting the adaptation potential for ecosystems in South-America, Africa and Asia (IPBES, 2018; Pendrill et al., 2019; Fuchs et al., 2020). Emerging literature suggests that coastal and riverine flood risks in Europe could be amplified through the global financial system, and generate a systemic financial crisis (Mandel et al., 2021) (Figure 13.26). For 3°C GWL and without adaptation, northern Atlantic flight routes and European ports are projected to be increasingly disrupted by changing winds, waves, and sea level rise (Section 13.6.1.2) (Williams and Joshi, 2013; Irvine et al., 2016; Williams, 2016; Becker et al., 2018; Camus et al., 2019; Verschuur et al., 2020).

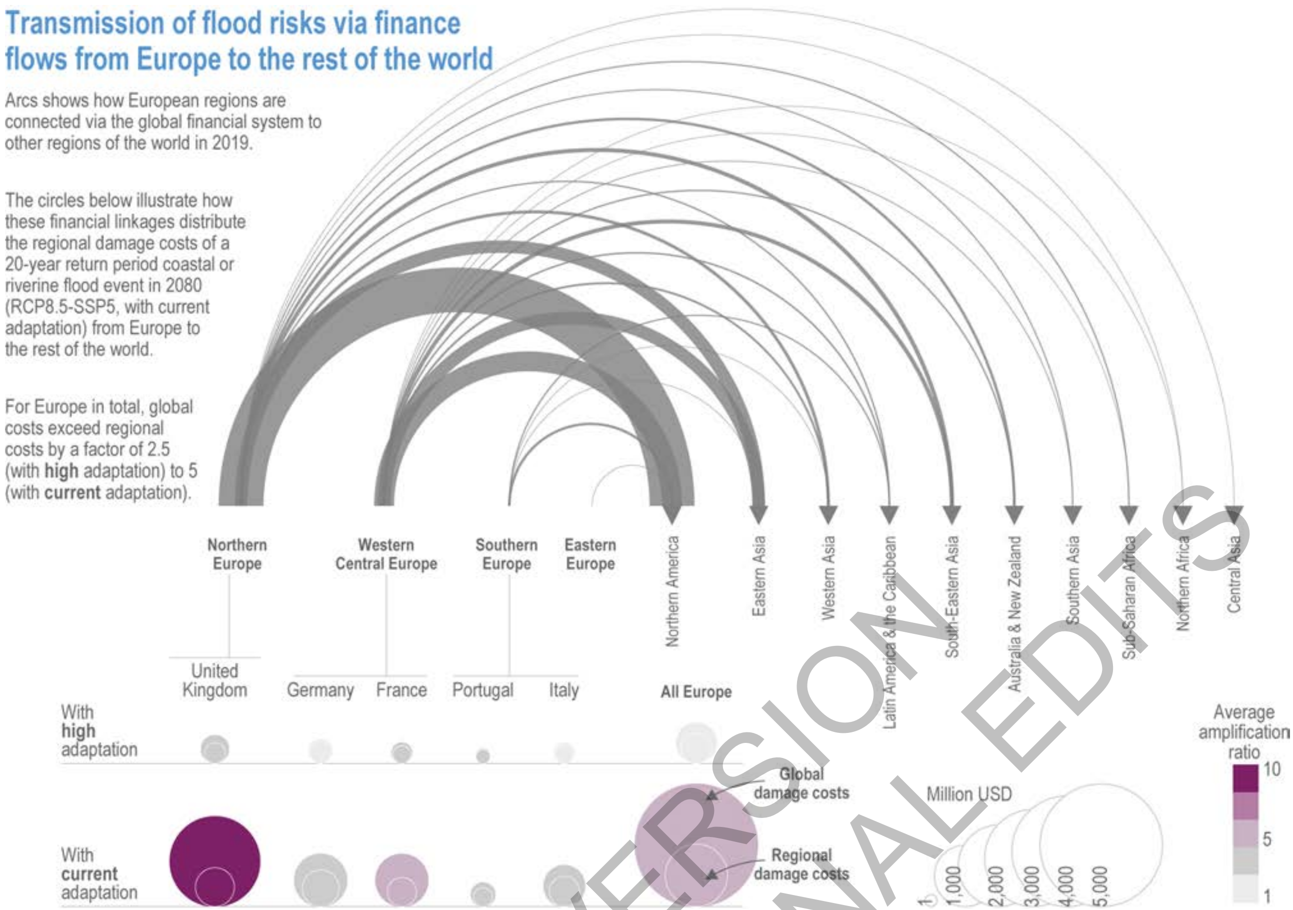

Figure 13.26: The transmission of coastal and riverine flood risks via finance flows from Europe to the Rest of the World. (Mandel et al., 2021).

13.9.3 European Territories Outside Europe

European territories outside Europe are critically exposed to climate risks such as increased forest fires (Russian Siberia) (Sitnov et al., 2017) (Chapter 10), climate change-induced biodiversity losses and sea level rise (UK, Spanish, Portuguese, French and Dutch overseas regions and territories) (Ferdinand, 2018; Sieber et al., 2018) (Chapters 12 and 15). Climate risks emerging from these territories include smoke and dust from Siberian forest fires (Sitnov et al., 2017), and, depending on European health-risk mitigation measures, dengue and other mosquito-transmitted diseases (13.7) (Schaffner and Mathis, 2014). Some marine protected areas (MPA, 13.4.3) in European overseas territories are increasingly affected by changes originating in far-field upstream areas. These changes ultimately undermine their ability to curb biodiversity losses and provide ecosystem services (Schaffner and Mathis, 2014; Robinson et al., 2017). Adaptation options and regulations developed within Europe apply in these territories, despite *low confidence* that they meet local and regional adaptation challenges and address the aspiration for social justice, promotion of local solutions and consideration of traditional knowledge (Ferdinand, 2018; Terorotua et al., 2020).

13.9.4 Solution Space and Adaptation Options

European countries can address interregional risks at the place of origin or destination, e.g., by developing local adaptation capacity in trading partner countries and in European territories outside Europe(Petit and Prudent, 2008; Benzie et al., 2019; Adams et al., 2020; Terorotua et al., 2020), by providing international adaptation finance (Dzebo and Stripple, 2015; BMUB, 2017), by developing insurance mechanisms suitable for adaptation, or European climate services to support global adaptation (Linnerooth-Bayer and Mechler, 2015; Brasseur and Gallardo, 2016; Street, 2016; Cavelier et al., 2017) (Cross-Chapter Box INTEREG in Chapter 16). Along the supply chain, risks can be reduced by trade diversification and alternative sourcing (Benzie and Persson, 2019; Adams et al., 2020). Within Europe, risks can be reduced by integrating interregional climate risks into national adaptation strategies and plans and mainstreaming into EU policies (e.g., Common Agricultural Policy, trade agreements) (Benzie et al., 2019; Benzie and Persson, 2019; Groundstroem and Juhola, 2019; Adams et al., 2020). There is *high confidence* that the exposure of European countries to interregional risks can be reduced by international governance (Dzebo and Stripple, 2015; Cramer et al., 2018; Persson and Dzebo, 2019) (Cross-Chapter Paper 4), e.g., fulfilling the targets of environmental agreements such as the Convention for Biological Diversity (IPBES, 2018). There is *emerging evidence* that supporting adaptation outside Europe may generate economic co-benefits for Europe (Román et al., 2018).

13.10 Detection and Attribution, Key Risks and Adaptation Pathways

13.10.1 Detection and Attribution of Impacts

Since AR5, scientific documentation of observed changes attributed to global warming have proliferated (*high confidence*). These include ecosystem changes detected in previous assessments, such as earlier annual greening and onset of faunal reproduction processes, and relocation of species towards higher latitudes and altitudes (*high confidence*), and impacts of heat on human health, and productivity (*high confidence*) (Figure 13.27 and Table SM13.22) (Vicedo-Cabrera et al., 2021). Formal attribution of impacts of compound events to anthropogenic climate change is just emerging for example in the recent crop failures due to heat and drought (Toreti et al., 2019a). Also, there is *high agreement* and *medium evidence* that particular events attributed to climate change have induced cascading impacts and other impact interactions (Smale et al., 2019; Vogel et al., 2019). In the recent decades (2000-2015), economic losses intensified in southern Europe (*high confidence*) and were detected for parts of WCE and NEU (*medium confidence*). The methodology for detection and attribution is presented in Chapter 16.2.

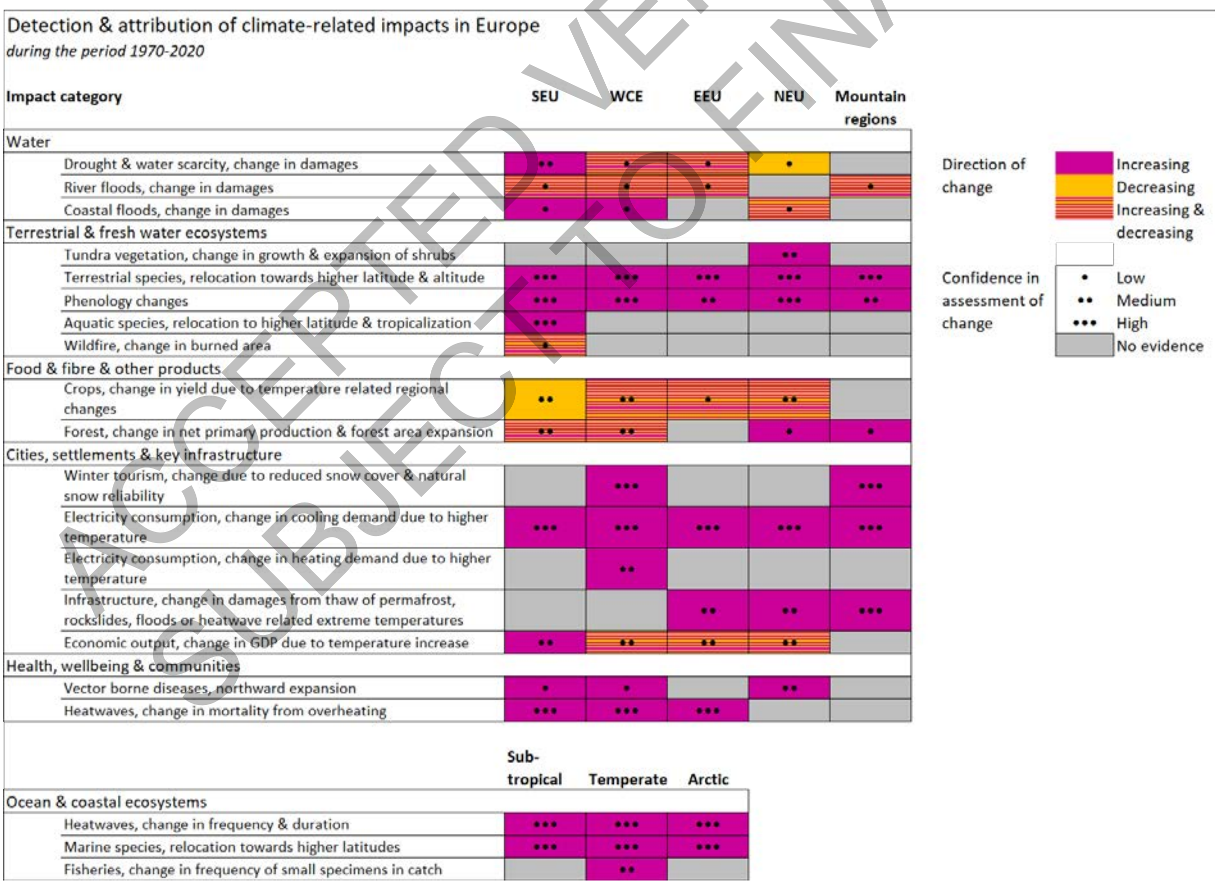

Figure 13.27: Detected changes and attribution (D&A) of climate-related impacts on land (top) and in the ocean (bottom). Assessment based on peer reviewed literature in this chapter that reported observed evidence with at least 90% significance and usually with 95% significance or more (Table SM13.22).

13.10.2 Key Risks Assessment for Europe

Key risks (KRs) are defined as a subset of climate risks which can potentially become or are already severe now (Section 16.5). The selection process included a review of KRs already identified in AR5 Chapter 23 and a review of the large number of new evidence on projected risks presented in Sections 13.2-13.9. Key risks are reinforced by evidence from the detection and attribution assessment (Section 13.10.1) and new evidence from WGI AR6 Chapters 11 and 12 on regional climatic impact drivers and extremes (Ranasinghe et al., 2021; Seneviratne et al., 2021). Several expert opinion workshops of lead and contributing authors led to further refinements, adjustment and consensus building around the key risks' characteristics, which ultimately guided the construction of the burning embers (Figures 13.28-13.32) (SM13.10). There is *high confidence* that under low or medium adaptation, high to very high risks are projected at 3°GWL (Figure 13.28 and Sections 13.10.2.1-13.10.2.4). Most risks are assessed as moderate up to 1.5°GWL (Figure 13.28).

This section also includes an assessment of the solution space using illustrative adaptation pathways which show alternative sequences of options to reduce risks as climate changes (SM13.10). Low effectiveness measures are followed by measures of a higher effectiveness, while accounting for path-dependency of decisions (Toreti et al., 2019b; Haasnoot et al., 2020a). The process to derive the pathways draws on evidence from the feasibility and effectiveness assessments (Sections 13.2, 13.5, 13.6, 13.7).

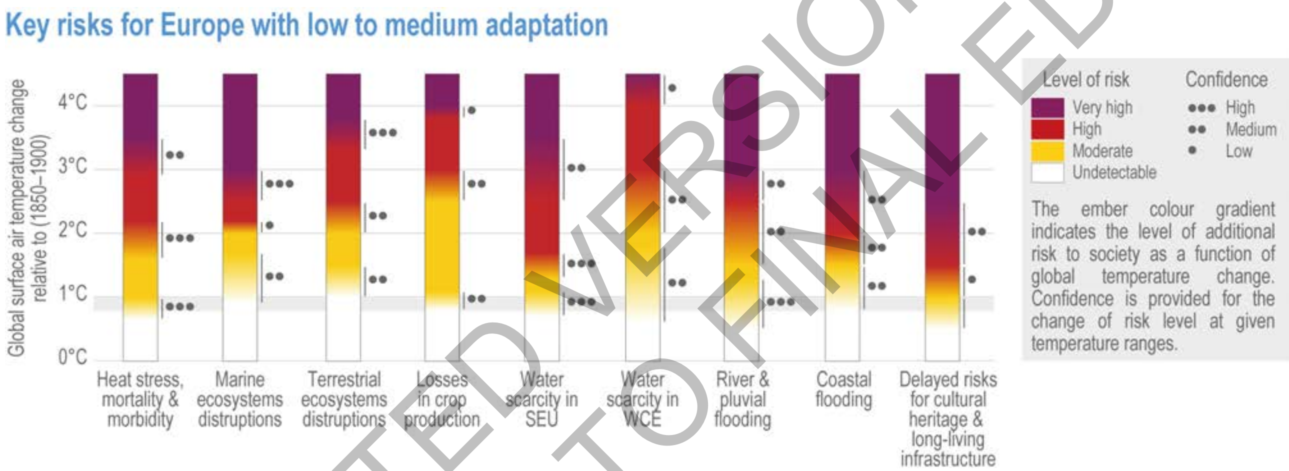

Figure 13.28: Burning ember diagrams for low to medium adaptation. More details on each burning ember are provided in Sections 13.10.2.1-13.10.2.4 and SM13.10. Some burning embers are shown again in Figure 13.29-13.34 alongside burning embers with high adaptation.

13.10.2.1 KR1: Risks of human mortality and heat stress and of ecosystems disruptions due to heat extremes and increase in average temperatures

This key risk cut across humans and ecosystems and severe consequences are mainly driven by an increasing frequency, intensity and duration of heat extremes and increasing average temperatures (*high confidence*) (Urban, 2015; Forzieri et al., 2017; Feyen et al., 2020; Naumann et al., 2020; Ranasinghe et al., 2021). The risk of human heat stress and mortality is largely influenced by underlying socio-economic pathways, with consequences being more severe under SSP3, SSP4 and SSP5 scenarios than SSP1 (*very high confidence*) (Figure 13.22, Section 13.6.1.5.2, Section 13.7.1.1, Hunt et al., 2017; Kendrovski et al., 2017; Rohat et al., 2019; Casanueva et al., 2020). SSPs impact natural systems as well but are not yet well studied. The impact of warming in marine systems are often synergistic with SLR in coastal systems and ocean acidification driven by the rise in CO_2, while habitat fragmentation and land use have important synergies in terrestrial systems (Sections 13.3.1.2 and 13.4.1.2, *high confidence*). More intense heatwaves on land and in the ocean, particularly in Mediterranean Europe (Section 13.4, CCP 4, Darmaraki et al., 2019b; Fox-Kemper et al., 2021), are expected to cause mass mortalities of vulnerable species and species extinction, altering the provision of important ecosystem goods and services (Marbà and Duarte, 2010).

The burning embers on risks for humans (Figure 13.29a) differentiate between present and medium adaptation conditions, drawing on SSP2 and SSP4 (and to a lesser extent SSP3), and high adaptation conditions, drawing on SSP1 and papers using various temperature adjustment methods (Table SM13.25). There is *high confidence* that the risk is already moderate now because it has been detected and attributed with *high confidence* (13.10.1). The transition from moderate to high risk for human health is assessed to happen after 1.5°C GWL in a scenario with present to medium adaptation and implies 2- 3 fold increase (compared to moderate risk levels) in magnitude of consequences such as mortality, morbidity, heat stress and thermal discomfort (Rohat et al., 2019; Casanueva et al., 2020; Naumann et al., 2020). At this level, the risk will also become more persistent across the continent due to increase in heat events exceeding critical thresholds for health (Ranasinghe et al., 2021) (*high confidence* on the direction of change and temperature transition, but *medium confidence* on the magnitude).

The burning embers on risk for terrestrial and marine ecosystems and some of their services is shown in Figure 13.28, second and third ember from left (Tables SM13.26 SM13.27). The transition to moderate risk is currently happening as warming already results in changes in timing of development, species migration northwards and upwards, desynchronization of species interactions, especially at the range limits, with cascading and cumulative impacts through ecosystems and food webs (Sections 13.3 and 13.4; Figure 13.8 and 13.12) (*high confidence*). While some terrestrial ecosystems are already impacted today such as Alpine, cryosphere and peatlands, the impacts are not widespread and severe yet across a wide range of terrestrial systems. Around 2°C GWL, losses accelerate in marine ecosystem and appear across systems, including habitat losses especially in coastal wetlands (Roebeling et al., 2013; Clark et al., 2020), biodiversity and biomass losses (Bryndum-Buchholz et al., 2019; Lotze et al., 2019) and ecosystem services such as fishing (Raybaud et al., 2017) (*high confidence* on the direction of change, but *medium confidence* on the local and regional magnitude). The transition is happening at slightly higher warming in terrestrial systems due to higher number of thermal refugia in terrestrial systems causing relocation but not already severe impacts (*medium confidence*) (Chapter 2).

There is *medium confidence* that high adaptation or conditions posing low challenges for adaptation (e.g. SSP1) in the context of human health can delay the transition from moderate to high risk (Åström et al., 2017; Ebi et al., 2021). The illustrative adaptation pathways in Figure 13.29b,c show the sequencing of options to a high adaptation future for NEU and SEU. Whether or not adaptation measures are effective to reduce risk severity for people's health depends on local context (*high confidence*) (Figure 13.29, Section 13.6.2 and 13.7.2). Some adaptation options are found to be highly effective across Europe irrespective of warming levels, including air conditioning and urban planning (*high confidence*) (Sections 13.6.2 and 13.7.2, Jenkins et al., 2014b; Donner et al., 2015; Dodoo and Gustavsson, 2016; Åström et al., 2017; Dino and Meral Akgül, 2019; Venter et al., 2020), although air conditioning increasingly faces some feasibility constraints (Figure 13.20). Building interventions alone have low to medium effectiveness independent of the region. Many behavioural changes such as personal and home heat protection have already been implemented in SEU (Section 13.7.2, Martinez et al., 2019). To reach high adaptation, a combination of low, medium, and high effectiveness measures in different sectors and sub-regions is needed, many of which entail systems' transformations (Chapter 16) (e.g., heat proof land management) and remain effective at higher warming levels (*medium confidence*) (Díaz et al., 2019). These transformations have long lead times, therefore requiring timely start of implementation including regions that are not yet experiencing high heat stress (e.g. NEU) (*high agreement, medium evidence*).

Autonomous adaptation of species via migration in response to climate change is well documented in contemporary, historical and geological records (Chapter 2, Cross-Chapter Box PALEO in Chapter 1). However, the projected rate of climate change can exceed migration potential, leading to evolutionary adaptation or increased extinction risk (Chapters 2 and 3; Sections 13.3 and 13.4). A reduction of non-climatic stressors, such as nutrient loads, resource extraction, habitat fragmentation or pesticides on land, are considered important adaptation options to increase the resilience to climate-change impacts (Sections 13.3 and 13.4, Ramírez et al., 2018) (*high confidence*). A major governance tool to reduce climatic and non-climatic impacts is the establishment of networks of protected areas (Sections 13.3.2 and 13.4.2) especially when aggregated, zoned or linked with corridors for migration (*high confidence*), as well as a cost-effective adaptation strategy with multiple additional co-benefits (Berry et al., 2015; Roberts et al., 2017). Reforestation, rewilding and habitat restoration are long term strategies for reducing risk for biodiversity loss supported by assisted migration and evolution (Section 13.3.2, 13.4) though current laws and regulations do not include species migration (*high confidence*) (Prober et al., 2019; Fernandez-Anez et al., 2021).

Very high risks are expected beyond 3°C GWL due to the magnitude and increased likelihood of serious consequences, as well as to the limited ability of humans and ecosystems to cope with these impacts. There is *high confidence* that even under high adaptation scenarios for human systems or autonomous adaptation of natural systems, the risk will still be high at 3°C GWL and beyond (Section 13.7.2, Hanna and Tait, 2015; Spencer et al., 2016) with *medium confidence* on the temperature range of the transition. Projected sea level rise will strongly impact coastal ecosystems (*high confidence*), minimising their contribution to shoreline protection (Section 13.10.2.4).

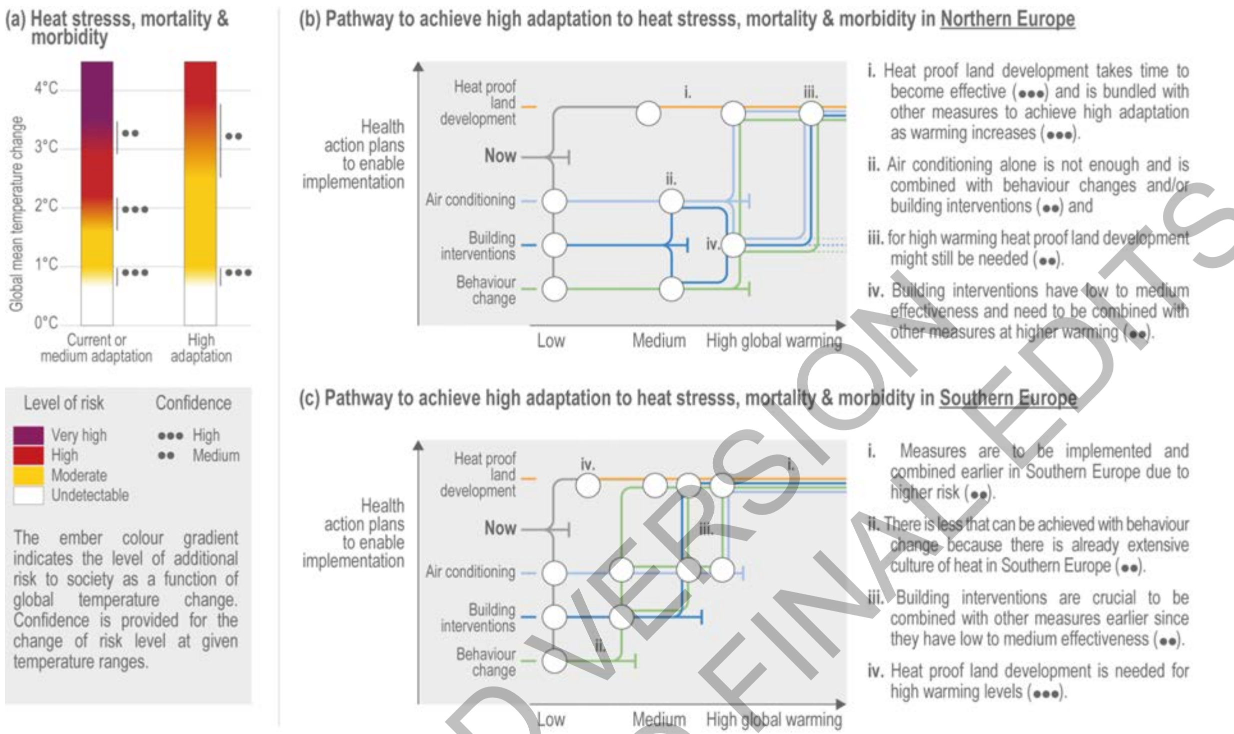

Figure 13.29: (a) Burning ember diagrams for the risk to human health from heat. The low/medium adaptation scenario corresponds to present, SSP2 and SSP4 socio-economic conditions. The high adaptation includes SSP1 and adaptation needed to maintain current risk levels. (b-c) Illustrative adaptation pathways for NEU (top) and SEU (bottom) and key messages based on the feasibility and effectiveness assessment in Figures 13.20 and 13.24. Grey shading means long lead time and dotted lines signal reduced effectiveness. The circles imply transfer to another measure and the bars that the measure have reached a tipping point. (Tables SM13.24, SM13.25)

13.10.2.2 KR2: Risk of losses in crop production, due to compound heat and dry conditions, and extreme weather

KR2 encompasses agriculture productivity (Figure 13.30a). It is mainly driven by the increase in the likelihood of compound heat and dry conditions and extremes and their impact on crops. There is *high confidence* that climate change will increase the likelihood of concurrent extremely dry (Table SM13.28) and hot warm seasons with higher risks for WCE, EEU (particularly north-western Russia) and SEU leading to enhanced risk of crop failure and decrease in pasture quality (Section 13.5.1) (Zscheischler and Seneviratne, 2017; Sedlmeier et al., 2018; Seneviratne et al., 2021). The risk is already moderately severe due to multiple crop failures in the last decade in WCE and Russia (Section 13.5.1, Hao et al., 2018; Pfleiderer et al., 2019; Vogel et al., 2019). Under high-end scenarios, heat and drought extremes are projected to become more frequent and widespread as early as mid-century (Toreti et al., 2019a). For present to moderate adaptation and at least up to 2.5°GWL, negative consequences are mostly in SEU (Bird et al., 2016; EEA, 2019c; Moretti et al., 2019; Feyen et al., 2020). The transition from moderate to high risk is projected to happen around 2.7°C GWL when hazards and risk will become more persistent and widespread in other regions (Section 13.1, Deryng et al., 2014; Donatelli et al., 2015; Webber et al., 2018; Ceglar et al., 2019; Ranasinghe et al., 2021; Seneviratne et al., 2021). This temperature increase will trigger shift of agricultural zones, onset of early heat stress, losses in maize yield of up to 28% across EU-28, and regional disparity in losses and gains in wheat, which are not able to offset losses across the continent (Deryng et al., 2014; Szewczyk et al., 2018; Ceglar et al., 2019). There will be also broader adverse impacts such as reduction of grassland biomass production for fodder, increases in weeds and reduction in pollination (Castellanos-Frias et al., 2016; Nielsen et al., 2017; Brás et al., 2019) (*medium confidence*). Combined with socio-economic development, increased heat and drought stress and reduced irrigation water availability in SEU are projected to lead to abandonment of farmland (Holman et al., 2017). Around 4°C GWL, the risk is very high due to persistent heat and dry conditions (Ben-Ari et al., 2018) and the emergence of losses also in NEU which would be much higher without the assumed CO_2 fertilisation (Deryng et al., 2014; Szewczyk et al., 2018; Harrison et al., 2019).

Farmers have historically adapted to environmental changes and such autonomous adaptation will continue. Higher CO_2 levels have a fertilisation effect on plants that is considered to decrease production risks (Deryng et al., 2014). Adaptation solutions to heat and drought risks include changes in sowing and harvest dates, increased irrigation, changes in crop varieties, the use of cover crops, and mixed agricultural practices (Section 13.5.2; Figure 13.14 and Figure 13.30b). Under high adaptation, the use of irrigation can substantially reduce risk by both reducing canopy temperature and drought impacts (*high confidence*) (Section 13.5.2, Webber et al., 2018). Some reductions of maize yields in SEU are still possible, but are balanced by gains in other crops and regions (Deryng et al., 2014; Donatelli et al., 2015; Webber et al., 2018; Feyen et al., 2020). At 3°C GWL and beyond, the adaptive capacity is reduced (Ruiz-Ramos et al., 2018). Crop production is a major consumer of water in agriculture (Gerveni et al., 2020), yet a potentially scarcer supply of water in some regions must be distributed across many needs (KR3, Section 13.10.2.3), limiting availability to agriculture which is currently the main user of water in many regions of Europe (Section 13.5.1) (*high confidence*). Where the ability to irrigate is limited by water availability, other adaptation options are insufficient to mitigate crop losses in some sub-regions, particularly at 3°C GWL and above, with an increase of risk from north to south and higher risk for late-season crops such as maize (*high confidence*). Under these conditions, land abandonment is projected (Holman et al., 2017) (*low confidence*).

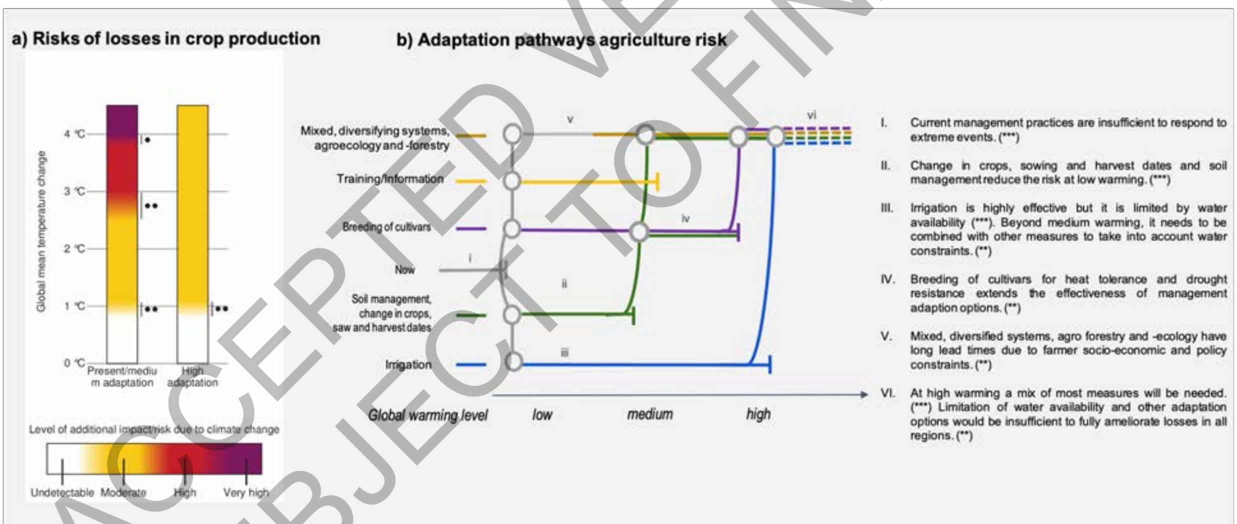

Figure 13.30: (a) Burning ember diagrams for losses in crop production with present or medium adaptation condition and with high adaptation. Panel (b) Illustrative adaptation pathways and key messages based on the feasibility and effectiveness assessment in Figure 13.14. Grey shading means long lead time and dotted lines signal reduced effectiveness. The circles imply transfer to another measure and the bars that the measure have reached a tipping point (Table SM13.28).

13.10.2.3 KR3: Risk of water scarcity to multiple interconnected sectors

Risks related to water scarcity across multiple sectors can become severe in WCE and to a much larger extent in SEU based on projections of drought damage, population and sectors exposed and increases in water exploitation (Figure 13.31a; Table SM13.29). In EEU, uncertainty in hydrological drought projections and risk consequences is higher (Greve et al., 2018; Ranasinghe et al., 2021; Seneviratne et al., 2021) and the available number of publications is lower, not allowing a conclusion on how risk levels change with GWL. Yet, there is emerging evidence that drought related risks increase with warming beyond 3°C GWL also in

EEU (Seneviratne, 2021 #12291for hydrological drought and 4°C GWL, Kattsov and Porfiriev, 2020). Evidence from the D&A assessment suggests that the risk is already moderate in SEU (e.g. 48 million people exposed to moderate water scarcity between 1981-2010) (Section 13.10.1, Figure 13.31a) (*high confidence*).

Risks have a high potential to lead to cascading impacts well beyond the water sector since water scarcity affects a number of highly interconnected sectors in Europe, from agriculture and livestock farming to energy (hydropower and cooling of thermal power plants) and industry (e.g., shipping) (Blauhut et al., 2015; Stahl et al., 2016; Bisselink et al., 2020; Cammalleri et al., 2020). Extensive water extraction will augment pressures on water reserves, impacting the ecological status of rivers and ecosystems dependent on them (Grizzetti et al., 2017). Socioeconomic conditions contributing to severe consequences are when more residents settle in drought-prone regions, or when the share of agriculture in GDP declines (*high confidence*). For Europe, risks of water scarcity will be higher under SSP5 and SSP3 than under SSP1 (*medium confidence*) (Byers et al., 2018; Arnell et al., 2019; Harrison et al., 2019). Transition to high risks is projected to occur below 2°C GWL in SEU and associated with more persistent droughts (Section 13.1.3) and at 2°C GWL with 54% increase of the population facing at least moderate levels of water shortage (Byers et al., 2018). This transition will happen at higher warming in WCE since risks are projected to increase less rapidly (transition between 2-3°C GWL) (*medium confidence*) (Section 13.2.1.2, Byers et al., 2018). At 3°C GWL and beyond, water scarcity will become much more widespread and severe in already water scarce areas in SEU (*high confidence*) and will expand to currently non-water scarce regions in WCE (*medium confidence*) (Section 13.2.1.2, Bisselink et al., 2018; Naumann et al., 2018; Harrison et al., 2019; Koutroulis et al., 2019; Cammalleri et al., 2020; Spinoni et al., 2020). Decrease in hydropower potential in SEU and WCE are expected beyond 3°GWL (Figure 13.16).

To reduce risk severity, adaptation measures both at supply and demand level have been suggested (Section 13.2.2, Figure 13.6, Figure 13.31b, Garnier and Holman, 2019; Hagenlocher et al., 2019). Several measures are already in place, showing high technical and institutional feasibility (Section 13.2.2.2 and 13.5.2.1). The effectiveness of options varies regionally (in particular between northern and southern regions). For example, in SEU many water reservoirs are already in place. Irrigation is used to support agriculture where rainfed supplies are not sufficient (13.5.2). Their future extension depends on available precipitation. Also, wastewater reuse can only be effective if sufficient wastewater is available. Improvements in water efficiency and behavioural changes are very effective in SEU (>25% of damages avoided) (Section 13.2.2.2). Investments in large water infrastructures and advanced technologies (incl. storage), water transfer, water recycling and reuse and desalination allow to buy time and therefore to cope with additional warming (Papadaskalopoulou et al., 2016; Greve et al., 2018). Beyond 2.5°C GWL, transformational adaptation is needed to lower risk levels, such as planned relocation of industry, abandonment of farmland or the development of alternative livelihoods (Holman et al., 2017). In WCE the solution space to water scarcity is expanding with considerable potential for investments in large water infrastructure and advanced technologies (incl. storage), for reducing risks above 3°C GWL (Greve et al., 2018). Under medium warming a larger portfolio of measures might be needed in SEU in particular, although it may not be able to completely avoid water shortages at high warming.

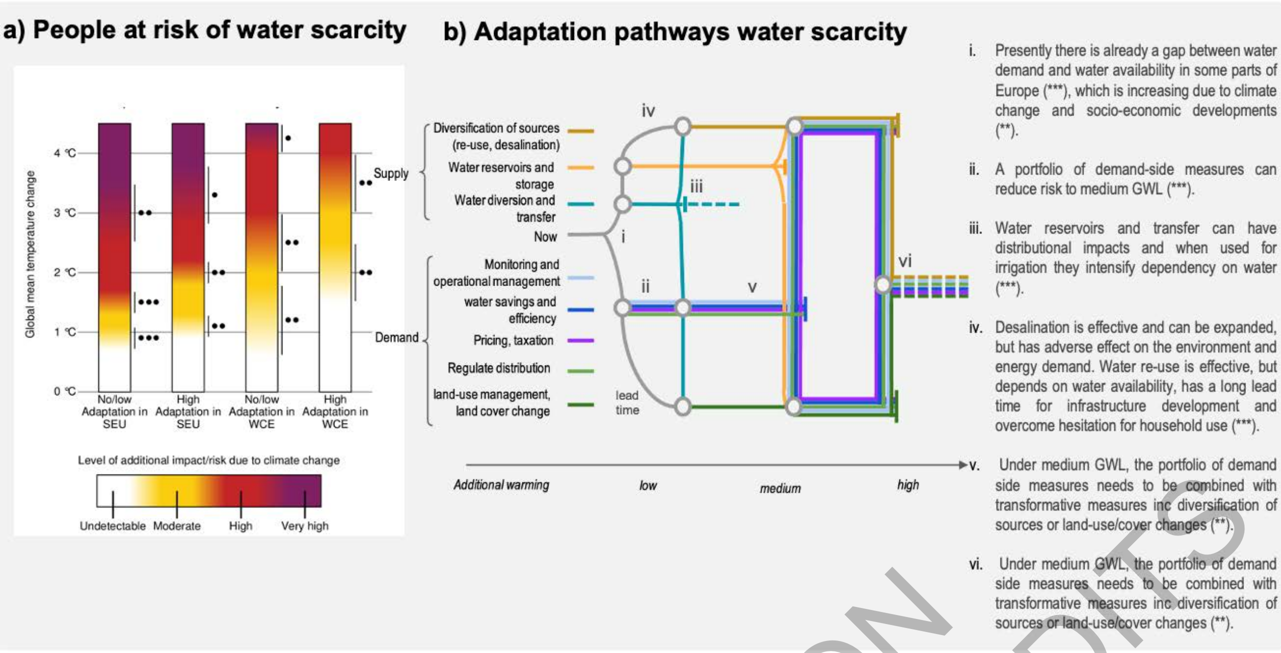

Figure 13.31: (a) Burning ember diagrams for the risk of water scarcity with no/low adaptation and with high adaptation for SEU and WCE. (b) Illustrative adaptation pathways and key messages (see Figure 13.6). Grey shading means long lead time and dotted lines signal reduced effectiveness. The circles imply transfer to another measure and the bars that the measure have reached a tipping point (Table SM13.29).

13.10.2.4 KR4: Risks to people, economies and infrastructures due to coastal and inland flooding

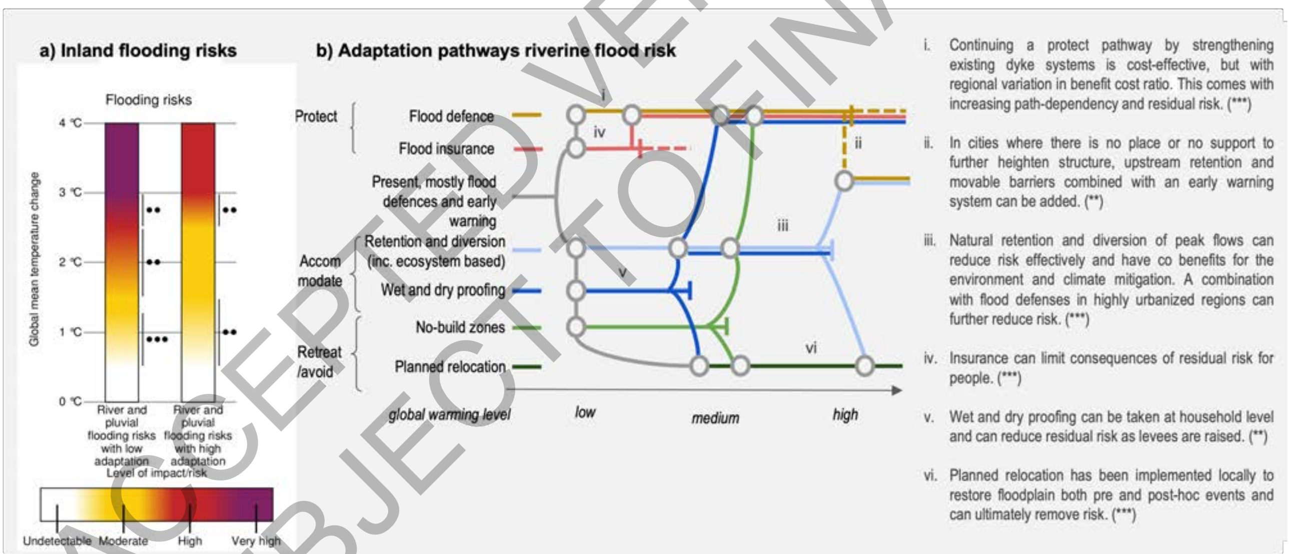
Damages and losses from coastal and river floods are projected to increase substantially in Europe over the 21st century (*high confidence*) (Section 13.2.1, SM13.10). Coastal areas have already started to be affected by sea level rise (Box13.1; Section 13.10.1) and human exposure to coastal hazards is projected to increase in the next decades (*high confidence*), but less under SSP1 (20%) than SSP5 (50%) by the end of the century (*medium confidence*) (Merkens et al., 2016; Reimann et al., 2018a). Under low adaptation (i.e. coastal defences are maintained but not further strengthened), severe consequences include increase in expected annual damage by a factor of at least 20 for 1.5-2.1°C GWL (i.e.. high risks) and by 2-3 orders of magnitude between 2 and 3°C GWL in EU-28 (i.e. very high risk) (*medium confidence*) (Figure 13.28, 13.34c; Section 13.2.1.1); (Vousdoukas et al., 2018b; Haasnoot et al., 2021b). Under high adaptation (i.e. lowlands are protected where it is economically efficient), expected annual damages still increase by a factor of 5 above 2°C GWL (Section13.2, Vousdoukas et al., 2020). Sea-levels are committed to rise for (Fox-Kemper et al., 2021), submerging at least 10% of the territory in 12 countries in Europe after millennia if GWL exceed 1.5-2.5°C (Clark et al., 2016), and this represents a major threat for the European and Mediterranean cultural heritage (Figure 13.28, Cross-Chapter Box SLR in Chapter 3, CCP4, Marzeion and Levermann, 2014; Reimann et al., 2018b).

Pluvial and riverine flood events in Europe have been attributed to climate change, but the associated damages and losses also depend on land use planning and flood risk management practices (*medium confidence*) (Section 13.10.1, Ranasinghe et al., 2021). Exposure to urban flooding will increase with urbanization (Jongman et al., 2012; Jones and O'Neill, 2016; Dottori et al., 2018; Paprotny et al., 2018b). Flooding is projected to rise with temperature in Europe, with e.g. a doubling of damage costs and people affected from river flood for low adaptation above 3°C GWL (Alfieri et al., 2018). Inland flooding represents a key risk for Europe due to the extent of settlements exposed, the frequency of the hazards, the risks to human lives associated with flash floods and the limited adaptation potential to pluvial flooding (e.g. difficulty to upgrade urban drainage systems (Dale et al., 2018; Dale, 2021). Hence, risks can become very high from 3°C GWL (Figure 13.32a).

A range of adaptation options to coastal flooding exists and adaptation is possible in many European regions if started on time (Section 13.2 and Figure 13.32d). Continuing a protection pathway is cost-effective in urbanized regions for this century (Vousdoukas et al., 2020), but there is *high agreement* that it comes with residual risk if coastal defences fail during a storm. This residual risk can be reduced through early warning and evacuations, insurance and accommodate measures (Section 13.2.2). Soft limits to protection have been identified under high GWL, in particular due to the rate of change and delayed impacts of long-term SLR (*medium confidence*) (Hinkel et al., 2018; Haasnoot et al., 2020a). Ecosystem based solutions such as wetlands can reduce waves' propagation, provide co-benefits for the environment and climate mitigation, and reduce costs for flood defences (*medium confidence*) (Section 13.2.2.1). At higher GWL, ecosystems are projected to experience reduced effectiveness due to temperature increase and increased rate of SLR combined with lack of sediment and human pressures (Cross-Chapter Box SLR in Chapter 3). Retention and diversion can be effective for compound flooding or for estuaries with a limited storm surge duration, but there is lack of knowledge on their effectiveness (Sections 13.2.2).

In the case of river flooding, adaptation has the potential to contain damage and losses up to 3°C GWL (Figure 13.32b, Jongman et al., 2014; Alfieri et al., 2016), provided they are implemented on time and that the technical, social and financial barriers are addressed (Sections 13.2.2 and 13.6.2). Residual risks can be reduced through early warning and evacuations, insurance and accommodate measures (see Section 13.2.2, Kreibich et al., 2015). Accommodation strategies such as retention and ecosystem-based solutions require space, which is not always available in cities. Both protection and flood retention are effective in reducing inland flooding risk across Europe, but with regional variation in the benefit-to-cost ratio (Alfieri et al., 2016; Dottori et al., 2020) (*medium confidence*). Furthermore, upgrading drainage systems to accommodate increase in pluvial flooding is costly, technically complex and requires time (Dale et al., 2018; Dale, 2021).

Avoiding developments in risk-prone areas can reduce both coastal and inland flooding risks and can be followed by planned relocation, particularly in less-populated areas. To align relocation with social goals and to achieve positive outcomes long lead times are needed (Haasnoot et al., 2021a).



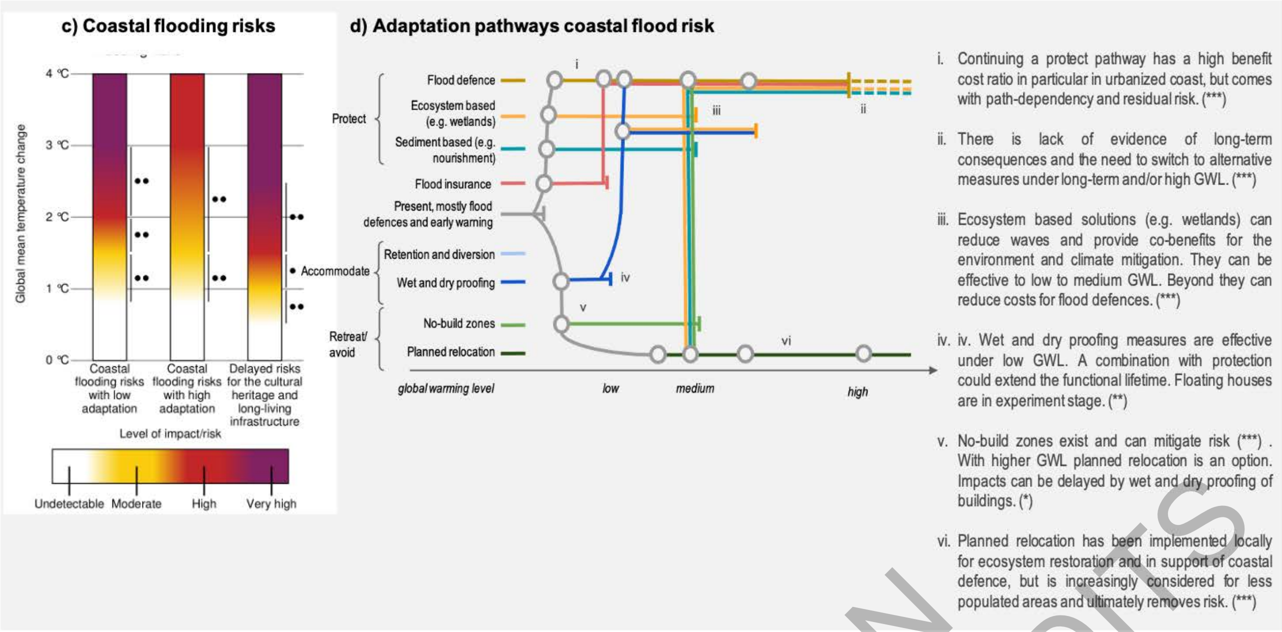


Figure 13.32: (a) Burning ember diagram for the risks from riverine and pluvial flooding with and without adaptation. (b) Illustrative adaptation pathways to riverine flooding risks. (c) Burning ember diagram for the risks from coastal flooding with and without adaptation. (d) Illustrative adaptation pathways to coastal flooding risks. Grey shading means long lead time and dotted lines signal reduced effectiveness. The circles imply transfer to another measure and the bars that the measure have reached a tipping point.(Tables SM13.30, SM13.31)

13.10.3 Consequences of Multiple Climate Risks for Europe

European regions are affected by multiple key risks simultaneously; while there is a wide range in quantifications, there is high agreement that consequences for socio-economic and natural systems can be substantial, with more severe consequences in the south than in the north *(very high confidence*); there is some indication also for a west to east gradient, with higher uncertainty in eastern part of WCE and EEU which makes adaptation more challenging (*medium confidence*). Furthermore, the food-water-energy-land use nexus plays an important role in amplifying overall risk levels in Europe (*medium confidence*) (Forzieri et al., 2016; Harrison et al., 2016; Byers et al., 2018; Arnell et al., 2019; Harrison et al., 2019; Kebede et al., 2021). Southern Europe, European cities and coastal areas are projected to become hotspots of multiple risks (Cramer et al., 2018; Forzieri et al., 2018; Guerreiro et al., 2018) (*high confidence*). The number of people exposed to multiple KRs in Europe are projected to at least double at 3°C GWL compared to 1.5°C GWL (Forzieri et al., 2017; Byers et al., 2018; Arnell et al., 2019), but risk levels are already higher at 1.5°C GWL than today for a number of KRs (Figure 13.28) (*medium confidence*).

Economic losses and damages for European economies from multiple KRs are projected increase (*high confidence*) (Figure 13.34, Szewczyk et al., 2018; Feyen et al., 2020; Kalkuhl and Wenz, 2020), potentially quadruple at 3°C GWL compared to 1.5°C GWL (Feyen et al., 2020). Existing estimates of projected economic costs for Europe, based on integrated assessment or computable general equilibrium models, are however *likely* to be underestimations of the true costs because of incomplete coverage of biophysical impacts, in particular low-probability high impact events, and disruptive risk propagation channels (Lamperti et al., 2018; Stoerk et al., 2018; Schewe et al., 2019; Piontek et al., 2021). The main driver for this increase in economic losses and damages is mortality due to heat stress (*medium confidence*), followed by reduced labour productivity, coastal and inland flooding, water scarcity and drought (*medium confidence*) (Figure 13.33; Section 13.6.1.3). While losses are highest in SEU for both 1.5°C and 3°C GWL and increase by a factor of more than three between these GWLs, the projected economic damages and losses also increase significantly in WCE (by a factor of 4 from 1.5°C to 3°C GWL; 40% of total losses in EU-28 at 3°C GWL) and in NEU (almost 10% of total losses at 3°C GWL) (Szewczyk et al., 2018; Szewczyk et al., 2020). Adaptation is projected to reduce macroeconomic costs, but residual costs remain, particularly for warming above 3°C GWL (*medium confidence*) (De Cian et al., 2016; Bosello et al., 2018; Parrado et al., 2020).

Figure 13.33: Economic losses/damages and gains due to projected climate risks, for 1.5°C and 3°C GWL relative to no additional warming; macroeconomic effects measured in GDP or welfare. Effect for EEU report for Russia as a whole country, deviating from the definition of EEU in this chapter. Effects may deviate from sectoral assessments in Sections 13.2-13.7 due to different degree of coverage of risk channels (Table SM13.23).

13.10.4 Knowledge Gaps

Information on risk levels and development are available for 1.7°C, 2.5°C and > 4°C GWL, making the determination of transitions for the burning embers challenging and impairing a comprehensive assessment across key risks. Further efforts to extend the SSP narratives to Europe can contribute to a more disaggregated understanding of risk severity for different vulnerability and exposure conditions, but the evidence to date remains limited to few sectors (CCP4, Kok et al., 2019; Pedde et al., 2019; Rohat et al., 2019). There is only very *limited evidence* on the extent and timing of residual risks under different GWL, even with high adaptation.

There is *medium confidence* on the effectiveness of adaptation beyond 3°C GWL particularly where risks are high to very high (Figures 13.28-13.32). There is *limited evidence* on the effectiveness of specific adaptation options at different levels of warming that also include consideration of lead and lifetimes. An integrated assessment, which projects the impacts on crop production by examining the potential availability of water for agricultural purposes together with other adaptation measures, is missing.

Transboundary risks, interactions between commodity and financial markets, market imperfections, non-linear socio-economic responses, and loss of ecosystem services, may amplify losses for European economies. Available models may underestimate the full costs of climate change as they generally neglect systemic risks, tipping points, indirect and intangible losses and limits to adaptation (Dafermos et al., 2018; Lamperti et al., 2018; van Ginkel et al., 2020; Dasgupta et al., 2021; Ercin et al., 2021; Piontek et al., 2021). With increasing global warming, compound, low likelihood, or unprecedented extremes such as the European dry and hot summer 2018 or the extreme rainfall following storm Desmond in the UK in 2015, become more frequent (AR6 WGI Cross-Chapter Box 11.2). These events can have catastrophic consequences for Europe, but the extent of economic and non-economic damages and losses remain largely uncertain.

13.11 Societal Adaptation to Climate Change across Regions, Sectors and Scales

Building on our sectoral analysis in previous sections, this section looks across European sectors, vulnerable groups, and regions to assess how climate change impacts are being responded to in general by state (Section 13.11.1) and non-state (Section 13.11.2) actors, and their synergies and dependencies. Sections 13.11.3 assess if and how system transformations have emerged and implications for the SDGs and climate resilient development pathways (CRDPs).

13.11.1 Policy Responses, Options and Pathways

13.11.1.1 Progress on Adaptation Planning and Implementation

The solution space for climate change adaptation has expanded across European regions since AR5 (*high confidence*). European countries are increasingly planning to adapt to observed impacts and projected climate risks across scales of government (Lesnikowski et al., 2016; Russel et al., 2020) (*high confidence*). Whereas in 2009, only nine EU countries had developed a National Adaptation Strategy (NAS) (Biesbroek et al., 2010; EEA, 2014), by mid-2020 all EU Member States and several other European countries had adopted at least a NAS and/or revised and updated prior strategies (Figure 13.34, bottom, Klostermann et al., 2018; EEA, 2020a). Progress is also observed at the level of the European Union with the adoption of the new EU strategy on adaptation to climate change in 2021 (European Comission, 2021a) and regionally, particularly in federalist and decentralised states (Steurer and Clar, 2018; EEA, 2020c; Pietrapertosa et al., 2021), and locally, with an increasing number of European cities planning for climate risks (Aguiar et al., 2018; Reckien et al., 2018; Grafakos et al., 2020) (Section 13.6.2.1;Box 13.3;Chapter 6) (*high confidence*). There is evidence of action across sectors and scales, even in European countries where national adaptation frameworks are absent (Figure 13.34) (De Gregorio Hurtado et al., 2015; Pietrapertosa et al., 2018; Reckien et al., 2018) (*medium confidence*). However, the implementation gap identified in AR5 (Chambwera et al., 2014), i.e. the gap between defined goals and ambitions and actual implemented actions on the ground, persists in Europe (Aguiar et al., 2018; Russel et al., 2020; UNEP, 2021).

The drivers of adaptation progress in Europe differ across sectors and regions. Common drivers include: experienced climatic events, improved climatic information, societal pressures to act, projected economic and societal costs of climate change, participation in (city) networks, societal and political leadership, and changes in national and European policies and legislation (*medium evidence, high agreement*) (EEA, 2014; Massey et al., 2014; Reckien et al., 2018). The availability of human, knowledge, and financial resources appears important for proactive adaptation(Termeer et al., 2012; Sanderson et al., 2018)(Termeer et al., 2012; Sanderson et al., 2018)(Termeer et al., 2012; Sanderson et al., 2018)(Termeer et al., 2012; Sanderson et al., 2018), while adaptation is also strongly dependent on economic and social development (Sanderson et al., 2018) (*high confidence*). How adaptation is governed differs substantially across Europe (Clar, 2019; Lesnikowski et al., 2021). Political commitment, persistence and consistent action across scales of government is critical to move beyond planning for adaptation (Step A to C in Figure 13.34) and to ensure adequacy of implementation (Step D and E in Figure 13.34) (Howlett and Kemmerling, 2017; Lesnikowski et al., 2021; Patterson, 2021).

The scope of climate risks included in European adaptation policies and plans (Step B in Figure 13.34) is generally broad (EEA, 2018a). Systemic and cascading risks (Section 13.10) are often recognized, but most conventional risk assessment methods that inform adaptation planning are ill-equipped to deal with these effects (Adger et al., 2018). For example, transboundary risks emerging in regions outside of Europe are considered only by a few countries such as the UK and Germany (Section 13.9.3). European climate change adaptation strategies and national policies are generally weak on gender, LGBTQI+, and other social equity issues (Cross-Chapter Box GENDER in Chapter 18, Boeckmann and Zeeb, 2014; Allwood, 2020).

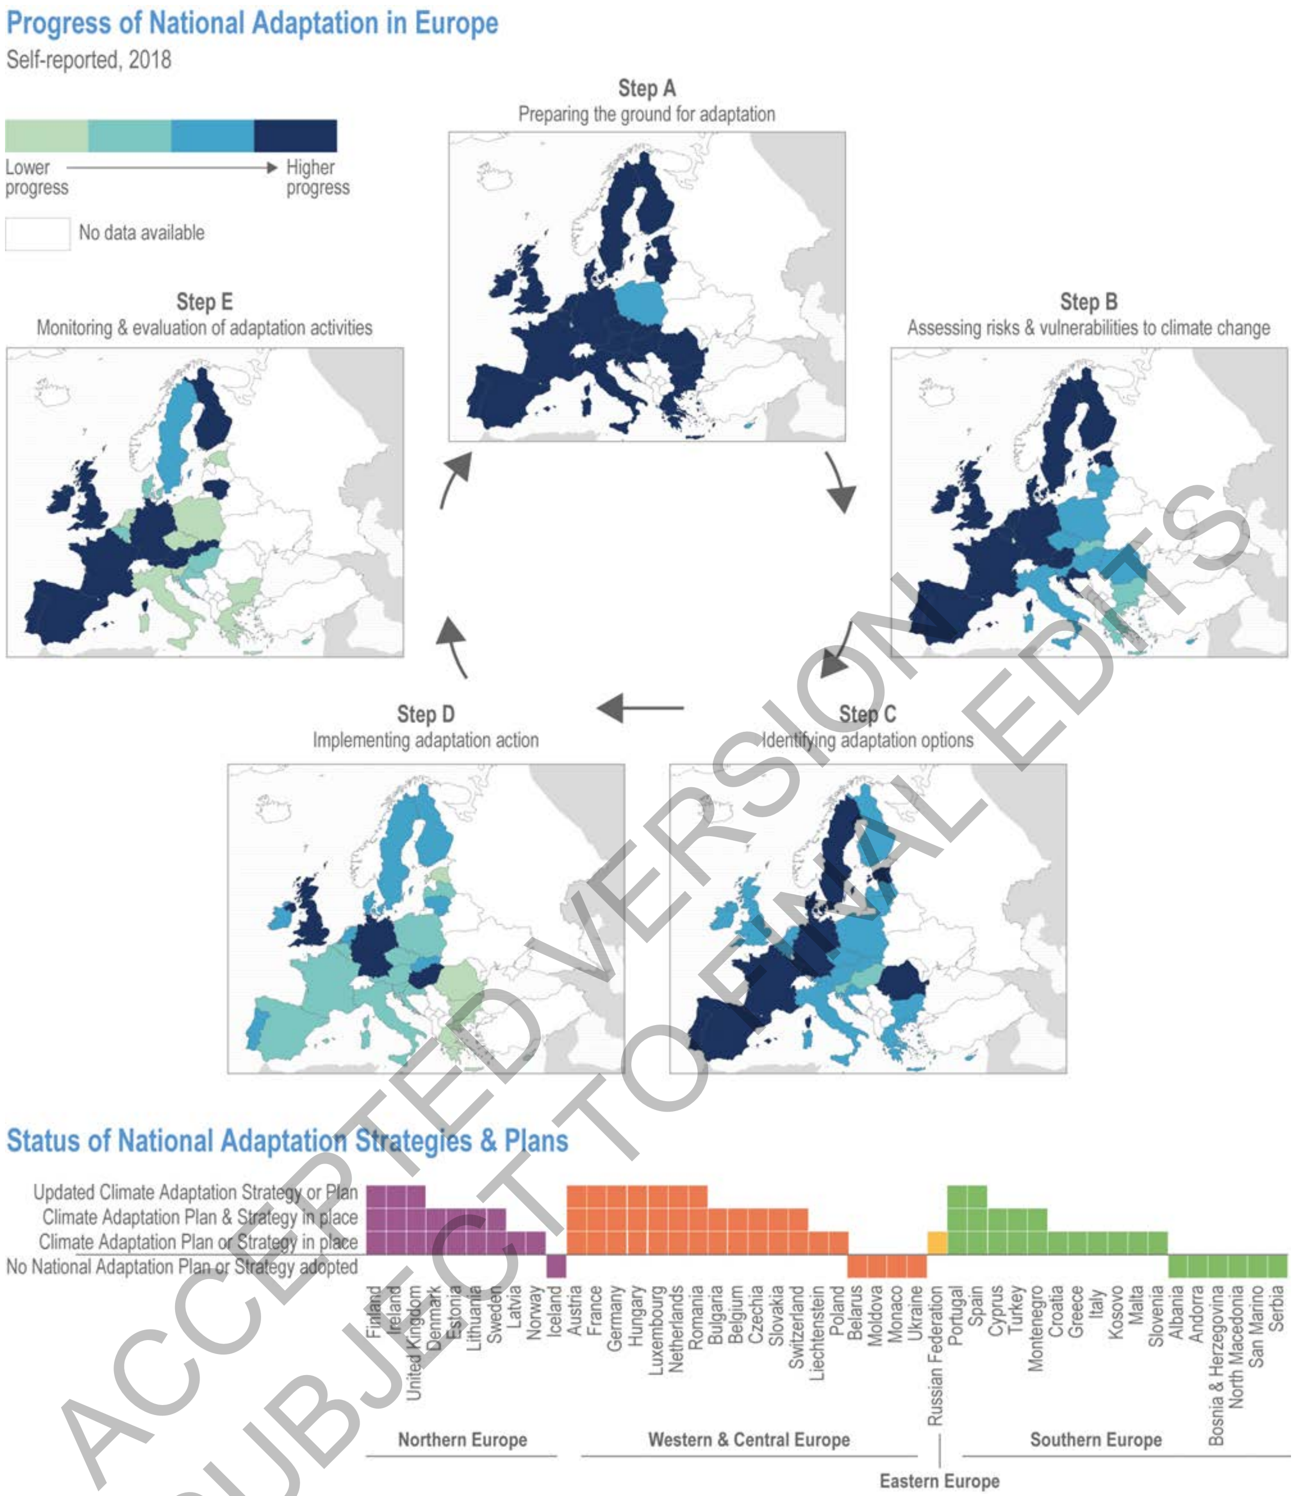

Figure 13.34: Progress of National Adaptation in Europe in 2018 and Status of National Adaptation Plans and Strategies in 2020. Data on the progress of national adaptation are from the self-reported status of EU members, as documented in the Adaptation Scoreboard for Country fiches (SWD(2018)460). The status of national adaptation plans and strategies data are from EEA Report 6/2020 (2020a), the ClimateADAPT portal (EEA, 2021a) and from the Grantham Institute database Climate Change Laws of the World (Grantham Research Institute, 2021).

Many near-term investment decisions have long-term consequences, and planning and implementation (Step C and D in Figure 13.34) can take up to decades, particularly for critical infrastructure planning in Europe (Zandvoort et al., 2017; Pot et al., 2018). Consequently, there are calls to expand planning horizons, to consider long-term uncertainties to prevent lock-in decision dependencies, to seize opportunities and synergies from other investments (e.g., socio-economic developments and systems transitions) and to broaden the range of considered possible impacts (e.g. Frantzeskaki et al., 2019; Marchau, 2019;

Oppenheimer et al., 2019; Haasnoot et al., 2020b). Yet, high GWL scenarios beyond 2100 are often not considered in climate change adaptation planning due to a lack of perceived usability, missing socio-economic information, constraining institutional settings, and conflicting decision-making timeframes (*medium confidence*) (Lourenco et al., 2019; Taylor et al., 2020). High GWL scenarios are often seen as having a low probability of occurrence, resulting in inaction or incremental rather than transformative adaptation responses to projected climate risks (Dunn et al., 2017). Extending planning horizons to beyond 2100 increases deep uncertainties for decision-makers as a result of unclear future socio-economic and climatic changes. For adaptation to sea level rise along Europe's coast, for example, there are already considerable uncertainties during this century (Fox-Kemper et al., 2021).

Adaptive planning and decision making are still limited across Europe (*high confidence*). Prominent examples of adaptive plans include the flood defence systems for the City of London (Ranger et al., 2013; Kingsborough et al., 2016; Hall et al., 2019) and the Netherlands (Van Alphen, 2016; Bloemen et al., 2019) Adaptation pathways have been also developed for planning of urban water supply (Kingsborough et al., 2016; Erfani et al., 2018), urban drainage (Babovic and Mijic, 2019) and wastewater systems (Sadr et al., 2020) (Cross-Chapter Box DEEP in Chapter 17). Flexible strategies are increasingly considered by European countries (e.g. Stive et al., 2013; Kreibich et al., 2015; Bubeck et al., 2017; Haasnoot et al., 2019), but require appropriate design to be effective (Metzger et al., 2021).

Monitoring and evaluation of adaptation action is only done in some European countries (Figure 13.34, part E), but is important for adjusting planning, if needed (Hermans et al., 2017; Haasnoot et al., 2018), and enhancing transparency and accountability of progress (Mees and Driessen, 2019). In the Netherlands, a comprehensive monitoring system has been put in place, including signals for adaptation that support decisions on when to implement adaptation options or to adjust plans (Hermans et al., 2017; Haasnoot et al., 2018; Bloemen et al., 2019).

13.11.1.2 Mainstreaming and Coordination

Coordinated responses are necessary to prevent inefficient and costly action (Biesbroek, 2021), balance under- and over-reaction to climate risks (Peters et al., 2017; Biesbroek and Candel, 2019), avoid redistributing vulnerability and maladaptive actions (Atteridge and Remling, 2018; Albizua et al., 2019; Neset et al., 2019), and ensure timely implementation (Benson and Lorenzoni, 2017) (*high confidence*). Since AR5, progress has been made to increase coordinated adaptation actions, but so far this is limited to a few sectors (mostly water management and agriculture) and European countries and regions (mostly SEU, WCE depending on impact) (Lesnikowski et al., 2016; Biesbroek and Delaney, 2020; Booth et al., 2020) (*high confidence*) (Section 13.11.2). Despite evidence of emerging bottom-up (e.g., citizens and business initiatives) and top-down initiatives (e.g., governmental plans and instruments to ensure action), there are considerable barriers to mainstreaming adaptation (Runhaar et al., 2018) (*high confidence*).

While mainstreaming of adaptation into other policy domains has been advocated as an enabler for adaptation, it may have resulted incremental rather than transformational adaptation, and may not be sufficient to close the adaptation gap (Andersson and Keskitalo, 2018; Remling, 2018; Scoville-Simonds et al., 2020).

13.11.1.3 Climate Services and Local Knowledge

Climate services to support adaptation decision-making of governments and businesses across Europe have rapidly increased since AR5, partly as a result of national and EU investments such as the Copernicus C3S service (*high confidence*) (Street, 2016; Soares and Buontempo, 2019). These services are increasingly used in NEU, SEU and WCE for example in energy and risk prevention in coastal and riverine cities, stimulating regulations and bottom-up initiatives (Cavelier et al., 2017; Le Cozannet et al., 2017; Reckien et al., 2018; Howard et al., 2020). However, climate service efficacy is rarely systematically evaluated (Cortekar et al., 2020). Barriers to use include: lack of perceived usefulness of climate information to organisations and expertise to use the information, outdated statistics, mismatch between needs and type of information made available, insufficient effective engagement between providers and recipients of climate information and lack of business models to sustain climate services over time (*high evidence, medium agreement*) (Cavelier et al., 2017; Räsänen et al., 2017; Bruno Soares et al., 2018; Christel et al., 2018; Oberlack and Eisenack, 2018; Hewitt et al., 2020). Adaptation decision support platforms also face challenges regarding updating, training and engagement with users (EEA, 2015; Palutikof et al., 2019).

In addition to scientific knowledge, traditional and local knowledges can enable adaptation action (Huntington et al., 2017) as is the case with indigenous-led ecosystem restoration in the European Arctic (Brattland and Mustonen, 2018). There is a need to draw on surviving Indigenous knowledge systems in Europe (Greenland, Nenets, Khanty, Sámi, Veps, Ingrian) as unique, endemic ways of knowing the world that can position present and historical change in context and offer unique reflections of change in the future (Ogar et al., 2020; Mustonen et al., 2021).

13.11.1.4 Financing Adaptation and Financial Stability

Dedicated financial resources for the implementation of NAS and plans are a key enabling factor for successful adaptation (*high confidence*) (Russel et al., 2020) (Chapter 17). Yet, only 14 EU countries have announced such budget allocations in their plans and strategies; and even if budget numbers are available, they are difficult to compare (EEA, 2020b). Current adaptation spending varies greatly across and within European countries, partly reflecting (sub-)national adaptation priorities or financing sources targeting investment projects (López-Dóriga et al., 2020; Russel et al., 2020) and competing statutory priorities (Porter et al., 2015). European government budgets are also burdened by climate change damages today, particularly after huge flooding events, and austerity following financial crises, limiting anticipatory action (Penning-Rowsell and Priest, 2015; Miskic et al., 2017; Schinko et al., 2017; Slavíková et al., 2020). National adaptation funding in EU member states is complemented by EU funding (e.g. European Structural and Investment Funds (ESIF), European Regional Development Funds, and LIFE program). While the EU spending target on climate action increased from 20% in 2016-2020 to 25% in 2021-2026, most spending is going into mitigation, not adaptation (Berkhout et al., 2015; Hanger et al., 2015; EEA, 2020b).

With higher warming levels, financing needs are *likely* to increase (*high confidence*) (Mochizuki et al., 2018; Bachner et al., 2019; Parrado et al., 2020) governments can address this higher need by cutting other expenditures, increasing taxes, or by increasing the fiscal deficit (Miskic et al., 2017; Mochizuki et al., 2018; Bachner et al., 2019). Yet, the requirement for fiscal consolidation that will be needed after the COVID-19 pandemic (Cross-Chapter Box COVID in Chapter 7) may also lead to a cessation of adaptation spending, as evidenced by the expenditure drop in coastal protection in Spain after the financial crisis 2008 (López-Dóriga et al., 2020). Governments can shift the financial burden to beneficiaries of adaptation, as e.g., suggested for coastal protection and riverine flooding (Jongman et al., 2014; Penning-Rowsell and Priest, 2015; Bisaro and Hinkel, 2018). There is also an increase in financial mechanisms to accelerate private adaptation actions, including adaptation loans, subsidies, direct investments, and novel public-private arrangements. For example, the European Investment Bank created a finance facility to support European regions through loans to implement adaptation projects (EEA, 2020b).

Since AR5, new evidence has emerged that climate change may deteriorate financial stability both at the global and European scale (Campiglio et al., 2018; Dafermos et al., 2018; Lamperti et al., 2019; ECB, 2021a). The European Central Bank, the European Systemic Risk Board, and several national central banks in NEU and WCE have started to systematically assess the consequences of climate risks for financial stability and plan to integrate climate stress testing into their supervisory tools (Batten et al., 2016; ECB, 2021a; ECB, 2021b).

13.11.2 Societal Responses, Options and Pathways

13.11.2.1 Private-sector

Within the private sector, there tends to be a preference for ‘soft’ (e.g., knowledge generation) than ‘hard’ (e.g., infrastructure) adaptation measures (Goldstein et al., 2019), in contrast to government-led responses typically favouring hard measures (Pranzini et al., 2015). However, there also remains diversity across sectors and organisations in the degree and type of adaptation response (Trawöger, 2014; Dannevig and Hovelsrud, 2016; Ray et al., 2017; Ricart et al., 2018). Whereas some sectors such as flood management, banking and insurance, and energy (Bank of England, 2015; Gasbarro and Pinkse, 2016; Bank of England, 2019; Wouter Botzen et al., 2019) have generally made moderate progress on adaptation planning across

Europe, there are key vulnerable economic sectors that are in earlier stages, including aviation (Burbidge, 2015), ports and shipping (Becker et al., 2018; Ng et al., 2018), and ICT (EEA, 2018b) (*high confidence*). There is also some evidence of 'short-sighted' adaptation or maladaptation; for example, in winter tourism there is a preference for technical and reactive solutions (e.g., artificial snow) that will not be sufficient under high levels of warming (Section 13.6.1.4).

Where adaptation is considered by companies, it is typically triggered either by the experience of extreme weather events that led to business disruptions (McKnight and Linnenluecke, 2019) or is included into corporate risk management in response to regulatory, shareholder or customer pressure (Averchenkova et al., 2016; Gasbarro et al., 2017). For instance, following the implementation of the recommendations of the Task Force on Climate-Related Financial Disclosure (TFCD) by the European Commission in 2019, 50 publicly listed companies revealed their exposure to their physical climate risks in 2020 (CDSB, 2020). But even if companies experience extreme weather events or stakeholder pressure, they may not adapt because they underestimate their vulnerability (Pinkse and Gasbarro, 2019) (Table 13.1). For example, key barriers to adaptation among Greek firms include both external (e.g., lack of support/guidance) and internal factors (e.g., few resources, managerial perceptions (Halkos et al., 2018). Lack of knowledge, feeling climate change is not a salient risk, and lack of social learning or collaboration, appear to be key barriers to private-sector adaptation (Dinca et al., 2014; André et al., 2017; Romagosa and Pons, 2017; Esteve et al., 2018; Luís et al., 2018; Ng et al., 2018) (Section 13.16.2.2). There remains little research on private-sector awareness of or responses to cascading or compound risks associated with climate change (Miller and Pescaroli, 2018; Pescaroli, 2018).

13.11.2.2 Communities, Households and Citizens

Planned behavioural adaptation remains limited amongst European households (*high confidence*), with few examples that can be considered transformative (e.g., structural, long-term, collective (Wilson et al., 2020)) (*medium confidence*). One Swedish survey of householders at risk of extreme weather events (e.g., floods, storms) found evidence of some organisational measures (e.g., bringing possessions inside prior to a storm, preparing for power cuts with candles, etc.) but very few households took any other (technical, social, nature-based, or economic) measures (Brink and Wamsler, 2019). Similarly, few at risk of flooding are taking action (Stojanov et al., 2015) (Sections 13.2.1, 13.6.1); for example, little public take-up of available municipal support for individual adaptation in Germany (Wamsler, 2016). Water efficiency measures in anticipation of, or response to, drought are also limited (Bryan et al., 2019), although water reuse in Mediterranean and some other EU (e.g., UK, Netherlands) countries is increasing (Aparicio, 2017) (Section 13.2). Amongst the adaptation responses recorded, few are perceived as opportunities (Taylor et al., 2014; Simonet and Fatorić, 2016). There is currently little European research on public responses to risks other than flooding, heat stress and drought, such as vector-borne disease, and to multiple and cascading risks (van Valkengoed and Steg, 2019) (Section 13.7).

Perceived personal responsibility for tackling climate change remains low across the EU (Figure 13.35) and partly explains why household adaptation remains limited (*high confidence*) (Taylor et al., 2014; van Valkengoed and Steg, 2019), despite risk perception apparently growing (Figure Box 13.2.1, Capstick et al., 2015; Poppel et al., 2015; BEIS, 2019). Householders' risk perception and concern about climate change fluctuates in response to media coverage and significant weather or socio-political events (*high confidence*) (Capstick et al., 2015). On average across Europe, and particularly in relation to gradual change, non-experts continue to under-estimate climate change risks compared to experts (*medium confidence*) (Taylor et al., 2014), have low awareness of adaptation options, and confuse adaptation and mitigation (Harcourt, 2019), suggesting a need for improved climate literacy amongst the public. Indeed, fostering learning and coping capacity supports robust adaptation pathways (Jäger et al., 2015).

There is strong public support for adaptation policy (e.g., building flood defences), particularly within the UK, France, Norway and Germany (Doran et al., 2018). Although, in some cases such public adaptation can undermine motivation for householders to take adaptation measures (Section 13.2), public adaptation can also increase householder motivations, with perceived efficacy of action a strong predictor of adaptation (*high confidence*) (Moser, 2014; van Valkengoed and Steg, 2019). However, there are also structural and economic barriers to household adaptation due to lack of policy incentives or regulations. For example, water-saving devices in homes could halve consumption, but lack of economic benefits to householders are barriers to adoption; while lack of standards as well as societal hesitation may explain low levels of water reuse in Europe (EEA, 2017c) (Section 13.2). Conversely, water meters and higher tariffs have been found to reduce water consumption only in combination with other measures (EEA, 2017c; Bryan et al., 2019).

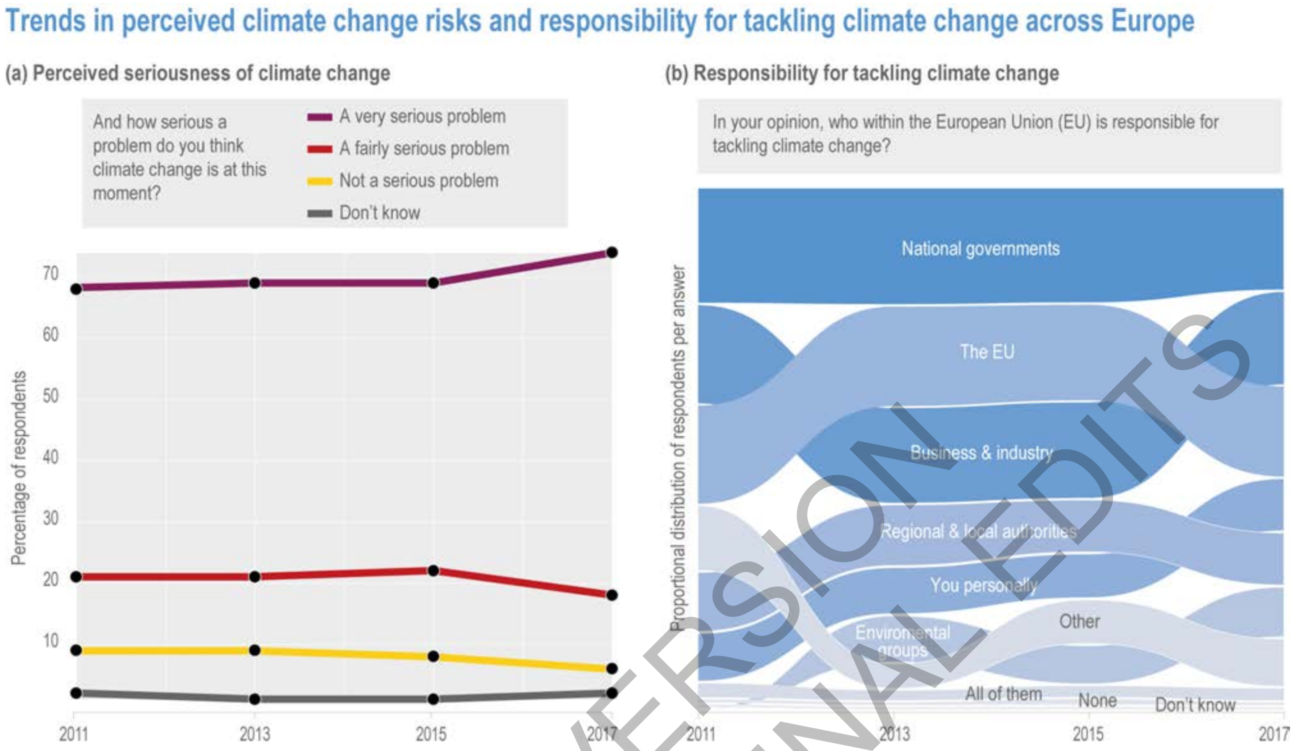

Figure 13.35: Trends in perceived climate change risks and responsibility for tackling climate change across EU-28; data collected from around 1,000 respondents per country for each year surveyed (European Comission, 2017)

As well as temporal trends in climate change risk perception, the literature since AR5 continues to show much heterogeneity (both within and between nations) amongst householders in respect of risk perception (*high confidence*). Higher climate change risk perceptions observed in Spain, Portugal, Iceland, and Germany (Figure 13.2); at individual level, women, younger age groups, more educated, left-leaning, and those with more 'self-transcendent' values perceive more negative impacts from climate change, although the strength of these relationships varies across European nations (Clayton et al., 2015; Doran et al., 2018; Poortinga et al., 2019; Duijndam and van Beukering, 2021). Stronger evidence exists since AR5 that experience of extreme weather events can shape climate change risk perceptions, if these events are attributed to climate change or evoke negative emotions (*high confidence*) (Clayton et al., 2015; Demski et al., 2017; Ogunbode et al., 2019). Proximity to climate hazards does not predict adaptation responses in a straightforward way: in Portugal, those living by the coast were more *likely* to attribute local natural hazards to climate change and to take some adaptive measures (Luís et al., 2017); while waterside residents in flood-prone regions of France and Austria were more resistant to relocation, due to higher place attachment (Adger et al., 2013; Rey-Valette et al., 2019; van Valkengoed and Steg, 2019; Seebauer and Winkler, 2020). Migration from threatened regions is discussed in Section 13.8.1.3.

13.11.3 Adaptation, Transformation and Sustainable Development Goals

The implementation of far-reaching and rapid systemic changes, including both adaptation and mitigation options (de Coninck et al., 2018) remains less researched in societal systems than natural ones (Salomaa, 2020) that enhance multilevel governance and institutional capabilities, and enables lifestyle/behavioural change and technology innovation. Adaptation responses across European regions and sectors, are more often incremental than transformative (*medium confidence*), with possible exceptions including water-related examples in for example the Netherlands (Section 13.2.2) and some cities (Box 13.3). Transformative options may be better able to exploit new opportunities and co-benefits (EEA, 2019a) (Box 13.3) (Cross-Chapter Box HEALTH in Chapter 7). Transitions towards more adaptive and climate resilient systems are often the result of responses to crises which create windows of opportunity for systemic changes (Johannessen et al., 2019) (cf. Chapter 18). This includes extreme weather events, financial crises (e.g., Malmö; (Anderson, 2014; Isaksson and Heikkinen, 2018)) and the COVID-19 pandemic (e.g., Milan), which have disrupted the status quo and accelerated innovation and implementation (e.g., Milan; Box 13.3, Cross-Chapter Box COVID in Chapter 7).

[START BOX 13.3 HERE]

Box 13.3: Climate Resilient Development Pathways in European Cities

Climate resilient development (CRD) in European cities offers synergies and co-benefits from integrating adaptation and mitigation with environmental, social and economic sustainability (Geneletti and Zardo, 2016; Grafakos et al., 2020). Climate networks (e.g., Covenant of Mayors), funding (e.g., Climate-KIC), research programs (e.g., Horizon Europe), European and national legislation, international treaties, and the identification of co-benefits, contribute to the prioritisation of climate action in European cities (Heidrich et al., 2016; Reckien et al., 2018; CDP, 2020). Still, mitigation and adaptation remain largely siloed and sectoral (Heidrich et al., 2016; Reckien et al., 2018; Grafakos et al., 2020). An assessment of the integration of mitigation and adaptation in urban climate change action plans in Europe found only 147 cases in a representative sample of 885 cities (Reckien et al., 2018).

In European cities, CRD is most evident in the areas of green infrastructure, energy efficient buildings and construction, and active and low-carbon transport (Pasimeni et al., 2019; Grafakos et al., 2020). Nature-based solutions (NbS), such as urban greening, often integrate adaptation and mitigation in sustainable urban developments and are associated with increasing natural and social capital in urban communities, improving health and wellbeing, and raising property prices (Geneletti and Zardo, 2016; Pasimeni et al., 2019; Grafakos et al., 2020). Barriers to CRD in European cities include limitations in: funding, local capacity, guidance documents and quantified information on costs, co-benefits and trade-offs (Grafakos et al., 2020). Pilot projects are used to initiate CRD transitions (Nagorny-Koring and Nochta, 2018). Malmö (Sweden) and Milan (Italy) are two examples to illustrate the strategies and challenges of two European cities attempting to implement CRDP.

Malmö (population 0.3M): Since the 1990s, Malmö has been transitioning toward an environmentally, economically and socially sustainable city, investing in eco-districts (redeveloped areas that integrate and showcase the city's sustainability strategies) and adopting ambitious adaptation and mitigation targets. The city has focused on energy efficient buildings and construction, collective and low carbon transportation, and green spaces and infrastructure (Anderson, 2014; Malmo Stad, 2018). Malmö has developed creative implementation mechanisms, including a "climate contract" between the city, the energy distributor and the water and waste utility to co-develop the climate-smart district, Hyllie (Isaksson and Heikkinen, 2018; Kanters and Wall, 2018; Parks, 2019). Flagship eco-districts play a central role in the city's transition, in the wider adoption of CRD and in securing implementation partners (Isaksson and Heikkinen, 2018; Stripple and Bulkeley, 2019). The city has also leveraged its status as a CRD leader to attract investment. The private sector views CRD as profitable, due to the high demand and competitive value of these developments (Holgersen and Malm, 2015). Malmö adopted the SDGs as local goals and the city's Comprehensive Plan is evaluated on these, e.g., considering gender in the use, access and safety of public spaces, and emphasizing development that facilitates climate resilient lifestyles (Malmo Stad, 2018). Malmö also engages stakeholders via dialogue with residents, collaboration with universities and partnerships with industry and service providers (Kanters and Wall, 2018; Parks, 2019). Despite measurable and monitored targets, and supportive institutional arrangements, sustainability outcomes for the flagship districts have been tempered by developers' market-oriented demands (Holgersen and Malm, 2015; Isaksson and Heikkinen, 2018) and there is limited low-income housing in climate-resilient districts (Anderson, 2014; Holgersen and Malm, 2015).

Milan (population 1.4M): Milan is taking a CRD approach to new developments (Comune di Milano, 2019). From 2020, new buildings must be carbon neutral and reconstructions must reduce the existing land footprint by at least 10%. The Climate and Air Plan (CAP) and the city's Master Plan (Comune di Milano, 2019) focus on low-carbon, inclusive and equitable development. The CAP is directed at municipal and private assets, and individual to city-scale actions. In 2020, Milan released a revised Adaptation Plan and the Open Streets project to ensure synergies between the COVID-19 response and longer-term CRD. Examples include strengthening neighbourhood-scale disaster response and reallocating street space for walking and cycling (Comune di Milano, 2020). Milan emphasizes institutionalization of CRD via a dedicated resilience department, and through active participation in climate networks and projects that support learning and exchange. Climate network commitments are cited in the city's Master Plan and CAP guidelines as driving more ambitious deadlines and emissions targets (Comune di Milano, 2019). Implementation of Milan's plans remains a challenge, despite dedicated resources and commitment.

[END BOX 13.3 HERE]

Considerable barriers exist that prevent system transitions from taking place in Europe, including institutional and behavioural lock-ins such as administrative routines, certain types of legislation, and dominant paradigms of problem solving (Johannessen et al., 2019; Roberts and Geels, 2019) (*high confidence*). For example, near-term and sectoral decision-making constrains transformative options for water-related risks (Section 13.2). Breaking through these lock-ins requires substantive (political) will, (un)learning of practices, resources, and evidence of what works. Trade-offs exist between the depth, scope, and pace of change in transforming from one system to another, suggesting that designing system transformations is a careful balancing act (Termeer et al., 2017). Aspiring in-depth and comprehensive transformational changes might create a consensus frame to work towards; but it might not offer concrete perspectives to act on the ground. Taking small steps and quick-wins offer an alternative pathway (Termeer and Dewulf, 2018).

Adaptation responses can also be understood in terms of their trade-offs and synergies with SDGs (Papadimitriou et al., 2019; Bogdanovich and Lipka, 2020). In terms of synergies, analysis of the Russian NAP found that successful completion of the NAP's first phase could lead to significant progress towards 15 of the 17 goals (Bogdanovich and Lipka, 2020). European water adaptation (e.g., flood protection) can similarly support freshwater provision; and water-secured environments support socio-economic growth (Sadoff et al., 2015) since people and assets tend to accumulate in areas protected from flooding and supplied with water, reducing the incentive for autonomous adaptation (de Moel et al., 2011; Hartmann and Spit, 2016; Di Baldassarre et al., 2018). In health, behavioural measures to reduce mental health impacts (e.g., gardening, active travel) can have broader health benefits (SDG 3) as well as help reduce emissions (Section 13.7; SDGs 7 and 13). Conversely, growing use of air conditioning for humans and livestock represents a potential trade-off between adaptation and mitigation (Sections 13.5,13.6, 13.7, 13.10). As noted in Section 13.8, addressing poverty (SDG 1) - including energy poverty (SDG 7) and hunger (SDG 2) - and inequalities (SDG 10) - including gender inequality (SDG 5) - improves resilience to climate impacts for those groups that are disproportionately affected (women, low-income and marginalised groups). Also, more inclusive and fair decision-making can enhance resilience (SDG 16; Section 13.4.4); although adaptation measures may also lead to resource conflicts (SDG 16; Section 13.7). Climate adaptation, particularly nature-based solutions, also supports ecosystem health (SDGs 14 and 15) (Dzebo et al., 2019). Economic trade-offs appear to be more common across adaptation strategies, for example reduced employment arising from land use change measures (Papadimitriou et al., 2019). There are also trade-offs between large-scale mitigation measures (e.g., wind farms) and adaptation options that rely on ecosystem services (e.g., water regulation; Section 13.3-13.4); and conversely, some adaptation options (e.g., air conditioning) may negatively impact mitigation. Figure 13.36 summarises the synergies between adaptation and SDGs as identified by 167 European cities in 2019; particularly prominent are reported biodiversity and health benefits most often arising from societal (e.g., informational) and structural (e.g., technological/engineering) measures. Beyond the urban context, biodiversity co-benefits from agro-ecology are also recognised (Section 13.5). Sustainable behaviour change measures have been found to be particularly *likely* to lead to synergies with SDGs (Papadimitriou et al., 2019).

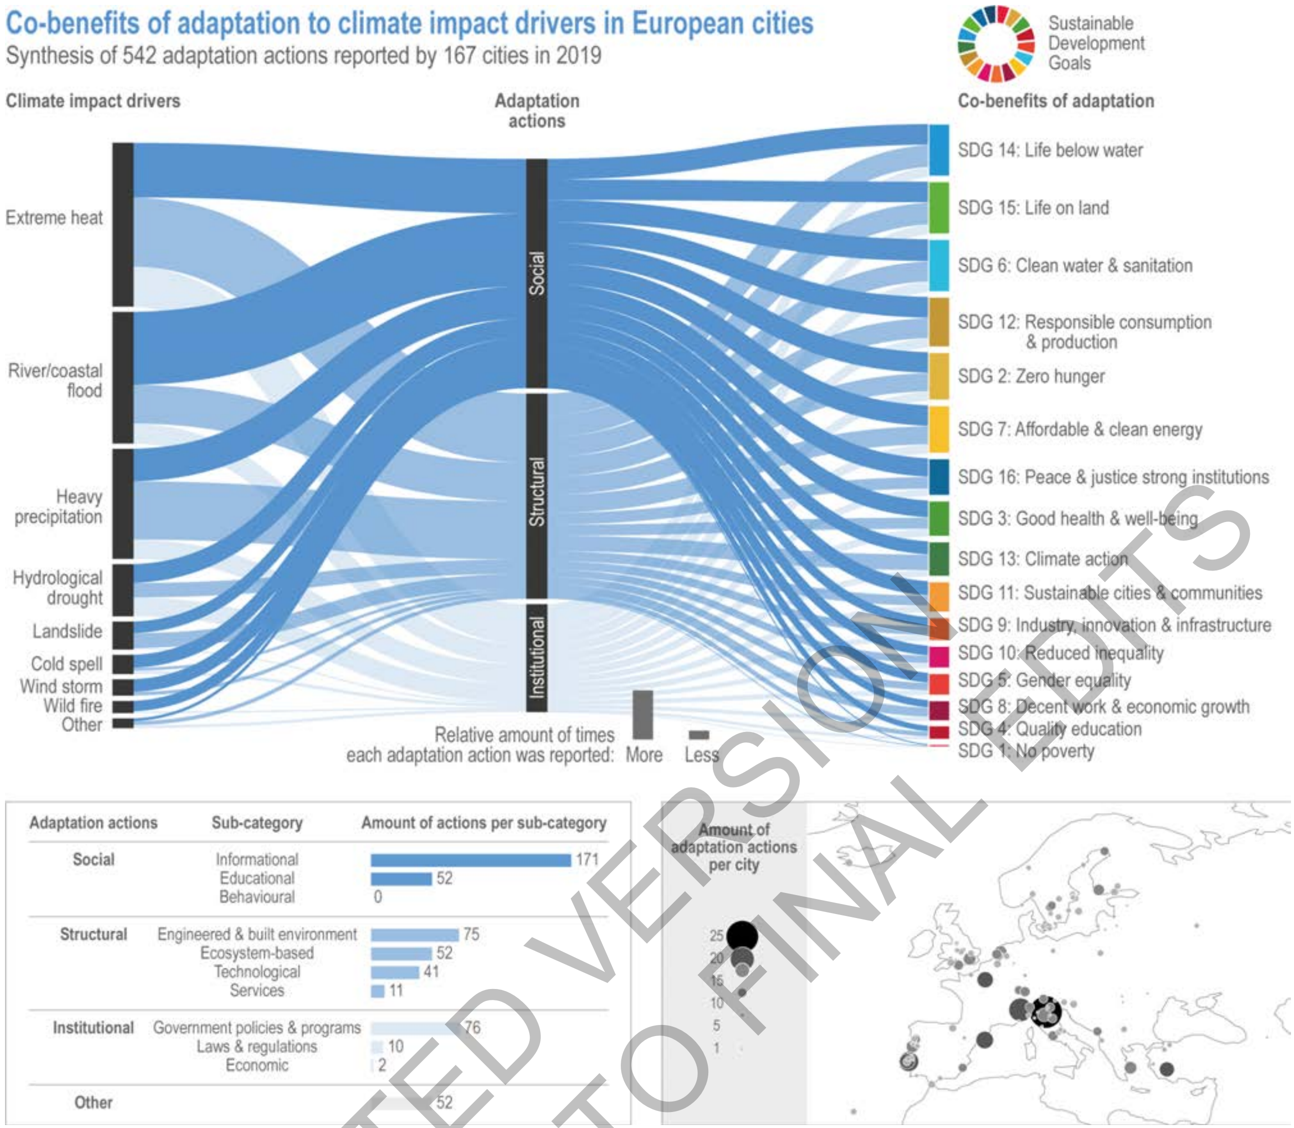

Figure 13.36: Co-benefits for SDGs from adaptation actions. Shows how European cities have assessed the sustainability co-benefits of taking adaptation actions. Data was extracted from the Carbon Disclosure Project (CDP) database using the 2019 dataset; of the 861 European cities submitting data, 167 provided data on their adaptation actions and so this data is shown here (CDP, 2019). CDP categories of climate hazards were recategorized into WG1 Climate Impact Drivers (e.g., cold spell, heavy precipitation); CDP adaptation actions were reclassified into AR5 adaptation options ('social', 'structural' and 'institutional'; 'other' includes actions falling outside these AR5 categories); and CDP co-benefits were recategorized as SDGs. Panel 2 shows that all SDGs except one (SDG 17) were identified as a co-benefit of adaptation, although more environmental co-benefits were identified than social or economic ones. Panel 2 shows that societal actions were most common, followed by structural, then institutional. Informational measures were particularly common. Panel 3 shows how many actions were taken by different European cities.

[START FAQ13.1 HERE]

FAQ 13.1: How can climate change affect social inequality in Europe?

The poor and those practising traditional livelihoods are particularly exposed and vulnerable to climate change. They rely more often on food self-provisioning and settle in flood-prone areas. They also often lack the financial resources or the rights to successfully adapt to climate-driven changes. Good practice examples demonstrate that adaptation can reduce inequalities.

Social inequalities in Europe arise from disparities in income, gender, ethnicity, age, as well as other social categorisations. In the European Union, about a fifth of the population (109 million people) at present, live under conditions of poverty or social exclusion. Moreover, poverty is unequally distributed across Europe, with higher poverty levels in the eastern parts of Europe. The oldest and youngest in society are often most vulnerable.

The poor and those practising traditional livelihoods are particularly vulnerable and exposed to climate risks. Many depend on food self-provisioning from lakes, the sea, and the land. With higher temperatures, the availability of these sources of food is *likely* to be reduced, particularly in southern Europe. Poorer households often settle in flood-prone areas and are therefore more exposed to flooding. Traditional pastoralist and fishing practices are also negatively affected by climate change across Europe. Semi-migratory reindeer herding, a way of life among Indigenous and traditional communities (Komi, Saami, Nenets) in the European Arctic, is threatened by reduced ice and snow cover. Almost 15% of the EU population (in some countries more than 25%) already cannot meet their healthcare needs for financial reasons, while they are at risk of health impacts from warming.

In addition to being more exposed to climate risks, socially vulnerable groups are also less able to adapt to these risks, because of financial and institutional barriers. More than 20% of people in the South and East of Europe live in dwellings that cannot be cooled to comfortable levels during summer. These people are particularly vulnerable to risks from increasing heatwave days in European cities e.g. when they already face energy poverty. They may also lack the means to protect against flooding or heat, e.g., when they do not own the property. Risk-based insurance premiums, which are intended to help people reduce climate risks, are potentially unaffordable for poor households. The ability to adapt is also often limited for Indigenous People, as they often lack the rights and governance of resources, particularly when in competition with economic interests such as resource mining, oil and gas, forestry, and expansion of bioenergy.

Adaptation actions by governments can both increase and decrease social inequality. The installation of new or the restoration of existing green spaces may increase land prices and rents due to a higher attractiveness of these areas, leading to potential displacement of population groups who cannot afford higher prices. On the other hand, rewilding and restoration of ecosystems can improve the access of less privileged people to ecosystem services and goods, such as the availability of freshwater. At city level, there are examples of good practice in climate-resilient development that consider social equity which integrate a gender-inclusive perspective in its sustainable urban planning, including designing public spaces and transit to ensure women, disabled people and other groups can access and feel safe using these public amenities (see Box 13.3).

[END FAQ13.1 HERE]

[START FAQ13.2 HERE]

FAQ 13.2: What are the limits of adaptation for ecosystems in Europe?

Land, freshwater and ocean organisms and ecosystems across Europe are facing increasing pressures from human activities. Climate change is rapidly becoming an additional and, in the future, a primary threat. Ongoing and projected future changes are too severe and happen too fast for many organisms and ecosystems to adapt. More expensive and better implemented environmental conservation and adaptation measures can slow down, halt, and potentially reverse biodiversity and ecosystem declines, but only at low or intermediate warming.

Ecosystem degradation and biodiversity loss have been evident across Europe since 1950, mainly due to land use and overfishing. However, climate-change is becoming a key threat. The unprecedented pace of environmental change has already surpassed the natural adaptive capability of many species, communities, and ecosystems in Europe. For instance, the space available for some land ecosystems has shrunk, especially in Europe's polar and mountain areas, due to warming and thawing of permafrost. Across Europe, heatwaves and droughts and their impacts such as wildfires add further acute pressures, as seen in the 2018 heatwave, which impacted forest ecosystems and their services. In the Mediterranean Sea, plants and animals cannot shift northward and are negatively affected by marine heatwaves. Food-web dynamics of European ecosystems are disrupted as climate change alters the timing of biological processes, such as spawning and migration of species, and ecosystem composition. Moreover, warming fosters the immigration of invasive species that compete with–and can even out-compete–the native flora and fauna.

In a future with further and even stronger warming, climate change and its many impacts will become increasingly more important threats. Several species and ecosystems are projected to be already at high risk at 2°C global warming, including fishes and lake and river ecosystems. At 3°C global warming, many European ecosystems, such as coastal wetlands, peatlands, and forests, are projected to be at much higher risk of being severely disrupted than in a 2°C warmer world. For example, Mediterranean seagrass meadows will *very likely* become extinct due to more frequent, longer, and more severe marine heat waves by 2050. Several wetland and forest plants and animals will be at high risk to be replaced by invasive species that are better adapted to increasingly dry conditions, especially in boreal and Arctic ecosystems.

Current protection and adaptation measures, such as the Natura 2000 network of protected areas, have some positive effects for European ecosystems. However, these policies are not sufficient to effectively curb overall ecosystem decline, especially for the projected higher risks above 2°C global warming. Nature-based solutions, such as the restoration of wetlands, peatlands, and forests, can serve both ecosystem protection and climate-change mitigation through strengthening carbon sequestration. Some climate change mitigation measures such as reforestation and restoration of coastal ecosystems can strengthen conservation measures. These approaches are projected to reduce risks for European ecosystems and biodiversity, especially when internationally coordinated.

Not all climate-change adaptation options are beneficial to ecosystems. When planning and implementing adaptation options and Nature-based Solutions, trade-offs and unintended side effects should be considered. On one hand, engineering coastal protection measures (seawalls, breakwaters, and similar infrastructure) in response to sea level rise reduce the space available for coastal ecosystems. One the other hand, Nature-based Solutions can also have unintended side effects, such as increased methane release from larger wetland areas and large-scale tree planting changing the albedo of the surface.

[END FAQ13.2 HERE]

[START FAQ13.3 HERE]

FAQ 13.3: How can people adapt at individual and community level to heat waves in Europe?

Heatwaves will become more frequent, more intense and will last longer. A range of adaptation measures are available for communities and individuals before, during and after a heat wave strikes. Implementing adaptation measures are important to reduce the risks of future heat waves.

Heat waves will affect people in different ways, risks are higher for the elderly, pregnant women, small children, people with pre-existing health conditions and low-income groups. By 2050, about half of the European population may be exposed to high or very high risk of heat stress during summer, particularly in Southern Europe and increasingly in Eastern and Western and Central Europe. The severity of heat-related risks will be highest in large cities, due to the urban heat island effect.

In southern Europe people are already aware of the risks of heat extremes. Consequently, governments and citizens have implemented a range of adaptation responses to reduce the impacts of heat waves. However, there are limits to how much adaptation can be implemented. At 3°C global warming there will be substantial risks to human lives and productivity, which cannot be avoided. In the parts of Europe where heat waves are a relatively new phenomena, such as many parts of North and Western and Central Europe, public awareness of heat extremes is increasing and institutional capacity to respond is growing.

Preparing for heat waves is an important first step. Implementing and sustaining effective measures, such as national or regional early warning and information systems, heat wave plans and guidelines, and raising public awareness through campaigns are successful responses. Evidence suggests that such measures have contributed to reduced mortality rates in Southern and Western and Central Europe. At city level, preparing for heat waves can sometimes require urban redesign. For example, green-blue spaces, such as recreational parks and ponds in cities, have been shown to reduce the average temperature in cities dramatically and to provide co-benefits, such as improved air quality and recreational space. The use of cool materials in asphalt, increasing reflectivity, green roofs, and building construction measures are being considered in urban planning for reducing heat risks. Citizens can prepare themselves by using natural ventilation, using approaches to stay cool in heat waves, green roofs and green facades in their buildings.

During heat waves, public information that is targeted at people and social care providers is critical, particularly for the most vulnerable citizens. Governments and NGOs play an important role in informing people about how to prepare and what to do to avoid health impacts and reduce mortality. Coordination between vital emergency and health services is critical. Individuals can take several actions to effectively protect themselves from heat: 1) decreasing exposure to high temperatures (e.g., avoid outdoor during hottest times of the day, access cool areas, wear protective and appropriate clothing); 2) keep hydrated (e.g., drink enough proper fluids, avoid alcohol, etc.), 3) be sensitive to the symptoms of heat illness (dizziness, heavy sweating, fatigue, cool and moist skin with goosebumps when in heat, etc.).

Once the heat wave has ended, evaluation of what worked well and how improvements can be made is key to prepare for the next heat wave. Governments can, for example, evaluate whether the early warning systems provided timely and useful information, whether coordination went smoothly, or assess estimated number of lives saved as results of the measures implemented. Sharing these lessons learned is critical to allow other cities and regions to plan for heat extremes. After the heatwave, citizens can reflect if their responses were sufficient, whether investments are needed to be better prepared, and draw key lessons about what (not) to do when the next heat wave strikes.

[END FAQ13.3 HERE]

[START FAQ13.4 HERE]

FAQ 13.4: What opportunities does climate change generate for human and natural systems in Europe?

Not all climate change impacts across Europe pose challenges and threats to natural communities and human society. In some regions, and for some sectors, opportunities will emerge . Although these opportunities do not outweigh the negative impacts of climate change, considering these in adaptation planning and implementation is important to benefit from them. Nevertheless, Europe will face difficult decisions balancing the trade-offs between the adaptation needs of different sectors, regions and adaptation and mitigation actions.

Opportunities of climate change can be 1) positive effects of warming for specific sectors and regions, such as agriculture in northern Europe and 2) co-benefits of transformation of cities or transport measures that reduce the speed and impact of climate-change while improving air quality, mental health and wellbeing. Windows of action for transformation opportunities for large-scale transitions and transformation of our society may be accelerated through new policy initiatives in response to the COVID crisis, such as the European New Green Deal and Building Back Better.

As warming and droughts impact southern Europe most strongly, direct opportunities from climate change are primarily in northern regions, thereby increasing existing inequalities across Europe. Across Europe, positive effects of climate change are fewer than negative impacts and are typically limited to some aspects of agriculture, forestry, tourism, and energy sectors. In the food sector, opportunities emerge by the northward movement of food production zones, increases in plant growth due to CO_2 fertilisation, and reduction of heating costs for livestock during cold winters. In the energy sector, positive effects include increased wind energy in the southwestern Mediterranean, and reduced energy demand for heating across Europe. While climatic conditions for tourist activities are projected to decrease for winter tourism (e.g. lacking sufficient snow) and summer tourism in some parts of Europe (e.g. too hot), conditions may improve during spring and autumn in many European locations. Fewer cold waves will reduce risks on transport infrastructure, such as cracking of road surface, in parts of Northern and Eastern Europe particularly by the end of the century.

Indirect opportunities emerge from the co-benefits of implementing adaptation actions. Some of these co-benefits are wide-spread but need careful consideration in order to be utilized. For example, Nature-based Solutions to adaptation can make cities and settlements more liveable, increase the resilience of agriculture, and protect biodiversity. Ecosystem-based adaptation can attract tourists and create recreational space. There are opportunities to mainstream adaptation into other developments and transitions, including the energy or agricultural transitions and COVID19 recovery plans. Transformative solutions to achieve sustainability may be accelerated through larger changes of, for example behaviour, energy, food or transport, to better exploit new opportunities and co-benefits. Implementation of adaptation actions can also help to make progress towards achieving the Sustainable Development Goals.

Inclusive, equitable and just adaptation is critical for climate resilient development considering SDGs, gender, as well as Indigenous knowledge and local knowledge and practices. Implementation requires political commitment, persistence and consistent action across scales of government. Upfront mobilization of political, human and financial capital in implementation of adaptation actions is key, even when the benefits are not immediately visible.

Table of Contents

Executive Summary

Since AR5, climate change impacts have become more frequent, intense, and have affected many millions of people from every region and sector across North America (Canada, US and Mexico). Accelerating climate change hazards pose significant risks to the wellbeing of North American populations and the natural, managed and human systems on which they depend (*high confidence*[1]). Addressing these risks have been made more urgent by delays due to misinformation about climate science that has sowed uncertainty, and impeded recognition of risk (*high confidence*). {14.2, 14.3}

Without limiting warming to 1.5°C, key risks to North America are expected to intensify rapidly by mid-century (*high confidence*). These risks will result in irreversible changes to ecosystems, mounting damages to infrastructure and housing, stress on economic sectors, and disruption of livelihoods, mental and physical health, leisure, and safety. Immediate, widespread, and coordinated implementation of adaptation measures aimed at reducing risks and focused on equity have the greatest potential to maintain and improve the quality of life for North Americans, ensure sustainable livelihoods, and protect the long-term biodiversity, and ecological and economic productivity in North America (*high confidence*). Enhanced sharing of resources and tools for adaptation across economic, social, cultural and national entities enables more effective short- and long-term responses to climate change. {14.2, 14.4, 14.5, 14.6, 14.7}

Past and Current Impacts and Adaptation

Over the past 20 years, climate change impacts across North America have become more frequent, intense and affect more of the population (*high confidence*). Despite scientific certainty of the anthropogenic influence on climate change, misinformation and politicization of climate change science has created polarization in public and policy domains in North America, particularly in the US, limiting climate action (*high confidence*). Vested interests have generated rhetoric and misinformation that undermines climate science and disregards risk and urgency (*medium confidence*). Resultant public misperception of climate risks and polarized public support for climate actions is delaying urgent adaptation planning and implementation (*high confidence*). Including Indigenous knowledge, communication and outreach as well as collaborations to co-create equitable solutions are critical for successful climate action. {Box 14.1, 14.3, 14.7}

Climate change has negatively impacted human health and wellbeing in North America (*very high confidence*). High temperatures have increased mortality and morbidity (*very high confidence*), with impacts that vary by age, gender, location, and socioeconomic conditions (*very high confidence*). Changes in temperature and precipitation have increased risk of vectorborne (*very high confidence*), waterborne (*high confidence*), and foodborne diseases (*very high confidence*). Changes in climate and extreme events have been linked to wide-ranging negative mental health outcomes (*high confidence*). The loss of access to marine and terrestrial sources of protein has impacted the nutrition of subsistence-dependent communities across North America (*high confidence*). Climate change has increased the extent of warmer and drier conditions favourable for wildfires (*medium confidence*) that increase respiratory distress from smoke (*very high confidence*). {14.5.2, 14.5.6, Box 14.2}

North American food production is increasingly affected by climate change (*high confidence*), with immediate impacts on the food and nutritional security of Indigenous Peoples. Climate change and extreme weather events have impacted North American agroecosystems (*high confidence*), with crop-specific effects that vary in direction and magnitude by event and location. Climate change has generally reduced agricultural productivity by 12.5% since 1961, with progressively greater losses moving south from Canada to Mexico and in drought-prone rainfed systems (*high confidence*) while favorable conditions increased yields of maize, soybeans in regions like the US Great Plains. Loss of availability and access to marine and terrestrial sources of protein has impaired food security and nutrition of subsistence-dependent

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

Indigenous Peoples across North America (*high confidence*). Climate change has impacted aquaculture (*high confidence*) and induced rapid redistribution of species (*very high confidence*), and population declines of multiple key fisheries (*high confidence)*. {14.5.4, 14.5.6, 14.7}

Climate change has impaired North American freshwater resources and reduced supply security (*high confidence*). Reduced snowpack and earlier runoff (*high confidence*) have adversely affected aquatic ecosystems and freshwater availability for human uses (*medium confidence*). Recent severe droughts, floods and harmful algal and pathogen events have caused harm to large populations and key economic sectors *(high confidence*). Heavy exploitation of limited water supplies, especially in the western US and northern Mexico, and deteriorating freshwater management infrastructure, have heightened the risks (*high confidence*). Effective examples of freshwater resource adaptation planning are already underway, but coordinated adaptation implementation across multiple conflicting interests and users is complicated and time consuming (*high confidence*). {14.5.1, 14.5.2, 14.5.3}

Extreme events and climate hazards are adversely affecting economic activities across North America and have disrupted supply-chain infrastructure and trade (*high confidence).* Larger losses and adaptation costs are observed for sectors with high climate exposures, including tourism, fisheries, and agriculture (*high confidence*) and outdoor labor (*medium confidence)*. Disaster planning and spending, insurance, markets, and individual and household level adaptation have acted to moderate effects to date (*medium confidence)*. Entrenched socioeconomic vulnerabilities have amplified climate impacts for marginalized groups, including Indigenous Peoples due to the impact of colonialism and discrimination (*medium confidence*). {14.5.4, 14.5.5, 14.5.6, 14.5.7, 14.5.9, Box 14.1, Box 14.5, Box 14.6}

North American cities and settlements have been affected by increasing severity and frequency of climate hazards and extreme events *(high confidence*), which has contributed to, infrastructure damage, livelihood losses, damage to heritage resources, and safety concerns. Impacts are particularly apparent for Indigenous Peoples for whom culture, identity, commerce, health and wellbeing are closely connected to a resilient environment (*very high confidence*). Higher temperatures have been associated with violent and property crime in the US (*medium confidence*) yet the overall effects of climate change on crime and violence in North America are not well understood. {14.4, 14.5.5, 14.5.6, 14.5.8, 14.5.9, Box 14.1}

Terrestrial, marine, and freshwater ecosystems are being profoundly altered by climate change across North America (*very high confidence*). Rising air, water, ocean and ground temperatures have restructured ecosystems and contributed to the redistribution (*very high confidence*) and mortality (*high confidence*) of fish, bird, and mammal species. Extreme heat and precipitation trends on land have increased vegetation stress and mortality, reduced soil quality, and altered ecosystem processes including carbon and freshwater cycling (*very high confidence*). Warm and dry conditions associated with climate change have led to tree die-offs (*high confidence*) and increased prevalence of catastrophic wildfire (*medium confidence*) with an increase in the size of severely burned areas in western North America (*medium confidence*). Nature-based solutions and ecosystem-based management have been effective adaptation approaches in the past but are increasingly exceeded by climate extremes *(medium confidence*). {14.5.1-3, Box 14.7}

Climate-driven changes are particularly pronounced within Arctic ecosystems and are unprecedented based on observations from multiple knowledge systems (*very high confidence*). Climate change has contributed to cascading environmental and socio-cultural impacts in the Arctic (*high* to *very high confidence*) that have adversely, and often irreversibly, altered Northern livelihoods, cultural activities, essential services, health, food and nutritional security, community connectivity, and wellbeing (*high confidence*). {14.5.2, 14.5.4, 14.5.6, 14.5.7, 14.5.8, Box 14.6}

Future Risks and Adaptation

Climate hazards are projected to intensify further across North America (*very high confidence*). Heat waves over land and in the ocean as well as wildfire activity will intensify; sub-Arctic snowpack, glacial mass and sea ice will decline (*virtually certain*); and sea level rise will increase at geographically differential rates (*virtually certain*). Humidity-enhanced heat stress, aridification, and extreme precipitation events that lead to severe flooding, erosion, debris flows, and ultimately loss of ecosystem function, life and property, are projected to intensify (*high confidence*). {14.2}

Health risks are projected to increase this century under all future emissions scenarios (*very high confidence*) but the magnitude and severity of impacts depends on the implementation and effectiveness of adaptation strategies (*very high confidence*). Warming is projected to increase heat-related mortality (*very high confidence*) and morbidity (*medium confidence*). Vectorborne disease transmission, waterborne disease risks, food safety risks and mental health outcomes are projected to increase this century (*high confidence*). Available adaptation options will be less effective or unable to protect human health under high-emission scenarios (*high confidence*). {14.5.6, Box 14.2}

Climate-induced redistribution and declines in North American food production are a risk to future food and nutritional security (*very high confidence*). Climate change will continue to shift North American agricultural and fishery suitability ranges (*high confidence*) and intensify production losses of key crops (*high confidence*), livestock (*medium confidence*), fisheries (*high confidence*), and aquaculture products (*medium confidence*). In the absence of mitigation, incremental adaptation measures may not be sufficient to address rapidly changing conditions and extreme events, increasing the need for cross-sectoral coordination in implementation of mitigation and adaptation measures (*high confidence*). Combining sustainable intensification, Indigenous knowledge and local knowledge based-approaches, and ecosystem-based methods with inclusive and self-determined decision making will result in more equitable food and nutritional security (*high confidence*). {14.5.1-4, 14.5.6,14.7, Croxx-Chapter Box INDIG in Chapter 18, Cross-Chapter Box MOVING PLATE in Chapter 5}

Escalating climate change impacts on marine, freshwater, and terrestrial ecosystems (*high confidence*) will alter ecological processes (*high confidence*) and amplify other anthropogenic threats to protected and iconic species and habitats (*high confidence*). Hotter droughts and progressive loss of seasonal water storage in snow and ice will tend to reduce summer season stream flows in much of western North America, while population growth, extensive irrigated agriculture and the needs of threatened and endangered aquatic species will continue to place high demands on those flows (*high confidence*). {14.2.2, 14.5.1, 14.5.2, 14.5.3, 14.5.4, 14.5.6, Box 14.7.1}

Market and non-market economic damages are projected to increase to the end of the century from climate impacts (*high confidence*). Estimates for the costs of climate inaction are substantial across economic sectors, infrastructure, human health and disaster management. Hard limits to adaptation may be reached for outdoor labor (*medium confidence*) and nature-based winter tourism activities (*very high confidence*). At higher levels of warming, climate impacts may pose systemic risks to financial markets through impacts on transportation systems, supply-chains, and major infrastructure as well as global scale challenges to trade (*medium confidence).* {14.2.2, 14.5.4, 14.5.8, 14.5.7, 14.5.9, 14.5.5, Box 14.5, Box 14.6}

Solution Space, Governance

Self-determination for Indigenous Peoples is critical for effective adaptation in Indigenous communities (*very high confidence*). Throughout North America, Indigenous Peoples are actively addressing the compound impacts of climate change, and historical and ongoing forms of colonialism (*very high confidence*). Indigenous knowledge underpins successful understanding of, responses to, and governance of climate change risks. Western scientific practices and technology may not be sufficient in addressing future natural resource management challenges. Supporting Indigenous self-determination, recognizing Indigenous Peoples' rights, and supporting Indigenous knowledge based-adaptation are critical to reducing climate change risks to achieve adaptation success (*very high confidence*). {14.7.3, Box 14.1}

Equitable, inclusive and participatory approaches that integrate climate impact projections into near-term and long-term decision-making reduce future risks (*high confidence*). Government and private investment are increasingly investing in early warning and rapid response systems, climate and ecological forecasting tools, and integrated climate scenario planning methods. Widespread adoption of these practices and tools for infrastructure planning, disaster risk reduction, ecosystem management, budgeting practices, insurance, and climate risk reporting supports planning for a future with more climate risks (*high confidence)*. Increased capacity to support the equitable resolution of existing and emerging resource disputes (local to international) will reduce climate impacts on livelihoods and improve the effectiveness of resource management (*high confidence*). {14.5.5, 14.5.10, 14.7}

Near- and long-term adaptation planning, implementation, and coordination across sectors and jurisdictions supports equitable and effective climate solutions (*high confidence*). Recognition of the need for adaptation across North America is increasing but action has been mostly gradual, incremental, and reactive (*high confidence)*. Current practices will be increasingly insufficient without coordination and integration of efforts through equitable policy focused on modifying land use impacts, consumption patterns, economic activities, and emphasizing nature-based solutions (*high confidence*). Transformational, long-term adaptation action that reduces risk and increases resilience can address rapidly escalating impacts in the mid to latter part of the 21st century, especially if coupled with moderate to high mitigation measures (*high confidence*). {14.7}

14.1 Introduction and Point of Departure

Earth's climate is currently changing in significant ways as a result of human activities, and future projections indicate continued and possibly accelerating change without reductions in greenhouse gas (GHG) emissions (Gutiérrez et al., In Press; IPCC, In Press). Climate change affects human and natural systems; this chapter provides an assessment of present and future climate change impacts, risks, and adaptation for North America, including Mexico, Canada, and the United States (US) and coastal waters within the 370 km exclusive economic zone. We do not consider Hawaii and other island territories of the US in depth as they are assessed in Chapter 15 (Small Islands). Chapter 14 assesses evidence from Arctic Canada and Alaska, which is synthesized in the Polar Regions Cross-Chapter Paper (CCP6).

Evidence from Indigenous knowledge (IK) systems is included in this chapter to assess climate change risks and solutions in North America following the framing provided in Chapter 1 Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC) (Abram et al., 2019) and Special Report on Climate Change and Land (SRCCL) (IPCC, 2019a). Indigenous Contributing Authors provided this assessment, reflecting the importance of meaningfully including IK in assessment processes (Ford, 2012; Ford et al., 2016; Hill et al., 2020). This addition represents an important advancement since AR5 (IPCC, 2013; IPCC, 2014).

Our main point of departure was the Fifth Assessment Report (AR5) for WGII (IPCC, 2014). Key findings drawn from the Executive Summary for the North America chapter are summarized in Table 14.1. Subsequent IPCC reports such as Special Report on Global Warming of 1.5°C (SR1.5) (Hoegh-Guldberg et al., 2018; IPCC, 2018), SROCC (IPCC, 2019b), and SRCCL (IPCC, 2019a) also informed the assessment. We additionally incorporated recent national climate assessments of the US (USGCRP, 2018) and Canada (Bush and Lemmen, 2019; Warren and Lulham, 2021) as well as the 6th Mexican national communication of climate change to the United Nations (SEMARNAT and INECC, 2018).

Table 14.1: Key findings from AR5 North America Chapter (Romero-Lankao et al., 2014b).

General topic	AR5 finding
Climate hazards	Climate has changed in North America, with some changes attributed to human activities.
	Climate hazards, especially related to heatwaves, heavy precipitation, and snowpack, are expected to change in ways that are adverse to natural and human systems.
Natural ecosystems	Warming, increasing carbon dioxide (CO_2) concentrations, sea level rise (SLR), and climate extremes are stressing ecosystems.
Human systems	Water resources that are already stressed in many parts of North America are expected to become further stressed by climate change. Current adaptation options can address water supply deficits but responses to flooding and water quality concerns are more limited.
	Climate change has affected yields of major crops, and projections indicate continued declines, although with variability.
	Extreme climate events have affected human health, although climate change-related trends and attribution to climate change were not confirmed.
	Multiple aspects of climate change have affected livelihoods, economic activities, infrastructure, and access to services.
	Much infrastructure is vulnerable to extreme weather events and unless adaptation investments are made, vulnerability to future climate change persists and increases.

	Most sectors of the North American economy have been affected by and have responded to extreme weather, including hurricanes, flooding, and intense rainfall.
Adaptation	Technological innovation, institutional capacity-building, economic diversification, and infrastructure design are adaptations for reducing current climate impacts as well as future risks due to a changing climate.
	Predominantly, North American governments have undertaken incremental adaptation assessment and planning at the municipal level. Limited proactive, anticipatory adaptation is directed at long-term investment for energy and public infrastructure.

Chapter 14 sections are organized to address themes and content as contained in the IPCC-approved outline for regions. Regional climate changes assessed within North America are keyed to Figure 14.1 using *italicized* four-letter abbreviations (e.g., *CA-ON, US-SE, MX-NW*). The assessment addresses recent and future climate for North America, the impacts, risks and adaptation within sectors, key risks (KR), the nature of adaptation and sustainable development pathways as well as two additional sections on Indigenous Peoples and perceptions of climate change. Seven Boxes are used to highlight topics of interdisciplinary nature while four Frequently Asked Questions (FAQ) were produced in plain language for communication to the public. The chapter utilizes the framework as well as designated terms in the standardized process for evaluating and characterizing the degree of certainty in assessment findings developed through the expert judgment process (Mach et al., 2017) (see WGII 1.3.4) (references to other relevant chapters in this WGII report are abbreviated in this manner). The WGII Glossary provides definitions for terms and concepts used across the report.

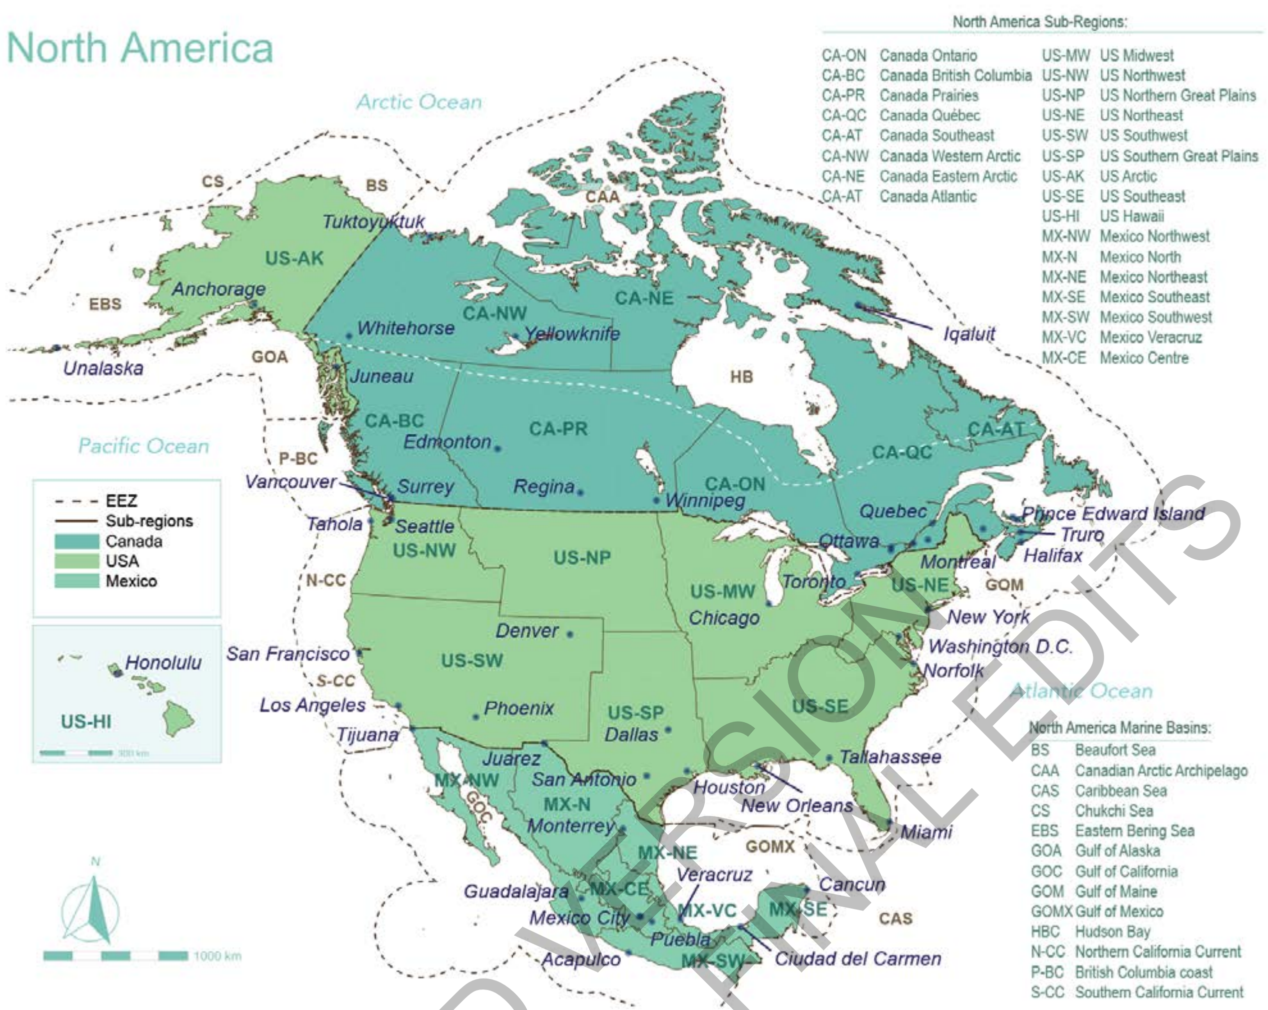

Figure 14.1: North American regions and subregions, adapted from national climate assessments, and city names, referred to in discussion of local and regional climate change impacts and adaptation.

14.1.1 Context

With a 2019 total population of over 494 million people (US 329 million, Mexico 128 million and Canada 37 million), North America comprises 6.4% of the global population. Relative to other countries, North America has low population densities (Mexico 64 people/km^2; US 35/km^2; Canada, 4/km^2) (United Nations, 2019). Population projections indicate a steady growth in the three countries, which will exert pressure on consumption and increase risks under climate change (United Nations, 2019). North America is also responsible for about a quarter of global greenhouse gas (GHG) emissions. Since 1990, North American GHG emissions have increased by almost 18% (Ritchie and Roser, 2020) and in 2019 the region was responsible for 5.9 MtCO_2 emissions worldwide (Friedlingstein et al., 2020). In terms of annual CO_2 emissions per capita, in 2019 Canada had 15 metric tons CO_2 per person (tCO_2/person), the US had 16 tCO_2/person, and Mexico had 3.4 tCO_2/person (Friedlingstein et al., 2020).

14.2 Current and Future Climate in North America

Trends in observed and projected physical climate variables, and changes in extreme weather and climate events, are summarized in this section. Many of the assessments here are adapted from AR6 WGI (IPCC, In Press), especially chapters 11 (Seneviratne et al., 2021) and 12 (Ranasinghe et al., 2021) and the WGI Atlas (Gutiérrez et al., In Press) (references to chapters in WGI are hereafter abbreviated I.11, I.12, I.Atlas, etc.). I.12.4.6 assesses North American climatic impact drivers without assessing their impacts or associated risks. WGI assessments are augmented in this section with regionally specific support from recent national climate assessments or original literature.

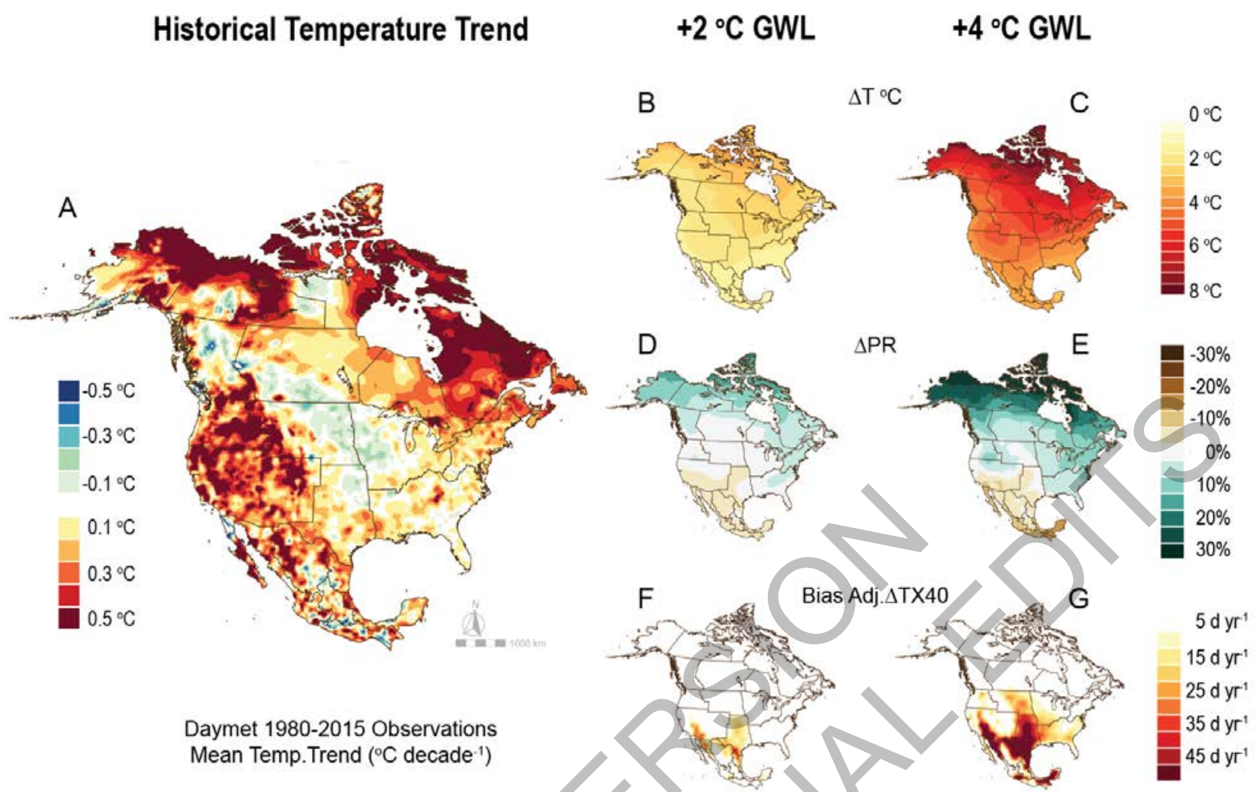

Figure 14.2: Observed and projected climate changes across North America. Black boundary lines delineate North American subregions (Fig. 14.1). Data were extracted from WGI online atlas, where data set details can be found. A) recent observations; (B)-(G) from an ensemble of CMIP6 projections. A) Observed annual mean temperature trend over land for period 1980-2015. B, C) Projected change in annual mean temperature over land relative to 1986-2005 average, associated with 2°C or 4°C global warming. D, E) Like (B, C), but for projected percentage change in annual precipitation. F, G) Like (B, C), but for projected change in number of days/year with maximum temperature > 40°C ("TX40").

14.2.1 Observed Changes in North American Climate

Climate changes directly related to increasing mean and extreme temperature, including reduced snowpack, sea and lake ice and glacier extent, and marine heatwaves, can be attributed to human activity and are affecting most of North America (*high confidence*). Upward trends in annual mean temperature across North America since 1960 are wide-spread (I.Atlas) but nonuniform (Figure 14.2a). Pronounced polar amplification of warming is observed in high latitudes (Figure 14.1a), particularly in winter (Vose et al., 2017; Zhang et al., 2019a) (I.Atlas). As average temperature rises, extreme high temperature records across North America are being set more frequently than extreme cold records (Meehl et al., 2016) and the probability of cold extreme events is reduced (I.11). Trends in daily maximum and minimum temperature are significant in high latitudes (*US-AK, CA-NW, CA-NE*). Summertime daily maximum temperature is increasing in southwestern desert regions (*US-SW, MX-NW*) (Martinez-Austria et al., 2016; Martinez-Austria and Bandala, 2017; Navarro-Estupinan et al., 2018).

Annual precipitation has increased in recent decades in northern and eastern areas (*CA-PR, CA-QU, US-NP, US-SP, US-MW, US-NE, US-AK*) (*high confidence*), and has decreased across the western part of the continent (*CA-BC, US-SW, US-NW, MX-NW*) (*medium confidence*), with considerable spatial variability within these regions (Zhang et al., 2019a; Gutiérrez et al., In Press). Elsewhere across North America there is *limited evidence* and *low agreement* on detection of observed trends in total precipitation and river flood hazards. The intensity and frequency of one-day heavy precipitation events have *very likely*[2] increased since the mid-20th Century across most of the US (*US-NP, US-MW, US-NE*, but not in *US-SE*) and in Mexico, but no detectable trend is reported in Canada (Zhang et al., 2019a) (I.11). Recent flooding events along the mid-latitude Pacific Coast have been attributed to increasingly intense atmospheric river (AR) events (Gershunov et al., 2019; Vano et al., 2019) (I.8) but there is *low confidence* in detecting trends in AR activity.

Snowpack and snow extent across much of Canada and the western US have declined as temperatures have increased (Kunkel et al., 2016; Mote et al., 2018; Mudryk et al., 2018; Derksen et al., 2019) (I.12; I.Atlas) (*very high confidence*). Warm "snow droughts", describing a deficit of snowpack available for runoff even in the absence of a winter precipitation deficit (Cooper et al., 2016; Harpold et al., 2017), have become more common in North American mountains (Sproles et al., 2016; Nicholls et al., 2018; Pershing et al., 2018). Glaciers have retreated over the past half-century at high elevation across North America (Frans et al., 2018; Zemp et al., 2019) and in the Arctic (Burgess, 2017; Box et al., 2019; Derksen et al., 2019). Lake ice in Canada, south of the Arctic region delineated in Figure 14.1, has declined (Alexeev et al., 2016; Derksen et al., 2019).

There is limited evidence of trends in meteorological or hydrologic droughts over the historical record (Wehner et al., 2017) (I.8 and I.11 discuss multiple perspectives on drought), but there is *medium confidence* in increasing atmospheric evaporative demand acting to intensify surface aridity during recent droughts (Williams et al., 2020) (I.11; *US-SW*). The ongoing multi-decadal dry period in the Colorado River Basin is as extreme as any drought in the past thousand years (Murphy and Ellis, 2019; Williams et al., 2020).

The proportion of hurricanes in stronger categories has *likely* increased globally over the past 40 years, with *medium confidence* that the onshore propagation speed of hurricanes making landfall in the US has slowed detectably since 1900 (Kossin, 2018) (I.11), contributing to detectable increases in local rainfall and coastal flooding associated with these storms. There is *high confidence* (I.11) that anthropogenic climate change contributed to extreme precipitation associated with recent intense hurricanes, such as Harvey in 2017.

North American sea ice extent and volume (thickness) have declined up to 10% per decade since 1981 (Ding et al., 2017; Mudryk et al., 2018; Derksen et al., 2019; IPCC, 2019c)(I.9), with changes accelerating during this time (Schweiger et al., 2019) (*robust evidence, high agreement*), resulting in longer and larger periods of open water (Wang et al., 2018a). Recent (2018) sea ice extent in the Bering Sea was the lowest in a 5,500 yr record and appears to lag atmospheric CO_2 by ~2 decades (Jones et al. 2021). High Arctic sea ice retreat since 1971 and increases in open water duration in the most recent decade are unprecedented (Box et al., 2019) and most pronounced in the Chukchi, Bearing, and Beaufort Seas (*US-AK, CA-NW*) (*high confidence*) (Wang and Overland, 2015; Jones et al., 2020).

Warming of North American offshore waters is significant and attributable to human activities, particularly along the Atlantic coast, contributing to sea level rise (SLR) through thermal expansion (IPCC, 2019c) (I.9) (*very high confidence*). Rates of SLR have accelerated along most North American coasts during the past three decades, excepting coastlines in southern Alaska and northeastern Canada where land is rising (I.12). Tidal flooding frequency has increased in the North Pacific from once every 1-3 years to every 6-12 mo (Sweet et al., 2014).

Acidification of North American coastal waters has occurred in conjunction with increased atmospheric CO_2 concentration (Mathis et al., 2015; Jewett and Romanou, 2017; Claret et al., 2018) combined with other local acidifying inputs such as nitrogen and sulphur deposition (Doney et al., 2007) and freshwater nutrient input (Strong et al., 2014; IPCC, 2019c) (*very high confidence*). Oxygen minimum zones, particularly in the North Pacific south of *US-AK*, have expanded in volume and O_2 has declined since 1970 (IPCC, 2019c).

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range

14.2.2 Projected Changes in North American Climate

Climate changes related to warming temperature, including more intense heat waves over land and in the ocean, diminished snowpack, sea ice reduction and SLR, are projected with *high confidence* and are strongly sensitive to future greenhouse gas concentrations (Figure 14.2). Climatic hazards affected by hydrologic change, including humidity-inclusive heat stress, extreme precipitation, and more intense storms, are projected to intensify.

Pronounced amplification of warming across the Arctic and continental intensification of warming (Figure 14.1bc) is projected with *high confidence* (Doney et al., 2007; Vose et al., 2017). Extreme heat waves are projected to intensify, particularly in *MX-NW, MX-N, MX-NE, US-SW, US-NP* and *US-SP* (Figure 14.2f-g) and become more frequent and longer in duration as average temperature rises across North America (I.11). Extreme cold events are projected to decrease in severity (Wuebbles et al., 2014)(I.12).

Total precipitation is projected to increase across the northern half of North America (*very high confidence*) and decrease in southwestern North America (*MX-SW, MX-NW, US-SW*) (*medium confidence*) (Fig 14.2d-e, I.Atlas). Further increases in the intensity of locally heavy precipitation are *very likely* across the continent, as a greater fraction of precipitation falls in intense events (Easterling et al., 2017; Prein et al., 2017a; Zhang et al., 2019a).

High-humidity hazards are projected to increase (*medium confidence*) in regions around the Gulf of Mexico and southeastern North America (*US-SE, US-SP, MX-NE, MX-SE*) (Zhao et al., 2015). In subtropical regions that are less influenced by moisture from the Gulf of Mexico (including *US-SW, US-SP, MX-NW* and *MX-N*), the combination of higher temperature and less total precipitation leads to projections of increased aridity: drier surface conditions, higher evaporative demand by plants, and more intense droughts-(Jones and Gutzler, 2016; Easterling et al., 2017; Escalante-Sandoval and Nuñez-Garcia, 2017) (I.12).

As temperatures rise, snow extent, duration of snow cover and accumulated snowpack are *virtually certain* to decline in sub-Arctic regions of North America (McCrary and Mearns, 2019; Mudryk et al., 2021) (I.Atlas), with corresponding effects on snow-related hydrologic changes (*high confidence*). These include declines in snowmelt runoff (Li et al., 2017); increased evaporative losses during snow ablation (Foster et al., 2016; Milly and Dunne, 2020); and increases in the frequency of rain-on-snow events (Jeong and Sushama, 2018a) and consecutive snow drought years in western North America (Marshall et al., 2019a).

Climate change is projected to magnify the impact of tropical cyclones in *US-NE, MX-NE, US-SP,* and *US-SE* by increasing rainfall (Patricola and Wehner, 2018) and extreme wind speed (*high confidence*) and slowing the speed of land-falling storms (Kossin, 2018)(I.11) (*limited evidence, low confidence*). The coastal region at severe risk from tropical storms is projected to expand northward within *US-NE* (Kossin et al., 2017) (*medium confidence*).

Additional reduction in polar sea ice is *virtually certain* (Mudryk et al., 2021)(I.12), with the North American Arctic projected to be seasonally ice-free at least once per decade under 2°C of global warming (*high confidence*) (Mudryk et al.; IPCC, 2019b; Mioduszewski et al., 2019). Duration of freshwater lake ice across the northern US and southern Canada is projected to diminish (*high confidence*) (Dibike et al., 2012; Mudryk et al., 2018; Sharma et al., 2019) (I.12).

Ocean surface temperature is *very likely* to increase in future decades in waters around North America (Jewett and Romanou, 2017; Greenan et al., 2019a), but at a slower rate than air temperature over the continent. Rates of change are projected to be relatively higher in northern latitudes, with most rapid warming in summer in the Arctic and Bering Sea (*US-AK, CA-NW*) (Wang and Overland, 2015; Wang et al., 2018a; Hermann et al., 2019).

SLR is *virtually certain* to continue along North American coastlines except for parts of *US-AK* with geographically variable rates of rise (I.9, I.12, Box 14.4). Relatively greater SLR is projected along the *US-SE, CA-AT* and *MX-SW* coastlines and relatively less along *CA-BC* and *US-NW* (Fasullo and Nerem, 2018; Greenan et al., 2019a; IPCC, 2019b) (I.9, I.12, Box 14.4).

Ocean acidification along North American coastlines is projected to increase (*very high confidence*) (Jewett and Romanou, 2017). The frequency and extent of oxygen minimum and hypoxic zones are projected to increase, with less confidence, exacerbated by climate-driven eutrophication and increasing stratification (Altieri and Gedan, 2015; IPCC, 2019b).

[START FAQ14.1 HERE]

FAQ 14.1: How has climate change contributed to recent extreme events in North America and their impacts?

Multiple lines of evidence indicate that climate change is already contributing to more intense and more frequent extreme events across North America. The impacts resulting from extreme events represent a huge challenge for adapting to future climate change.

Extreme events are a fundamental part of how we experience weather and climate. Exceptionally hot days, torrential rainfall, and other extreme weather events have a direct impact on people, communities, and ecosystems. Extreme weather can lead to other impactful events such as droughts, floods or wildfires. In a changing climate, people frequently ask whether extreme events are generally becoming more severe or more frequent, and whether an actual extreme event was caused by climate change.

Because really extreme events occur rarely (by definition), it can be very difficult to assess whether the overall severity or frequency of such events has been affected by changing climate. Nevertheless, careful statistical analysis shows that record-setting hot temperatures in North America are occurring more often than record-setting cold temperatures as the overall climate has gotten warmer in recent decades. The area burned by large wildfires in the western US has increased in recent decades. Observed trends in extreme precipitation events are more difficult to detect with confidence, because the natural variability of precipitation is so large and the observational database is limited.

Our understanding of how individual extreme weather events have been influenced by climate change has improved greatly in recent years. Climate scientists have developed a formal technique ("event attribution", described in Working Group I FAQ 11.3) for assessing how climate change affects the severity or frequency of a particular extreme event, such as a record-breaking rainfall event or a marine heat wave. This is a challenging task, because any particular event can be caused by a combination of natural variability and climate change. Event attribution is typically carried out using models to compare the probability of a specific event occurring in today's climatic environment, relative to the probability that the same event might have occurred in a modelled climate in which atmospheric greenhouse gases have not risen due to human activities. Using this strategy, multiple studies estimated that the historically extreme rainfall amount that fell across the Houston area from Hurricane Harvey (2017) was 3 to 10 times more *likely* as the result of climate change.

The *impacts* from extreme events depend not just on physical climate system hazards (temperature, precipitation, wind, etc.), but also on the exposure and vulnerability of humans or ecosystems to these events. For example, damage from landfalling hurricanes along the coast of the Gulf of Mexico is expected to increase as very strong hurricanes become more frequent and intense due to climate change. But damage would also increase with additional construction along the shoreline, because coastal development increases *exposure* to hurricanes. And if some structures are constructed to poor building standards, as was the case when hurricane Andrew made landfall in Florida in 1992, then *vulnerability* to hurricane-caused impacts is increased.

Climate change also contributes to impacts from extreme events by making some building codes and zoning restrictions inadequate or obsolete. Many North American communities limit development in areas known to be flood-prone, to minimize exposure to flooding. But as climate change expands the areas at risk of exposure to flooding beyond historical floodplains, the impacts of potential flooding are increased, as Hurricane Harvey demonstrated. Adapting to climate change may require retrofits for existing structures and revised zoning for new construction. Some structures and neighbourhoods may need to be abandoned altogether to accommodate expanded flooding risk.

Climate change can be an *added stress* that increases impacts from extreme events, combined with other non-climatic stressors. For example, climate change in western North America has contributed to more extreme fire weather. The devastating impacts of recent wildfire outbreaks, such as occurred across western Canada in 2016 and 2017, the western United States in 2018 and 2020, and both countries in 2021, are to some extent associated with expanded development and forest management practices (such as policies to suppress low-intensity fires, allowing fuel to accumulate). The effects of development and forest management have dramatically increased the exposure and vulnerability of communities to intense wildfires. Climate change has added to these stressors: warming temperature leads to more extreme weather conditions that are conducive to increasingly severe wildfires.

Biodiversity is affected by climate change in this way too. For example, numerous bird populations across North America are estimated to have declined by up to 30% over the past half-century. Multiple human-related factors, including habitat loss and agricultural intensification, contribute to these declines, with climate change as an added stressor. Increasingly extreme events such as severe storms and wildfires can decimate local populations of birds, adding to existing ecological threats.

[END FAQ 14.1 HERE]

14.3 Perception of Climate Change Hazards, Risks, and Adaptation in North America

14.3.1 Climate Change as a Salient Issue

The majority of the climate science community has reached consensus that mean global temperature has increased and human activity is a major cause (Oreskes, 2004; Anderegg et al., 2010; Cook et al., 2013; Cook et al., 2016; IPCC, In Press), setting the context for public policy action. Despite expert scientific consensus on anthropogenic climate change, there is polarization and an ongoing debate over the reality of anthropogenic climate change in the public and policy domains, with attendant risks to society (*high confidence*) (Doran and Zimmerman, 2009; Ballew et al., 2019; Druckman and McGrath, 2019; Hornsey and Fielding, 2020; Wong-Parodi and Feygina, 2020). Public perception of consensus regarding anthropogenic climate change can be an important gateway belief, which establishes a crucial precondition for public policy action (van der Linden et al., 2015; van der Linden et al., 2019) by influencing the assessment of climate change risks and opportunities, and formulation of appropriate mitigation and adaptation responses (Ding et al., 2011; Bolsen et al., 2015; Drews and Van den Bergh, 2016; Doll et al., 2017; Mase et al., 2017; Morton et al., 2017). Trust in experts, institutions and environmental groups is also important (Cologna and Siegrist, 2020; Termini and Kalafatis, 2021).

Rhetoric and misinformation on climate change and the deliberate undermining of science have contributed to misperceptions of the scientific consensus, uncertainty, disregarded risk and urgency, and dissent (*high confidence*) (Ding et al., 2011; Oreskes and Conway, 2011; Aklin and Urpelainen, 2014; Cook et al., 2017; van der Linden et al., 2017). Additionally, strong party affiliation and partisan opinion polarization contribute to delayed mitigation and adaptation action, most notably in the US (*high confidence)* (van der Linden et al., 2015; Cook and Lewandowsky, 2016; Bolsen and Druckman, 2018; Chinn et al., 2020) but with similar patterns in Canada (*medium confidence*) (Lachapelle et al., 2012; Kevins and Soroka, 2018). Vocal groups can affect public discourse and weaken public support for climate mitigation and adaptation policies (Aklin and Urpelainen, 2014; Lewandowsky et al., 2019) (*medium confidence*). Vested economic and political interests have organized and financed misinformation and "contrarian" climate change communication (Brulle, 2014; Farrell, 2016b; Farrell, 2016a; Supran and Oreskes, 2017; Bolsen and Druckman, 2018; Brulle, 2018). Traditional media – print and broadcast – frame and transmit climate change information and play a crucial role in shaping public perceptions, understanding, and willingness to act (Happer and Philo, 2013; Schmidt et al., 2013; Hmielowski et al., 2014; Bolsen and Shapiro, 2018; King et al., 2019; Chinn et al., 2020). The journalistic norm of "balance" (giving equal weight to climate scientists and contrarians in climate change reporting) biases coverage by unevenly amplifying certain messages that are not supported by science, contributing to politicization of science, spreading misinformation, and reducing public consensus on action (Boykoff and Boykoff, 2004; Boykoff and Boykoff, 2007; Cook et al., 2017). Much online social media discussion of climate change takes place in ''echo chambers'' – a social network amongst like-minded people in communities dominated by a single view that contributes to polarization (Williams et al., 2015; Pearce et al., 2019), and the spread of misinformation (Treen et al., 2020).

14.3.2 Public Perceptions, Opinions and Understanding of Climate Change

In a 2018 survey across 26 nations, people in Canada and Mexico ranked climate change as the top global threat, whereas in the US climate change ranked third (Poushter and Huang, 2019). The public's responses to the causes of climate change and risk perceptions in Canada (Mildenberger et al., 2016) and US (Howe et al., 2015) revealed variations among regions (Figure 14.3) and less acceptance of climate change in rural regions than in urban areas. Canadian regions have higher acceptance of climate change (e.g., recognize it is happening and attributable to human activity) than the most liberal areas in the US (Lachapelle et al., 2012; Mildenberger et al., 2016). Western Canadian regions with high carbon intensity economies had lower acceptance of climate change than the rest of Canada, whereas in the US perceptions were more stable across regions (Lachapelle et al., 2012). A recent survey in Mexico found that for 73% of respondents climate change represents a major economic, environmental and social threat, and in the most vulnerable states (*MX-SE*), the perception is that climate change impacts and extreme events have considerable implications for the way of life in communities (Zamora Saenz, 2018). In a 2017 survey, Azócar et al. (2021) found 85% of respondents from Mexico acknowledged anthropogenic climate change. Peoples' experience with extreme events (e.g., hurricanes, high temperatures), socio-demographic characteristics, level of marginalization and economic and social exclusion, as well as education levels were important factors influencing perception of climate change in Mexico (Corona-Jimenez, 2018; Alfie and Cruz-Bello, 2021; Azócar et al., 2021). Drawing upon Indigenous knowledge (Box 14.1) as well as lived experience of recent changes in ice, weather patterns, and species' phenology and distribution, Indigenous Peoples recognize that change is occurring in their communities and have effective solutions that are grounded in Indigenous worldviews (Harrington, 2006; Turner and Clifton, 2009; Norton-Smith et al., 2016a; Savo et al., 2016; Maldonado et al., 2017; Chisholm Hatfield et al., 2018).

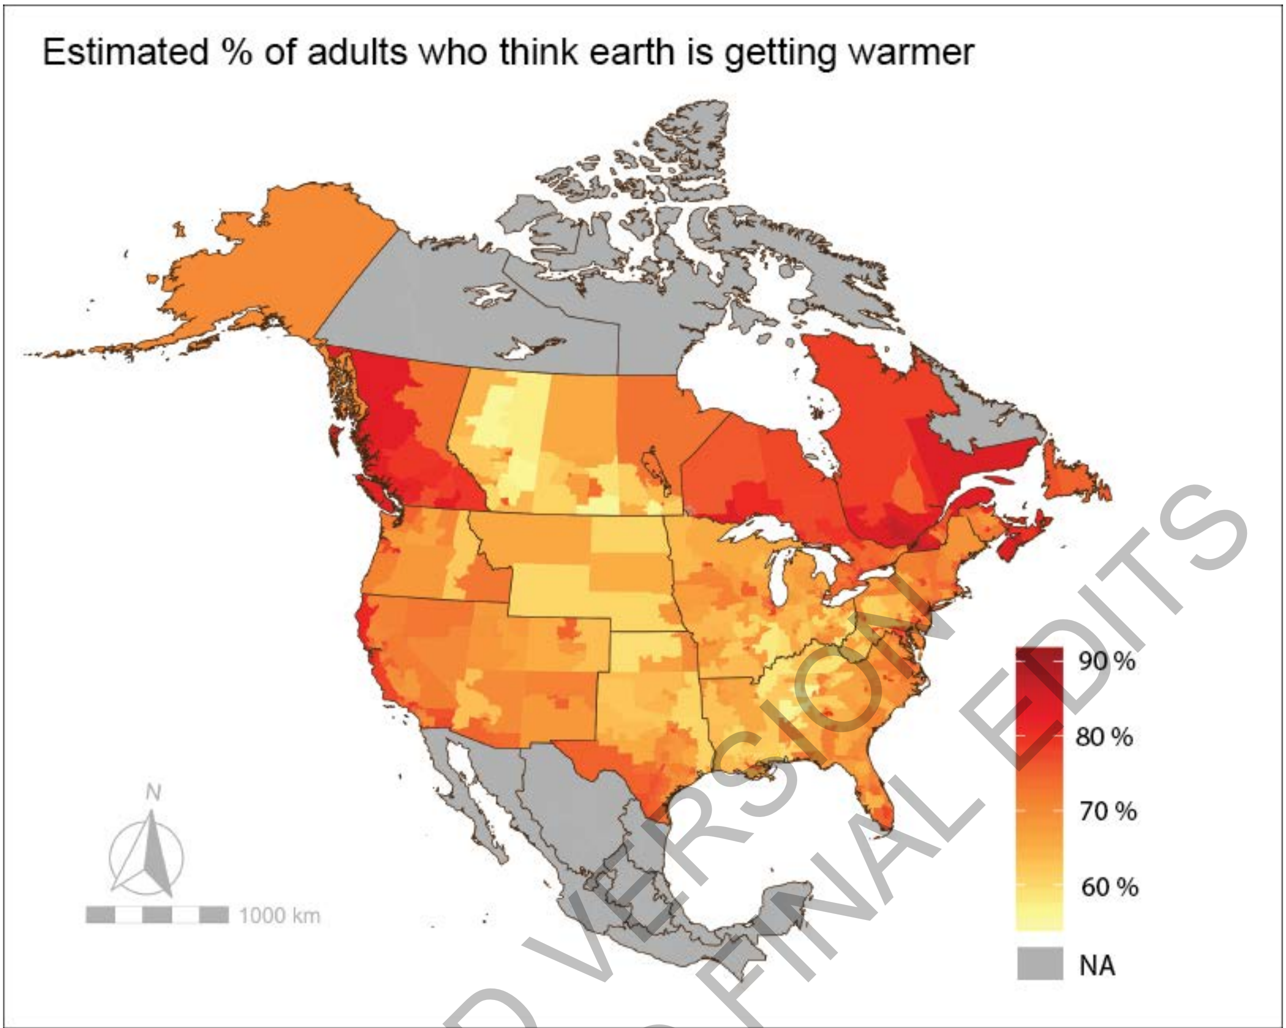

Figure 14.3: Regional distribution of public perception that "the Earth is getting warmer" as a surrogate for public acceptance that climate change is happening (% of population). Scale is the Canadian federal electoral district or riding level and US Congressional District. The three northern territories and Labrador, in Canada, did not meet population thresholds for modelling. The figure updates Mildenberger et al. (2016) and is based on equivalent public surveys in both countries -- Canadian "Earth is getting warmer" and US "global warming is happening" undertaken in 2019. Equivalent surveys and modelling for Mexico are not available at this time.

14.3.3 Building Consensus on Climate Change

Building consensus for action on climate change is influenced by individual factors (e.g., ideology, worldview, trust, partisan identity, religion, education, age) and the broader societal context (e.g., culture, media coverage and content, political climate, economic conditions) *(high confidence*) (McCright and Dunlap, 2011; Brulle et al., 2012; Hornsey et al., 2016; Arbuckle, 2017; Pearson et al., 2017; Bolsen and Shapiro, 2018; Ballew et al., 2020; Cologna and Siegrist, 2020; Goldberg et al., 2020). In a multi-country assessment of acceptance of global warming influenced by ideology (e.g., conspiratorial ideation, individualism, hierarchy, and left–right and liberal–conservative political orientation), the US uniquely had the strongest link to doubt out of 25 countries for all factors, while Canada's dominant influence on non-acceptance was conservative political ideology, and for Mexico, there were no ideological effects (Hornsey et al., 2018).

Political affiliation and partisan group identity contribute to polarization on the causes and state of climate change, most notably in the US (*medium confidence*). Fewer US Republicans hold the belief that human activity causes climate change than Democrats (Bolsen and Druckman, 2018; Druckman and McGrath, 2019). Partisanship in the US with respect to climate change has evolved over the period 1997 to 2016; initially, it was limited, but since 2008, there has been a widening, more entrenched partisan "divide" (Dunlap et al., 2016). The millennial generation (born 1980s, 1990s), emerging as the largest US population cohort, has a potentially important political influence – reduction in polarization – as they show relatively higher levels of concern and acceptance of climate change science than older age groups. Political affiliation does not have as strong an effect on their climate change beliefs (Corner et al., 2015; Ross et al., 2019).

Communicating to educate or enhance knowledge on climate change science or consensus does not necessarily lead individuals to revise their beliefs (Bolsen et al., 2015; Druckman and McGrath, 2019) (*medium confidence*). People may reject new information that conflicts with their beliefs or not consider it credible, as political ideology and partisan affiliation are strong influences (Arbuckle, 2017). The climate change issue may create resistance from individuals with conservative political ideologies and hierarchical, individualistic worldviews because it ascribes responsibility to developed, industrialized countries for emissions and brings about more environmental regulation (Stevenson et al., 2015). Lack of trust in scientific consensus on climate change may actually originate from opposition by US conservatives to the perceived advocacy for different climate change policy approaches that challenge their worldviews (Bolsen and Druckman, 2018).

14.3.4 Factors Influencing Perceptions of Climate Change Risks and Adaptation Action

Projected climate change risk, urgency and necessary adaptations are perceived and understood differently by the public, communities, professional groups, climate scientists, and public policy makers (*high confidence*) (Bolsen et al., 2015; Drews and Van den Bergh, 2016; Morton et al., 2017; Treuer et al., 2018). People can engage with climate change across three dimensions: cognitive - knowledge, affective - feelings, and behavioural - responses and actions (Galway, 2019; Brosch, 2021). Risk assessment can be influenced by values regarding the subject under evaluation (Allison and Bassett; Stevenson et al., 2015) and can interact with other risks and change over time (Mach et al., 2016). Communities and practitioners (e.g., farmers, foresters, water managers) are influenced in their willingness to modify current practices and adopt new measures based on how they perceive, understand, and experience climate change uncertainty, risk and urgency as well as political and social norms (van Putten et al., 2015; Doll et al., 2017; Mase et al., 2017; Morton et al., 2017; Zanocco et al., 2018). Place-based and local-focused assessments allow individuals to more readily assess and adapt to risks as well as identify roles and responsibilities in the face of multiple, interacting, and often unequally distributed climate change impacts (Khan et al., 2018; Galway, 2019). Interest in preserving local archaeological sites threatened by SLR initiated collaboration and co-production of knowledge among disparate US communities -- citizens, archaeologists, preservationists, planners, land managers, and Indigenous Peoples (Fatorić and Seekamp, 2019; Dawson et al., 2020).

Psychological distancing -- the perception that the greatest impacts occur sometime in the distant future and to people and places far away – can lead to discounting of risk and the need for adaptation (Leviston et al., 2014; Mildenberger et al., 2019) (*medium confidence*). Communication directed at local and personal framing of climate change impact and risk information is one option for addressing low salience (Bolsen et al., 2019), particularly related to established risks such as SLR, flooding, and wildfires in North America (Mildenberger et al., 2019). "Personalized" risk communications have had mixed results creating behavioural change and policy support, and even caused resistance (Schoenefeld and McCauley, 2016). Communication focused extensively on risks and dangers of climate change can produce fear or dread, lessen agency and create fatalism that hinders action (Giddens, 2015; Mayer and Smith, 2019); it also can be labelled alarmist (Leiserowitz, 2005). Detailed SLR flooding maps for the San Francisco Bay area did not increase climate risk assessment but lessened personal risk perception of those with a strong belief in climate change although policy preferences and support for adaptation did not change (Mildenberger et al., 2019). Defining coherent groups based on variations in beliefs, risk perceptions, and policy preferences offers opportunities for effectively engaging with segments of the population instead of using the same approach for everyone (*low confidence*) (Maibach et al., 2011; Chryst et al., 2018). As an example, the US population was segmented into a continuum ranging from the "Alarmed", the dominant group who were "Concerned", then the Cautious, Disengaged, Doubtful, and least prevalent, the Dismissive (Chryst et al., 2018).

[START BOX 14.1 HERE]

Box 14.1: Integrating Indigenous 'Responsibility-Based Thinking' into Climate Change Adaptation and Mitigation Strategies

Indigenous Peoples throughout North America have experienced five centuries of territorial expropriation, loss of access to natural resources and in many cases, barriers to the use of their sacred sites (Gabbert, 2004; Louis, 2007). The history of Indigenous struggles to preserve distinct cultural knowledges and assert autonomy in the face of colonialism has shaped land-use patterns and relationships with traditional territories (Alfred and Corntassel, 2005; Tuhiwai Smith, 2021) (Cross-Chapter Box INDIG, Chapter 18). Climate change is now creating additional challenges for Indigenous Peoples. For example, increased water scarcity due to higher temperatures and diminished precipitation have led to reduced crop yields for Maya farmers in the Yucatan (Sioui, 2019). Thawing permafrost in subarctic Canada (Quinton et al., 2019) has interfered with the land-based livelihoods of the Indigenous Dene Peoples (CCP6).

Recent climate-related changes represent cultural threats similar to the ones that occurred when European settlement began in the Americas over 500 years ago (Whyte, 2016; Whyte, 2017). Thus, for Indigenous Peoples, who often disproportionately bear the impacts of climate change, such changes are not novel, but seen as 'déjà vu' (Whyte, 2016). Since livelihoods and subsistence are often directly dependent on the land and water, Indigenous Peoples have direct insights into the localized impacts of global environmental change. Indeed, Indigenous Peoples consider themselves stewards of the land (and water), and have a spiritual duty to care for the land and its flora, fauna, and aquatic community, or 'Circle,' of beings. Indigenous knowledge (IK) has gained recognition for its potential to bolster western scientific research about climate change. Many recent examples demonstrate the scientific value of IK for resource management in climate change adaptation and mitigation (e.g. Kronik and Verner, 2010; Maldonado et al., 2013; Wildcat, 2013; Etchart, 2017; Nursey-Bray et al., 2019). For example, Indigenous practices have not only contributed to the present understanding of North American forest fires, but also that the practice of frequent small-scale anthropogenic fires, also called cultural burns, is a key method to prevent large-scale destructive fires (14.7.1). The growing interest and recognized value in these practices, particularly in California, has led to formal agreements with state and federal agencies (Long et al., 2020a; Lake, 2021).

Indigenous relationships with the land are commonly informed and guided by a cultural ethic of 'responsibility-based thinking' (Sioui and McLeman, 2014). The Indigenous cultural ethic informs and mediates personal and collective conduct with a sense of duty or responsibility toward human and other-than-human relations (see Sioui, 2020). The Indigenous responsibility-based outlook stems from a cultural paradigm that understands that it is human beings who must learn to live *with* the land (Cajete, 1999; Pierotti and Wildcat, 2000; McGregor et al., 2010a; McGregor, 2014). This way of thinking instils in its adherents an inherent awareness that the other-than-human realm is capable of existing and thriving without humans. Thus, it is for our own sake (as humans) that we learn to live according to certain, ever-shifting, parameters, requiring us to remain acutely attuned to our physical surroundings. This Indigenous cultural precept is perhaps among the most significant contributions of Indigenous Peoples to the rest of humanity in the face of climate change.

Indigenous relationships with natural systems continue to be mediated by cultural orders of governance and legal systems that pre-date, by several millennia, European traditions in North America. Napolean (2012) describes Indigenous legal orders as dynamic and encompassing knowledge that is simultaneously legal, religious, philosophical, social, and scientific. Customary Indigenous legal orders (e.g. Borrows, 2002; Napolean, 2012) stand in contrast to Eurocentric understandings of law, which are closely related to, and founded on, the Western principles of rights. Indigenous legal orders are based on duties, obligations and responsibilities to the land and all beings, including humans, animals, plants, future generations and the departed/ancestors (Borrows, 2002; Borrows, 2010a; Borrows, 2010b; Borrows, 2016). Indigenous spiritual laws centred on the values of responsibility and accountability to the land, and how these differ, in theory and in practice, from Western law, which is based on "universal" principles, with little consideration for the local environmental context (Craft, 2014). Research has elucidated these Indigenous understandings about how their land-based responsibilities act as the foundation of how humans must operate according to the land on which they live and depend.

With increasing climate change threats to land-based subsistence and cultural practices, Indigenous Peoples are increasingly taking their rightful leadership roles in resource co-management arrangements and other stewardship activities (14.5.2.2). Indeed, Indigenous Peoples are increasingly assuming leadership positions with regard to land governance and climate change action, as the stewards of their traditional territories since time immemorial. Therefore, it is imperative for Indigenous scholars, Elders, and knowledge holders to occupy leadership roles in climate change adaptation and mitigation, especially when their territories are concerned (14.7; CCP6). For instance, Indigenous "resurgence" paradigms draw on the strengths of traditional land-based culture and knowledge with regard to Indigenous leadership in land governance and stewardship (Alfred and Corntassel, 2005; Alfred, 2009; Simpson, 2011; Corntassel and Bryce, 2012; Coulthard, 2014; Alfred, 2015). Indigenous leadership in climate change policy, therefore, can ensure that Indigenous right to self-determination is respected and upheld to allow Indigenous Peoples to continue to carry out their cultural responsibilities to the land, for the benefit of all North Americans (Powless, 2012; Etchart, 2017).

In Northern Canada, a fusion of leading-edge western science and IK on permafrost informed the co-development of predictive decision support tools and risk management strategies to inventory and manage permafrost and adapt to permafrost thaw (CCP6). Permafrost thaw in the Dehcho region of Canada is widespread and occurring at unprecedented rates (WGI). The *Dehcho Collaborative on Permafrost* (DCoP) aims to improve the understanding of and ability to predict and adapt to permafrost thaw (http://scottycreek.com/DCoP/). DCoP's collaborative approach, which places Indigenous Peoples in leadership positions, generates the new knowledge, predictive capacity and decision-support tools to manage natural resources that support Indigenous Dene Peoples' ways of life. Indigenous-academic partnerships can enhance climate change adaptation and mitigation capacity and provide openings for more holistic co-management approaches that recognize and affirm the central role of Indigenous Peoples as stewards of their ancestral territories, especially as they face accelerating climate change impacts. Academic researchers and their Indigenous partners can support climate change resilience via mobilizing IK in stewardship and adaptation; researching governance arrangements, economic relationships and other factors that hinder Indigenous efforts in these areas; proposing evidence-based policy solutions at international and national scales; and outlining culturally relevant tools for assessing vulnerability and building capacity will also support climate change resilience. IK underpins successful climate change adaptation and mitigation (*very high confidence*) (see Green and Raygorodetsky, 2010; Kronik and Verner, 2010; Alexander et al., 2011; Powless, 2012; Ford et al., 2016; Nakashima et al., 2018). The inclusion of IK in adaptation and mitigation not only supports Indigenous cultural survival but also enables governments to recognize the territorial sovereignty of Indigenous Peoples.

Responsibility-based philosophies of Indigenous Peoples from across the continent support the development of climate change adaptation and mitigation strategies that promote responsible and respectful relationships with the environment over the long term. Adapting to change, in all its forms, has since time immemorial been one of the defining characteristics of Indigenous cultures on Turtle Island (the American continent). In the Yucatan, one Elder explained that with regards to climate change impacts in the region, the Maya have always dealt with "*k'ech*", or change, and that accepting and responding to change is part of the Maya identity and responsibility (Sioui, 2020). Given successive failures in adequately and effectively responding to climate change, it has become urgent for the rest of the human collective to (re)learn from Indigenous cultures to (re)consider our responsibility/ies to the land—the world over—and to reorient our societal imperatives to better respond and react to *change*. Such a process of learning from IK could foster the development of climate change policies that promote responsible and respectful relationships with the environment over the long term, and prove to be more effective and holistic. Although most inhabitants of North America are non-Indigenous, it is possible and beneficial for our societies to learn to think and act in a more responsibility-based way about our relations to the land, and, by extension, about climate change policy. A collective commitment to protecting and advancing Indigenous territorial rights, so Indigenous Peoples can continue to reassert their spiritual duty and role as stewards of their traditional territories, benefits of all human and other-than-human 'Peoples'.

[END BOX 14.1 HERE]

14.4 Indigenous Peoples and Climate Change

Indigenous knowledge and science are resources for understanding climate change impacts and adaptive strategies (*very high confidence*) (SM14.1, Table SM14.1). The Indigenous Peoples of North America have and continue to contribute substantially to the growing literature, scholarship, and research on climate change (Barreiro, 1999; Houser et al., 2001; Mustonen, 2005; Bennett et al., 2014; Maynard, 2014; Merculieff et al., 2017; FAQI, 2019; Ijaz, 2019; BIA, 2021). For thousands of years, Indigenous Peoples have developed and relied on their own knowledge systems for sustaining their health, cultures and arts, livelihoods, and political security (Battiste and Henderson, 2000; Colombi, 2012; Nelson and Shilling, 2018). Diverse Indigenous knowledge systems in North America consider weather and climate as major dimensions of understanding the relationship between society and the environment. Indigenous Peoples have distinct knowledge of climate change, over extensive temporal measures (Trosper, 2002; Barrera-Bassols and Toledo, 2005; Gearheard et al., 2013). The basis of this knowledge is often Indigenous Peoples' long and profound relationships to the environment, that is to the ecosystems, waters, ice, lands, territories, and resources in their homelands. The relationships were forged by adaptation to a particular environment and involve systematic activities. Indigenous harvesters, including hunters, fishers, agriculturalists, and plant gatherers, observe and monitor environmental change, and engage in systematic reflection with one another about trends over short term and long-term periods (Sakakibara, 2010; Sánchez-Cortés and Chavero, 2011; Kermoal and Altamirano-Jiménez, 2016; Metcalfe et al., 2020b). The holistic perspective of the interrelated and interdependent nature of ecosystems is a distinct characteristic of Indigenous knowledge and often contrasts with findings and results of science alone. Indigenous harvesters, agriculturalists, leaders, culture-bearers, educators, and government employees develop theoretical and practical knowledge of seasonal and climate change that seeks to furnish the best available knowledge and information to inform climate change policy and decisions (Barrera-Bassols and Toledo, 2005; McNeeley and Shulski, 2011). Examples of theoretical knowledge systems include Indigenous calendars of seasonal change and systems of laws and protocols for environmental stewardship (Kootenai Culture Committee, 2015; Donatuto et al., 2020) (Box 14.1).

The practice and use of Indigenous knowledge systems is recognized and affirmed by the United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP) (UNGA, 2007), and consistent with reports and guidance from UN bodies including the High Commissioner for Human Rights (Bachelet, 2019), Expert Mechanism on the Rights of Indigenous Peoples (UNGA, 2015; UNGA, 2018), the Permanent Forum of Indigenous Issues (Dodson, 2007; Cunningham Kain et al., 2013; Sena and UNPFII, 2013; Sena, 2014; Quispe and UNPFII, 2015), and the Special Rapporteur on the Rights of Indigenous Peoples (Toledo, 2013; UNGA, 2017)(Cross-Chapter Box INDIG in Chapter 18). Rights to self-determination, to control over territorial development, and cultural integrity, make it important that climate scientists practice equitable engagement of Indigenous knowledge and Indigenous knowledge holders. There is a growing literature of success and lessons learned from co-production of knowledge between Indigenous knowledge systems and diverse scientific traditions relating to climate change (Behe et al., 2018; Latulippe and Klenk, 2020; Camacho-Villa et al., 2021).

Current and projected climate change impacts disproportionately harm Indigenous Peoples' livelihoods and economies (*very high confidence*). Indigenous Peoples' livelihoods in North America include a range of activities closely tied to traditional lands, waters, and territories. These activities support a core economic base and an array of sustenance, including financial stability, food security, health and nutrition, safety, and adequate provisions and reserves of important supplies and resources and the passing down of traditional knowledge. Indigenous lives and livelihoods are at risk in the following ways. Indigenous persons are more at risk of losing their lives due to factors that are exacerbated by climate change impacts (Ford et al., 2006; Barbaras, 2014; Khalafzai et al., 2019). Indigenous Peoples' livelihood practices are being distressed, interrupted, and in some cases, made entirely inaccessible. Livelihood activities known and anticipated to be impacted by climate change are food security (Meakin and Kurtvits, 2009; Wesche and Chan, 2010; Nyland et al., 2017), harvesting of fish, plants, and wildlife (Dittmer, 2013; Parlee et al., 2014; Jantarasami et al., 2018b; ICC Alaska, 2020), agriculture (St. Regis Mohawk Tribe, 2013; Shinbrot et al., 2019; Settee, 2020), transportation (Swinomish Indian Tribe Community, 2010; Hori et al., 2018a; Hori et al., 2018b), and tourism and recreation (ICC Canada, 2008). Indigenous Peoples have been active in gathering to assess the impacts of climate change on their livelihoods, one example being the Bering Sea Elders Advisory Group (Bering Sea Elders Advisory Group and Alaska Marine Conservation Council, 2011; Bering Sea Elders Group, 2016).

Climate change impacts have harmful effects on Indigenous Peoples' public health, physical health, and mental health, including harmful effects connected to the cultural and community foundations of health (*very high confidence*). Health and climate change is a major issue for Indigenous Peoples (Ford, 2012; Ford et al., 2014; Gamble et al., 2016; Jantarasami et al., 2018b; Middleton et al., 2020a; Donatuto et al., 2021)(14.5.6). Climate change impacts and risks affect Indigenous Peoples' health negatively in different ways. Indigenous health, as tied to nutrition and exercise, is threatened when local foods are less available and harvesting activities are less possible to practice (Norton-Smith et al., 2016b; Rosol et al., 2016; Gonzalez et al., 2018). Indigenous Peoples experience widespread public health concerns from severe droughts (Stewart et al., 2020; Schlinger et al., 2021; Wiecks et al., 2021), extreme heat (Doyle et al., 2013; Campo Caap, 2018; Kloesel et al., 2018a; Meadow et al., 2018; ITK, 2019; Ute Mountain Ute Tribe and Wood Environment Infrastructure Solutions Inc, 2019; Whyte et al., 2021), unpredictable precipitation patterns (Chavarria and Gutzler, 2018; Tom et al., 2018; Tlingit and Haida, 2019; Schlinger et al., 2021), flooding and coastal erosion (Jamestown S'klallam Tribe, 2016; Norton-Smith et al., 2016b; Puyallup Tribe of Indians, 2016; Marks-Marino, 2019; Ristroph, 2019; Marks-Marino, 2020b; Schlinger et al., 2021), wildfires and wildfire smoke (Edwin and Mölders, 2018; USEPA, 2018; Christianson et al., 2019a; ITK, 2019; Marks-Marino, 2020a; Mottershead et al., 2020; Woo et al., 2020; Wiecks et al., 2021), algal blooms (Peacock et al., 2018; Gobler, 2020; Donatuto et al., 2021; Preece et al., 2021; Schlinger et al., 2021), storms and hurricanes (Rioja-Rodríguez et al., 2018), influxes of invasive species (Pfeiffer and Huerta Ortiz, 2007; Pfeiffer and Voeks, 2008; Voggesser et al., 2013; Bad River Band of Lake Superior Tribe of Chippewa Indians and Abt Associates Inc., 2016; Scott et al., 2017; Reo and Ogden, 2018; Middleton et al., 2020a), and changing production systems (Rioja-Rodríguez et al., 2018). Indigenous Peoples' mental health is at risk and has already been affected negatively by climate change (Donatuto et al., 2021). Water security is one of the most serious concerns to Indigenous Peoples' health and wellbeing (Vanderslice, 2011; Cozzetto et al., 2013a; Redsteer et al., 2013; Hanrahan et al., 2014; Chief et al., 2016; Gamble et al., 2016; Jantarasami et al., 2018b; Kloesel et al., 2018a; Tom et al., 2018; Martin et al., 2020a; Arsenault, 2021). When some people are less able to practice traditional, cultural, social, and family activities, they can become alienated, compounding the negative effects of traumas Indigenous persons already experience. Traumas include historic and continuing land dispossession, assimilation, social marginalization and discrimination, and food and financial insecurities. The practice of cultural traditions are associated with education, harvesting and agriculture, exercise, positive social relationships, and family life, which play foundational roles in the achievement of physical, public, and mental health (Bell et al., 2010; Cunsolo Willox et al., 2015; Jantarasami et al., 2018b; Norgaard and Tripp, 2019; Billiot et al., 2020b; Adams et al., 2021; Donatuto et al., 2021).

Indigenous Peoples are affected dramatically by climate-related disasters and other climate-related extreme environmental events (*very high confidence*). Indigenous Peoples face numerous threats and have already been harmed by and are planning for extreme weather events with associations to climate change, including hurricanes and tornadoes (Oneida Nation Pre-Disaster Mitigation Plan Steering Committee and Bay-Lake Regional Planning Commission, 2016; Emanuel, 2019; Cooley, 2021; Marks-Marino, 2021; Zambrano et al., 2021), heat waves (Confederated Tribes of the Umatilla Indian Reservation, 2016; Wall, 2017; La Jolla Band of Luiseno Indians, 2019; Mashpee Wampanoag, 2019; Wiecks et al., 2021), ocean warming and marine heat waves (Hoh Indian Tribe, 2016; Port Gamble S'klallam Tribe, 2016; Port Gamble S'klallam Tribe, 2020; State of Alaska, 2020; Muckleshoot Tribal Council, 2021; Port Gamble S'klallam Tribe, 2021), wildfires (Voggesser et al., 2013; Billiot et al., 2020a; Cozzetto et al., 2021b; Gaughen et al., 2021; Morales et al., 2021; National Tribal Air Association, 2021; Zambrano et al., 2021), permafrost thaw (Haynes et al., 2018; Low, 2020), flooding (Riley et al., 2011; Ballard and Thompson, 2013; Brubaker et al., 2014; Thompson et al., 2014; Burkett et al., 2017; Quinault Indian Nation, 2017; Ristroph, 2019; Sharp, 2019; Thistlethwaite et al., 2020b), and drought (Knutson et al., 2007; Chief et al., 2016; Redsteer et al., 2018; Sioui, 2019; Bamford et al., 2020; Sauchyn et al., 2020). Some Indigenous Peoples are facing climate change impacts that generate community-led permanent relocation and resettlement as an adaptation option (Maldonado et al., 2021). Coastal erosion is one climate change issue that is often connected to Indigenous Peoples planning to resettle, including vulnerability connected to higher sea levels and storm surges (Quinault Indian Nation, 2017; Bronen et al., 2018; Affiliated Tribes of Northwest Indians, 2020). Adapting to new settlement areas threatens the continuity of communities. In a number of cases, Indigenous Peoples' having less access to adequate infrastructure is a driver of vulnerability to climate related disasters and extreme weather events (Doyle et al., 2018; Patrick, 2018; Cozzetto et al., 2021a; Indigenous Climate Action et al., 2021). Disasters and extreme events are particularly severe when their impacts are compounded by inadequate infrastructure. Lack of flood protection infrastructure on Indigenous reserve communities, leads to displacement, loss of homes, and perpetuates disproportionate levels of risk to extreme weather events (Cunsolo et al., 2020; Fayazi et al., 2020; Yellow Old Woman-Munro et al., 2021).

Indigenous self-determination and self-governance are the foundations of adaptive strategies that improve understanding and research on climate change, develop actionable community plans and policies on climate change, and have demonstrable influence in improving the design and allocation of national, regional, and international programs relating to climate change (*very high confidence*). Historical and contemporary developments have crystallized international norms recognizing the distinct status, role, and rights of Indigenous Peoples in the form of significant international human rights instruments. Premier among them is the UNDRIP (UNGA A/RES/61/295), which has received universal consensus since its adoption by the UN General Assembly. UN member States have affirmed the right of self-determination (Article 3, UNDRIP) regarded as the prerequisite to the exercise and enjoyment of all other human rights.

The integrity of the environment is impacting all of humanity, including Indigenous Peoples, their lands, territories, resources and their communities. Through self-determination, durable, sustainable, and robust contributions from those with close, symbiotic relationships with the environment can be revealed in favor of all humanity. Indigenous Peoples of North America have been engaged in wide-ranging activities to address climate change (Doolittle, 2010; Parker and Grossman, 2012; Abate and Kronk, 2013; STACCWG, 2021). They include actions in the spheres of education (Donatuto et al., 2020; McClain, 2021; Morales et al., 2021), development of Indigenous knowledge and science (Maldonado et al., 2016; AFN, 2020; Ferguson and Weaselboy, 2020; Huntington et al., 2021a; Jones et al., 2021; Sawatzky et al., 2021), adaptation planning and implementation (Angel et al., 2018a; Tribal Climate Adaptation Guidebook Writing Team et al., 2018; Hepler and Kronk Warner, 2019; Tribal Adaptation Menu Team, 2019; Metcalfe et al., 2020b), and political action and diplomacy (including treaty-based diplomacy) (Grossman, 2008; Kronk Warner and Abate, 2013; Callison, 2015).

14.5 Observed Impacts, Projected Risks, and Adaptation by Sector

14.5.1 Terrestrial and Freshwater Ecosystems and Communities

14.5.1.1 Terrestrial Ecosystems: Observed Impacts and Projected Risks

Evidence continues to mount about the impacts of recent climate change on species and ecosystems (Weiskopf et al., 2020) (Table 14.2) (*very high confidence*). Ranges and abundances of species continue to shift in response to warming throughout North America (Cavanaugh et al., 2014; Molina-Martínez et al., 2016; Tape et al., 2016; Miller et al., 2017; Pecl et al., 2017; Zhang et al., 2018a) (Cross-Chapter Box MOVING PLATE in Chapter 5) (*very high confidence*). Future climate change will continue to affect species and ecosystems (IPBES, 2018) (*high confidence*), with differential responses related to species characteristics and ecology (D'Orangeville et al., 2016; Weiskopf et al., 2019). Climate change is projected to adversely affect the range, migration, and habitat of caribou, an important food and cultural resource in the Arctic (Leblond et al., 2016; Masood et al., 2017; Barber et al., 2018b; Borish, Accepted) (CCP6).

Climate-induced shifts in the timing of biological events (phenology) continue to be a well-documented ecological response (Vose et al., 2017; Lipton et al., 2018; Vose et al., 2018; Molnar et al., 2021) (Table 14.2) (*very high confidence*). Reduced snow season length may potentially lead to adverse camouflage effects on animals that change coat colour (Mills et al., 2013; Mills et al., 2018). Human conflicts with bears are expected to increase in response to shifts in hibernation patterns (Johnson et al., 2018) and food resources (Wilder et al., 2017; Wilson et al., 2017).

Severe ecosystem consequences of warming and drying are well documented (*very high confidence*) (Table 14.2). Significant ecosystem changes are expected from projected climate change (*high confidence*), such as in Mexican cloud forests (Helmer et al., 2019), North American rangelands (Polley et al., 2013; Reeves et al., 2014), and montane forests (Stewart et al.; Wright et al., 2021). Permafrost thaw is projected to increase in Alaska and Canada (DeBeer et al., 2016) (see also AR6, WG I, Chapter 12), accelerating carbon release

(Schaefer, 2104) (CCP6, see also AR6, WG I, Chapter 5) and affecting hydrology. Predicting which species or ecosystems are vulnerable is challenging (Stephenson et al., 2019), although paleoecological data (e.g., pollen, tree rings) provide context from past events to better understand current and future transformations (Nolan et al., 2018).

Climate change impacts on natural disturbances have affected ecosystems (*very high confidence*) (Table 14.2 and Box 14.2), and these impacts will increase with future climate change (*medium confidence*). Facilitated by warm, dry conditions, "mega-disturbances" and synergies between disturbances that include wildfires, insect and disease outbreaks, and drought-induced tree mortality continue to affect large areas of North America (Cohen et al., 2016; Young et al., 2017a; Hicke et al., 2020), overwhelming adaptive capacities of species and degrading ecosystem services (Millar and Stephenson, 2015; Stewart et al., 2021). This era of mega-disturbances is expected to become more widespread and severe in coming decades (Cook et al., 2015; Seidl et al., 2017; Buotte et al., 2019), with potentially significant impacts on ecosystems (Allen et al., 2015; Crausbay et al., 2017; Schwalm et al., 2017; Coop et al., 2020; Dove et al., 2020 Thompson et al. 2020, Stewart et al. 2021). Effects include widespread tree mortality (Allen et al., 2015; Kane et al., 2017; van Mantgem et al., 2018) and accelerated ecosystem transformation (Guiterman et al., 2018; Crausbay et al., 2020; Munson et al., 2020) (*medium confidence*).

14.5.1.2 Freshwater Ecosystems: Observed Impacts and Projected Risks

Climate change, either directly (warming water) or indirectly (glacier and snow inputs), has affected biogeochemical cycling and species composition in North American aquatic ecosystems (Moser et al., 2005; Saros et al., 2010; Preston et al., 2016) (Table 14.2) (*very high confidence*), possibly amplifying other human-caused stresses on these systems (Richter et al., 2016). Excess nutrients associated with high farm animal density can be transported during intense rainfall events (expected to increase with climate change) causing algal blooms, fish kills, and other detrimental ecological effects (Huisman et al., 2017; Coffey et al., 2019).

Projected climate change will cause habitat loss, alter physical and biological processes, and decrease water quality in freshwater ecosystems (Poesch et al., 2016; Crozier et al., 2019) (*high confidence*). Projected river warming of 1-3ºC is expected to reduce thermal habitat for important salmon and trout species in the northwestern US by 5–31% (Isaak et al., 2018) and in Mexico (Meza-Matty et al., 2021), and for multiple fish species in Canada (Poesch et al., 2016). Cold-water streams at higher elevations will warm less and therefore may become climate refugia (Isaak et al., 2016). Projected warming of mountain lake ecosystems (Roberts et al., 2017b; Redmond, 2018) will affect ecosystem processes (Preston et al., 2016; Redmond, 2018; Moser et al., 2019). Loss of cold water inputs from retreating glaciers are expected to adversely affect alpine stream ecosystems (Fell et al., 2017; Giersch et al., 2017). For anadromous fish species (e.g., Chinook salmon), future warming will reduce habitat suitability from river headwaters to oceans (Crozier et al., 2021).

Freshwater ecosystems across North America are increasingly at risk from extreme drought, compounded by human demands for water (14.5.3) (Kovach et al., 2019). Implications for aquatic and riparian species can vary, but it is widely agreed that these systems are highly sensitive to fluctuations in the hydrologic cycle, which can increase competition by invasive species and compromise connectivity between potential cold-water refugia (Melis et al., 2016; Poff, 2019).

14.5.1.3 Adaptation in Terrestrial and Freshwater Ecosystems

Adaptation efforts to assess vulnerability of species and ecosystems, predict adaptive capacity, and identify conservation-oriented options have increased markedly across North America (e.g., Hagerman and Pelai, 2018; Keeley et al., 2018; Thurman et al., 2020; Peterson St-Laurent et al., 2021; Thompson et al., 2021). Scenario-based planning, an approach for addressing uncertainty, continues to gain traction and is regularly applied by the US National Park Service (Star et al., 2016). Nonetheless, barriers to implementation of specific actions often exist (e.g., inflexible policies, lack of resources and stakeholder buy-in, political will), hampering progress (Stein et al., 2013; Shi and Moser, 2021). Efforts to evaluate the efficacy of implemented adaptation actions are also lacking (Prober et al., 2019), but some cases show progress. For example, ongoing efforts are quantifying how variable water releases from the Colorado River's Glen

Canyon Dam affect endangered fish species (Melis et al., 2016). Nature-based solutions (NbS) for adaptation (Box 14.7) are increasingly evaluated, especially at larger scales.

Effective climate-informed ecosystem management requires a well-coordinated suite of adaptation efforts (e.g., assessment, planning, funding, implementation, and evaluation) that is co-produced among stakeholders, Indigenous Peoples, and across sectors (Millar and Stephenson, 2015; Dilling et al., 2019) (*high confidence*). New applications of conventional strategies can be modified to achieve conservation goals under climate change (USGCRP, 2019). For example, mechanical thinning and prescribed burning (to reduce fuel loads and benefit ecosystems) could be used in combination with planting species better suited to new conditions to build resilience in western US forests to longer and hotter drought conditions (Bradford and Bell, 2017; Vernon et al., 2018). Protection of buffer areas, such as riparian strips in arid regions and boreal ecosystems, reduces water temperature, builds resistance to invasive species, increases suitable habitat (Johnson and Almlof, 2016), and facilitates protection of freshwater systems from runoff during and after intense rain events (National Research Council, 2002).

Innovative approaches may facilitate species' responses to climate change, particularly when vulnerability is exacerbated by habitat loss and fragmentation. Strategies include improved landscape connectivity for species dispersal (Carroll et al., 2018; Littlefield et al., 2019; Lawler et al., 2020; Thomas, 2020) or assisted migration (also called managed relocation) to climatically suitable locations (Schwartz et al., 2012; Dobrowski et al., 2015). Examples include translocation of salmon in the Columbia River (Holsman et al., 2012), genetic rescue (assisted gene flow increases genetic diversity to address local maladaptation) (Aitken and Whitlock, 2013), and locating and conserving climate refugia, such as in alpine meadows of the Sierra Nevada (Javeline et al., 2015; Morelli et al., 2016). Maintaining diverse spawning habitats and salmon runs can increase resilience of salmonid populations to climate change (Schoen et al., 2017; Crozier et al., 2021). Newer modelling approaches can facilitate the visualization of future management scenarios, per a recent study of fires in the southwestern US (Loehman et al., 2018), in addition to technologies in genomics for monitoring species and modifying adaptive traits (Phelps, 2019).

Adaptation actions have important limitations (Dow et al., 2013), particularly in the context of biodiversity conservation goals. "Hard" limits include species extinctions and vegetation mortality events, despite conservation action (i.e., besides significant emissions reductions to mitigate warming, few if any interventions could have prevented these losses). In contrast, "soft" adaptation limits exist primarily as a function of the social-ecological value systems of local communities and government entities that are reflected as goals and objectives in their management plans for ecosystems and species across North America. Soft limits are often mutable or can be removed altogether (Dow et al., 2013). In contrast, human modifications of landscapes that change or irreparably damage can limit adaptation by reducing connectivity and therefore range shifts (Parks and Abatzoglou, 2020).

[START BOX 14.2 HERE]

Box 14.2: Wildfire in North America

Recent Observations, Attribution to Climate Change, and Projections

Anthropogenic climate change has led to warmer and drier conditions (i.e., fire weather) that favour wildland fires in North America (see AR6, WGI, Chapter 12; *high confidence*). In response, increased burned area in recent decades in western North America has been facilitated by anthropogenic climate change (*medium confidence*). Annual numbers of large wildland fires and area burned have risen in the last several decades in the western US (USGCRP, 2017; USGCRP, 2018), and area burned has increased in Canada (the number of large fires has declined slightly recently) (Gauthier et al., 2014; Natural Resources Canada, 2018; Hanes et al., 2019). Attribution studies have reported that climate change increased burned area in Canada (1959-1999) (Gillett et al., 2004) as well as the western US (1984–2015) (Abatzoglou and Williams, 2016) and California (1972-2018) (Williams et al., 2019a). Decreased precipitation was the primary climate change cause of increased burned area in the western US, with warming a secondary influence (Holden et al. 2018), whereas warming (through aridity) was most important in a California study (Williams et al., 2019a). A drier atmosphere (including reduced precipitation) has been linked to climate change through altered large-scale atmospheric circulation, which then facilitated greater burned area in the western US (Zhang et al., 2019c). Through anomalous warm and dry conditions, anthropogenic climate change contributed to the extreme fires of 2016 (Kirchmeier-Young et al., 2019; Tan et al., 2019) in western Canada and the extreme fire season in 2015 in Alaska (Partain et al., 2017). These studies did not include human activities that influence fire-climate relationships (Syphard et al., 2017).

Warming has led to longer fire seasons (Westerling, 2016) and drier fuels (Williams et al., 2019a). Warmer and drier fire seasons in the western US during 1985-2017 have contributed to greater burned area of severe fires (Parks and Abatzoglou, 2020). Simultaneity in fires increased during 1984-2015 (Podschwit and Cullen, 2020), challenging firefighting effectiveness and resource sharing. In Mexico, fires have been correlated with dry conditions (Kent et al., 2017; Marin et al., 2018; Zuniga-Vasquez et al., 2019). Wildland fire activity in the grasslands of the US Great Plains has increased during the last several decades (Donovan et al., 2017) related to antecedent precipitation or aridity that affected fuel quantity (Littell et al., 2009).

Climate change is projected to increase fire activity in many places in North America during the coming decades (see also AR6, WGI, Chapter 12) (Boulanger et al., 2014; Williams et al., 2016; Halofsky et al., 2020), via longer fire seasons (Wotton and Flannigan, 1993; USGCRP, 2017), long-term warming (Villarreal et al., 2019; Wahl et al., 2019), and increased lightning frequency in some areas of the US and Canada (Romps et al., 2014; Finney et al., 2018; Chen et al., 2021) (*medium confidence*). Unusually extensive and severe fires have occurred in the Arctic tundra during recent extremely warm and dry years, suggesting that continued warming may increase the probability of such fires in the future (Hu et al., 2015). In drier non-forest ecosystems in the western US, fires are limited by fuel availability and vegetation productivity; warming will decrease productivity, leading to lower burned area (Littell et al., 2018).

Impacts on Natural Systems

Although fire is a natural process in many North American ecosystems, increases in burned area and severity of wildland fires have had significant impacts on natural ecosystems (*medium confidence*). The length of streams and rivers impacted by fire has increased in the US along with burned area (Ball et al. 2021). Mega-fires can cause major changes in the structure and composition of ecosystems, particularly where human alterations are significant (Stephens et al., 2014; Loehman et al., 2020). Unusually severe fires may have led to the conversion of forest to grassland in the US Southwest (Haffey et al., 2018). Recent warming and drying have limited post-fire tree seedling and shrub establishment, limiting ecosystem recovery (Davis et al., 2019; O'Connor et al., 2020; Rodman et al., 2020). In boreal forests, soil carbon is being lost through increasingly severe or frequent fires (Walker et al., 2019).

Projected future fire activity will continue to affect ecosystems and alter their structure and function (*medium confidence*) (Coop et al., 2020; Loehman et al., 2020). Increased fire activity (Stevens-Rumann et al., 2018; Stevens-Rumann and Morgan, 2019; Turner et al., 2019a; Cadieux et al., 2020), further warming and drying that stresses tree seedlings, and model projections of stand-replacing fires at the forest-non-forest boundary in the western US (Parks et al., 2019) have raised the possibility of shifts in species composition or vegetation type (Halofsky et al., 2020). These projections suggest high variability in ecosystem responses depending on interactions between vegetation type, moisture stress, disturbances regimes, and human alterations (Hurteau et al., 2008; Kitzberger et al., 2017; Littell et al., 2018; Hurteau et al., 2019; Loehman et al., 2020; O'Connor et al., 2020).

Impacts on Human Systems

Increased fire activity, partly attributable to anthropogenic climate change, has had direct and indirect effects on mortality and morbidity, economic losses and costs, key infrastructure, cultural resources, and water resources (*medium confidence*), although other factors, such as increasing populations in the wildland-urban interface, also contributed. During 2000–2018, significant fire events claimed 315 lives in the US (NOAA, 2019); the economic impacts (capital, health, indirect losses from economic disruption) from the 2018 California fires were US$149 billion (Wang et al., 2021). Poor air quality from fires caused increased respiratory distress (*very high confidence*); exposure extends long distances from the fire source (Section 14.5.6.3). In addition to public and private property damage and loss, fires have caused irretrievable losses from archaeological and historical sites (Ryan et al., 2012). Post-fire conditions have created unanticipated challenges for communities' water supply operations (Bladon et al., 2014; Návar, 2015; Martin, 2016) by altering water quality and availability (Smith et al., 2011; Bladon et al., 2014; Robinne et al., 2020) or public safety by increasing exposure to mass wasting events after extreme rainfall events (Cui et al., 2019; Kean et al., 2019). California utilities have proactively shut down parts of their electricity grid to reduce risk of fire during extreme weather, and substantial numbers of people will be increasingly vulnerable to this action in the coming decades (Abatzoglou et al., 2020).

In the US, annual costs of federal wildland fire suppression have increased by a factor of 4 since 1985 (USGCRP, 2018) and were US$1.5-3B during 2016-202 (NIFC, 2021). Annual costs of fire protection in Canada have risen 2–3 fold from 1970–2017, to CAD$1.0-1.4B during 2015-2017 (2017 dollars) (Natural Resources Canada, 2021). In one of its worst fire seasons, British Columbia expended over CAD$500M in 2017 for fire suppression (Natural Resources Canada, 2018). The number of days of synchronous fire danger is expected to double in the western US by 2051-2080, thereby increasing demands on fire suppression resources (Abatzoglou et al., 2021).

The 2016 Fort McMurray fire ranks as the costliest natural disaster in Canada to date (CAD$3B in insured damages) (Mamuji and Rozdilsky, 2018; IBC, 2020). More than 88,000 people were evacuated; many were not aware of the high pre-existing fire risk and had limited warning to prepare and leave (McGee, 2019). The community subsequently required extensive social support and experienced mental health challenges (Government of Alberta, 2016; Cherry and Haynes, 2017; Mamuji and Rozdilsky, 2018; Brown et al., 2019a; McGee, 2019). Although a broad recovery plan was developed (Regional Municipality of Wood Buffalo, 2016), reconstruction and economic recovery has been slow (Mamuji and Rozdilsky, 2018).

Wildland fire was identified as a top climate change risk facing Canada (Council of Canadian Academies, 2019) and poses a challenge to communities and fire management (Coogan et al., 2019). Projected area burned in Canada using RCP2.6 will increase annual fire suppression costs to CAD$1B by end of century (60% increase relative to 1980-2009) and to CAD$1.4B using RCP8.5 (119% increase) (Hope et al., 2016). In the US, cumulative costs of fire response through 2100 are projected to be US$23B (2015 dollars) per year under RCP8.5 (EPA, 2017). Lower emissions scenarios reduce these future cumulative costs by US$55M (EPA, 2017) to US$7-9B (2005 dollars) (Mills et al., 2015a). Fire increases from future warming will reduce timber supply in eastern Canada (Gauthier et al., 2015; Chaste et al., 2019) and increase post-fire sedimentation in watersheds of the western US (Sankey et al., 2017).

Adaptation

Wildland fire risks are not equitably distributed as they intersect with exposure and socioeconomic attributes (e.g., age, income, ethnicity) to influence vulnerability and adaptive capacity (Wigtil et al., 2016; Davies et al., 2018; Palaiologou et al., 2019) (*medium confidence*). Individuals in rural areas, low-income neighbourhoods, and immigrant communities as well as renters in California had less capacity to prepare for and recover from fire (Davies et al., 2018). In the US, 29 million people live in areas with significant potential for wildfires and 12 million are socially vulnerable (Davies et al., 2018). In Canada, there are 117 million ha of wildland-human interface (14% of total land area), and 96% of populated places have some wildland-urban interface within 5 km (Johnston and Flannigan, 2018).

There is growing recognition of the need to shift fire management and suppression activities to co-exist with more fire on the landscape. This includes widespread use of prescribed fire across landscapes to increase ecological and community-based resilience (Schoennagel et al., 2017; McWethy et al., 2019; Tymstra et al., 2020) (*high agreement, medium evidence*). Otherwise, the unprecedented combination of increased human exposure and size of recent megafires creates community risks that may exceed conventional operational and forest management response capacity and budgets (Podur and Wotton, 2010; Wotton et al., 2017; Loehman et al., 2020; Moreira et al., 2020; Parisien et al., 2020) particularly with ongoing population and infrastructure expansion into the wildland-urban interface (Canadian Council of Forest Ministers, 2016; Coogan et al., 2019).

Climate-informed post-fire ecosystem recovery measures (e.g., strategic seeding, planting, natural regeneration), restoration of habitat connectivity, and managing for carbon sequestration (e.g., soil conservation through erosion control, preservation of old growth forests, sustainable agro-forestry) are critical to maximize long-term adaptation potential and reduces future risk through co-benefits with carbon mitigation (Davis et al., 2019; Hurteau et al., 2019; Coop et al., 2020; Stewart et al., 2021). Innovation in and scaling up the use of prescribed fire and thinning approaches are contributing to pre-and post-fire resilience goals, including use of Indigenous Peoples burning practices that are receiving a new level of awareness (Kolden, 2019; Marks-Block et al., 2019; Long et al., 2020b) (Box 14.1).

The tools FireSmart Canada (https://www.firesmartcanada.ca), Firewise USA (https://www.nfpa.org/) and Think-Hazard Mexico (https://thinkhazard.org) were devised to reduce fire risks and create fire-resilient communities. They provide design guidance at building, lot, subdivision and community scales, and instruct citizens on creating defensible space (National Fire Protection Association, 2013; Firesmart Canada, 2018). Implementation has been fragmented and variable as it depends on voluntary uptake by individuals, business and communities across a range of adaptive capacities and fire-exposed landscapes (Smith et al., 2016a).

Many vulnerable groups do not have access to financial or physical resources to reduce fire risk (Collins and Bolin, 2009; Palaiologou et al., 2019).

Although innovative, holistic approaches to wildland fire management are becoming more common across North America, broader application is necessary to address the growing risks (*medium confidence*). A social-ecological perspective blends ecosystem complexity, scale and processes into land use planning along with community values, perception, and capacities as well as institutional arrangements (Smith et al., 2016a; Spies et al., 2018). A risk assessment perspective expands from short-term, reactive fire response to landscape-scale, long-term prevention, mitigation, and preparedness with community and practitioner engagement (Coogan et al., 2019; Sherry et al., 2019; Johnston et al., 2020; Tymstra et al., 2020).

[END BOX 14.2 HERE]

14.5.2 Ocean and Coastal Social-Ecological Systems

14.5.2.1 Observed Impacts and Projected Risks of Climate Change

Warming of surface and subsurface ocean waters has been broadly observed across all North American marine ecosystems from the polar Arctic to the subtropics of Mexico (*virtually certain*) (Hobday et al., 2016; Jewett and Romanou, 2017; Pershing et al., 2018; Smale et al., 2019a). Higher ocean temperatures have directly affected food-web structure (Gibert, 2019) and altered physiological rates, distribution, phenology, and behaviour of marine species with cascading effects on food-web dynamics (*very high confidence*) (Gattuso et al., 2015; Pinsky and Byler, 2015; Sydeman et al., 2015; Poloczanska et al., 2016; Frölicher et al., 2018; Le Bris et al., 2018; Free et al., 2019; Stevenson and Lauth, 2019; Barbeaux et al., 2020; Dahlke et al., 2020). Pacific coastal waters from Mexico to Canada and US mid-Atlantic coastal waters have a high proportion of species (>5% of all marine species) near their upper thermal limit, representing hotspots of risk from marine heatwaves (*medium confidence*) (Smale et al., 2019a; Dahlke et al., 2020). Kelp, a macro-algae, forms important habitat for other marine species, and its biomass has decreased 85–99% in the past 4–6 decades off Nova Scotia, Canada, replaced by invasive and turf algae; this is associated directly with warming waters (Filbee-Dexter et al., 2016).

Climate change has induced phenological and spatial shifts in primary productivity with cascading impacts on foodwebs (*high confidence*) (Siddon et al., 2013; Stortini et al., 2015; Sydeman et al., 2015; Stanley et al., 2018). This includes widespread starvation events of fish, birds (e.g., tufted puffins in Bering Sea in 2016/2017 and Cassin's Auklets in British Columbia in 2014/2015) and marine mammals (gray whales along both coasts of North America) (Sydeman et al., 2015; Duffy-Anderson et al., 2019; Jones et al., 2019b; Cheung and Frölicher, 2020; Piatt et al., 2020), which challenge protected species and fisheries management (section 14.5.4) (Chasco et al., 2017; Wilson et al., 2018; Barbeaux et al., 2020; Free et al., 2020; Holsman et al., 2020). Climate change has altered foraging behaviour and distribution of North Atlantic right whales and their target copepod prey (Record et al., 2019) increasing entanglement rates in lobster and snow crab fishing gear on the East coast of the US and Canada as lobster and crab distributions also shift due to changing water temperatures (Meyer-Gutbrod et al., 2018; Davies and Brillant, 2019). Similarly, whale entanglements in fishing gear along the Pacific coast has increased 20 fold (Hazen et al., 2018). Projected shifts in the North Pacific Transition Zone (NPTZ) by up to 1000 km northward (by the end of the century under RCP8.5) combined with changes in coastal upwelling (Polovina et al., 2011; Hazen et al., 2013; Rykaczewski et al., 2015) could alter up to 35% of elephant seal and bluefin tuna foraging habitat (Robinson et al., 2009; Kappes et al., 2010).

In North American Arctic marine systems, rapid warming is significant, with cascading impacts beyond polar regions (CCP6), and presents limited opportunities (tourism, shipping, extractive) but high risks (shipping, and fishing industries, Indigenous subsistence and cultural activities) (*high confidence*)(Gaines et al., 2018; IPCC, 2019b; Samhouri et al., 2019; Free et al., 2020; Holsman et al., 2020) (see sections 14.5.4; 14.5.9; 14.5.11;CCP6). Both direct hazards and indirect food web alterations from sea ice loss have imperilled seabirds, marine mammals, small boat operators, subsistence hunters and coastal communities (Sigler et al., 2014; Allison and Bassett, 2015; Huntington et al., 2015; Hauser et al., 2018; Raymond-Yakoubian and Daniel, 2018; Dezutter et al.) (CCP6). Increasingly favourable environmental conditions due to warming combined with shipping and other activities has raised the rate of invasive species movement into the Arctic (Mueter et al., 2011). Sea ice loss due to climate change is expected to accelerate over the next century (14.2, WG1 9.3.1).

Coral reefs in Gulf of Mexico and along the coasts of Florida and Yucatan Peninsula are facing increasing risk of bleaching and mortality from warming ocean waters interacting with non-climate stressors (*very high confidence*) (Cinner et al., 2016; Hughes et al., 2018; Sully et al., 2019; Williams et al., 2019b). Coral reefs are contracting in equatorial regions and expanding poleward (Lluch-Cota et al., 2010; Jones et al., 2019a). Loss of coral habitat leads to loss of ecosystem structure, fish habitat, and food for coastal communities and impacts tourism opportunities (14.5.7) (Weijerman et al., 2015a; Weijerman et al., 2015b). Without mitigation to keep surface temperatures below a 2.0ºC increase by the end of the century, up to 99% of coral reefs will be lost. However, 95% of reefs will still be lost even if warming is kept below 1.5ºC (*high confidence)* (Hoegh-Guldberg et al.; Hoegh-Guldberg et al., 2019a). In Florida, by 2100, an estimated US$24–55B may be lost in recreational use and value derived by people knowing the reef exists and is healthy (Lane et al., 2013; Hoegh-Guldberg et al., 2019b) as coral reefs decline (14.5.9).

SLR has led to flooding, erosion and damage to infrastructure along the western Gulf of Mexico, the southeast US coasts, and the southern coast of the Gulf of St Lawrence (14.2) (Daigle, 2006; Lemmen et al., 2016; Frederikse et al., 2020) (*very high confidence*). Mangroves, important nurseries for fish and climate refugia for corals (Yates et al., 2014), are under threat from climate change along the east coast of Mexico (Pedrozo Acuña, 2012). SLR, storm surge and attendant erosion of coastlines and barrier habitats are projected to have large impacts on coastal ecosystems, maritime industries (14.5.9), urban centres and cities (14.5.5) along the Gulf of Mexico, Caribbean Sea, Southeast US, the southern Gulf of St Lawrence and the Pacific Coast of Mexico (Box 14.4) (Semarnat, 2014; Sweet et al., 2017; Vousdoukas et al., 2020). Coastal archaeological and historical sites are especially vulnerable to SLR (Anderson et al., 2017; Hestetune et al., 2018; Hollesen et al., 2018).

Future seawater CO_2 levels have been shown in laboratory studies to negatively impact Pacific and Atlantic squid, bivalve, crab, and fish species (Pacific cod), and indirectly alter food-web dynamics (Kaplan et al., 2013; Long et al., 2013b; Gledhill et al., 2015; Seung et al., 2015; Punt et al., 2016; Swiney et al., 2017; Hurst et al., 2019; Wilson et al., 2020) (*high confidence*). Long-term exposure to CO_2 reduced growth of Atlantic halibut (Gräns et al., 2014), whereas some cultured oysters (Fitzer et al., 2019) and key Alaskan commercial fish species show tolerance for high CO_2 waters (i.e., juvenile walleye pollock) (Hurst et al., 2012). Ocean acidification has already caused shellfish growers in the US and Canada to modify hatchery procedures and farming locations to protect the most vulnerable life-stages (Cross et al., 2016) and is projected to increasingly impact shellfish resources in the central and NE Pacific and Atlantic coasts (Seung et al., 2015; Punt et al., 2016) (Section 14.5.4).

Open ocean oxygen minimum zones (OMZ) are expanding in the North Atlantic, the North Pacific California Current and tropical oceans due to warming waters, stratification, and changes in precipitation (*medium confidence*) (Deutsch et al., 2015b; Breitburg et al., 2018; Claret et al., 2018; Ito et al., 2019) (WGI, 3.6.2). Hypoxic (extreme low oxygen) events along coasts, which are partially influenced by climate change, have been documented for all three countries, with events more prevalent on the east coast and around the Gulf of Mexico due to a regional oceanography dominated by rivers and estuaries carrying land-based nutrients (Breitburg et al., 2018). Hypoxia has directly caused large mortality events for fish and crabs in US estuaries in the Northwest Atlantic (Chesapeake Bay), Northeast Pacific (Puget Sound) and the Gulf of Mexico (Froehlich et al., 2015; Rakocinski and Menke, 2016; Sato et al., 2016; Kolesar et al., 2017). OMZs and hypoxic events are projected to increase over the next century and may limit where fish can move (*medium confidence*) (Deutsch et al., 2015b; Stortini et al., 2015; Bianucci et al., 2016; Li et al., 2016).

Favourable conditions for harmful algal blooms (HABs) have expanded due to warming, more frequent extreme weather events (Gobler et al., 2017; Pershing et al., 2018; Trainer et al., 2019) and increased stratification, CO_2 concentration, and nutrient inputs (Wells et al., 2015; Gobler et al., 2017; Griffith and Gobler, 2019) *(high confidence*). Increased occurrence of HABs (McCabe et al., 2016; Yang et al., 2016; Gobler et al., 2017; USGCRP, 2018) has induced ecological impacts and societal costs (see 14.5.4 for fishery closures). During the 2013–2016 Pacific Marine Heat Wave (MHW; Box 14.3), a *Pseudo-nitzschia* diatom bloom off the US West Coast caused extensive closures of crab and razor clam fisheries (Trainer et al., 2019), with economic and socio-cultural impacts beyond those in the fisheries sector (Ritzman et al., 2018).

Beaching of massive *Sargassum* seaweed mats (*Sargassum natans* and *S. fluitans*) have been reported across the Caribbean and Gulf of Mexico from 2011-present day, affecting US and Mexico nearshore ecosystems, human health and the tourism industry (Franks et al., 2016; Resiere et al.; Wang et al., 2019). Costs of beach clean-up is high, with Texas spending over USD$2.9 million annually (Webster and Linton, 2013). Attribution of *Sargassum* blooms to climate change is still tenuous and complicated by multiple drivers and few observational data sources (Wang et al., 2019) (*low confidence*).

[START BOX 14.3 HERE]

Box 14.3: Marine Heatwaves

Marine heat waves (MHWs) are periods of discrete anomalously high (compared to 30-year history) sea surface temperatures that persist for a minimum 5 days but up to several months (Hobday et al., 2016; Frölicher et al., 2018; Holbrook et al., 2019; Laufkötter et al., 2020). There have been MHWs attributed to climate change in every marine system of North America including large areas of the Northwest Atlantic (2012), Caribbean Sea (2015), Bering Sea (2016-2018), and central through Northeast Pacific (2013-2016) (NOAA, 2018; Holbrook et al., 2019; Smale et al.). MHW events have affected kelp forests (Arafeh-Dalmau et al., 2019), corals (Eakin et al., 2018), seagrasses, bottom-dwelling organisms, marine birds (Loredo et al., 2019; Smale et al., 2019a) mammals (Suryan et al., 2021), fish and shellfish and marine dependent human communities (Huntington et al., 2020; Fisher et al., 2021; Suryan et al., 2021). Increased sea temperatures directly increase metabolic demand and change productivity and behaviour of fish species (Stock et al., 2017; Free et al., 2019) as well as inducing rapid redistribution of species poleward and to deeper colder waters (Pecl et al., 2017; Rheuban et al., 2017; Crozier et al., 2019; Stevenson and Lauth, 2019; Yang et al., 2019; Barbeaux et al., 2020; Cheung and Frölicher, 2020). In the Pacific, from the Baja Peninsula to the Bering Sea, there is evidence of widespread shifts in coastal biota and multi-trophic level starvation of seabirds and whales from combined metabolic demand and reduced prey quality associated with protracted MHWs across multiple regions (CCP6)(Sydeman et al., 2015; Duffy-Anderson et al., 2019; Sanford et al., 2019; Smale et al., 2019a) (Suryan et al. 2021). The distribution of two economically important North American species, Bering Sea Pacific cod (Pinsky et al., 2013b; Stevenson and Lauth, 2019; Barbeaux et al., 2020; Spies et al., 2020) and American Lobster (Rheuban et al., 2017), have shifted north. MHW-induced loss of coral reefs across tropical North American waters has varied in severity regionally. For instance, in 2015 and 2016, extensive, severe bleaching affected more than 30% of corals off the southeast US and a large proportion of US Hawaiian Islands, but had moderate to no impact off the Mexican Yucatan Peninsula (Frieler et al., 2013; Weijerman et al., 2015a; Weijerman et al., 2015b; Cinner et al., 2016; van Hooidonk et al., 2016; Hughes et al., 2018; Sully et al., 2019; Williams et al., 2019b). Some reefs are exhibiting recovery following efforts focused at reducing non-climate stressors (e.g. overfishing, nutrient pollution and tourism use). MHWs are increasing in intensity and frequency(Hobday et al., 2016; Smale et al., 2019a) with largest increases in frequency and spatial coverage projected for the Gulf of Mexico, US southern East Coast and US Pacific Northwest (Ranasinghe et al., 2021) and pose a key risk to marine systems in North America (14.5.2, Ch 3, 16,).

[END BOX 14.3 HERE]

14.5.2.2 Adaptation: Current State, Barriers and Opportunities

Emerging technologies and cooperative marine management are approaches to facilitate adaptation but require coordination and investment for implementation.(Gattuso et al., 2018; Miller et al., 2018; Holsman et al., 2019; Karp et al., 2019) (*high confidence*). Advancements in oceanographic and ecological nowcasting and forecasting tools (i.e., O_2, pH, temperature, aragonite saturation state, sea ice conditions) can reduce climate impacts by supporting fisheries and aquaculture adaptation along US coasts (Section 14.5.4) (Cooley et al., 2015; Irby et al., 2015; Siedlecki et al., 2015; Siedlecki et al., 2016; Siddon and Zador, 2017).

Forecasts and warnings reduce human exposure to HAB toxins in the Great Lakes, the west coast of Florida, east coast of Texas and the Gulf of Maine (Anderson et al., 2019).

Ocean management that utilizes a portfolio of nested, multi-scale, climate-informed and ecosystem-based management approaches in North American waters can increase the resilience of marine ecosystems by addressing multiple stressors simultaneously (Marshall et al., 2018; Holsman et al., 2019; Smale et al., 2019a; Holsman et al., 2020) (*high confidence*). Integrated Ecosystem Assessments (Foley et al., 2013; Levin et al., 2014) are increasingly used to provide strategic advice and context for harvest allocations and bycatch avoidance (Zador et al., 2017) and early warnings of ecosystem-wide change (e.g., sentinel species, ecological indicators) (Cavole et al., 2016; Hazen et al., 2019; Moore and Kuletz, 2019). Dynamic ocean management policies may improve resilience of marine species and ecosystems to climate (Hyrenbach et al., 2000; Maxwell et al., 2015; Dunn et al., 2016; Tommasi et al., 2017a; Tommasi et al., 2017b; Hazen et al., 2018; Wilson et al., 2018; Holsman et al., 2019; Karp et al., 2019) (*medium confidence*). New proactive and rapid management approaches have been developed to minimize impacts of increasingly frequent entanglements of protected species, caused by climate-driven changes in prey and fishery activities (Corkeron et al., 2018; Meyer-Gutbrod et al., 2018). Dynamic closure areas are being used to address these issues and reduce loggerhead turtle bycatch in Hawaiian shallow-set longline fisheries (Howell et al., 2015; Lewison et al., 2015), blue whale ship-strike risk in near-real time (Hazen et al., 2017; Abrahms et al., 2019b), and bycatch of multiple top predator species in a West Coast drift gillnet fishery (Hazen et al., 2018).

Improved coordination and planning at multiple scales will be important for marine species conservation and recovery as species redistribute across fishery areas, marine protected zones, and international and jurisdictional boundaries (Cross-Chapter Box MOVING PLATE in Chapter 5) (Pinsky et al., 2018; Karp et al., 2019) (Section 14.5.4). Indigenous Peoples' co-management with federal and state partners of marine resources and protected species is an important approach (see Section 14.5.4, Chapter 5, Chapter 6, and CCP6) (Galappaththi et al., 2019).

Securing broodstocks for rebuilding and supplementation can be challenging for marine populations already in decline (e.g., blue king crab in Alaska, steelhead salmon in Puget Sound, white abalone in California, most groundfish in Northeast US and Canada) (14.5.4; Table SM14.8). Marine protected areas can attenuate climate impacts through trophic redundancy, preserving ecological processes, biodiversity, and climate refugia (Roberts et al., 2017a; Schoen et al.), although benefits decrease after mid-century (or sooner for high latitude marine protected areas) as species reach their thermal limit, unless coupled with greenhouse gas (GHG) mitigation (Bruno et al., 2018). Transport, relocation and cultivation of resistant breeds of salmon, oysters, corals, marine mammals, and other keystone species as well as hatchery supplementation of impaired populations of fish and shellfish are species conservation and recovery methods that will be in greater demand under climate change, although unintended environmental impacts must be considered. Options for protecting and restoring coral reefs to prevent loss of ecosystem function are under development with Florida reef species (Gattuso et al., 2018; National Academies of Sciences, 2019). An emerging approach for financing the protection of reefs involves re-categorizing reefs as "natural infrastructure" which has allowed for use of insurance to rebuild lost reefs (Storlazzi et al., 2019).

14.5.3 Water Resources

Climate change poses increasing threats to North American aquatic ecology, water quality, water availability for human uses, and flood exposure, through reductions in snow and ice, increases in extreme precipitation, and hotter droughts. Adaptation will be impeded in cases where there are conflicts over competing interests or unintended consequences of uncoordinated efforts, heightening the importance of cooperative, scenario-based water resource planning and governance (*high confidence*).

14.5.3.1 Observed Impacts

North American water resources continue to be affected by ongoing warming, with impacts driven by reductions in snow and ice, increases in extreme precipitation, and hotter droughts (Section 14.2) (Fleming and Dahlke, 2014; Mortsch et al., 2015; Dudley et al., 2017; Fyfe et al., 2017; McCabe et al., 2017; Chavarria and Gutzler, 2018; Lall et al., 2018; Bonsal et al., 2019; USGCRP, 2019) (*high confidence*). The cascading effects of severe droughts, floods, sediment mobilization, harmful algal blooms (HABs) and pathogen contamination episodes have revealed the vulnerability and exposure of large numbers of people and economic activities to those hazards.

North America's dams, levees, wastewater-management and water conveyance facilities have improved water supply safety and have reduced flood and drought risks, but a substantial portion of that infrastructure is aging and inadequate for modern conditions (Ho et al., 2017; Tellman et al., 2018; Carlisle et al., 2019; FEMA, 2019; ASCE, 2021). Increasingly heavy precipitation from a variety of storm types has affected parts of North America (Feng et al., 2016; Prein et al., 2017a; Kunkel and Champion, 2019; Kunkel et al., 2020), contributing to contamination from combined sewer overflows (Olds et al., 2018) and increased flood damages that are partially attributed to anthropogenic climate change (van der Wiel et al.; Davenport, 2021). Extreme precipitation events have overwhelmed water control infrastructure, imperilling public safety and contributing to extensive damages in parts of North America(Kytomaa et al., 2019; Vano et al., 2019; White et al., 2019). Damages stem from extremity of the event and prior land use and infrastructure decisions (*high confidence).*

In South Carolina, five days of heavy rainfall in October 2015 caused the failure of more than 50 dams and some levees, significantly magnifying destruction from the floodwaters (FEMA, 2016). Slow-moving, destructive storms like hurricanes Harvey (2017) and Florence (2018) have caused significant flooding (van Oldenborgh et al., 2017; Paul et al., 2019b). In those cases, urban sprawl may have altered storm dynamics (Zhang et al.), while increased asset exposure to the flood hazard amplified the multi-billion dollar losses (Klotzbach et al., 2018; Trenberth et al., 2018). A substantial fraction of the damage from hurricane Harvey's extreme rainfall has been attributed to anthropogenic climate change (Emanuel, 2017; Risser and Wehner, 2017) (Box 14.5). A near-disaster at California's Oroville dam in 2017 was caused by inadequate infrastructure design and maintenance together with an unusually large number of atmospheric river (AR) storms. The event required emergency reservoir spills while the state was beginning recovery from the extreme 2012–2016 drought (Vano et al., 2019; White et al., 2019).

In Mexico, some poor neighbourhoods and informal settlements are located in areas exposed to recurrent flooding. Residents often lack access to public services and technical resources for risk reduction, which heightens their vulnerability (Castro and De Robles, 2019).

Population growth and urban development have increased the exposure and vulnerability of Canadian communities to flood damages, with cumulative damages (including uninsured losses) exceeding US $10B in the past decade (The Geneva Association et al., 2020). Recurring floods are particularly costly (e.g., New Brunswick (Beltaos and Burrell, 2015; Kovachis et al., 2017)). Floods in High River, AB (2013) and Gatineau, QC (2017, 2019) initiated considerations of building flood resilience including planned retreat (Saunders-Hastings et al., 2020).

Extended and severe droughts in the western US, northern Mexico and Canadian Prairies, exacerbated by higher temperatures, have caused economic and environmental damage (Williams et al., 2013; AghaKouchak et al., 2015; Diaz et al., 2016; Bain and Acker, 2018; Lopez-Perez et al., 2018; Ortega-Gaucin et al., 2018; Xiao et al., 2018; Martinez-Austria et al., 2019; Bonsal et al., 2020; Martin et al., 2020b; Milly and Dunne, 2020; Overpeck and Udall, 2020). Droughts have intensified tensions among competing water use interests and accelerated depletion of groundwater resources (14.5.4) (Pauloo et al., 2020) *(high confidence)*.

Climate trends are affecting riverine, lake and reservoir water quality (*medium confidence*). Droughts and increased evapotranspiration have impaired water quality by concentrating pollutants in diminished water volumes (Paul et al., 2019a). Cyanobacterial blooms and pathogen exposure events are increasing in frequency, intensity, and duration in North America (Taranu et al., 2015). They are closely associated with observed changes in precipitation intensity and associated nutrient loading (e.g., agricultural runoff, sanitary sewer overflows), elevated water temperatures and eutrophication (Michalak et al., 2013; Michalak, 2016; Trtanj et al., 2016; Chapra et al., 2017; IBWC, 2017; Williamson et al., 2017; Olds et al., 2018; Coffey et al., 2019). These events endanger human and animal health, recreational and drinking water uses, aquatic ecosystem functioning, and cause economic losses (Michalak et al., 2013; Bullerjahn et al., 2016; Chapra et al., 2017; Huisman et al., 2018). Households and communities dependent on substandard wells, unimproved water sources, or deficient water provision systems are more *likely* than others to experience climate-related impairment of drinking water quality (14.5.6.5) (Allaire et al.; Baeza et al., 2018; California State Water Resources Control Board, 2021; Navarro-Espinoza et al., 2021; Water and Tribes Initiative, 2021).

14.5.3.2 Projected Impacts and Risks

Climate change is projected to amplify current trends in water resource impacts, potentially reducing water supply security, impairing water quality, and increasing flood hazards to varying degrees across North America (*high confidence*). Examples are presented in Table 14.3.

Table 14.3: Selected Projected Water Resource Impacts in North America.

Climatic Drivers and Processes	Examples of Future Risks/Impacts	Location (see Figure 14.1)	References
Warming-induced reductions in mountain snow and glacial mass	Projected decreases in annual and late-summer streamflow from high-elevation reaches of snow-fed rivers, affecting stream ecology and water supplies, (*high confidence*)	US-NW, US-SW CA-BC, CA-PR	(Jost et al., 2012; Solander et al., 2018; Bonsal et al., 2019; Milly and Dunne, 2020)
Earlier seasonal snowmelt runoff	Greater winter/early spring flooding risks and reduced summer surface water availability, intensifying seasonal mismatch with water demands *(high confidence*), Increased challenges for balancing multi-purpose reservoir objectives (e.g. flood-management, water supply, ecological protection and hydropower) (*high confidence*)	US-NW, US-SW CA-BC, CA-PR,	(Cohen et al., 2015; Dettinger et al., 2015; Bonsal et al., 2019; Bonsal et al., 2020; RMJOC, 2020; Bureau of Reclamation, 2021d)
Earlier seasonal snowmelt runoff	Possible reductions in water supply security *(medium confidence*); Reduced viability of some small-scale irrigation systems *(medium confidence)*	US-SW	(Medellin-Azuara et al., 2015; Ullrich et al., 2018; Bai et al., 2019; Milly and Dunne, 2020; Ray et al., 2020; Bureau of Reclamation, 2021b; Bureau of Reclamation, 2021a; Bureau of Reclamation, 2021c)
Changes in seasonal timing and/or total annual runoff	Impacts on electric power generation *(medium confidence*) varying by location and type of generation	US-SW, US-NW CA-QC	(Haguma et al., 2014; Bartos and Chester, 2015; Guay et al., 2015; Turner et al., 2019b; RMJOC, 2020; Bureau of Reclamation, 2021d)
Changes in seasonal timing and/or total annual runoff	Impacts on urban water supplies	CA-QC	(Foulon and Rousseau, 2019)

Warming-related increased imbalance between renewable surface water supplies and consumptive water demands	Greater pressures on groundwater resources, possible increased aquifer depletion, reduced baseflow into surface streams and reduced long-term water supply sustainability *(medium confidence*)	US-SW, US-SP, US-SE, MX-N, MX-NW	(Bauer et al., 2015; Molina-Navarro et al., 2016; Russo and Lall, 2017; Brown et al.; Nielsen-Gammon et al., 2020; Bureau of Reclamation, 2021b)
Warming-related drought amplification	Reduced water availability for human uses and ecological functioning *(medium to high confidence*) varying by location; increased evaporative losses from reservoirs.	Widespread especially: US-SW, US-NP, US-SP CA-PR MX-NW, MX-N	(Prein et al., 2016; Dibike et al., 2017; Lall et al., 2018; Paredes-Tavares et al., 2018; Martinez-Austria et al., 2019; Tam et al., 2019; Martin et al., 2020b; Milly and Dunne, 2020; Overpeck and Udall, 2020; Williams et al., 2020; Bureau of Reclamation, 2021b)
Heavier and/or prolonged rainfall events	Flooding, infrastructure and property damage *(medium to high confidence*) varying by location; increased erosion and debris flows with impacts on public safety, reservoir sedimentation and stream ecology -- hazards amplified in watersheds affected by wildfires.	Widespread; especially: US-SE, US-NE, US-NP, US-SP, US-SW CA-BC MX-CE; MX-NE; MX-SE	(Feng et al., 2016; Emanuel, 2017; Prein et al., 2017a; Prein et al., 2017b; Haer et al., 2018; Kossin, 2018; Mahoney et al., 2018; Thistlethwaite et al., 2018; Curry et al., 2019; Larrauri and Lall, 2019; Wobus et al., 2019; Ball et al., 2021)
Heavier and/or prolonged rainfall events	Water quality impairment, increasing HAB events due to increased sediment and nutrient loading together with warming. Greatest impacts in humid areas with extensive agriculture *(medium confidence to high confidence*) varying by location.	US-MW, US-NE, US-SE, US-NP, US-SP CA-ON, CA-AT, MX-NE, MX-NW	(Alam et al., 2017; Chapra et al., 2017; Sinha et al., 2017; Ballard et al., 2019)
Increasingly variable precipitation,	Highly variable precipitation poses challenges for water management, worsening water supply and flooding risks. Atmospheric River (AR) events are projected to increase variability by dominating future North American west coast precipitation *(medium confidence)*	US-SW, US-NW, CA-BC	(Gershunov et al., 2019; Huang et al., 2020)
Hotter summer season	Evaporative losses from reservoirs are projected to increase significantly (*very high confidence*)	US-SW, US-NW, US-NP	(Bureau of Reclamation, 2021b)

Projected long-term reduction in water availability in the US Southwest and northern Mexico, e.g., from the Colorado and Rio Grande Rivers, will have substantial ecological and economic impacts given the region's heavy water demands (*high confidence*) (Lall et al., 2018; Paredes-Tavares et al., 2018; Martinez-Austria et al., 2019; Milly and Dunne, 2020; Williams et al., 2020). Increased water scarcity will intensify the need to address competing interests across state and national boundaries, including honouring commitments to Indigenous Peoples who have long struggled with inadequate access to their water entitlements and marginalization in water resource planning (Mumme, 1999; Cozzetto et al., 2013b; Mumme, 2016; McNeeley, 2017; Radonic, 2017; Robison et al., 2018; Curley, 2019; Water and Tribes Initiative, 2020; Wilder et al., 2020).

Increased scarcity of renewable water relative to legally allocated or desired uses may develop in many parts of North America. A detailed analysis of projected water demands (consumptive uses) and availability found increasingly frequent shortages in several watersheds across the United States (Brown et al., 2019b). This might lead to maladaptive increased groundwater mining, or alternatively to policies promoting sustainable balancing of water consumption with renewable supplies, for example by facilitating voluntary water transfers or improving enforcement of groundwater rights (Colorado River Basin Stakeholders, 2015; California Natural Resources Agency et al., 2020; Colorado Water Conservation Board, 2020; Pauloo et al., 2020).

Climate change is projected to reduce groundwater recharge in major US Southwest aquifers (e.g., Southern High Plains, San Pedro and Wasatch Front), exacerbating their ongoing depletion due to unsustainable pumping. Other aquifers, especially those farther north, face uncertain or possibly increasing recharge (Meixner et al., 2016) *(medium confidence*).

Projected changes in temperature and precipitation present direct risks to North American water quality, varying with regional and watershed contexts (Chapra et al., 2017; Coffey et al., 2019; Paul et al., 2019a), and related to streamflow, population growth (Duran-Encalada et al., 2017) and land use practices (Mehdi et al., 2015) (*medium confidence*). HABs increase in frequency across the US (Wells et al., 2015) with the highest risk projected for the Great Plains and Northeast US, and greatest economic impacts from lost recreation value in Southeast US (Chapra et al., 2017).

The diversity of climate regimes across North America results in regional differences in water-related climate change risks (Figure 14.4).

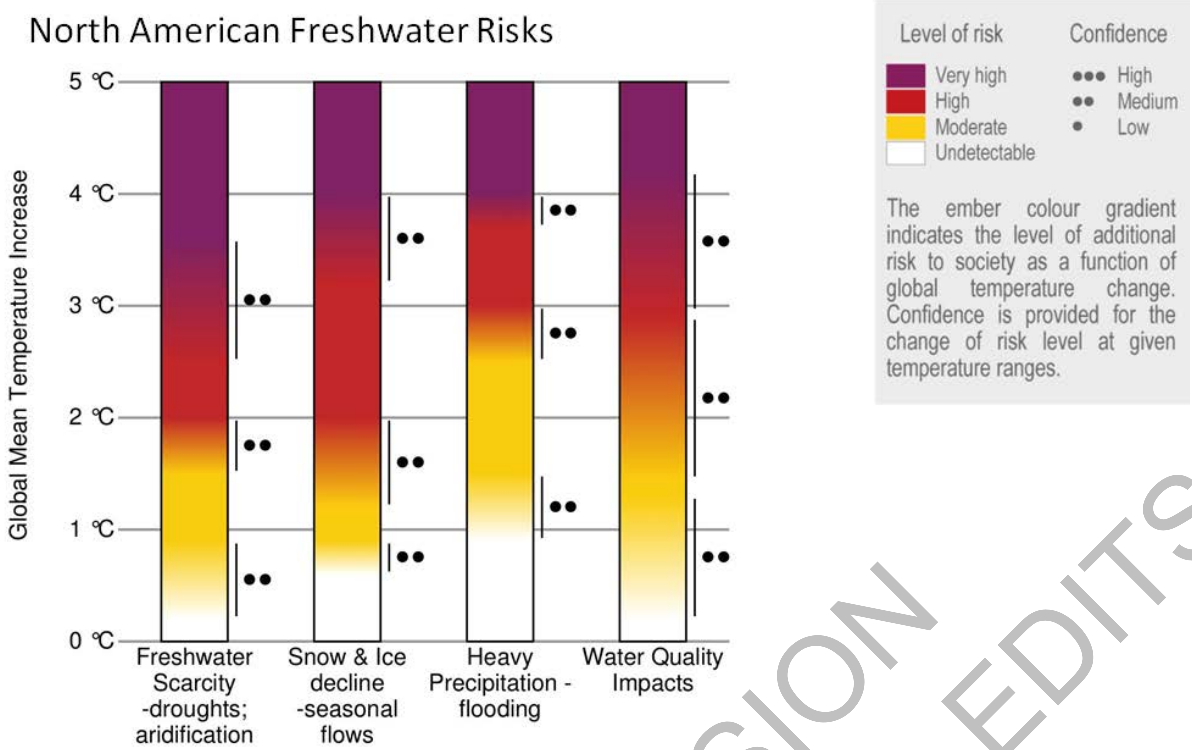

Figure 14.4: Freshwater resource risks as a function of global mean surface temperature increase relative to preindustrial (1850-1900). Estimated sensitivities are based on references cited in Table 14.3, see SM14.4.

14.5.3.3 Adaptation

North American water planners and policy makers have abandoned stationarity assumptions (Milly et al., 2015) to address climate change. Transboundary institutions, government agencies, and professional organizations are taking the lead on adaptation planning and implementation. (ASCE, 2018b; Clamen and Macfarlane, 2018; International Joint Commission (IJC), 2018). Major water agencies are using climate scenarios to identify vulnerabilities and evaluate adaptation options (Yates et al., 2015; Vogel et al., 2016; California Department of Water Resources, 2019; Ray et al., 2020; Bureau of Reclamation, 2021d). The Water Utility Climate Alliance advises municipal water providers, to address uncertainty by considering a wide range of plausible future climate conditions (WUCA, 2010). In some areas, the impacts of wildfires on water supply resiliency are being considered (Martin, 2016). Many North American Indigenous Peoples are engaged in climate change adaptation planning although these efforts may be hampered by the complicated legal and administrative setting in which they must operate (Norton-Smith et al., 2016a; McNeeley, 2017).

Recent climate extremes have heightened governmental attention to climate change impacts (e.g., (California Natural Resources Agency et al., 2020). Droughts have exposed shortcomings in water management and governance (Gray et al., 2015; Xiao et al., 2017b; Lopez-Perez et al., 2018) spurring legislation and administrative changes to improve groundwater regulation and documentation of water rights (California Department of Food and Agriculture, 2017; Miller, 2017; Lund et al., 2018; Hanak et al., 2019).Water allocation policies are being reassessed to enhance equity, sustainability and flexibility through shortage sharing agreements, improved groundwater regulation and voluntary water transfers. Developments include an interstate drought management agreement for the Colorado River (US Law, 2019), and agreements between the US and Mexico to provide pulse flows to benefit the ecology of the Colorado River Delta (Pitt and Kendy, 2017). State-wide water planning in Colorado has emphasized building drought resilience (e.g. by facilitating temporary water transfers) (Colorado State Government, 2015; Yates et al., 2015). At local scales there have been innovations in cooperative watershed protection and water resource planning (Cantú, 2016). Indigenous Peoples are playing an increasing role in identifying equitable and resilient options for adaptation by contributing their knowledge and voicing their perspectives on the importance of healthy water bodies for human and environmental well-being (Norton-Smith et al., 2016a; Water and Tribes Initiative, 2020). Collaboration between stakeholders, policymakers and scientists is increasingly common in water resources adaptation planning and assessment.

Examples of adaptation include increasing adoption of water-saving irrigation methods in California (Cooley, 2016), experimentation with using flood waters to enhance groundwater recharge (Kocis and Dahlke, 2017; California Department of Water Resources, 2018), and agricultural land management programs, including developing riparian buffers to protect water quality (14.5.4) (Mehdi et al., 2015) (Schoeneberger et al., 2017). Indigenous Peoples are building upon traditional practices to adapt to the effects of climate change, for example by working jointly to recharge local aquifers (Basel et al., 2020).

Water right laws, interstate compacts and international treaties regarding transboundary water shape the context for climate change adaptation, but the possibility of long-term climate change typically was not contemplated at their inception. Gaps in coverage and vaguely defined terms can lead to tensions and disputes, especially in areas facing increased aridity, creating difficulties for adaptation. For example, unregulated pumping of groundwater for irrigation during short-term droughts can serve as an adaptation to acute conditions, (14.5.4) but if persisting long-term, can deplete finite groundwater resources and dewater hydrologically connected rivers. Such outcomes have engendered bitter and costly interstate conflicts in the US, some reaching the US Supreme Court including *Texas v New Mexico* (Rio Grande) and *Florida v. Georgia* (Apalachicola-Chattahoochee-Flint).

Trans-boundary rivers that exemplify the need to address climate impacts include the Colorado (Gerlak et al., 2013), Columbia (Cosens et al., 2016), and Rio Grande/Rio Bravo (Mumme, 1999; Mumme, 2016; Garrick et al., 2018; Payne, 2020). Drought emergencies can open opportunities for progress on collaborative adaptive governance, but such windows may quickly close when wetter conditions return (Sullivan, (2019).

Water serves a wide variety of environmental functions and human uses as it moves through North America's river basins, so the impacts of climate change are expected to be widespread and multifaceted. This increases the importance of collaborative adaptation efforts that are equitable, transparent and give voice to differing values, perspectives, and entitlements across a broad socioeconomic spectrum of urban and rural, Indigenous and non-Indigenous participants (Miller et al., 2016; Cosens et al., 2018). Adaptation planning may be hampered by conflicting interests, jurisdictional boundaries, and inherent interconnections between actions and impacts at different points throughout a watershed or river basin. Differential power relationships, decision-making authority and access to information also can interfere with effective adaptive governance, while equitable processes for decision-making bolstered by reliable shared information can help to overcome those impediments (Cosens et al., 2016; Arnold et al., 2017; Cosens et al., 2018; Porter and Birdi, 2018).

Across North America, there are growing signs of progress toward adaptive water governance and implementation of climate-resilient, and ecosystem-based, water management solutions (Colorado River Basin Stakeholders, 2015). California's approach to groundwater sustainability regulation intends to foster such collaborative problem-solving by giving local Groundwater Sustainability Agencies the authority to design locally appropriate plans to meet state-defined sustainability goals (State of California, 2014; Miller, 2017). As evidenced by the US interstate disputes, the greatest difficulties arise in cases where stark upstream-downstream differences in interests leave little room for mutual benefit. Severe aridification may test the limits of adaptive capacity.

Research on water diplomacy recommends broadening negotiations beyond a narrow focus on zero-sum issues, like rigid water allocations, to embrace a more diverse set of shared interests including the need for flexibility to respond to changing conditions. A process for ongoing inclusive engagement of a watershed's stakeholders in mutual social, policy and science learning is important. Such mutual learning can build trust and establish a common platform of credible information for co-creation of adaptation solutions. In addition, better understanding of the policy positions and constraints of others can help stakeholders to identify workable solutions to contentious water management issues (Payne, 2020; Wilder et al., 2020). Cooperation between Mexico and the US on mapping and assessment of transboundary aquifers is a product of such ongoing engagement (Callegary et al., 2018; Sanchez et al., 2018). Other examples of the benefits of sustained engagement are provided by a set of co-management arrangements between state, federal and Indigenous authorities on water management for fishery restoration in the US Pacific Northwest (Tsatsaros et al., 2018), and Indigenous involvement in multi-level co-management of water resources in Canada's Northwest Territories (Latta, 2018).

14.5.4 Food, Fibre, and Other Ecosystem Products

14.5.4.1 Observed Impacts and Projected Risks: Agriculture, livestock, and forestry

Climate change has affected crops across North America through changes in growing seasons and regions, extreme heat, precipitation, water stress, and soil quality (Table 14.1, 5.4.1; Figure 5.3) (Mann and Gleick, 2015; Galloza et al., 2017; Otkin et al., 2018). These changes directly influence crop productivity, quality and market price (*high confidence*) (Kistner et al., 2018; Reyes and Elias, 2019). Effects of historical climate change on maize, soybean, barley and wheat crop yields vary from strong increases to strong decreases (e.g. >-0.5 to >+0.5 t ha-1yr-1 for maize) within North America's agroecological regions, even for the same crop (Ray et al., 2019). Across North America, climate change has generally reduced agricultural productivity by 12.5% since 1961, with progressively greater losses moving south from Canada to Mexico (Ortiz-Bobea et al., 2021), yet responses are highly differential across regions and crops. Some crop loss events are partially attributed to climate change (*high confidence*) such as the 2012 Midwest and Great Plains drought, which cost agriculture USD$30B (Smith and Matthews, 2015; Rupp et al., 2017). Aridity is extending northward, altering crop suitability ranges (Fig 14.4); up to 50% of distributional shifts in growing regions for US crops between 1970-2010 may be related to climate change (Lant et al., 2016; Cho and McCarl, 2017). Irrigation is expanding to areas formerly largely dependent on rainfall (Wang et al., 2018b).

Without adaptation, climate change is projected to reduce overall yields of important North American crops (e.g., wheat, maize, soybeans) (*high confidence*) (Chen et al., 2017; Levis et al., 2018) (Tables SM14.3-4). For example, projected heat stress (RCP8.5) reduced midcentury (2040–2069) maize and cotton yields by 12-15% of historical yields (1950–2005), with the US-SW suffering the largest impacts (Elias et al., 2018) (Table SM14.5). Warming and heat extremes will delay or prevent chill accumulation, affecting perennial crop development (e.g. fruit set failure), yield (e.g., walnuts, pistachios, stone fruit), and quality (e.g. grapes) (*medium confidence*) (Parker et al., 2020). Warming will alter the length of growing seasons of cold-season crops (e.g., broccoli, lettuce) and will shift suitability ranges of warm-season California crops (e.g., tomatoes) (*medium confidence*) (Marklein et al., 2020). Increasing atmospheric CO_2 will enhance yields yet reduce nutrient content of many crops (*high confidence*); a CO2 concentration of 541 ppm (seen by 2050 in RCP 8.5) would reduce per capita nutrient availability in North American diets by 2.5–4.0% (Beach et al., 2019). Crop pest and pathogen outbreaks are expected to worsen under climate change (*high confidence*) (Deutsch et al., 2018; Wolfe et al., 2018; Zhang et al., 2019a).

Climate change is anticipated to cause declines in livestock production across North America (*high confidence;* Table 14.4 & SM14.6) (Havstad et al., 2018; Murray-Tortarolo et al., 2018); increases in extreme temperature raise the risk of livestock heat stress, disease, and pest impacts (Rojas-Downing et al., 2017). Projected aridification reduces forage production in the Southwest US and Northern Mexico (*high confidence*) (Polley et al., 2013; Reeves et al., 2014; Cooley, 2016; Bradford et al., 2020) and transforms grasslands to woody shrublands (Briske et al., 2015; Murray-Tortarolo et al., 2018), while warmer and wetter conditions in the northern regions (CA-PR, US-NW, US-NP) may enhance rangeland production by extending growing seasons (*high confidence*) (Hufkens et al., 2016; Derner et al., 2018; Zhang et al., 2019a). Increased CO_2 will enhance production (*medium confidence*), but reduce forage quality (*high confidence*) in US-NP and US-NW (Table SM14.6) (Derner et al., 2018).

Climate change impacts on forests (14.5.1, Box 14.2) may affect timber production by altering tree species distributions, productivity, and wildfire and insect disturbances (*medium confidence*). Southern or drier locations may shift from forests to other vegetation types, whereas higher latitude areas may experience forest expansion (Brecka et al., 2018). Tree species composition is projected to change with climate change (Wang et al., 2015; Bose et al., 2017). Tree growth may increase or decrease from changes in temperature or moisture depending on location, with lower growth expected from warming in water-limited areas (Littell et al., 2010). Increased productivity associated with more favourable climate conditions is projected for boreal forests (Brecka et al., 2018), although in some regions, growth will reverse and decline with additional warming (D'Orangeville et al., 2018; Chaste et al., 2019). As a result of these changes, timber yields in North America may increase in the future (Beach et al., 2015; EPA, 2015a) or decrease (Boulanger et al., 2014; McKenney et al., 2016; D'Orangeville et al., 2018; Thorne et al., 2018; Chaste et al., 2019) depending on location and mechanisms included. Wildfires and insect outbreaks are projected to increase with future climate change, thereby limiting biomass (Gauthier et al., 2015; Bentz et al., 2019; Chaste et al., 2019).

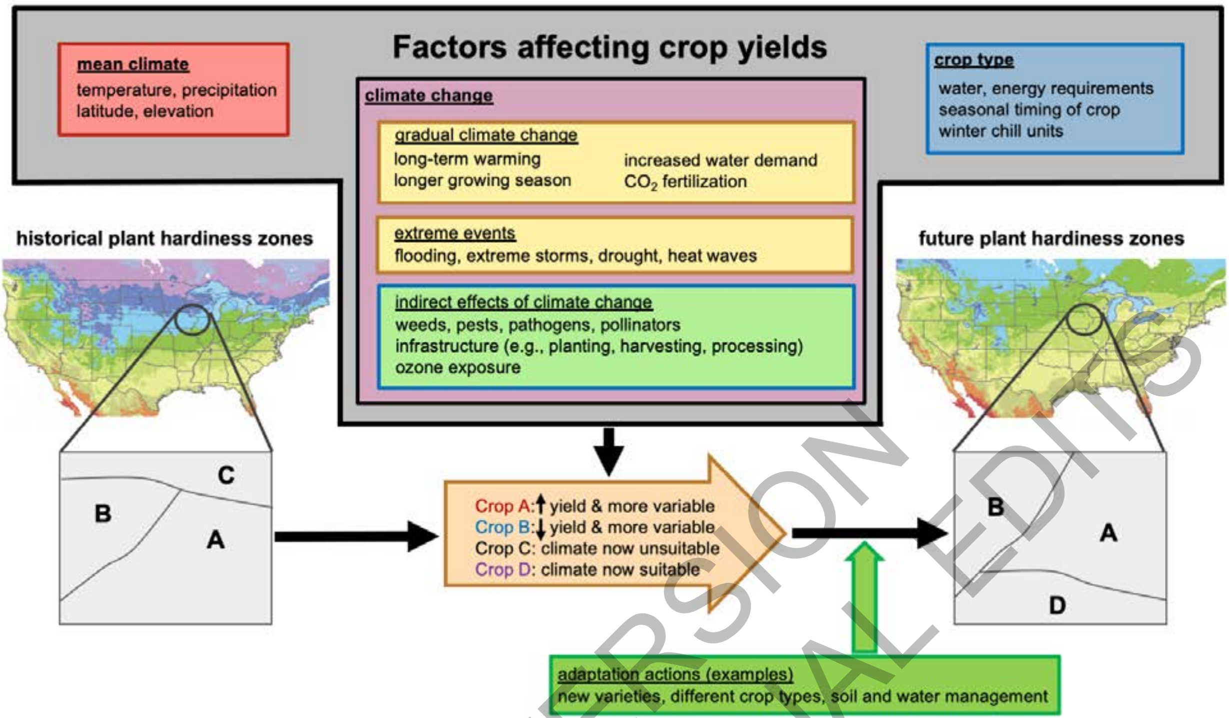

Figure 14.5: Crop responses to climate change will depend on existing mean climate, the type of climate change, and characteristics of crop types. Hypothesized responses for Crop Types A, B, C, and D include changing crop yields or changing crop area. Adaptation actions may alter hypothesized responses; maps from Matthews et al. (2019)

14.5.4.2 Observed Impacts and Projected Risks: Fisheries and Aquaculture

Climate impacts outlined in Section 14.5.2 have induced yield losses for multiple subsistence, recreational, and commercial fisheries (*very high confidence*) and contributed to commercial fishery closures across North America (Figure 14.6, Table SM14.7, 14.5.1, 14.5.3) (Lynn et al., 2014; Barbeaux et al., 2020; Fisher et al., 2021). Climate-driven declines in productivity are widespread (*high confidence*) (Figure 14.6), although a few increases are observed in northern regions (*medium confidence*) (Cunningham et al., 2018; Crozier et al., 2019; Zhang et al., 2019b). Redistribution of species has increased travel distance to fishing grounds, shifted stocks across regulatory and international boundaries, and increased interactions with protected species (*very high confidence*) (Cross-Chapter Box MOVING PLATE in Chapter 5) (14.5.2) (Morley et al., 2018; Free et al., 2019; IPCC, 2019c; Rogers et al., 2019; Stevenson and Lauth, 2019; Young et al., 2019) (Figure 14.6, Table SM14.7). Climate shocks have reduced yield and increased instability in fishery revenue (*high confidence*) (Fisher et al., 2021).

Declines in yield and poleward stock redistributions (avg. ~20.6 km decade^{-1}) are expected to continue under climate change, and increase in magnitude with atmospheric carbon (*high confidence*) (Table 14.4) (Hare et al., 2016; Pecl et al., 2017; Rheuban et al., 2017; Morley et al., 2018; Smale et al., 2019a; Szuwalski et al., 2021). For example, without adaptation, end of century losses of Bering sea pollock yield (relative to persistence scenarios) is *likely* to reach 50% under moderate (RCP4.5) and 80% under low (RCP8.5) mitigation scenarios, respectively (Holsman et al., 2020). Expanding HABs, pathogens, and altered ocean chemistry (OA and dissolved oxygen) will reduce yields and increase closures of fisheries along all North American coasts (*medium confidence*) (14.5.2) (Deutsch et al., 2015a; Ekstrom et al., 2015; Seung et al., 2015; Punt et al., 2016; Howard et al., 2020). For fisheries that represent 56% of current US fishing revenue, projected annual net losses under high emission scenarios (RCP 8.5; 2021-2100) may reach double that of low emission scenarios (RCP2.6) (Moore et al., 2021).

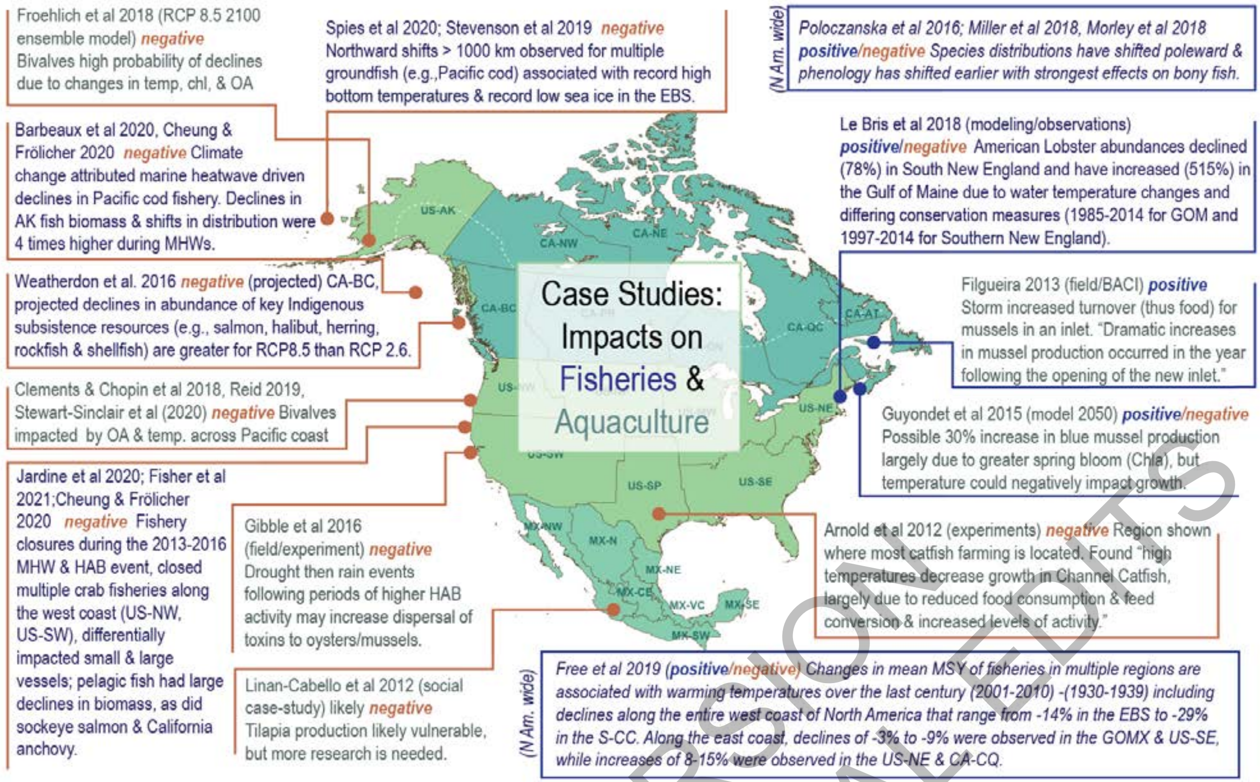

Figure 14.6: Climate change impacts on North American fisheries and aquaculture

Warming waters and OA have impacted aquaculture production in North America (*high confidence*) (Figure 14.6) (Clements and Chopin, 2017; Reid et al., 2019; Stewart-Sinclair et al., 2020). Under climate change (RCP8.5), declines in marine finfish and bivalve aquaculture become *likely* by mid-century (Froehlich et al., 2018; Stewart-Sinclair et al., 2020). Adaptation is possible but uncertain (Bitter et al., 2019; Fitzer et al., 2019; Reid et al., 2019), especially with increasing extreme events. Nature-based aquaculture solutions (e.g., conservation aquaculture, restorative aquaculture) could aid carbon mitigation and local-level adaptation, especially for seaweed and bivalve culture (Box 14.7) (Froehlich et al., 2017; Froehlich et al., 2019; Reid et al., 2019; Theuerkauf et al., 2019).

Table 14.4: Observed and projected impacts to food and fibre resources.

Climate Driver	Observed Change[1]	Reference	Projected change	Reference
Agriculture and livestock (Tables SM14.2-5)				
Extreme events	Estimates of yield reduction from heat stress for both maize and cotton indicate that historically, US-SW heat stress reduced cotton yield by 26% and maize yield by 18% compared to potential yield. Extreme heat was associated with increased crop failure in MX-CE, US-SW; Hailstorm increased frequency observed in MX coinciding with the most vulnerable stage or flowering period of maize; extreme precipitation damages to soil, increased erosion, and reduced crop yields observed in MX and US-MW	(Altieri and Nicholls, 2009; Mastachi-Loza et al., 2016; Elias et al., 2018; Kistner et al., 2018; Reyes and Elias, 2019)	Projected heat stress (RCP8.5) reduces midcentury (2040–2069) maize and cotton yields by 12-15% of historical yields (1950–2005) with largest impacts in US-SW additional drought-related stress in US-MW could reduce maize and soybean yields by ~5% and ~10%, respectively, by late century under RCP 4.5 ; warming and extreme heat (>35%) will delay (or prevent) chill accumulation, impacting perennial crop development, yields, and quality (US-SW). Increases in extreme temperature raise the risk of livestock heat stress, disease, and pest impacts.	(Jin et al.; Rojas-Downing et al., 2017; Elias et al., 2018; Parker et al., 2020)
Mean growing season precipitation decline, mean temperature increase, drought	Across the US Great Plains (US-SP, US-NP) between 1968-2013 climate change induced 3.55%, -0.55%, and 0.94% change in yield for (irrigated and non-irrigated) maize, sorghum and soybeans (respectively); Droughts and increasing temperatures reduced soil fertility in MX and contributed to soil erosion and degradation and suitability loss of 18-22%; Experimental and simulated reductions in water supply of 25-50% result in similar magnitude declines in yield for multiple food and forage crops (e.g., wheat, maize)	(Frisvold and Konyar, 2012; Leskovar et al., 2012; Aladenola and Madramootoo, 2014; Galloza et al., 2017; Havstad et al., 2018; Kukal and Irmak, 2018)	Warming alters the length of growing seasons of cold-season crops and shifts suitability ranges of warm-season California crops; aridification reduces forage production US-SW, MX-N; warming is associated with reduced livestock growth and fertility, increased pathogens in US-SE, US-SP, US-MW, US-NE, and reduced milk production in US-MW.	(St-Pierre et al., 2003; Polley et al., 2013; Key and Sneeringer, 2014; Reeves et al., 2014; Cooley, 2016; Hristov et al., 2018; Ortiz-Colón et al., 2018; Bowling et al.; Bradford et al., 2020; Marklein et al., 2020) (Hufkens et al., 2016; Derner et al., 2018; Zhang et al., 2019b)
Multiple drivers	Climate change reduced total factor productivity of agriculture and livestock in North America by 12.5% (ranging from approx. -35% to +8%) between 2016-2015; losses have been greatest in Mexico (-30% to -25% Figure5), and lowest in Canada (>0%);Reduced yield in MX, US; increased weed, pest pressure in US-NE, US-MW, US-NP, US-NW	(Garruña-Hernández et al.; Loreto et al.; Wolfe et al., 2018; Torres Castillo et al., 2020; Ortiz-Bobea et al., 2021)	Projected declines in yield and changes of in suitability ranges for maize (-18%-+5%), sorghum (-16 to +12%), and wheat (-38 to -15%) in MX (RCP 4.5, 8.5; 2040-2099); northward shifts in the suitable area for 6 crops from the central US (2100); Warming accompanied by increased CO_2 may benefit crop production of small grains in southern Canada up to 3 ºC GWL, although benefits decline after 2.5ºC GWL. Increased CO_2 enhances production but reduces forage quality US-NP,US-NW. Without adaptation, 2ºC GWL	(Calderón-García et al.; Herrera-Pantoja and Hiscock; Lant et al., 2016; Chen et al., 2017; Montiel-González et al.; Reyer et al.; Derner et al., 2018; Deutsch et al., 2018; Levis et al., 2018; López-Blanco et al.; Murray-Tortarolo et al.; Wolfe et al., 2018; Gomez Diaz et al.; Qian et al.; Zhang et al., 2019b; Arce Romero et al.)

			increased insect-caused production losses ~36% and~44% for maize and wheat, respectively.	
Aquaculture and fisheries (Tables SM14.6, SM14.8)				
Extreme events	MHW and HAB event of 2014-2016 resulted in multiple fishery closures along the west coast (US-NW, US-SW); disparate impacts observed between small and large vessels with greatest impacts on small vessel revenue and fishery participation; impacts were highest for ports in the CC-N and least for fishing communities with diverse livelihoods and harvest portfolios; In the EBS, GOA, and N-CC, declines in fish biomass and shifts in distribution were 4 times higher and greater during MHWs than that of general warming over the same period; pelagic fish showed largest decrease in biomass (7%), as did Sockeye salmon and California anchovy; Increased risk to hatcheries and low lying pond systems from severe storms. Extreme heat is associated with reduced productivity of aquaculture species.	(Handisyde et al., 2017; Food Agriculture Organization of the United Nations; Froehlich et al., 2019; Reid et al., 2019; Bertrand et al., 2020; Cheung and Frölicher, 2020; Jardine et al., 2020; Sippel et al., 2020; Fisher et al., 2021)	Projected doubling of MHW impact levels by 2050 amongst the most important fisheries species (over previous assessments that focus only on long-term climate change)	(Cheung and Frölicher, 2020)
Multiple drivers	Climate shocks reduce catch, revenue and county-level wages and employment among commercial harvesters in US-NE; climate variability 1996 - 2017 is responsible for a 16% (95% CI: 10% to 22%) decline in county-level fishing employment in New England; impacts mediated by local biology and institutions; Seafood is an important source of nutrients and protein for Indigenous Peoples in CA-BC; polices that incorporate nutrition in fisheries management are limited in North America	(Marushka et al., 2019; Oremus, 2019) (14.5.6 Health)	Declines in North American catch potential of flatfish are projected under RCP8.5 for the EBS, GOA, GOMX, US-SE, and US-NE; declines in productivity projected for multiple species in MX, with largest declines in productivity (>35%) for abalone and pacific sardine; Impacts are greatest for artisanal species ; projected declines in fish community biomass for all North American coasts except US-SW and the Canadian Arctic; declines are greater under RCP8.5 than RCP2.6. Modest increases (up to 10%) in landings of CA-QC and CA-AT surf clams and shrimp are projected under RCP2.6 by 2100 while declines in snow crab up to 16% are expected (RCP2.6,8.5); Mussel landings projected to increase 21%., while declines in shellfish and lobster landings (2090) are twice as high under RCP 8.5 (42%-54%) as RCP 2.6.	(Weatherdon et al., 2016; Cheung, 2018; Carozza et al., 2019; Cisneros-Mata et al.; Reum et al., 2019; Tai et al., 2019; Mendenhall et al., 2020; Wilson et al., 2020)

			Shellfish, snow crab landings projected to decline in CA-QC and CA-QT; declines under RCP 8.5 are double that of RCP 2.6; Climate change reduces EBS blue king crab recovery in simulations; Relative to US and CA, MX has strongest benefits in net catch under RCP2.6 relative to RCP8.5 (>30% increase in catch); increases of 70% in catch potential projected for the Canadian Arctic (CA-NE,CA-NW) under RCP 8.5 (versus minimal changes under RCP2.6); high resolution and size spectrum models project declines in groundfish catch and biomass in S-EBS; shifting transboundary stocks may increase challenges.	
Ocean and lake acidification	OA reduced maximum sustainable yield, catch and profits of EBS Tanner crab in simulations; survival of larval and juvenile red king crab (RKC) in the lab decreased 97-100% with decreasing pH;No appreciable effects of pH on larval growth of walleye pollock in the lab (Hurst, 2013); Mixed evidence of impacts of changes in pH on freshwater or saltwater finfish aquaculture; OA reduced growth, calcification, attachment and increased mortality in calcifying molluscs and seaweeds in US, CA; OA may benefit non-calcifying seaweeds.	(Long et al., 2013a; Seung et al., 2015; Punt et al., 2016; Clements and Chopin; Handisyde et al., 2017; Swiney et al., 2017; Food Agriculture Organization of the United Nations; Froehlich et al.; Reid et al., 2019; Stewart-Sinclair et al.)	Projected declines for some shellfisheries and flatfish due to OA and temperature; OA conditions under RCP 8.5 reach critical risk thresholds for mollusc harvests earlier in northern regions than southern areas; OA risk to shellfisheries is highest in N-CC;OA caused 1% additional decline in Arctic cod populations by 2100 under RCP8.5;OA influences management reference points of Northern Rock sole. OA and temperature reduce probability of recovery in simulations of EBS blue king crab.	(Ekstrom et al., 2015; Reum et al., 2019; Steiner et al., 2019; Wilson et al., 2020; Punt et al., 2021)
Mean temperature increase	Species distributions have shifted poleward and phenology has shifted earlier with strongest effects on bony fish. Warming over the last century (2001-2010) - (1930-1939) is associated with declines in MSY along the entire west coast of North America that range from -14% in the EBS to -29% in the CC-S. Along the east coast, declines of -3% to -9% were observed in the GOMX and US-SE, while increased of 8-15% were observed in the US-NE and CA-CQ. Mixed positive and negative growth and mortality responses for aquaculture species in North America; Juvenile red king crab survival decreases as temperatures increase in lab experiments . American Lobster abundances	(Poloczanska et al., 2016; McCoy et al., 2017; Swiney et al., 2017; Le Bris et al., 2018; Miller et al., 2018; Food Agriculture Organization of the United Nations; Free et al., 2019; Froehlich et al.; Reid et al., 2019; Weiskerger et al., 2019; Bertrand et al., 2020; Le et al., 2020)	By end of century, North America fish biomass, catch potential and revenue are ~9% higher in RCP 2.6 than RCP 8.5 and differences are greatest for US fisheries (relative to CA, MX; Projected poleward redistributions (reported ranges of 10.3 to 39.1 km decade^{-1}) and to depth decrease access to shellfisheries in CA-QC and subsistence species in CA-BC (-28% by 2100), with impacts increasing N to S and under RCP 8.5 as compared to RCP 2.6.; Climate change (RCP8.5) is projected to shift the relative % of catch and profits for US - Canada transboundary stocks under RCP8.5 (but not RCP2.6). Projected decreases in biomass of historically large fisheries US-NA and CA-QC, and US-AK	(Weatherdon et al., 2016; Cheung, 2018; Froehlich et al., 2018; Morley et al., 2018; Greenan et al., 2019b; Steiner et al., 2019; Sumaila et al., 2019; Bryndum-Buchholz et al., 2020; Holsman et al., 2020; Palacios-Abrantes et al., 2020; Reum et al., 2020; Sumaila and Zwaag, 2020; Whitehouse and Aydin, 2020; Wilson et al., 2020)

declined (78%) in South New England and have increased (515%) in the Gulf of Maine due to water temperature changes and differing conservation measures (between 1985 and 2014 for GOM and 1997 and 2014 for Southern New England).	and important subsistence species in CA-WA and CA-BC, while some increases in the North Atlantic; Declines are greater under RCP 8.5 relative to RCP 2.6; in EBS (US-AK) community biomass, catches, and mean body size decreased by 36%, 61%, and 38%, respectively under RCP 8.5 (2100). Climate change causes projected declines in global marine aquaculture production under RCP 8.5 with impacts greater for bivalve than finfish and with significant disparities among regions in direction and magnitude of changes; greatest declines for finfish aquaculture expected in Northern regions (GOA, CA-BC, CA-CQ), and large declines for bivalve production (declines of 20-100%) for Canada. Declines become more probable by 2050-2070.

14.5.4.3 Food and Fibre Adaptation: Cross Cutting Themes

Across food and fibre systems, climate resilience is enhanced through diversifying income and harvest portfolios and increasing local biodiversity and functional redundancy (*high confidence*) (Messier et al., 2019; Rogers et al., 2019; Young et al., 2019; Aquilué et al., 2020; Fisher et al., 2021). Ecosystem-based practices and sustainable intensification (increasing yields while minimizing resource demand and ecosystem impacts) (Cassman and Grassini; Rockström et al., 2021) will help the sector meet food production demands under climate change (*medium confidence*), but effectiveness generally declines and is less certain after 2050 in scenarios without carbon mitigation (*high confidence*) (Bermeo et al., 2014; Gaines et al., 2018; Costello et al., 2020; Free et al., 2020; Holsman et al., 2020). Across the sector, successful adaptation is underpinned by approaches that meaningfully consider the coupled social-ecological networks around food and fibre production and value Indigenous Knowledge (*very high confidence*) (Box 14.1) (FAO, 2018; Steele et al., 2018; Calliari et al.). Integrated modeling, participatory planning and inclusive decision making promote effective and equitable adaptation responses (*very high confidence*) (Figure 14.7, 14.7) (Toledo-Hernández et al., 2017; Eakin et al., 2018; Monterosso and Conde, 2018; Alexander et al., 2019; Hodgson and Halpern, 2019; Holsman et al., 2019; Samhouri et al., 2019; Barbeaux et al., 2020; Hollowed et al., 2020), while a paucity of high resolution and locally tailored climate change information remains a barrier to adaptation (Ekstrom et al., 2015; Donatti et al., 2017; Young et al., 2019).

Figure 14.7: Adaptation in North American food sectors modified from Cottrell et al. (2019).

14.5.4.4 Food and Fibre Adaptation: Agriculture, Livestock, and Forestry

Land management and horticulture approaches that preserve and improve soil structure and organic matter can reduce erosion (*high confidence*) (Section 14.5.1, 3) (Lal et al., 2011; Bisbis et al., 2018), and preserving biodiversity and water, changing planting dates, and double cropping are effective climate adaptation strategies (Bisbis et al., 2018; Hernandez-Ochoa et al., 2018; Monterroso-Rivas et al., 2018; Wolfe et al., 2018). Traditional agriculture inherently includes climate adaptive practices that enhance biodiversity, soil quality and agricultural production (e.g., multiple cultivars, heat-tolerant heritage cattle breeds) (Bermeo et al.; Gomez-Aiza et al., 2017; Ortiz-Colón et al., 2018). Agroecology and agroforestry (Box 14.7) in North America has expanded from (but not replaced) traditional and rural practices in Mexico (Metcalfe et al., 2020a) as a sustainable and climate-resilient alternative to industrial agriculture (Schoeneberger et al., 2017) that increases productivity (by 6-65% depending on the crop), enhances microclimatesand provides co-benefits for GHG mitigation (Abbas et al., 2017; Cardinael et al., 2017; Schoeneberger et al., 2017; Snapp et al., 2021). Irrigation is an effective adaptation strategy in key agricultural areas (Miller, 2017; Lund et al., 2018) and could stabilize food security in rain-fed regions (e.g., southeastern Mexico) (Spring, 2014); water allocation must balance multiple needs and rights (*medium confidence*) (14.5.3) (Brown et al., 2015b; Levis et al., 2018; Gomez Diaz et al., 2019). Heritage livestock breeds, changing species, and precision ranching technology may promote ranch and rangelands resilience (Zhao et al., 2013). In loblolly pine plantations in the southern US, effective adaptation includes reducing tree density and, less effectively, shifting to slash pine (Susaeta et al., 2014). Salvage logging following forest disturbances (e.g., insect outbreaks) can increase timber harvest (Bogdanski et al., 2011; USDA Forst Service, 2011; Han et al., 2018; Morris et al., 2018a).

14.5.4.5 Food and Fibre Adaptation: Fisheries and Aquaculture

Proactive and ecosystem-based management increases climate resilience in fisheries (*high confidence*) but effectiveness after 2050 may be limited without global carbon mitigation (*medium confidence*) (Gaichas et al., 2017; Gaines et al., 2018; Kritzer et al., 2019; Barbeaux et al., 2020; Free et al., 2020; Holsman et al., 2020). Flexibility (e.g., mobility, diverse incomes or harvest portfolios) underpins climate resilience across regions, management policies, and fisheries, although small-scale fisheries have less scope for adaptation (Aguilera et al., 2015; Young et al., 2019). Climate-informed and dynamic management (Hazen et al., 2018) improves modeled fishery performance (*medium confidence*) (see section 14.5.2) (Froehlich et al., 2017; Tommasi et al., 2017a; Tommasi et al., 2017b; Karp et al., 2019; Barbeaux et al., 2020), yet planning and policies that directly incorporate climate change information remain limited (Skern-Mauritzen et al., 2015; Marshall et al., 2019b). Expanding aquaculture across North America will *likely* address deficits in nutritional and protein yields (Gentry et al., 2019; Costello et al., 2020), yet aquaculture initiatives have largely progressed without explicitly considering climate impacts (FAO, 2018; Froehlich et al., 2019) and critical elements for climate adaptation (e.g., climate-informed zoning, monitoring, insurance) are not widely implemented (Liñan-Cabello et al.; FAO, 2018 ; Stewart-Sinclair et al., 2020). Climate-informed and standardized aquaculture governance, and increased coordination with fishery and coastal management, is needed for climate resilience (*high confidence*) (Brugère et al., 2019; Froehlich et al., 2019; Free et al., 2020; Galparsoro et al., 2020).

14.5.5 Cities, Settlements and Infrastructure

Cities are complex social-ecological systems with large populations, concentrated wealth, ageing infrastructure, reliance on extrinsic and increasingly stressed natural systems, social inequality, differential institutional capacities, and impervious, heat-retaining surfaces (Maxwell et al., 2018a; Schell et al., 2020). These factors interact with location (e.g., proximity to coast, in a flood plain) to create city-specific vulnerabilities to climate change and requirements for resilience initiatives (Mercer Clarke et al., 2016). Cities are home to diverse cultural and social communities, including large Indigenous populations, who can be uniquely affected by climate change yet who bring valuable IK and leadership to urban adaptation efforts (Statistics Canada, 2020; Brown et al., 2021). The rural and remote settlements of North America also experience similar hazards and risks, but due to different factors such as geographic isolation, dependence on local food resources, and socioeconomic conditions (Kearney and Bell, 2019; Vodden and Cunsolo, 2021).

14.5.5.1 Observed Impacts

14.5.5.1.1 Rising temperatures and extreme heat

Extreme heat events are affecting natural assets and built infrastructure as well as individuals in cities and rural settlements across North America (*high confidence*) (Maria Raquel et al., 2016; Amec Foster Wheeler Environment and Infrastructure, 2017; Howell and Brady, 2019; Martinich and Crimmins, 2019). Key urban infrastructure systems (e.g., services in buildings, energy distribution) are interdependent and susceptible to cascading impacts (e.g., electricity supply disruption during a heat wave compromising another system like water delivery, high-rise cooling) (Brown et al., 2021). Urban social inequality and systemic racism has led to disproportionately higher exposure to urban heat island effects in low-income and minority neighbourhoods in US cities, due in part, to less green space and tree cover to offset heat retained in the built environment (Hoffman et al., 2020; Schell et al., 2020; Hsu et al., 2021). In the rural context, extreme heat contributes to migration out of small communities (e.g., cases reported in Mexico (Nawrotzki et al., 2015a)). Extreme heat events pose a significant risk to residents of small towns across North America due to limited resources to address heat impacts and attendant increased morbidity and mortality (McDonald et al., 2016; Guo et al., 2018; D'ulisse, 2019) (See 14.5.6.1).

Hot and dry conditions increase risk of wildfires close to human settlements through collateral impacts on properties, economic activity and human health (Box 14.2, 14.5.6.3). These environmental conditions also stress natural assets (e.g., urban forests, wetlands, household gardens, green walls) and performance of green infrastructure leading to higher operation and maintenance costs (*high confidence*) (Kabisch et al., 2017; Terton, 2017).

14.5.5.1.2 Storms and flooding

Short-duration, high-intensity rainfall and other extreme events (e.g., hurricanes, atmospheric river events) create significant flooding risks and impacts for cities in North America and negatively affect the lives, livelihoods, economic activities, infrastructure, and access to services (*high confidence*) (Amec Foster Wheeler Environment and Infrastructure, 2017; Curry et al., 2019). In 2016, US flooding events caused 126 fatalities and US$11B (2016) in damages (NOAA, 2019). In Canada, flooding accounts for 40% of the costs associated with weather-related disasters recorded since 1970 (Canadian Institute for Climate Choices, 2020); the most costly event was the 2013 Calgary flood (*CA-PR*) (CAD$1.8B in catastrophic insurance losses and CAD$6B in direct costs such as uninsured losses) (Office of the Auditor General of Canada, 2016). Mexico City is seasonally impacted by high-intensity rainfall events that generate local flooding (de Alba and Castillo, 2014). Rural and remote settlements are also threatened by floods; Indigenous lands in Canada are disproportionately exposed to flooding, with almost 22 % of residential properties at risk of a 100-year flood (Thistlethwaite et al., 2020a; Yumagulova, 2020).

Wind storms and hurricanes are significant climate hazards for North American cities and settlements, affecting urban forests, electricity distribution and service delivery, and damaging buildings and transportation infrastructure (Amec Foster Wheeler Environment and Infrastructure, 2017; British Columbia Hydro, 2019; Smith, 2020), with enduring impacts on small villages due to lost livelihoods and limited recovery capacity (e.g., Rio Lagartos and Las Coloradas in Mexico (*MX-SE*) after Hurricane Isidore) (Audefroy and Cabrera Sánchez, 2017). The Pacific coast of Mexico is also experiencing hurricanes such as Patricia (Category IV) in 2015 and Newton (Category I) in 2016 (CONAGUA, 2015; CONAGUA, 2016); hurricane Patricia affected 56 municipalities in the states of Colima, Nayarit and Jalisco (*MX-CE, MX-NW*) (Calleja-Reina, 2016).

14.5.5.1.3 Sea level rise

SLR interacts with shoreline erosion, storm surge and wave action, saline intrusion, and coastal flooding to directly threaten coastal cities and small communities in North America with impacts to public and private buildings and infrastructure, port and transportation facilities, water resources (*high confidence*) (NOAA National Weather Service, 2017; Boretti, 2019), and cultural heritage sites (Dawson et al., 2020) (Box 14.4). SLR is creating conditions where considerable financial investments are needed and, in many cases, are being raised to address adaptation needs (Fatorić and Seekamp, 2017; Hinkel et al., 2018; Greenan et al., 2019a) (see Box 14.4, CCP6). Across North America, high population density and concentrated development along the coast generates exposure to SLR impacts.

14.5.5.2 Projected Impacts and Risks

Evidence since the AR5 highlights increased risk to quality of life in cities and rural communities as a result of exposure to intensifying climate change hazards, and the compounding and interacting effects of climate and non-climate factors (*medium confidence*).

14.5.5.2.1 Rising temperatures and extreme heat

Extreme heat events are projected to increase in frequency and intensity across North America in the coming decades (14.2.2, Figure 14.2(F),(G)). Inland urban areas in southern and eastern US are susceptible to urban heat island effects, particularly the Midwest/Great Lakes regions (Krayenhoff et al., 2018) and Mexico City and many other cities in Mexico (Vargas and Magaña, 2020). Climate change (RCP8.5) interacting with urban form, development and systemic racism (Schell et al., 2020; Hsu et al., 2021), could worsen risks from extreme heat in North American cities, especially where there is limited adaptation *(high confidence*) (Krayenhoff et al., 2018). Impacts from extreme heat will be exacerbated when multiple hazards occur simultaneously (e.g., heat waves concurrent with droughts) (Mora et al., 2018; Zscheischler et al., 2018). Extreme heat events increase energy demand for space cooling in buildings, especially during peak demand periods and heat waves (IEA, 2018a). This can decrease cooling efficiency, increase emissions of GHG from electricity generation, increase refrigerant loads and associated emissions, and negatively affect air quality (IEA, 2018a). Major electrical grid failure (i.e., "blackouts") have increased across the US, and will continue to be particularly dangerous for human health when they coincide with extreme heat events (Stone et al., 2021). Efforts to increase resilience of the infrastructure that cities rely on are increasing (Climate-Safe Infrastructure Working Group, 2018)

Warmer and/or drier conditions may reduce water supply reliability for cities and small communities that rely on surface water sources fed by rain or snowmelt runoff (e.g., Victoria and Vancouver, Canada (*CA-BC*) (Metro Vancouver, 2016; Vadeboncoeur, 2016; Islam et al., 2017); San Pedro, Hermosillo and Los Pargas, Aguascalientes, México (*MX-NW, MX-CE*) (Vadeboncoeur, 2016; Soto-Montes-de-Oca and Alfie-Cohen, 2019); New York City, (*US-NE*) (N. Y. C. Department of Environmental Protection, 2014) and Washington State (*US-NW*) (Fosu et al., 2017) (see 14.5.3.2).

14.5.5.2.2 Storms and flooding

Annual and winter precipitation is expected to increase for most of Canada (14.2, Figure 14.2(D), (E)) and will increase flooding in cities and settlements (Bonsal et al., 2019) (*high confidence*). Although there is more geographical variation across the continental US (e.g., between high-latitude and subtropical zones), extreme precipitation events are projected to increase in frequency and intensity with impacts on flood hazards (Easterling et al., 2017) (14.5.3.2). Winter (snow and ice) storms are expected to increase in northern North America and decrease in southern North America under RCP 8.5 (Jeong and Sushama, 2018b). Projected increases in wind-driven rain exposure is an emerging consideration for moisture-resilient design and management of buildings, especially in western and northern Canada (Jeong and Cannon, 2020).

14.5.5.2.3 Sea level rise

In the US, many people are projected to be at risk of flooding from SLR (*high confidence*) (Box 14.4). A projected SLR of 0.9m by 2100 could place 4.2 million people at risk of inundation in US coastal counties, whereas a 1.8-m SLR exposes 13.1 million people (Hauer et al., 2016). In California, under an extreme 2-m SLR by 2100, US$150B (2010) of property or more than 6% of the state's GDP and 600,000 people could be affected by flooding (Barnard et al., 2019). A 1-m SLR would inundate 42% of the Albemarle-Pamlico Peninsula in North Carolina and incur property losses of up to US$14B (2016) (Bhattachan et al., 2018). In nine southeast US states, a 1-m SLR would result in the loss of more than13,000 recorded historical and archaeological sites with over 1,000 eligible for inclusion in the National Register for Historic Places (Anderson et al., 2017). SLR raises groundwater levels by impeding drainage and enhancing runoff during rain events (Hoover et al., 2017); coastal flooding enhances saltwater intrusion affecting drinking water supply in settlements (e.g., coast of Texas) (Anderson and Al-Thani, 2016).

In Canada, SLR is expected to increase the frequency and magnitude of extreme high water-level events (Greenan et al., 2019a) and to create widespread impacts on natural and human systems *(high confidence*) (Lemmen et al., 2016) (Box 14.4). Although coastal sensitivity is high in the Arctic, Canada's more populated regions are also sensitive to the impacts of SLR (Manson et al., 2019). The Mi'kmaq community of Lennox Island First Nation is exploring relocation options because of erosion from SLR (Savard et al., 2016).

In Mexico, crucial coastal tourism cities such as Cancun, Isla Mujeres, Playa del Carmen, Puerto Morelos and Cozumel (*MX-SE*) are at risk of SLR with an estimated economic impact of US$1.4 –2.3B (Ruiz-Ramírez et al., 2019) (14.5.7.1.12). Negative effects of the "coastal squeeze" phenomena (generated by SLR, land subsidence, sediment deficit, and current urbanization processes) have been documented on tourist destinations along the coasts of Mexican Gulf of Mexico and Mexican Caribbean. Zoning, limiting urbanization along the coastline, and using nature-base solutions (Box 14.7) are alternatives that could be applied to improve the adaptation of these destinations (Martínez et al., 2014; Salgado and Luisa Martinez, 2017; Lithgow et al., 2019).

Rural low-lying coastal areas are at risk from SLR where natural barriers or shoreline infrastructure are deteriorating and this interacts with remoteness, resource-dependent economies, and socioeconomic challenges to adaptive capacity (Bhattachan et al., 2018; Manson et al., 2019). The Northeast Atlantic region of North America (*CA-AT, US-NE*) is exposed to high risk by combined effects of land subsidence and climate-driven SLR (Lemmen et al., 2016; Sweet et al., 2017; Fleming et al., 2018; Greenan et al., 2018) (Box 14.4).

14.5.5.3 Adaptation

In North American cities, present-day adaptation responses extend beyond the traditional focus on infrastructure to include measures aimed to protect people, property, and ecosystems (*medium confidence*). Barriers to adaptation include challenges related to the local physical and environmental setting, effects of colonialism and racism, socioeconomic attributes of the population, institutional frameworks, and competing interests of city stakeholders (*medium confidence*). Current scale of adaptation is generally not commensurate with reducing risks from projected climatic hazards, although resources exist that provide guidance and examples of effective adaptation *(medium confidence*). Some remote Canadian communities have demonstrated strengths (e.g., strong social networks) that support resilience to climate change (Kipp et al., 2020; Vodden and Cunsolo, 2021). In some US cities with political resistance to action on climate change, adaptation measures focused on addressing extreme events (rather than climate change impacts) were able to make progress (Hamin et al., 2014). Enhanced public awareness of the risks from extreme events associated with climate change is important for motivating adaptation (Howe et al., 2019) (14.3) and developing a climate change agenda (Aragón-Durand, 2020).

Community-level planning tailors adaptation responses and disaster preparedness to the local context but misalignment of policies within and between levels of government can prevent implementation (Oulahen et al., 2018). Coordination, planning, and national support are needed to provide sufficient financial resources to implement climate-resilient policies and infrastructure (USGCRP, 2018) (see 14.7.3).

Public health measures to address extreme heat events are more common across North America, with a focus on vulnerable populations (e.g., City of Toronto, 2019) and innovative approaches for reaching at-risk populations with an overarching intent of prevention (*medium confidence*) (Guilbault et al., 2016) (14.4.6.1). The heatwave plan for Montreal includes visits to vulnerable populations, cooling shelters, monitoring of heat-related illness, and extended hours for public pools (Lesnikowski et al., 2017); efforts have reduced heat wave-related mortalities (Benmarhnia et al., 2016).

Other adaptation responses to reduce temperature effects include modifying structures (roofs, engineered materials) and the urban landscape through green infrastructure (e.g., urban trees, wetlands, green roofs), which increases climate resilience and quality of life by reducing urban heat effects, while additionally improving air quality, capturing stormwater, and delivering other co-benefits to the community (e.g., access to food, connection to nature, social connectivity) (Ballinas and Barradas, 2016; Emilsson and Sang, 2017; Kabisch et al., 2017; Krayenhoff et al., 2018; Petrovic et al., 2019; Schell et al., 2020) (Box 14.7) (*high confidence*). Green infrastructure can be flexible and cost-effective (Ballinas and Barradas, 2016; Emilsson and Sang, 2017; Kabisch et al., 2017). Initiatives can be “bottom-up” community-led adaptation with support from municipal governments, (e.g., East Harlem, New York City) (Petrovic et al., 2019). Valuing municipal natural assets (e.g., assigning economic value to cooling from urban forests or stormwater retention by urban wetlands) is becoming increasingly common in Canada and the US (Wamsler, 2015; Roberts et al., 2017a; Municipal Natural Assets Initiative, 2018). Guidance assists municipalities to identify, value, and account for natural assets in their financial planning and asset management programs (O'Neil and Cairns, 2017) and consider future climate (Municipal Natural Assets Initiative, 2018).

Meeting increasing demand for indoor space cooling with equitable access, requires new approaches to providing cooling (e.g., equipment efficiencies, refrigerants with lower global warming potential) and electricity production and transmission innovation (Shah et al., 2015; IEA, 2018a). While energy efficiency and building code standards are not directly established by local governments, they can encourage behaviour change via incentives (e.g., rebates on efficient equipment) or disincentives (e.g., more onerous permit approvals).

Experiences with droughts, heat waves and other weather extremes has led many municipal water managers to accept the importance of building resilience to the risks of future water shortages and costs posed by climate change (Metro Vancouver, 2016; Misra et al., 2021; WUCA, 2021). In the US SW, water utilities have introduced demand-management programs to encourage water conservation (e.g., tiered pricing, incentives for water-efficient appliances and fixtures, and rewards for replacing water-guzzling lawns with water-thrifty native vegetation) (Luthy et al., 2020; Baker, 2021) (14.5.3.3). Water providers also have increased their adaptive capacity by diversifying water sources (Hanak et al., 2015).

Adaptation to the risks of wildland-urban interface fire is underway (Kovacs et al., 2020) (Box 14.2) but the scope of adaptation required to sufficiently minimize wildfire risks for cities and settlements across North America has not been assessed (*medium confidence*). Leadership at the local level is increasingly supported by federal resources that provide guidance on hazard and exposure assessment, property protection, community resilience and emergency planning (National Research Council of Canada, 2021).

Cities and settlements in North America can be susceptible to multiple flooding hazards (i.e., coastal SLR, pluvial, fluvial); each presents unique adaptation challenges that can be addressed through structural (e.g., armouring coastlines, reservoirs, levees, floodgates; New York City commuter tunnels) and non-structural approaches (e.g., land use planning and zoning, expanding green infrastructure; Chetumal, Mexico) (Hardoy et al., 2014) (*high confidence*). Green infrastructure practices (Box 14.7) (e.g., open space preservation, floodplain restoration, urban forestry, de-channelization of streams) can reduce urban flooding, erosion, and harmful runoff (Kovacs et al., 2014; Angel et al., 2018b; Government of Canada, 2021c). Structural approaches have limitations and require trade-offs that could be addressed with a focus on socio-ecological solutions and stronger institutional coordination (e.g., flood risk management in Mexico City) (Aragón-Durand, 2020). In response to high intensity rainfall events, Mexico City invested in stormwater infrastructure, although additional benefits could have been realized if water supply needs had been incorporated (de Alba and Castillo, 2014). Some programs exist to facilitate stormwater and wastewater infrastructure updating to accommodate increased precipitation across North America. The US federal Clean Water State Revolving Fund, provides low-interest loans for states to upgrade infrastructure for climate change, with US$42B provided since 1987 (ASCE, 2019). In Canada, local governments are important leaders in managing engineered and green infrastructure decisions, incentivizing property-level flood protection, and ensuring service delivery (Government of Canada, 2021c). The civil engineering profession is playing an active role in facilitating an understanding of risks and prioritization of adaptation investments in communities (Tye and Giovannettone, 2021).The high concentration of valuable assets in cities requires mechanisms to facilitate replacement of assets including use of existing and proposed insurance mechanisms (14.7) *(medium confidence*).

Adaptation planning and implementation to address SLR and coastal flooding has been initiated across cities and settlements in North America but varies in preparedness (*high confidence*) (Box 14.4). Efforts are supported by SLR design guidelines. In Canada, the Government of British Columbia provided SLR projections for 2050 (i.e., +0.5m) and 2100 (i.e., +1m) in order to initiate community vulnerability and risk assessment, and adaptation planning (The Arlington Group Planning + Architecture Inc et al., 2013). Based on recent hurricane impacts in Yucatan, Mexico, recommendations to enhance the rules governing the Mexican Recovery Program included incorporating local and Indigenous knowledge when rebuilding houses and other structures on coasts (Audefroy and Cabrera Sánchez, 2017). Where adaptation in-place is insufficient, planned retreat is being considered as an sustainable option for reducing future risks (Saunders-Hastings et al., 2020).

[START BOX 14.4 HERE]

Box 14.4: Sea Level Rise Risks and Adaptation Responses for Selected North American Cities and Settlements

Approximately 95 million Americans lived in coastal communities in 2017 (US Census Bureau, 2019) and in 2013, Canada had roughly 6.5 million coastal residents (Lemmen et al., 2016), while Mexico had 19 million people living in coastal municipalities in 2015 (Azuz-Adeath et al., 2018). Sea level rise around North American coastlines (Figure Box14.4.1) is projected to be greatest along the coasts of Atlantic Canada, northern Gulf of Mexico for the US, and the Pacific coast of Mexico (IPCC, In Press). Sections 14.5.2.1, 14.5.5.1.3, 14.5.5.2.3 describe SLR impacts. Status of adaptation to SLR by local governments is variable (see Table Box 14.4.1, where progress is indicated by colour coding) and ranges from financed implementation to preliminary/preparatory/scoping studies and workshops. Adaptation planning and implementation to address SLR and coastal flooding have been initiated across many cities and settlements in North America but preparedness varies (*high confidence*).

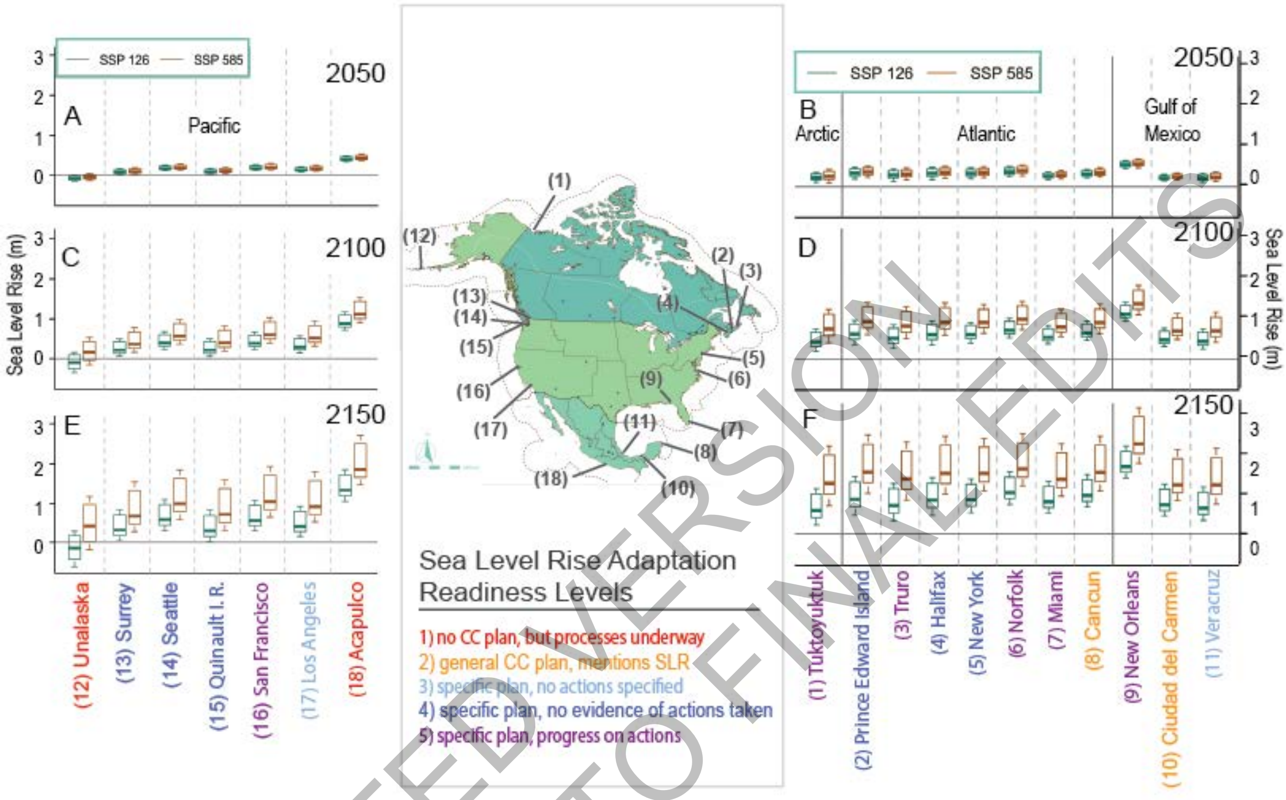

Figure Box 14.4.1: Sea Level Rise (SLR) projections for 2050, 2100 and 2150 for selected North American cities. Projections changes are relative to 2005, which is the central year for the 1994-2014 reference period. Horizontal lines in the boxes represent the median projection, boxes represent 25th to 75th percentile and whiskers the 10th to 90th percentile of SLR projections from all CMIP6 models as well as other lines of evidence (see Table 9.7 in WGI.9 for more details). Two SLR scenarios are provided for lower (SSP 126) and higher emissions (SSP 585), and are consistent with WGI AR6 Interactive Atlas. Numbers and colors (see Table Box14.4.1 for detailed readiness definitions) on the map and in the projections represent sites and status of SLR adaptation progress. Information supporting SLR adaptation status is summarized in Table Box14.4.1.

Table Box14.4.1. Status of adaptation actions associated with locations on SLR map, colour-coded according to level of SLR preparedness through Adaptation (as discoverable on government websites): No climate change adaptation action plan but processes underway such as workshops, studies, vulnerability assessments (red), General Climate Change Adaptation Action Plan which mentions SLR as a risk/issue/impact but no concrete actions developed (orange), Specific Plan for SLR but does not include specific actions (light blue), Specific Plan for SLR with concrete actions identified but no evidence of actions taken to date (med blue), and Specific Plan for SLR with evidence of progress on taking actions including allocating funding for projects (purple).

Ocean Basin	Site #	Area/City	Exposure (not exhaustive)	Does the area/city have an Adaptation Plan for SLR? If so, are they taking actions to implement it? (Status)
Arctic	1	Tuktoyuktuk, CA	Infrastructure, municipal services, transportation, homes, 900 people	Tuktoyaktuk Coastal Erosion Study completed March 2019. Additional investments in both planning and actual adaptation measures have occurred. Limited financial resources remain a barrier. (Government of Canada, 2020)

Atlantic	2	Prince Edward Island with Lennox Island, CA	PEI: residential, industrial and commercial infrastructure. Lennox Island: 10 out of 79 homes, causeway to the island, sacred grounds, sewage treatment systems	Prince Edward Island government released a five year climate change action plan in 2018 which includes both adaptation and mitigation (Prince Edward Island Government, 2018). Biennial progress reports were issued (Prince Edward Island Government, 2019). The Mi'kmaq community of Lennox Island First Nation has explored relocation options (Daigle et al., 2015).
	3	Truro, CA	A regional centre of 12,000 residents, which has been vulnerable to repeated floods for decades.	Town of Truro, County of Colchester and Millbrook First Nations commissioned a flood risk study 2014–2017 (CBCL, 2017; Sherren et al., 2019) triggered by the 2012 flooding. Outcome was Truro-Onslow dyke project -- a voluntary retreat with realignment of dyke infrastructure and habitat restoration by conversion of agricultural land into salt marsh habitat (Saunders-Hastings et al., 2020).
	4	Halifax, CA	Transportation causeways and bridges, marine facilities, municipal infrastructure.	HalifACT 2050 is a comprehensive plan adopted as of 2020 by the Halifax regional council which includes reducing GHGs and adapting to climate change including a coastal preparedness section 5.2.9. (Halifax Regional Council, 2020)
	5	New York, US	20 million people at risk by 2050; 40% of water treatment plans will be compromised by flooding, 60% of power plants will need to be relocated, transportation systems will need to be upgraded to avoid flooding	New York City has developed many adaptation plans for sustaining NYC in light of SLR and other climate hazards/impacts, especially since Hurricane Sandy affected the city in 2012. It is unclear how much of the planning has moved forward into implementation (NYC, 2013; New York City, 2015; NYC Mayor's Office of Resiliency, 2020).
	6	Norfolk, US	Homes, massive US naval base, shipyards, active waterfront, and deep water ports	City of Norfolk published a very specific Coastal Resilience Strategy in 2014. Capital improvement projects highlighted in this strategy have been funded (City of Norfolk Virginia, 2014). Plan for protecting Naval base and shipyard not evident.
	7	Miami, US	Homes, port, transportation infrastructure, tourism (hotels, restaurants, beaches)	Miami Dade County released a specific SLR Strategy in 2021. Actions in the plan include elevating roads and other infrastructure, designing ways to accommodate more water in and around buildings, building on higher ground and expanding waterfront parks and canals. The plan includes a map with current and planned adaptation projects in the county (Miami-Dade County, 2021).
	8	Cancun, MX	Tourism infrastructure (hotels, restaurants, beaches), homes, markets, service industry, transportation.	2013 Climate Change plan assigns adaptation in general to different government levels. No evidence of specific adaptation plan for SLR (Government of Quintana Roo, 2013)
Gulf of Mexico	9	New Orleans, US	Entire city, especially low-lying, low-income areas, is vulnerable as evidenced by Hurricane Katrina in 2005.	City of New Orleans adaptation is incorporated in the broader Louisiana coastal climate change adaptation plan (CPRA, 2023). The process includes very specific projects with updates on risk based implementation.
	10	Ciudad del Carmen, MX	Freshwater access, 11,000 homes, aquaculture	The Campeche State Climate Change plan was released in 2013 (Government of Campeche, 2013). The plan does not include any specific recommended actions to adapt to SLR in Cuidad del Carmen. Flood risk maps for Ciudad del Carmen were created in 2011 (Audefroy, 2019).

	11	Veracruz, MX	Freshwater access, sewage treatment systems, electrical and petrochemical industries	State of Veracruz published a Climate Change plan in 2008 (Government of Veracruz, 2008). Plan includes specific tables of actions needed to monitor and adapt to SLR. World Bank funded coastal adaptation in Veracruz focused on mangroves to dissipate storm surge but no investments in infrastructure to mitigate SLR.
Pacific	12	Unalaska, US	Loss of cultural resources, salinization of rivers/lakes,	Climate Change Adaptation and Vulnerability Assessment Workshops have been held with discussion of coastal erosion. SLR not viewed as important as impacts from sea ice and permafrost loss (Poe et al., 2016).
	13	Surrey (Greater Vancouver Area),CA	Disruption in flow of goods in/out of Port of Vancouver, communication facilities, road, rail and air transportation infrastructure, businesses and agriculture.	Surrey has a Coastal Flood Adaptation Strategy (CFAS) approved by Council (City of Surrey, 2019) with 46 actions (policy and program, local area infrastructure). Some local area infrastructure improvements received capital funding.
	14	Seattle, US	Low-lying areas, near-shore habitats, stormwater drains, roads, homes, businesses, socially vulnerable communities.	Seattle released a Climate Change Response Plan in 2017 which includes general approaches including development of risk maps for SLR which are also available online (City of Seattle, 2017).
	15	Quinault Indian Reservation (Tahola), US	650 residents and buildings.	Quinault Indian Reservation has a plan to move Tahola to higher ground, one half mile from the existing village (EPA, 2021).
	16	San Francisco, US	37,200 residents, 17,200 businesses and 167,300 jobs are vulnerable to inundation by 2100 at upper bounds of SLR, mostly along the bay side of the city.	SF has an active, SLR planning process as well as an iterative Sea Level Rise Action Plan (City of San Francisco, 2016), planning tools and iterative assessment (City and County of San Francisco, 2020).The process specifically addresses wastewater, water, transportation, power, public safety, open space, port, neighborhoods and changing shoreline.
	17	Los Angeles, US	Power plants, wastewater treatment plants, Port of Los Angeles, beaches, tourism	Los Angeles has commissioned a projected SLR impact report but not an action plan. The Port of Los Angeles is particularly vulnerable and, as of 2019, has a SLR Adaptation Plan (Newbold et al., 2019).
	18	Acapulco, MX	Tourism infrastructure (hotels, restaurants beaches), homes, markets, service industry, transportation.	No climate change plan exists although the Mexican Tourism Sector conducted a climate change vulnerability assessment covering Acapulco (Guerrero, 2017).

[END BOX 14.4 HERE]

14.5.6 Health and Wellbeing

Research examining climate change impacts on human health in North America has increased substantially since AR5 (Harper et al., 2021a). Using a systematic approach (Harper et al., 2021b), the assessment focused on advancements since AR5.

14.5.6.1 Heat-Related Mortality and Morbidity

High temperatures currently increase mortality and morbidity in North America (*very high confidence*), with impacts that vary by age, gender, location, and socioeconomic factors (*very high confidence*). Observed increases in heat-related mortality have been attributed to climate change in North America (Vicedo-Cabrera et al., 2021). Temperature effects on health vary based on how unusual the temperature is for that time and location (*medium evidence, high agreement*), highlighting the important role that temperature extremes and variability play in mortality and morbidity (Li et al., 2013; Lee et al., 2014; Barreca et al., 2016; Allen and Sheridan, 2018). Adaptation has played an important role in reducing observed heat-related deaths (Vicedo-Cabrera et al., 2018b).

Rising temperatures are projected to increase heat-related mortality across emission scenarios this century in North America (*very high confidence*), although the magnitude of increase varies geographically (Isaksen et al., 2014; Petkova et al., 2014; Wu et al., 2014; Weinberger et al., 2017; Anderson et al., 2018a; Limaye et al., 2018; Marsha et al., 2018; Morefield et al., 2018). The elderly (Isaksen et al., 2014; Limaye et al., 2018) and urban areas (Limaye et al., 2018) are projected to experience the greatest increase in heat-related mortality this century. Warming temperatures are also projected to increase heat-related morbidity (*medium confidence*). For instance, the incidence and treatment costs of asthma attributed to warmer temperatures are projected to increase in Texas by 2040-2050 (A1B) (McDonald et al., 2015).

While heat-related mortality is projected to increase across emissions scenarios and shared socio-economic pathways, fewer deaths are projected under both lower emissions scenarios and higher adaptation scenarios in North America (*very high confidence*). Heat-related mortality was projected to be 50% less under RCP4.5 compared to RCP8.5 in the US for SSP3 and SSP5 (Wu et al., 2014; Marsha et al., 2018) (Table 14.5).

Table 14.5: A summary of adaptation options for different health outcomes in North America.

Health outcome	Adaptation Options
Heat-related mortality and morbidity	Future temperature-related health impacts can be reduced by adaptation measures (Petkova et al., 2014; Wu et al., 2014; Mills et al., 2015b; Kingsley et al., 2016; Anderson et al., 2018b; Marsha et al., 2018; Morefield et al., 2018), including more effective warning and response systems and building designs, enhanced pollution controls, urban planning strategies, and resilient health infrastructure (*very high confidence*) (Figure Box 14.7.1).
Wildfire-relate mortality	Air quality indices are correlated with many respiratory conditions (Yao et al., 2013; Hutchinson et al., 2018), suggesting that providing air quality information to the public could reduce smoke-related health impacts (Yao et al., 2013; Rappold et al., 2017). Enhanced coordination between the health sector and fire suppression agencies can also reduce the health impacts of wildfire smoke via improving communication, weather forecasting, mapping, fire shelters, and coordinated decision making (Withen, 2015), including transnational and cross-jurisdictional actions.
Vectorborne disease	Prevention of vectorborne disease currently involves surveillance, reducing environmental risks, and promoting individual behaviours to reduce human-vector contact. Top ranked Canadian West Nile interventions include individual protection (i.e., window screens, wearing lightly coloured clothing), and regional management and mosquito-targeting interventions (i.e., larvicides, vaccination of animal reservoirs, modification of human-made larval sites) (Hongoh et al., 2016).
Waterborne disease	Climate change is projected to increase waterborne disease risks (*medium confidence*), particularly in areas with aging water and wastewater infrastructure in North America (*high confidence*). In Wisconsin, US, precipitation changes are projected to increase gastrointestinal illness in children this century (A1B, A2, B1) (Uejio et al., 2017). Slight reductions in precipitation-associated gastrointestinal illness is projected if water treatment infrastructure is upgraded slowly over time; however, if water treatment infrastructure is installed more rapidly, large decreases in precipitation-associated gastrointestinal illness incidence are projected (Uejio et al., 2017), highlighting the benefits of rapidly implementing adaptation actions.
Foodborne disease	Food safety programs play important roles in reducing the risk of climate-related foodborne disease (*high confidence*). Integrated health surveillance, more stringent refrigeration temperature controls to limit pathogen growth, targeted communication to public and food sector, and enhanced coordination between health and food sectors can reduce risk (Hueffer et al., 2013; Jones et al., 2013; Fillion et al., 2014; Doyle et al.,

	2015). In Mexico, the projected risk of Vibrio parahaemolyticus in oysters was 11 times higher in a high emissions scenario compared to a low emissions scenario by the end of the century; however, this risk could be substantially lowered with adaptation measures, including improving temperature control (Ortiz-Jiménez, 2018).
Mental health	Effectiveness of individual and/or group therapy, and place-specific mental health infrastructure, to treat mental health challenges is well-proven; yet, there is limited evidence evaluating these interventions within the context of climate change (e.g. Tschakert et al., 2017; Young et al., 2017b; Cunsolo and Ellis, 2018).

14.5.6.2 Cold-Related Mortality

Winter season mortality rates are generally high in high income regions such as North America, with most of that mortality due to cardiovascular diseases (Ebi and Mills, 2013). It is important to differentiate between mortality related to cold temperatures and mortality due to other factors that vary with season (Ebi and Mills, 2013; Ebi, 2015). Warmer temperatures do not always equate to lower winter mortality: many cold-related deaths do not occur during the coldest times of year or in the coldest places (*high confidence*) but occur during the beginning or end of the winter season (Barnett et al., 2012; Lee et al., 2014; Schwartz et al., 2015; Sarofim et al., 2016b; Smith and Sheridan, 2019). Warmer US cities generally experience more mortality from extreme cold events and cold temperatures than colder cities in the US and Canada (Lee et al., 2014; Gasparrini et al., 2015; Schwartz et al., 2015; Wang et al., 2016; Smith and Sheridan, 2019). While mortality rates linked to direct cold-exposure (e.g. hypothermia, falls, and fractures) is generally low, the relatively higher mortality during milder temperatures is thought to be largely due to respiratory infections and cardiovascular impacts (Lee et al., 2014; Gasparrini et al., 2015), which, although correlate with temperature, may not be caused by cold temperatures (Ebi and Mills, 2013; Ebi, 2015; Sarofim et al., 2016a). When separating the effects of cold temperatures from the effects of the winter season, one study found cold temperature did not drive mortality and suggested that winter season excess mortality was due to seasonal factors other than temperature (e.g. influenza, seasonal gatherings) (Kinney et al., 2015).

Mortality attributed to cold temperatures has increased in the US and remained stable in Canada from 1985-2012 despite increasing winter temperatures (Vicedo-Cabrera et al., 2018b). Some attenuation in cold-related mortality in Mexico and warmer US states is projected under climate change, but less so in colder climates in north-eastern US and Canada, with statistically insignificant trends in some regions and increasing cold-related mortality in other regions (Li et al., 2013; Mills et al., 2015b; Schwartz et al., 2015; Sarofim et al., 2016a; Wang et al., 2016; Gasparrini et al., 2017; Vicedo-Cabrera et al., 2018a; Lee et al., 2019). These reductions in cold-mortality are generally considered relatively small.

Observed and projected trends in winter mortality highlight that non-climate factors may have a greater role in driving winter mortality than cold temperature, and that these deaths are expected to occur with or without climate change (Ebi and Mills, 2013; Ebi, 2015; Sarofim et al., 2016a). This challenges the assumption that warmer winters due to climate change would dramatically lower winter season mortality (*medium evidence, medium agreement*).

14.5.6.3 Wildfire-Related Morbidity

Smoke from intensified wildfire activity in North America is associated with respiratory distress (*very high confidence*), and persists long distances from the wildfire and beyond the initial high-exposure time period (Hutchinson et al., 2018)(Box 14.2). Exposure to wildfire smoke increases hospital admissions (McLean et al., 2015; Alman et al., 2016; Reid et al., 2016; Yao et al., 2016; Rojas-Downing et al., 2017). Increased wildfire smoke from climate change is projected to result in more respiratory hospital admissions in the Western US by 2046-2051 (A1B) (Liu et al., 2016; Rojas-Downing et al., 2017).

The magnitude of health risks varies by age (Le et al., 2014; Reid et al., 2016; Liu et al., 2017a; Liu et al., 2017b), gender (Delfino et al., 2009; Rojas-Downing et al., 2017), socio-economic conditions (Henderson et al., 2011; Rappold et al., 2012; Reid et al., 2016), and underlying medical conditions (Liu et al., 2015). The intersectionality of these subgroups plays an important role in health-related vulnerability to wildfire smoke.

Among the elderly in the western US, risks of respiratory admissions from wildfire smoke was significantly higher for African American women in lower-education counties (Liu et al., 2017b). For Indigenous Peoples, medical visits for respiratory distress, heart disease, and headaches increased during a wildfire in California (Lee et al., 2009). In Northern Canada, Indigenous livelihoods were disrupted during a wildfire, which negatively impacted mental, emotional, and physical health (Dodd et al., 2018a; Howard et al., 2021).

14.5.6.4 Vectorborne Disease

Climate change creates conditions that enable earlier seasonal activity and general northern expansion of ticks (Ogden et al., 2014), increasing human exposure to tickborne diseases in North America (*very high confidence*). Lyme disease incidence and geographic extent has already increased in Canada and the US (Eisen et al., 2016), which has been associated with climate change (Ogden et al., 2014), including warmer temperature (Cheng et al., 2017; Lin et al., 2019). Climate change is projected to increase disease spread into new geographic regions, lengthen the season of disease transmission, and increase tickborne disease risk in North America across emissions scenarios throughout this century (*very high confidence*), with regional variability (Roy-Dufresne et al., 2013; Feria-Arroyo et al., 2014; Monaghan et al., 2015; Robinson et al., 2015; McPherson et al., 2017). Chagas disease is transmitted by triatomines, and most of the Mexican population (88.9%) already reside in areas with at least one infected vector species in both rural and urban populations (Carmona-Castro et al., 2018). Chagas has already extended its range into the southern US, and the triatomines' niche is projected to expand northward this century (Garza et al., 2014; Carmona-Castro et al., 2018) in both rural and urban areas (Carmona-Castro et al., 2018).

Climate change is projected to impact the distribution, abundance, and infection rates of mosquitoes in North America (*high confidence*), which will increase risk of mosquito-borne diseases including West Nile Virus, chikungunya, and dengue (*medium confidence*). The geographic distribution of West Nile virus is projected to expand in North America this century (A1B) (Harrigan et al., 2014). In the US and Canada, mosquitoes are projected to emerge earlier in the year and remain active longer into the fall; however, mosquito population dynamics vary by location with northern locations projected to have an increased vector abundance, and currently hot areas may become too hot, thus negatively affecting mosquito survival (A2, A1B, B1) (Chen et al., 2013; Morin and Comrie, 2013; Brown et al., 2015a).

Local transmission of chikungunya virus has emerged in Mexico and the US since AR5, and areas suitable for transmission are projected to expand (RCP4.5, RCP8.5) (Tjaden et al., 2017). Although chikungunya virus is not currently in Canada, climate change is projected to make southern British Columbia suitable for virus transmission this century, particularly under RCP8.5 (Ng et al., 2017).

The dengue mosquito vector is well-established in Mexico and southeastern US. In northwestern Mexico, incidence of dengue cases is associated with minimum monthly temperature (Diaz-Castro et al., 2017), and the geographic range of the vector in the US is restricted, in part, by low temperatures. Thus, a northward range expansion is projected; however, future dengue risk also depends on built environments and competition with other mosquito species (Colón-González et al., 2013a; Eisen and Moore, 2013). Climate change is projected to increase the geographic range and extend the seasonal activity of the dengue vector in the southern US by 2045-2065 (A1B); however, transmission is projected to be limited by low winter temperatures in the mainland US, potentially preventing its permanent establishment (Butterworth et al., 2017). In Mexico, increased dengue cases are projected this century (A1B, A2, B1) (Colón-González et al., 2013b).

14.5.6.5 Waterborne Disease

Heavy precipitation events are associated with contaminated drinking water and waterborne disease in North America (*high confidence*). Acute gastrointestinal illnesses increase with many hydro-climatological variables, including precipitation, streamflow, and snowmelt (Harper et al., 2011; Wade et al., 2014; Galway et al., 2015). Extreme precipitation is associated with *Campylobacter* and *Salmonella* infections in the US, particularly in counties characterized by farms and private well water (Soneja et al., 2016). In Canada, human *Giardia* infections are associated with increased temperature, precipitation, pathogen presence in livestock manure, and river water level and flow (Brunn et al., 2019). Land-use patterns and aquafer-types are associated with waterborne disease, and ecological zones with higher waterborne rates are projected to expand in range by 2080 in Canada (Brubacher et al., 2020).

In North America, stormwater and water treatment infrastructure play important roles in reducing waterborne disease risk during precipitation events (*high confidence*). In the US, heavy precipitation events are associated with higher rates of childhood gastrointestinal illness in municipalities with untreated drinking water, but not in municipalities with treated drinking water (Uejio et al., 2014). In Mexico, disparities in access to treated water are a key determinant of under age-5 morbidity (Jiménez-Moleón and Gómez-Albores, 2011; Romero-Lankao et al., 2014a). In remote communities in Alaska and Northern Canada, challenges in water service provision and maintenance can increase risk of waterborne disease during high impact weather events (Harper et al., 2011; Bressler and Hennessy, 2018; Harper et al., 2020). In older sections of many North American cities sewage treatment plant capacity is exceeded by overflow of combined sanitary and storm sewer systems during heavy precipitation events, resulting in bypass of untreated and microbiologically contaminated wastewater discharge into drinking water sources (Jagai et al., 2017; Olds et al., 2018; Staley et al., 2018). These sewer overflow events are associated with increased gastrointestinal illness across age groups (Jagai et al., 2017).

14.5.6.6 Foodborne Disease

Warmer air temperature, changes in precipitation, extreme weather events, and ocean warming can increase microbial pathogen loads in food (*very high confidence*). Indeed, temperature and extreme weather are top factors influencing food safety in Canada (Charlebois and Summan, 2015). Outbreaks of *Vibrio parahaemolyticus* have been associated with the consumption of raw oysters harvested from higher-than-usual ocean temperatures in Canada and Alaska (McLaughlin et al., 2005; Taylor et al., 2018). Warmer air temperature increases *Campylobacter*, *Salmonella*, and *E. coli* prevalence in Canadian meat products (Smith et al., 2019), higher microbial load in American produce (Ward et al., 2015), and increased *Campylobacter* spp., pathogenic *E. coli*, and *Salmonella* spp. infections in humans (Akil et al., 2014; Valcour et al., 2016; Uejio, 2017).

Climate change is projected to increase food safety risks (*medium confidence*); however, the actual burden of foodborne disease will depend on the efficacy of public health interventions (*high confidence*). Increased ciguatera fish poisoning is associated with increased SSTs and tropical storm frequency, and this risk is projected to increase this century (Gingold et al., 2014). *Campylobacter* infection in humans due to food contamination from flies is projected to increase this century in Canada (Cousins et al., 2019), and increased housefly populations are projected this century in Mexico (Meraz Jimenez et al., 2019). Climate change may also lead to new emerging foodborne disease risks. For instance, *V. cholerae* is a pathogen previously restricted to tropical regions; however, due to warming ocean temperatures, its detection has significantly increased along Canadian coasts (Banerjee et al., 2018).

Climate change is projected to increase human foodborne exposure to chemical contaminants (*medium confidence*). Increases in SST have been associated with greater accumulation of mercury in seafood, marine mammals, and fish (Ziska et al., 2016). This particularly increases food safety risks in the Arctic, with methylmercury and polychlorinated biphenyl (PCB) concentrations in high trophic animals projected to increase under high emission scenarios by 2100 (Alava et al., 2017; Alava et al., 2018).

Climate-related foodborne disease risks vary temporally, and are influenced, in part, by food availability, accessibility, preparation, and preferences (*medium confidence*). For example, seafood risks are more pronounced in coastal regions due to high seafood consumption (Radke et al., 2015). In Alaska and Northern Canada, where locally harvested foods are critical to diet, climate change may introduce new pathogens to local food sources through wildlife range changes, warming temperatures affecting safe fermentation and drying preparation methods, and food temperature control in belowground cold storage in or near permafrost (King and Furgal, 2014; Harper et al., 2015; Rapinski et al., 2018).

14.5.6.7 Nutrition

Agricultural productivity declines due to climate change (14.5.4) are projected to lower caloric availability and increase the prevalence of underweight people and climate-related deaths in North America by 2050

(IMPAACT) (Springmann et al., 2016a; Springmann et al., 2016b; Springmann et al., 2018); however, this lower caloric availability could also reduce obesity, which could result in deaths avoided (Springmann et al., 2016a; Springmann et al., 2016b). The climate-related deaths per capita due to reduced fruit and vegetable consumption is projected to exceed the mortality due to reduced caloric intake in North America by 2050, particularly in Canada and US (Springmann et al., 2016a; Springmann et al., 2016b). These climate change projections underscore the importance of focusing on nutritional security in North America, instead of only considering caloric intake.

Shifting to a more sustainable diet can have adaptation and mitigation co-benefits while simultaneously improving health outcomes for North Americans. Transitioning to more plant-based diets is projected to reduce climate-related deaths in Canada, US, and Mexico by 2050 (Springmann et al., 2016a; Springmann et al., 2016b), while simultaneously reducing food-related GHG emissions per capita in North America by 2050 (Springmann et al., 2018).

Nutrition impacts will not be experienced uniformly within countries (Shannon et al., 2015; Zeuli et al., 2018). In Alaska and Canada, Indigenous knowledge has documented how climate change has already impacted locally harvested foods and challenged nutrition security (Lynn et al., 2013; Petrasek MacDonald et al., 2013; Harper et al., 2015; Hupp et al., 2015; Bunce et al., 2016) (CCP6). For First Nations coastal communities in western Canada, decreased access to traditionally harvested seafood is projected to reduce nutritional status by 2050 (RCP2.5, RCP8.5), with higher nutritional impacts for men and older adults (Marushka et al., 2019). Substitution of seafood with non-traditional foods (i.e., chicken, canned tuna) would not replace the projected nutrients lost (Marushka et al., 2019), challenging assumptions that market food substitutions could be effective adaptation strategies for Indigenous Peoples.

14.5.6.8 Mental Health and Wellness

Climate change has had, and will continue to have, negative impacts on mental health in North America (*high confidence*) (Figure 14.8). Climate change impacts mental health through multiple direct and indirect pathways stemming from extreme weather events, slower, cumulative events, and vicarious or anticipatory events (Cunsolo Willox et al., 2013; Cunsolo Willox et al., 2014; Durkalec et al., 2015; Yusa et al., 2015; Schwartz et al., 2017; Trombley et al., 2017; Burke et al., 2018b; Cunsolo and Ellis, 2018; Dodd et al., 2018b; Hayes et al., 2018; Middleton et al., 2020b). Climate change disruptions to infrastructure, underlying determinants of health, and changing place attachment are also stressors on mental health (Vida et al., 2012; Cunsolo Willox et al., 2013; Burke et al., 2018b; Obradovich et al., 2018).

In North America, climate change has been linked to strong emotional reactions; depression and generalized anxiety; ecological grief and loss; increased drug and alcohol usage, family stress, and domestic violence; increased suicide and suicide ideation; and loss of cultural knowledge, and place-based identities and connections (Cunsolo Willox et al., 2013; Durkalec et al., 2015; Harper et al., 2015; Fernández-Arteaga et al., 2016; Schwartz et al., 2017; Trombley et al., 2017; Burke et al., 2018b; Cunsolo and Ellis, 2018; Clayton, 2020; Dumont et al., 2020).

Suicide is projected to increase in Mexico and the US by 2050 due to rising temperatures (RCP8.5) (Burke et al., 2018b) (*limited evidence*). Literature on climate change and mental health in North America is increasing; however, few population-level quantitative studies exist, although are increasing (e.g. Burke et al., 2018b; Kim et al., 2019; Dumont et al., 2020; Middleton et al., 2021).

Figure 14.8: Pathways through which climate change impacts mental health risk in North America.

14.5.7 Tourism and Recreation

Tourism is one of the largest and fastest growing industries in North America, contributing USD$2.5 trillion to North Americas' GDP in 2019 (WTTC, 2018; Duro and Turrión-Prats, 2019). The US is the world's largest tourism economy (USD$1839 billion contribution to global GDP in 2019), Mexico is ranked 9th (USD$196 billion) and Canada 13th (USD$108 billion) (WTTC, 2018). The tourism industry is both impacted by climate change and significantly contributes to it through the emission of GHGs from travel and activities (Becken and Hay, 2007). By 2060 under RCP8.5 Canada and the US are projected to benefit from climate-induced changes in tourism expenditures of up to 92% and 21% respectively, whereas Mexico could experience a 25% decrease (OECD, 2015; Scott et al., 2019a).

14.5.7.1 Observed Impacts and Projected Risks of Climate Change

14.5.7.1.1 Alpine and Nordic skiing, snowmobiling and other winter sports

Winter tourism activities with hard limits to adaptation, particularly those that occur at sea level where less precipitation is expected to fall as snow (i.e., Nordic skiing, snowmobiling, snowshoeing), are at the highest risk from climate change and may experience irreversible impacts well before 2°C of warming above pre-industrial levels (*high confidence*) (Figure 14.9). During record warm winters, alpine ski resorts in eastern Canada experienced reductions in ski season lengths of between 11 and 17 days (Rutty et al., 2017) and resorts in the US Northeast (*US-NE*) experienced decreased skier visits by 11.6% and reductions in operational profits of 33% amounting to US$40-52 million (Dawson et al., 2009). Even with advanced snowmaking as an adaptation to warmer temperatures, average ski season lengths are projected to decrease 8% (RCP2.6, 2050s) to 73% (RCP8.5, 2080s) in Ontario, Canada (*CA-ON*) (Scott et al., 2019b), 12% (RCP4.5, 2050s) to 22% (RCP8.5, 2080s) in Quebec, Canada (*CA-QC*), and 13% (RCP 4.5, 2050s) to 45% (RCP 8.5, 2080s) in the US Northeast (*US-NE*) (Wobus et al., 2017; Scott et al., 2020). Season length for snowmobiling and cross-country skiing is projected to decrease more dramatically (*high confidence*) by from 80% (RCP4.5) to 100% (RCP 8.5) by mid-century (Wobus et al., 2017) (also see CCP5). The number of outdoor skating-days may decrease by 34% in Toronto and Montreal and 19% in Calgary by 2090 under RCP8.5 (Robertson et al., 2015). The skating season length for the Rideau Canal in Ottawa, Canada, a UNESCO heritage site attracting 1.3 million visitors annually, may decrease by 3.8±2.0 days per decade with later opening dates of 2.6±1.5 days per decade (Jahanandish and Alireza, 2019).

14.5.7.1.2 Beach, coral reef, and protected areas tourism

Sea level rise, increased storm surge, wave action, algae blooms, extreme air temperatures, and changes in wind and precipitation patterns threaten coastal tourism infrastructure, submerge beaches, erode walking paths on coasts, and impact destination attractiveness, tourism demand, and recreation economies (*very high confidence*). Warm weather tourism activities, including beach tourism, snorkelling, and national park visitation will have more time to implement adaptation strategies to reduce climate risks as significant and widespread impacts are not expected until 3 to 4°C of warming (Fig 14.9) (Rutty and Scott, 2015; Atzori et al., 2018; Santos-Lacueva et al., 2018; Duro and Turrión-Prats, 2019). Thirty percent of hotels along the Gulf of Mexico and Caribbean Sea are exposed to flooding and 66% are located on eroding beaches (Lithgow et al., 2019). Coral reef cover in Akumal Bay, Mexico decreased by 79% between 2011 and 2014 (Gil et al., 2015; Manuel-navarrete and Pelling, 2015). The recreation value of coral reef tourism in Florida, Puerto Rico, and Hawai'i is expected to decrease by 90% by mid-century under RCP8.5 (EPA, 2017) (14.4.2). Wildfires and insect outbreaks have contributed to reduced desirability for tourism across forest and mountain regions (Bawa, 2017; Hestetune et al., 2018; White et al., 2020). Visitors to Utah's National Parks declined 0.5 to 1.5% during wildfire years between 1993 to 2015, resulting in US$2.7 to 4.5 million in lost revenue (Kim and Jakus, 2019) (see Box 14.2). Trees damaged by insects have caused campground and hiking trail closures in the western US and Alaska (Arnberger et al., 2018). SLR, flooding, coastal erosion, changing air and sea temperatures, changing humidity, and extreme weather events are putting cultural heritage sites at risks (Fatorić and Seekamp, 2017; Hollesen et al., 2018; Tetu et al., 2019).

14.5.7.1.3 Arctic tourism

Cruise and yacht tourism in the North American Arctic increased rapidly over the past decade as changes in sea ice has expanded open water areas and season length (Johnston et al., 2016; Pizzolato et al., 2016; Dawson et al., 2018). The risk of a major accident or incident among Arctic-going yachts and some expedition passenger vessels is very high relative to other ships (*high confidence*) due to the combined increases in mobile ice, especially along the Northwest Passage (Barber et al., 2018a; Howell and Brady, 2019; Copland et al., 2021; Lemmen et al., 2021), limited regulation for private yachts (Dawson et al., 2014; Dawson et al., 2017), the propensity for cruise ships to travel into newly ice-free and poorly charted areas, and the increasing number of non-ice strengthened vessels operating in the region (Dawson et al., 2018;

Copland et al., 2019; Copland et al., 2021). Compounding risks include a lack of hydrographic charting and the lack of emergency response infrastructure (e.g., spill response, search and rescue, salvage) (Amap, 2017). Tourism demand for polar bear viewing in Churchill, Manitoba, Canada may change due to climate-related declines in polar bear health (Gil et al., 2015; Manuel-navarrete and Pelling, 2015), but may be offset by 'Last Chance Tourism' (LCT), a niche tourism market of individuals who explicitly seek to visit vanishing landscapes and/or disappearing flora and fauna (Lemelin et al., 2010).The ethics of promoting LCT has been questioned considering that more visitation to sensitive sites increases local impacts as well as travel-related emissions (Groulx et al., 2016; Groulx et al., 2019).

14.5.7.2 Emerging Responses and Adaptation

Compared to other economic sectors (see section 14.5.8), the tourism industry has high adaptive capacity (*high confidence*) (Figure 14.9). Investments in climate-resilient infrastructure within Canadian National Parks have increased visitation rates during the shoulder seasons (Fisichelli et al., 2015; Lemieux et al., 2017; Wilkins et al., 2018), regional collaboration among US and Canadian park agencies has enhanced adaptive capacity through integrated planning and management (Lemieux et al., 2015), and technological advancements have reduced the vulnerability of alpine winter sports from warming temperatures (e.g., snowmaking, refrigerated surfaces, chemical additives) (Rutty and Scott, 2015; Scott et al., 2019b; Scott et al., 2020). Snowmaking as an adaptation strategy affects mitigation efforts by increasing the need for energy and fuel (Scott et al., 2019b).

Tourists are also highly adaptable and, depending on their levels of place attachment, location loyalty, and socio-demographics, are *very likely* to substitute the timing or location of their travel activity based on climate and climatic-driven environmental changes (Rutty and Scott, 2015; Atzori et al., 2018). Lemieux (2017) found that if the state of the Athabasca Glacier (CA-PR, Figure14.1) were to change negatively as a result of climate change, 83% would travel elsewhere, and if large infrastructure was built as an adaptive measure for viewing receding glaciers at Jasper National Park, 40% of tourists would no longer visit.

Hard and soft limits to adaptation exist in the tourism sector (Manuel-navarrete and Pelling, 2015). For example, machine-made snow without the use of environmentally harmful chemical additives that are banned in most jurisdictions, can only be made efficiently in temperatures below -2 °C, but projections indicate warming temperatures above this threshold (Wobus et al., 2017; Scott et al., 2019a). Multi-jurisdictional adaptation planning for parks and protected areas in the US has been hindered by a lack of funding, communication, and funding trade-offs that could be remedied through coordination (Lemieux et al., 2015). Social inequalities generated by the tourism development process must also be considered by climate-related interventions to avoid the perpetuation of inequalities that may exist, particularly in less developed regions and rapidly developing regions. For example, New developments in Hawai'i, Florida, Quebec, and popular resort areas in Mexico have led to social inequalities through increased property taxes leading to the marginalization of local residents away from these areas in favour of wealthy tourists (Manuel-navarrete and Pelling, 2015) (also see 14.5.9).

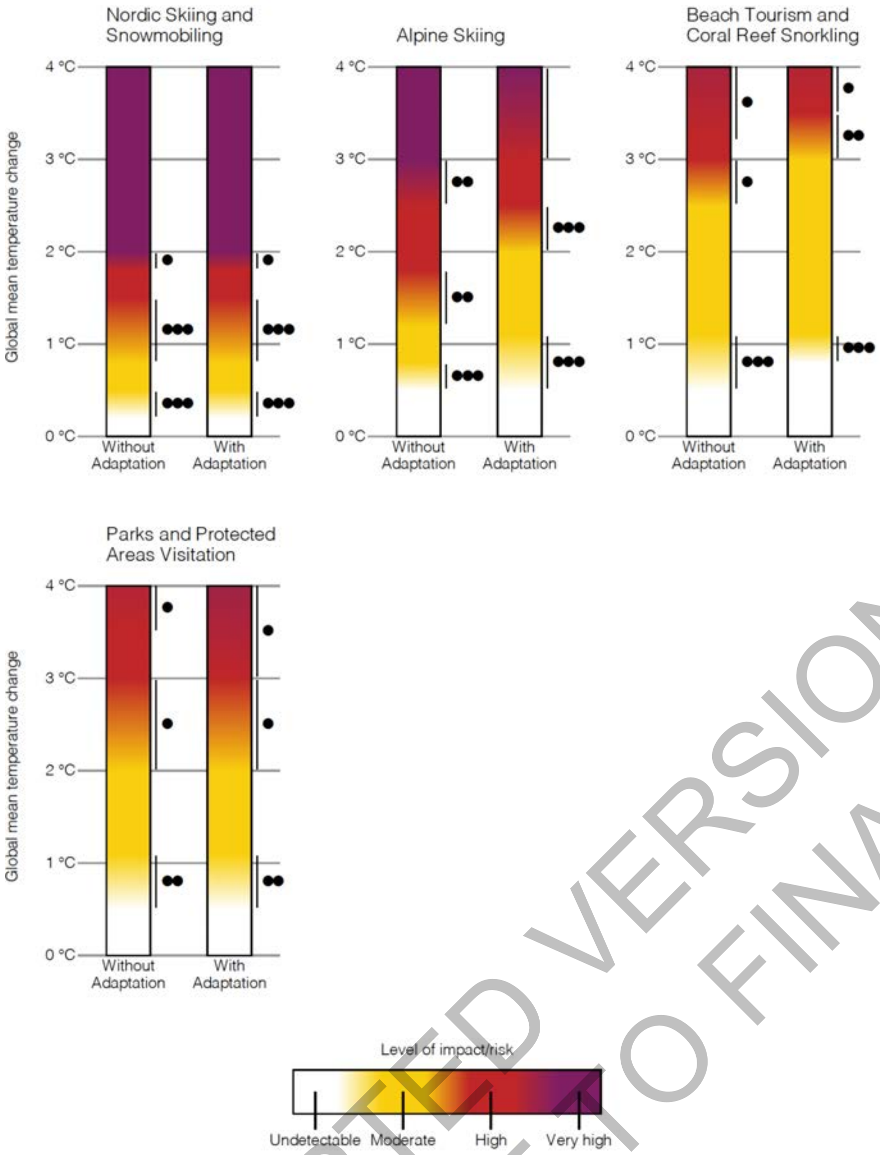

Figure 14.9: Burning ember of the relative risks to select tourism activities in North America with and without adaptation as a function of global mean surface temperature increase since pre-industrial times. Risks to tourism activities include: 1) season length reductions from warming temperatures for Nordic skiing and snowmobiling, 2) season length reductions from warming temperatures and precipitation changes for alpine skiing, 3) visitor experience changes as a result of warming surface and ocean temperatures for beach tourism and degrading coral reef systems for snorkelling, 4) visitor experience changes related to warming temperatures and changing landscape aesthetic for Parks and Protected Areas. Risks assessed cover all of North America (3, 4), or are specific to certain regions (1, 2). The supporting literature and methods are provided in Supplementary Materials (SM14.4).

14.5.8 Economic Activities and Sectors in North America

Economic sectors highly reliant on climate, such as agriculture, tourism, fisheries, and forestry, have higher levels of exposure and sensitivity (*high confidence)* and greater overall risk to climate change compared to other economic sectors such as mining, construction, and manufacturing (*medium confidence*). However, the cascading nature of climate impacts related to trade (Box 14.5), labour productivity (14.5.8.1.5), and infrastructure (14.5.8.1.2) means that there is no economic sector in North America that will be unaffected by climate change *(very high confidence*) (Figure 14.10). For Canada, this assessment is further supported by the Canadian Climate Assessment (Lemmen et al., 2021). The combined economies of Canada, Mexico and the US represented ~28% of the global GDP in 2019, with the US accounting for almost 90% of the total activity for North America (World Bank, 2020a). The risks posed at different GWLs for any given economic activity or sector are presented in Figure 14.10. By combining expert judgement with a systematic review of the literature for each sector, the information in this Figure represents a broader synthesis, especially for sectors with a smaller literature base and at higher GWLs. The assessment of the risks of climate change on tourism (14.5.7) and the interactions between sectors through trade (Box 14.5) are discussed separately.

14.5.8.1 Observed Impacts and Projected Risks of Climate Change

14.5.8.1.1 Agriculture, fisheries, and forestry

The wide range of observed and projected impacts of climate hazards on food and fibre in North America are documented in 14.5.4 (also see Chapter 5). Agriculture (USNW - corn and soybeans), fisheries (cod and pollock), and forestry (Boreal Forest timber yield) are expected to experience substantial and widespread risks by 2°C of global warming above pre-industrial (*medium to high confidence)* (Figure 14.10). Economic models generally show economic losses in the agricultural sector across North America, especially at higher GWL (14.5.4) (EPA, 2017; Boyd and Markandya, 2021), although the effects in local economies, especially rural areas of the US that are highly dependent on agriculture, will be substantial even at lower GWLs (Gowda et al., 2018). Full evaluations of climate risks for forestry and fisheries are presented in 14.5.1, 14.5.4 (also see 14.6), respectively.

14.5.8.1.2 Transportation

Transportation infrastructure, including roads, bridges, rail, air, sea, and pipelines, are highly vulnerable to rising temperatures, SLR, weather extremes, changing ice conditions, permafrost degradation, and flooding (*high confidence*), resulting in damage, disruption to operations, unsafe conditions, and supply-chain impacts (Board and Council, 2008; Natural Resources Conservation Service; Andrey and Palko, 2017; Jacobs et al., 2018; Lemmen et al., 2021) (Box 14.5). In the Mexican states of Veracruz, Tabasco, San Luis Potosí, Chiapas and Oaxaca, 105,000 infrastructure sites, mostly major connecting roads, were found to be at risk of flooding from tropical storms (De la Peña et al. 2018). Low water levels in the Great Lakes has severely impacted US grain transport (Attavanich et al., 2013). High intensity rain events destroyed 1,000km of roads and washed out hundreds of bridges and culverts in 2013 resulting in an estimated CAD$6 billion (2013 dollars) in damages and recovery costs in Alberta, Canada (*CA-PR*) (Palko and Lemmen, 2017). In 2019, the rail line from Winnipeg to Churchill Manitoba, which is the only ground transportation to the community and to Canada's only deep-water Arctic port, was reopened after being closed for over two years due to the cumulative effects of flooding, permafrost degradation, and political challenges (Lin et al., 2020). In the US, the number of heat-related train delays has increased (Bruzek et al., 2013; Chinowsky et al., 2019) and by the end of the century may cause economic losses of US$25 to 45 billion (RCP4.5) or US$35 to 60 billion (RCP8.5) (Chinowsky et al., 2019). Sea ice reduction in the North American Arctic has led to a rapid increase in ship traffic (Huntington et al., 2015; Phillips, 2016; Pizzolato et al., 2016; Huntington et al., 2021b; Li et al., 2021) with cascading risks related to invasive species introduction, accident rates, black carbon emissions, underwater noise pollution for marine mammals, and risks to subsistence harvesting activities in Indigenous communities. (Ware et al., 2014; Council of Canadian Academies, 2016, Huntington, 2021; Verna et al., 2016; Chan et al., 2019)

14.5.8.1.3 Energy, oil and gas, and mining

Climate change is increasing the demand for electric power for cooling and threatens existing power supply (*high confidence*) (see 14.5.5). Increased energy demand often occurs during peak energy usage and especially during heat waves (Cruz and Krausmann, 2013; Leong and Donner, 2015). Cooling represented 74% of peak electricity demand in Philadelphia on a particularly hot day in July 2011 (Waite et al., 2017; IEA, 2018b). In Canada, warming temperatures are expected to reduce demand for heating by 18 - 33% and increase demand for cooling by 14 - 126% by 2070 compared to 1959-89 and 1998-2014 baseline periods, respectively (Berardi and Jafarpur, 2020). The effects on hydropower are uneven across the region with the potential for increases in capacity in Canada but declines of over 20% in Mexico (RCP4.5 and RCP8.5) (Turner et al., 2017). Electricity demand in the US is projected to increase by 5.3 % per degree C rise in temperature (Hsiang et al., 2017). Energy infrastructure, such as drilling platforms, refineries and pipelines and evacuation routes are also increasingly vulnerable to higher sea levels, hurricanes, storm surges, mobile multi-year sea ice, erosion, inland flooding, wildfires, and other climate-related changes (Zamuda et al., 2018).

Operational efficiency and human safety at mining and energy production sites is expected to be adversely affected by increases in extreme events (Section 14.2), including storms, heavy rains, riverine flooding, and wildfires (*high confidence*). General remoteness of many mining sites (especially in the North American

Arctic) exacerbates risks related to emergency responses to extreme events such as wildfire (*medium confidence*). The 2016 Fort McMurray wildfire in Alberta Canada forced the evacuation of 88,000 people and the shutdown of mine operations. Damages were minimal because companies had undertaken proactive FireSmart interventions specifically developed for the industry (Council of Canadian Academies, 2019) (see Box 14.1). Onshore oil field production in Tabasco, Mexico, which accounts for 16% of the country's daily output, was interrupted by extensive flooding (Cruz and Krausmann, 2013). Two-thirds of mine operators globally, including major operators in North America, have experienced production challenges related to water shortages and flooding (Carbon Disclosure Project, 2013).Water availability stress due to climate change is lower in Canada than in the US and Mexico and mines in Canada may be less exposed to this risk (World Resourcs Institute, 2012), with some exceptions, i.e., water-intensive oil sands mining in the Athabasca River basin in Canada (Leong and Donner, 2016) (also see 14.5.3).Warming temperatures also has the potential to alter the nature, characteristics and quality of mineral resources such as kaolin or limestone (Phillips, 2016).

14.5.8.1.4 Construction

In the US, construction workers comprise 6% of the total workforce but accounted for 36% of all occupational heat-related deaths from 1992-2016 (Dong et al., 2019). It is expected that total labour hours among outdoor construction workers will decrease by 0.53 (+/- 0.01)% per °C based on existing warming trends (Hsiang et al., 2017) also see (EPA, 2017). Risks are expected to be exacerbated as SLR and storm surge expands the risk zone for coastal flooding exposing more property to inundation and enhancing construction demand (EPA, 2017) (Box 14.4, section 14.5.5.1.3). Meeting existing and projected demand for water in affected regions could also require building new desalination plants. Texas has constructed over 44 desalination plants across the state because of a lack of freshwater to meet potable water demand and due to climate driven droughts (Kloesel et al., 2018b). Other infrastructure damaged by floods and SLR will need to be reassessed and perhaps relocated away from the coast. Relocation requires availability of land that frequently does not exist within urban areas (Lithogow, 2019). Some US tribes and Indigenous groups in Canada lack the financial resources to build climate-resilient infrastructure such as housing and sewage treatment facilities to assure clean drinking water (Martínez et al., 2014; Salgado and Luisa Martinez, 2017; Lithgow et al., 2019).

Permafrost thaw in northern North America will result in increased construction and reconstruction needs (*medium confidence*) related to direct damage to buildings, roads, airport runways and other critical infrastructure including decreased bearing capacities of building and pipeline foundations, damage to road surfaces, and deterioration of reservoirs and impoundments used for wastewater and mine tailings containment (Pendakur, 2017; Meredith et al., 2019). Ice roads have become less safe due to warming, pavement damage has increased related to seasonal thaw/freeze cycles, and there have been interruptions in airport operations, water and sewage service, and school operations in the Canadian territories of Yukon and Nunavut (Canadian Western and Eastern Arctic – (*CA-WA* and *CA-EA*), fig 14.1) (Council of Canadian Academies, 2019). By the end of the century, the economic impact of projected reconstruction of Alaska's public infrastructure due to climate change (mainly from permafrost thaw) is estimated to range from USD$4.2B (RCP4.5) to USD$5.5B (RCP8.5) (Melvin et al., 2017; Markon et al., 2018).

14.5.8.1.5 Manufacturing

Twelve million Americans (Bureau of Labor Statistics, 2015), 1.5 million Canadians (Statistics Canada, 2020) and 9 million Mexicans (Statistics Mexico, 2021) are employed in manufacturing. The southeast US and Texas have the highest manufacturing output, with 34% of total US output ($700 billion per year). The impact of climate change on manufacturing varies greatly by region. Vulnerability of the sector to climate change stems from exposure of workers to increasing temperatures and humidity, exposure of facilities to SLR and flooding, and changes in water supply and quality required in many manufacturing processes (Lall et al., 2018).

14.5.8.1.6 Labour Productivity

Climate change is negatively affecting working conditions and labour productivity in North America (*medium confidence*) (Section 14.5.6.1 and Box 14.5). Working conditions in temperatures above a Heat Index of 85ºF (29.4ºC) are correlated with potentially hazardous health conditions (Tustin et al., 2018) and for every ºC increase in temperature, labour productivity is estimated to be reduced by 0.11% for low risk workers and 0.53% for high risk workers (i.e., construction, mining, agriculture and manufacturing) (Hsiang et al., 2017). By mid-century (RCP8.5), temperature increase, changing water availability and SLR, are projected to result in a 0.6% drop in labour productivity in auto, timber, textile and chemical manufacturing in the Southeast and Texas regions (Kinniburgh et al., 2015; Hsiang et al.). Labour productivity in the US automobile industry decreases by 8% for every six or more days of consecutive unusually hot weather (above 90ºF/32.2ºC) (Cachon et al., 2012). Thirty percent of California workers are employed in high-risk industries, such as agriculture, with exposure to high temperature leading to loss in productivity (Rogers et al., 2015). Under RCP8.5 increases in extreme temperatures, labour productivity in the US is projected to decrease, costing US$190 billion in lost wages by 2090 (EPA, 2017; Kjellstrom et al., 2019)(also see (Gubernot et al., 2014; Kiefer et al., 2016; Carter et al., 2018).

14.5.8.2 Current and Potential Adaptation

Adaptation options are highly diverse and sector-specific (EPA, 2017). Regardless of economic sector, companies that implement effective and rapid response options that address climate change stressors will have a competitive advantage (Gasbarro et al., 2016, Lemmen, 2021). Most companies focus on short-term risk management and consequently short-term adaptation is often favoured over long-term approaches particularly in the private sector, which will be ineffective for climate change risk reduction over the long term (Gasbarro et al., 2016).

Investment and coordination of climate services (forecasting) can support many economic sectors across North America. In 2017, 15% of S&P 500 companies publicly disclosed an effect on earnings from weather events, reflecting a growing trend (Williams et al., 2018).Existing US federal-sponsored planning tools provide guidance to states and to plan for SLR and flooding with large threats to commercial sectors (US Department of Transportation, 2015). The NOAA Coastal Services Center SLR and coastal inundation viewer (https://coast.noaa.gov/digitalcoast/tools/slr.html), the Army Corps of Engineers Sea Level Change Curve simulator, and Climate Central's interactive portal (Ocean at the Door) all provide access to visualizations of future sea level rise that are available to US coastal cities and towns for commercial planning purposes. Similar resources are being developed and are available for Canada including Canada's Climate Atlas (https://climateatlas.ca/).

Adaptation options for transportation and related infrastructure include engineering and technological solutions, as well as innovative policy, planning, management, and maintenance approaches (Natural Resources Conservation Service, 2008; Jacobs et al., 2018). For northern transportation, new technologies and infrastructure adaptations can be employed to facilitate heat extraction (e.g. air convection embankments, heat drains, thermosyphons, high albedo surfacing, gentle embankment slopes) (McGregor et al., 2010b; United Nations, 2020) Adaptation options for roads include changing pavement mixes to be more tolerant to heat or frost heaving, expanding drainage capacity, reducing flood risks, enhancing travel advisories and alerts, elevating or relocating new infrastructure where feasible and changing infrastructure design requirements to include climate change considerations or to introduce new flood event thresholds (Natural Resources Conservation Service, 2008; EPA, 2017; Pendakur, 2017). Railroads are testing temperature sensors on rail tracks to provide early warning of buckling. Sensors that signal when tracks are approaching dangerous temperatures may help to avoid accidents (Hodge et al., 2014; Chinowsky et al., 2019).

Adapting building codes more uniformly to changing climate conditions such as SLR, storms, winds and wildfires reduces risk (Olsen, 2015; Maxwell et al., 2018b). North America has not, on the whole, adapted its building code regulations to consider the dynamic challenges of climate change, although some specific efforts have been made, including the addition of requirements for wildfire within California's building codes and Canada's Climate-resilient building and core public infrastructure initiative, which involves updating building codes and standards to improve climate resiliency (Lacasse et al., 2020) (Box 14.4). To enhance safety, some outdoor workers have been fitted with heat sensors to analyse/assess how warming may affect productivity and well-being (Runkle et al., 2019). Other options include raising public roads and seawalls, initiating buy-outs of property owners in flood-risk areas, and improving storm water drainage. Adopting approaches like the International Future Living Institute's Living Building Challenge (LBC) may inform future regulatory processes (Eisenberg, 2016). The LBC (https://living-future.org/basics/) has seven thematic areas that inform building design, although only a subset of those are relevant for climate change including water, energy, and materials considerations.

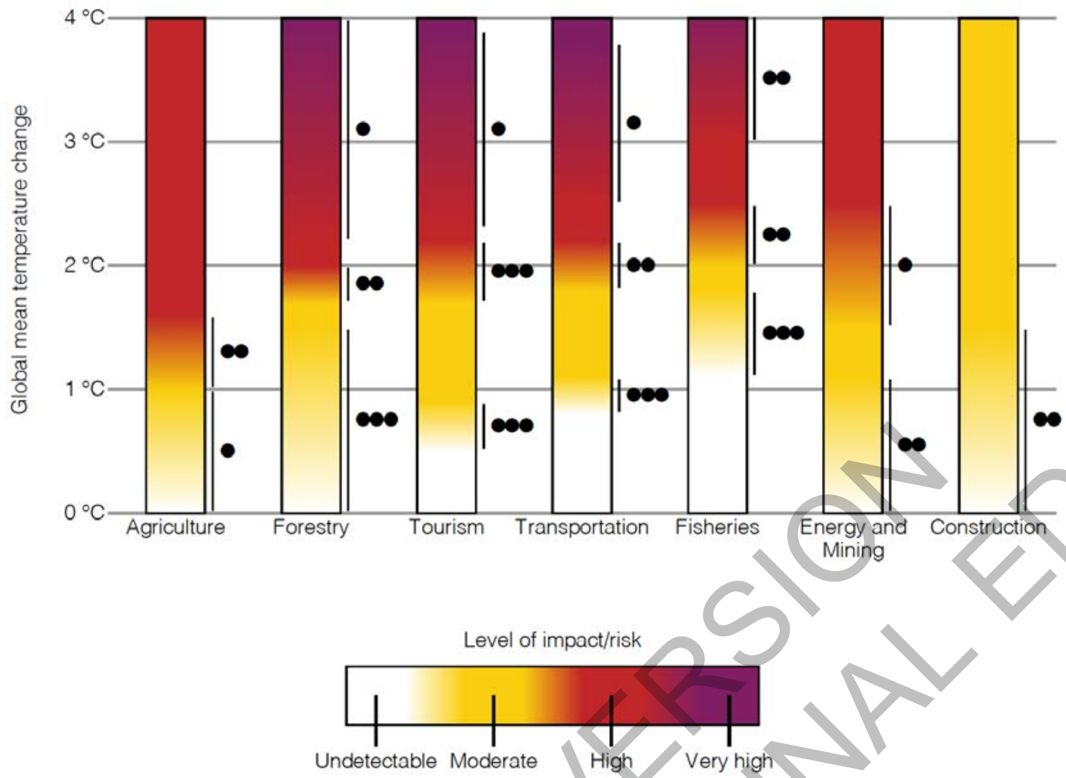

Figure 14.10: Burning Ember of the relative risks to economic sectors in North America as a function of projected global mean surface temperature increase since pre-industrial times. Impacts on economic sectors include: 1) changing crop yield leading to economic loss for agriculture, 2) changes in the quality and quantity of timber yields, 3) reductions in season length and economic viability for tourism activities, 4) increased maintenance and reconstruction costs to transportation infrastructure, 5) changes in fisheries catch, 6) reduced productivity in mining and energy operations, 6) reduced labour productivity in outdoor construction, and 7) increased maintenance and reconstruction costs to transportation systems. Risks to economic sectors and activities were sometimes assessed across all of North America (3, 4), within specific regions (1, 2), and for specific crops or species (1 - corn and soybean, 2 – cod and pollock). The supporting literature and methods are provided in Supplementary Material (SM14.4).

Box 14.5: Climate Change Impacts on Trade Affecting North America

In North America, trade - defined as the sum of export and import of goods and services - is valued at $1.3 trillion USD annually (2019 dollars) and represents 30% of North American GDP. Variations within the region are notable; Mexico relies on trade for 80% of its GDP and Canada for 66% (World Bank, 2020a). Canada and the US traded over USD$55.2 billion worth of products related to the agriculture industry between 2015 and 2018 (Government of Canada, 2019). Canada, the US and Mexico have the longest running trade pacts globally and these agreements have played a major role in supporting economic and social development in the region (see (Frankel and Rose, 2005; Eaton et al., 2016; World Bank, 2020b). However, recent changes to the North American Free Trade agreement do not clearly address climate change (Lucatello, 2019).

Climate risks may create shocks to the trade system by damaging infrastructure and disrupting supply-chains in North America (*medium confidence*). Sea level rise, flooding, permafrost thaw, landslides, and increased frequency and magnitude of extreme weather events are projected to impact transportation infrastructure which will pose challenges to the movement of goods, especially in coastal areas (Lantuit et al., 2012; Doré et al., 2016; Hjort et al., 2018; Koks et al., 2019; Lemmen et al., 2021). Maritime ports are at the greatest risk from climate hazards (Messner et al., 2013; Slack and Comtois, 2016), followed by roads, rail, and airports (Anarde et al., 2017). Due to the trans-national nature of trade, extreme weather disruptions in one region are likely to lead to cascading effects in other regions *(high confidence*) (Lemmen et al., 2021). For example, climate change will have negative impacts for global food and energy trade where reductions in crop production and fish stocks in some regions could cause food and fish price spikes elsewhere (Beaugrand et al., 2015; Lam et al., 2016; Shukla, 2019) (also see 14.5.4, Figure 14.10, and 5.11.8).

Climate change impacts may alter current trade practices and patterns with implications for regional economic development in North America, especially in the Arctic (*medium confidence*). Climate change is causing modal-shifts in cargo shipping. For example, lower water levels in lakes and rivers (e.g., Mackenzie River, Mississippi River) impact freight transport and may cause a shift from marine transport to more GHG-intensive rail, road, or air transport (Koetse and Rietveld, 2009; Du et al., 2017; Pendakur, 2017). Sea ice change is creating new Arctic marine trade corridors (Melia et al., 2016; Pizzolato et al., 2016; Ng et al., 2018; Bennett et al., 2020; Mudryk et al.), including shorter and potentially more economical routes such as the Northwest Passages (see CCP6, Box 6.1). Warming temperatures have also reduced the season length for ice roads, which are heavily relied upon to service remote communities and remote industries including forestry and mining (Pendakur, 2017) (see *14.5.8.1.2)*.

Effective and equitable trade policies can act as important adaptation strategies (*medium confidence*). Higher temperatures have had no direct effect on developed countries' exports, but have significantly reduced growth in exports among developing countries, which in turn can increase the price of goods that developed countries then import (Costinot et al., 2016; Constant and Davin, 2019). Schenker (2013) estimated that the climate impacts on trade from developing to developed countries could be responsible for 16.4% of the total expected cost of climate change in the US in 2100 and thus, North America would benefit from increased investment in effective and equitable trade policies and adaptation in developing regions. Under an RCP8.5 scenario (~2.6 to 4.8 degree C warming) and within current trade integration, climate change could lead to up to 55 million undernourished people by 2050; these projections decrease by 64% (20 million people) with the introduction of reduced trade tariffs and the lessening of institutional and infrastructure barriers (Janssens et al., 2020). Although most studies focus on global food security (agriculture), it is likely that the same challenges exist for other commodities and manufactured goods.

[END BOX 14.5 HERE]

[START BOX 14.6 HERE]

Box 14.6: The Costs and Economic Consequences of Climate Change in North America

Observed Impacts

Extreme weather events, including hurricanes, droughts, and flooding, and wildfires, have been partly attributed to anthropogenic climate change (e.g., Rupp et al., 2015; Emanuel, 2017); attribution table in Chapter 16) (*high confidence*). Direct, indirect and non-market economic damages from extreme events have increased in some parts of North America (*high confidence*). The number of extreme events with inflation-adjusted damages totalling more than US$1B has risen in the US over the past decades (NOAA, 2020; Smith, 2020), and similar increases have been observed in Canada (Boyd and Markandya, 2021). Factors other than climate change, including increases in exposure and the value of the assets at risk, also explain increasing damage amounts (Freeman and Ashley, 2017; Vano et al., 2018). Climate change explains a portion of long-term increases in economic damages of hurricanes (*limited evidence, low agreement*). Studies of US hurricanes since 1900 have found increasing economic losses that are consistent with an influence from climate change (Estrada et al., 2015; Grinsted et al., 2019), although another study finds no increase (Weinkle et al., 2018).

Formal attribution of economic damages from individual extreme events to anthropogenic climate change has been limited, but climate change could account for a substantial fraction of the damages (*limited evidence, medium agreement*). Two recent studies have shown approaches for how damages may be attributed for individual events in the US. Assuming a direct proportionality between attributable risk of the event to the attributable economic damages, one study suggested that 30-75% of the direct damages from Hurricane Harvey was caused by climate change, with a best estimate of US$67B out of an estimated US$90B total of attributable damages (Frame et al., 2020). Another study modeled the component of the flooding from Hurricane Sandy due to rising SLR and mapped that to coastal damages. That study estimated that US$8.1 billion (13% of the total) was attributable to the climate influence on SLR (Strauss et al., 2021).

The effect of climate change has been identified in aggregate measures of economic performance, such as GDP, in North America and globally (*medium confidence*)*,* although the magnitude of these changes is difficult to constrain (*medium confidence).* Climate change has been observed to affect national GDP level and economic growth (*low confidence*). The extent to which climate has affected GDP may be challenging to identify statistically (Cross-Working Group Box ECONOMIC in Chapter 16). Observed GDP effects are generally slightly negative in the US, higher and negative for Mexico, and the directionality of the effects in Canada varies by study and modeling approach (Burke et al., 2015; Colacito et al., 2018; Kahn et al., 2019).

Projected Risks

Projections of market and non-market economic damages demonstrate the substantial economic risks of climate impacts associated with high temperature pathways (RCP8.5) (*high confidence*). Since AR5, a wide range of estimates of the costs of climate change have been developed for the US (EPA, 2015a; Houser et al., 2015; EPA, 2017; Hsiang et al., 2017; Martinich and Crimmins, 2019), with ongoing processes to update national estimates for Canada and Mexico (Semarnat, 2009; NRTEE, 2011; Estrada et al., 2013; Sawyer et al., 2020). While the magnitude of the estimates depend on approach and assumptions in the methods and expectations of future socioeconomic conditions, these studies show substantial projected economic damages across North America by the end of the century, especially for warming greater than 4ºC (*high evidence, high agreement*). Whether these damages translate into GDP effects is not clear for Canada. Some modeling approaches show modest GDP increases in 2050 and 2100, while others suggest modest decreases although it is anticipated that the economic effects for Canada will be large and negative (Boyd and Markandya, 2021). Large costs and risks, such as those associated with extreme events such as wildfires (Hope et al., 2016) and the increased need for infrastructure replacement (Neumann et al., 2015; Maxwell et al., 2018a) will have compounding effects in the markets by disrupting economic activities (Box 14.5).

Market and non-market risks and costs will not be experienced equally across countries, sectors and regions in North America (*high confidence*). For the US, reductions in mortality, energy expenditures and improvements in agricultural yields are projected to result in net gains in the North and Pacific Northwest whereas in the South, higher heat-related mortality, increases in energy expenditures, SLR and storm surge are projected to result in economic losses by the end of century (Hsiang et al., 2017). No region in the US is expected to avoid some level of adverse effects (EPA, 2017; Martinich and Crimmins, 2019) (*medium evidence, high agreement*). Economic models generally show losses in the agricultural sector across North America, especially at higher GWL (Boyd and Markandya, 2021, EPA 2017). Some models show large gains in parts of Canada, although these models do not capture the full range of climate hazards including change in precipitation or extreme events (Boyd and Markandya, 2021).

Economics of Adaptation Opportunities

Economic analysis can help reveal where the avoided economic damages are greater than the costs of adaptation, improving decision-making for adaptation planning and efforts in North America (*high confidence*). Detailed assessment of total needs and costs of climate adaptation are limited (Sussman et al., 2014), but estimates suggest that the costs are large (*low evidence, high agreement*). Cost-benefit and other economic analyses that incorporate damage estimates are expanding for adaptation decision-making (Li et al., 2014), especially for technical options in areas with high exposure such as coastal areas in Mexico (Haer et al., 2018) and Alaskan infrastructure (Melvin et al., 2017). Cost-benefit analysis has also been applied to coordinating planning across jurisdictions in North America for SLR and flood control (Adeel et al., 2020). Adaptation costs in the US are lower on RCP4.5 compared to RCP8.5 emission pathways (Martinich and Crimmins, 2019). Adaptation, however, cannot be based solely on the cost benefit analysis due to the high level of uncertainty related to climate risks (Cross-Chapter Box DEEP in Chapter 17).

Improving projections of future economic risk and damages facilitates the development of tools that can be used for economic analysis of climate policies (*high confidence*). Monetized estimates of the damages from climate change have been developed and refined since AR5, motivated in part by efforts to estimate the Social Cost of Carbon (SCC) (National Academies of Sciences, 2017). Support for these efforts and the use of SCC in regulatory analysis of mitigation and adaptation efforts have been pledged across the national and sub-national governments of Canada, the US and Mexico. Harmonizing SCC and consistent use can further enhance coordination of mitigation and adaptation decision-making (Auffhammer, 2018; Aldy et al., 2021).Using these damages estimates can also inform other policy and tools that improve the consideration of climate impacts in markets and decision-making (Report of the Climate-Related Market Risk Subcommittee, 2020).

[END BOX 14.6 HERE]

14.5.9 Livelihoods

Exposure and vulnerability to climate hazards have varied across North America by region and by population (*high confidence*). These differences have been often underpinned by social and economic inequalities and have been observed between households, social groups, rural and urban communities, and Indigenous Peoples (*high confidence*). These vulnerabilities have also been observed to contribute to maladaptation (*medium confidence*) (14.5.9.1). Social and economic trends and development will determine near-term impacts on livelihoods from projected climate hazards; livelihoods will also adapt to the risks and opportunities (*high confidence*) (14.5.9.2). Actions to enhance the livelihoods of the most vulnerable social groups in North America will lessen the impacts of climate hazards on them (*high confidence*) (14.5.9.3).

14.5.9.1 Observed Impacts

Livelihoods are 'the resources used and the activities undertaken in order to live. Livelihoods are usually determined by the entitlements and assets to which people have access' (IPCC, 2018) (8.1.1). While often understood as subsistence or traditional ways of life (Oswal, 1991), livelihoods are often conceptualized more broadly as encompassing the economic, cultural, and social capitals or assets, capabilities, and activities that individuals, households, and social groups use as the means to make a living (DFID, 1999; Obrist et al., 2010).

Past and current patterns of development in North America have propagated and perpetuated vulnerabilities that have created differential impacts on livelihoods from climate hazards (*high confidence*). Predatory and extractive economies have underpinned economic activity in North America historically and currently. While generating substantial wealth, these patterns have also driven social and economic inequality (*medium evidence, high agreement*) (Jasanof, 2010; Shove, 2010; Klinsky et al., 2016; Robinson and Shine, 2018). Patterns of development that reinforce these structures remain a large contributor to current social-environmental risks and have affected all kinds of contemporary livelihoods (Cannon and Müller-Mahn, 2010; Koch et al., 2019) (also, see Chapter 18).

Climate impacts have damaged livelihoods across North America, especially those of marginalized people (*high confidence*) and deepened inequalities for these groups (*medium confidence*). Across North America, climate change has affected livelihoods with larger effects on individuals, households and communities that are already more vulnerable due to a range of pre-existing social and environmental stressors (Olsson et al., 2014; Hickel, 2017; Koch et al., 2019) such as Indigenous Peoples, urban ethnic minorities, and immigrants (Guyot et al., 2006; Gronlund, 2014; Klinenberg, 2015). These impacts have also contributed to a deepening of inequalities for marginalized groups (Audefroy and Cabrera Sánchez, 2017; García et al., 2018) (*medium evidence, high agreement*). As climate hazards further degrade their livelihoods, these groups have faced additional challenges to avoiding or escaping poverty (Ruiz Meza, 2014). Furthermore, these groups have needed to use their more limited resources to manage present challenges, restricting their future capacities to adapt (Tolentino-Arévalo et al., 2019). Climate impacts have also affected the livelihoods of the middle classes (Domínguez et al., 2020) who have become more vulnerable due to changes in their social and economic security (Garza-Lopez et al., 2018). Gender has also been recognized as a determinant of differential vulnerability with implications for women's livelihoods (Cross-Chapter Box GENDER in Chapter 18).

Migration and mobility have been an important part of livelihoods in North America (*high confidence*). Movement across North America has been reinforced by social, cultural and economic ties (Box 14.5). For example, middle class retirees from Canada and the US engage from temporary, seasonal to permanent migration to the warmer climates of the Southern US and Mexico, often benefiting from the lower cost of living (Domínguez et al., 2018). Temporary or semi-permanent labor migration, generally followed by remittances, has been an important part of livelihoods for rural areas in Mexico (*high confidence*) and has been employed as a response to climate hazards (*low evidence*). Drought in rural areas which are highly dependent on subsistence agriculture have observed migration to urban areas in Mexico (Nawrotzki et al., 2017). Evidence of international migration in response to climate hazards is sparse with difficulties in identifying a climate signal due to the multi-causal nature of migration decision-making (Cross-Chapter Box MIGRATE in Chapter 7). There is limited evidence of extreme weather events or climate hazards on migration from Mexico to the United States (Nawrotzki et al., 2015b; Nawrotzki et al., 2015c; Nawrotzki et al., 2016; Murray-Tortarolo and Salgado, 2021).

Pre-existing social vulnerabilities have also led to forced displacement from extreme weather events (*low confidence*). In the US, compounding effects of SLR and storm surge interacted with pre-existing social vulnerabilities of local communities to generate large-scale displacement after the effects of Hurricane Katrina on New Orleans in 2005 (Jessoe et al., 2018). The processes of relocation and recovery in New Orleans was further shaped by vulnerability where out-migration was more likely to be minorities and economically disadvantaged while the recovery was predominantly in neighborhoods that were wealthier prior to the disaster (Fussell et al., 2014; Fussell, 2015). Newer evidence from Hurricane Maria in Puerto Rico in 2017 has shown an initial spike in displacement with slower recovery with more vulnerable communities returning at higher rates (DeWaard et al., 2020); however, overall out-migration trends have been consistent with long-term economic migration (Santos-Lozada et al., 2020). Interactions of slower onset climate hazards with displacement, such as observed in Shishmaref, Alaska, have revealed the challenges in attribution of migration to climate as it intersects with socioeconomic conditions and lived experiences (Marino and Lazrus, 2015).

Maladaptation has also been occurring in livelihoods, especially as it relates to agricultural practices that are less resilient to climate hazards and competition for land use (*limited evidence, high agreement*). Focusing on examples in Mexico (see 14.5.4.3 for US and Canada examples), for some Mexican Indigenous Peoples, the replacement of ancestral farming practices with technological adaptations like transgenic crops has reduced their resilience by making them more dependent on external inputs and more expensive supplies while increasing putting their health at risk with herbicide and insecticide use (Mercer et al., 2012). Existing power structures have also interacted with climate hazards to generate maladaptive outcomes (Quintana, 2013). Mennonite communities in the northern state of Chihuahua, Mexico have pursued commercial agricultural markets that lead them to shift to transgenic crops and to overexploit local groundwater resources in a region experiencing multi-year droughts. These actions have led to conflict with other local farming groups with less economic capital to access groundwater (Quintana, 2013). Climate mitigation measures may also have adverse effects on local livelihoods with implications for adaptive capacity. The Reducing Emissions from Deforestation and Forest Degradation in Developing Countries (REDD+) mitigation program has been highlighted as a trade-off between an international/national carbon mitigation strategy and the ability of some Mexican rural communities to improve their food security (Barbier, 2014) (5.6.3.3).

14.5.9.2 Projected Risks

Livelihoods will evolve as a result of both challenges presented directly or indirectly from climate impacts as well as socioeconomic changes and technological developments (*high confidence*). Livelihoods, however, can be undermined by many of the projected climate risks with the impacts depending on adaptive capacity and adaptation limits (*high confidence*) (8.4.5.1). Real areas in Mexico and the southern US with agriculture-based livelihoods and projected reduction in precipitation will be adversely affected (Esperon-Rodriguez et al., 2016) (14.5.4). Outdoor workers in rural and urban areas will be exposed to higher health risks from higher temperatures and heatwaves (14.5.8). Reduced livelihoods will also be associated with adverse mental health effects (14.5.6.8).

Future climate hazards will deepen patterns of social inequality as vulnerable groups may also experience intersecting impacts that adversely affect their livelihoods (*medium confidence)*. Health, in particular, will be a key intersection as marginalized and disadvantaged groups often have poorer health status and hold occupations that may involve higher exposure to climate hazards. African Americans are expected to experience the largest impacts on their health status due to differential exposure and vulnerability to climate hazards (Marsha et al., 2016) (Section 14.5.6).

Displacement, migration and resettlement will increase along higher emission pathways (*medium confidence*). Combining projections of SLR and population scenarios for the US, Haer et al. (2013) and Hauer et al. (2016) have estimated the magnitude of the population at risk in coastal communities, numbering in the millions. In the near-term, where climate hazards influence out-migration, it will mostly augment existing patterns as migration is strongly influenced by existing social networks (7.3.2). Planned relocation and resettlements will reduce the exposure to climate hazards for the involved populations but could adversely affect their livelihoods in the absence of supportive programs (Jantarasami et al., 2018a) (7.3.2), since livelihood outcomes strongly depend on socioeconomic conditions.

14.5.9.3 Adaptation

Climate hazards undermine adaptation by damaging livelihoods (*high confidence*). Many actions that enhance and promote resilient livelihoods can have substantial benefit for adaptation to climate hazards (*medium confidence*). Livelihoods in the context of climate change are characterized by adjustments that then feedback into the assets that comprise a livelihood. Social capital - in the form of household and community cohesion - facilitates the development of adaptation strategies to the impacts of climate change in rural and urban communities at the household level and for small groups (Barbier, 2014; Nawrotzki et al., 2015b; Nawrotzki et al., 2015c). Cultural capital, especially in the form of local knowledge and Indigenous knowledge, can guide adaptation practices in North America (Akpinar Ferrand and Cecunjanin, 2014), preserving Indigenous cultures and enhancing future adaptation and resilience (Pearce et al., 2012 2015; Audefroy and Cabrera Sánchez, 2017) (Box 14.1). In Mexico, rain-water harvesting (practiced by some Mayan communities) and the use of local-traditional varieties of maize have assisted in the adaptation to climate impacts and promoted food security (Akpinar Ferrand and Cecunjanin, 2014; Hellin et al., 2014). Funding and support for these social adaptation strategies have been uneven (Barbier, 2014; Romeo-Lankao et al., 2014). The legacy of colonialism and historical patterns of development will continue to shape the adaptation responses and resiliency of Indigenous Peoples (Todd, 2015; Davis and Todd, 2017; Whyte, 2017; Cameron et al., 2019).

Migration is a common adaptation strategy to maintain and diversify people's livelihoods and will continue to play an important role when households manage climate and social risks (*high confidence)* (7.4.3). In the near-term, actions that enhance in-situ adaptive capacities as well as fostering safe and orderly migration can result in synergies for both adaptation and development (Cross-Chapter Box MIGRATE in Chapter 7). Populations that experience less mobility or cannot engage in voluntary migration as an adaptation may need additional support to adapt to climate hazards, for example northern communities that are at risk of climatic events (Hamilton et al., 2016). Policies associated with the transition from high GHG intensive extractive industries, sometimes referred to as "just transitions", may also support in-situ livelihoods if they also aim to address and redress existing inequalities to reduce vulnerabilities (McCauley, 2018); however, these policies could result in maladaptation if they create new inequalities or generate other environmental damages.

14.5.10 Violence, Crime, and Security

Elevated rates of various types of crime have been associated with higher temperatures in the US and Mexico (*medium confidence based on limited evidence and high agreement*) (14.5.10.1). If social relationships prevailing now and in the recent past continue, projections show future crime rates in the US and Mexico increasing with increasing temperatures (*low confidence*) (14.5.10.2). Degradation of human security and conflicts exacerbated by climate change—even outside of North America—will increase the demand for humanitarian assistance, foreign aid and resettlement (*medium confidence*) (14.5.10.2).

14.5.10.1 Observed Impacts

14.5.10.1.1 Violence and crime in the past and present

Crime, including violent crime, has been associated with higher temperatures in the US (*medium confidence*). Studies of crime statistics in the US have revealed a relationship between temperature and a range of violent crimes including aggravated assaults, rapes, and homicides; effects for property crimes are weaker (Ranson, 2014; Houser et al., 2015; Heilmann and Kahn, 2019; Mares and Moffett, 2019) (*limited evidence, medium agreement*). These effects have been observed in US urban centres (Hsiang et al., 2013; Mares, 2013; Ranson, 2014; Schinasi and Hamra, 2017; Heilmann and Kahn, 2019) and more generally across the US (Mares and Moffett, 2019). Differential effects have also been observed within urban areas. Observed higher rates of domestic and intimate partner violence during periods of high heat in less affluent neighbours in Los Angeles have been associated with disparities in access to air conditioning and greenery (Heilmann et al., 2021). By contrast, (Lynch et al., 2020a) found no significant correlation between annual homicide rate and annual temperature for New York City (Lynch et al., 2020b). For Mexico, (Burke et al., 2018a) found temperature linkages with intergroup killings by drug-trafficking organizations, homicides, and suicides. No linkages between temperature and crime have been reported for Canada. Differences in spatial and temporal aggregation of the crime statistics as well as in the measure of climate change or variability explain some of the differences between studies. Several causal pathways can explain these relationships (Miles-Novelo and Anderson, 2019; Lynch et al., 2020b). The dominant theory is that weather changes result in changes in behavioural patterns that lead to more opportunities for crimes. For example, studies that disaggregate by month often report significant positive associations between temperature anomalies and violent crime (especially aggravated assaults, rapes, and homicides), particularly in the cold season (Harp and Karnauskas, 2018; Mares and Moffett, 2019)). Smaller increases in crime during positive warm-season temperature anomalies may be due to people seeking shelter in cooler indoor spaces, decreasing crimes of opportunity (Gamble and Hess, 2012) (7.2.7).

The archaeological record has been used to infer linkages between climatic variability and social process, including violence (inferred with *medium confidence*). Past North American societies have been exposed to greater climatic variability than is documented in the instrumental record. Because future climatic conditions are likely to exceed those known for the recent past (Cross-Chapter Box PALEO in Chapter 1), the North American archaeological record can illuminate possible relationships between climate variability and violence that cannot be observed in the present record. In the upland US Southwest between A.D. 600 and 1280, one study found that violence significantly increased as climatically-controlled maize production decreased and interannual variability increased (Kohler et al., 2014) (*low evidence, high agreement*); massive emigration from the northern Southwest in the last half of the AD 1200s is connected with though not completely explained by climatic variability (Scheffer et al., 2021). In the central and southern Maya lowlands, following centuries of increasing populations and attempts to produce more maize (Roman et al., 2018), episodes of drought and/or increased summer temperatures in the 9th and 10th centuries AD (Dunning et al., 2012; Kennett et al., 2012) accompanied increased conflicts and social disintegration including collapse of long-lived dynasties, cessation of monumental inscriptions (Carleton et al., 2017) and emigration (*medium evidence, medium agreement*). Such findings reinforce research on contemporary societies that climate-induced farming shortfalls in regions dependent on agriculture may induce or exacerbate conflict, especially in interaction with unfavourable demographic, political, and socioeconomic factors (e.g. (Koubi, 2019))(*medium evidence, medium agreement*) (7.2.7.).

14.5.10.1.2 Security

Climate change poses risks to peace (16.5.2.3.8) that could affect North America (*medium confidence*). Military and security communities are adapting their planning, operations and infrastructure to current impacts of climate change in North America and globally (*medium agreement, medium evidence)*. Arctic nations are renewing their military capacity and expanding their constabulary presence around their existing boundaries (Choi, 2020). There is increasing awareness that climate change causes weather patterns and extreme events that directly harm military installations and readiness through infrastructure damage, loss of utilities, and loss of operational capability (Duffy-Anderson et al., 2019). Transboundary disputes and competition over resources such as fish (Østhagen, 2020) are a concern in the changing Arctic and increases in military and constabulary operations are being observed (Jönsson et al., 2012; Smith et al., 2018; Eyzaguirre et al., 2021).

14.5.10.2 Projected Risks

14.5.10.2.1 Violence and Crime

Projections of future crime derived from the empirical relationships between temperature and crime in the US show the potential for increased criminality under RCP8.5 compared to RCP4.5 (*low confidence*). For RCP8.5, holding all socioeconomic conditions at 2015 levels, violent crime could increase 0.6 –2.1% by mid-century and 1.9 –4.5% by late-century (Houser et al., 2015). The rise in property crime is projected to be smaller as property crime flattens at higher temperatures (Hsiang et al., 2013). Using relationships between crime and monthly temperatures established for five US regions by Harp and Karnauskas (2018), Harp and Karnauskas (2020) project 18,800 additional violent crimes annually beyond 2014 levels by the end of the 21st century under 1.5ºC warming, rising to 48,200 under 4ºC warming. Aggregating data by states weighted by population density, (Mares and Moffett, 2019) project an average annual increase of 0.94% across seven categories of violent and property crime for each anomalous ºC warming (an average annual increase of about 100,000 crimes). Changing socioeconomic conditions in the future may either reduce or exacerbate the projected contemporaneous relationship between temperature anomalies and crime (Agnew, 2011; Lynch et al., 2020b) whereas adaptation could weaken these relationships.

14.5.10.2.2 Defense and Security

Climate change will affect ecosystems (16.5.2.3), living standards (16.5.2.3.4), health (16.5.2.3.5), and food security (16.5.2.3.6) globally and these changes may exacerbate violence and political instability (*medium confidence)* with implications for national security in North America (*medium confidence*). Climate variability, hazards, and trends to date have played a role in exacerbating conflict, but the influence of climate appears to be minor and more uncertain than the roles of low socioeconomic development, low state capability and high intergroup inequality (Mach et al., 2019). More profound impacts from climate change on weather and seasons as well as changing socioeconomic conditions could lead to patterns of violence that cannot be predicted by projecting relationships between current climate and violence into the future (14.6.3) (Mach et al., 2019). If global levels of violence increase, there will be increased demand for international efforts, including disaster aid and humanitarian efforts (Eyzaguirre et al., 2021). Climate change and geopolitical goals interact in the Arctic (Smith et al., 2018). New transportation corridors and the potential access to natural resources could lead to competition for access to and control over the region (Estrada, 2021) (CCP6.2.6; Box CCP6.1; FAQ CCP6.2). Governance structures exist to manage geopolitical manoeuvring and to protect the human security of Arctic populations (14.5.10.3; 7.2.7.1).

14.5.10.3 Adaptation Options

14.5.10.3.1 Violence and Crime

Co-benefits from adaptation options include improving the liveability of and quality of life in cities, reducing socioeconomic vulnerability and exposure to locally higher temperatures (*medium confidence*). Urban settings in the US have disproportionately higher exposure to urban heat island effects in low-income and minority neighbourhoods in US cities (14.5.5.1). Co-benefits from adaptation responses in the urban landscape can reduce socioeconomic vulnerabilities and exposure to higher temperatures (14.5.5.3). Evaluation of adaptation efforts to reduce crime rates that have been associated with temperature are limited. In LA, a link has been inferred between violence and older buildings that may lack air conditioning (Heilmann et al., 2021). By contrast, access to air conditioning did not appear to lessen crime rates in Mexico (Baysan et al., 2019).

14.5.10.3.2 Defence and Security

Existing environmental and international agreements that consider climate risks can contribute to cooperation (*medium confidence*). Strengthening and empowering existing environmental and diplomatic avenues (e.g., the Arctic Council and international agreements such as the United Nations Convention on the Law of the Sea, and various subnational actors and agreements (CCP6.3.2)) to incorporate risks from climate impacts could enhance cooperative avenues for defusing conflict (Huebert et al., 2012). Improving the consideration of climate risks in efforts to expand economies and trade (Box 14.5), and improvements in peace-keeping (7.4.4) (Barnett, 2018) could also reduce future conflict risks.

14.6 Key Risks

Ten key risks from climate change were identified for North American based on definitions and assessment approaches outlined in Chapter 16, which were extended to include the development of a risk database and analysis that included expert evaluation of interactions between climate hazards and sectors (Figure 14.11, SM14.3).

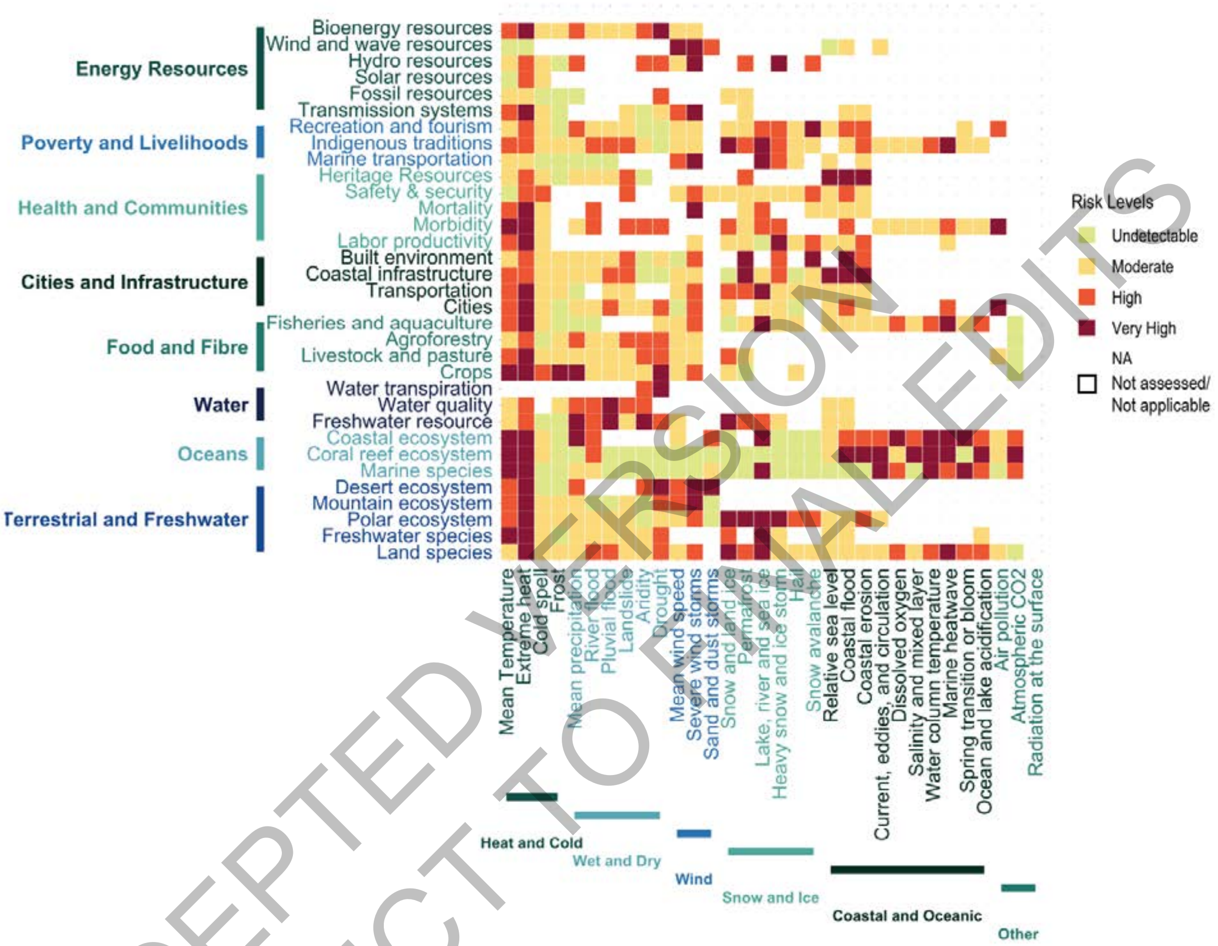

Figure 14.11: Rapid assessment of relative risk by sector (y axis) and climate hazard (x-axis) for North America based on an assessment of asset-specific vulnerability and exposure across climate hazards (see SM14.3 for methodological details). For each unique combination, the hazard by sector risk was ranked as very high (very high risk and *high confidence*), high (significant impacts and risk, *high to medium confidence*), medium (impacts are detectable and attributable to climate change, *medium confidence*), low or not detected (risk is low or not detectable). Blank cells are those where the assessment was not applicable or not conducted. Risks identified through the rapid assessment were further evaluated in the chapter assessments (see corresponding sector text for full assessment of risk and impacts).

14.6.1 Key Risks of Climate Change for North America

In North America, divergent perceptions regarding the attribution and implications of climate change pose a key risk to adaptation mainstreaming (KR1). This lack of adequate adaptation in turn amplifies threats to human life and safety from intensifying extreme events, fires, and storms (KR2). Climate change hazards pose risks to economic and social well-being (KR3), marine social-ecological systems (KR4), unique terrestrial ecosystems and their services (KR5), freshwater services (KR6), physical and mental health (KR7), food and nutritional security (KR8), and commerce and trade (KR9). Cumulatively, these risks interact to imperil the quality of life for North American communities, cities, and towns (KR10).

14.6.2 Key Risks across Sectors in North America

KR1: In the public and policy domains, divergent perceptions of anthropogenic climate change pose a risk of inaction on adaptation efforts to reduce exposure and socioeconomic vulnerability

Complex factors including individual beliefs, ideology, worldview, partisan identity, as well as societal context influence how the public, as well as professional groups, communities, and policy makers, perceive and understand climate change (14.3.3; 14.3.4) (*high confidence*). While there is expert scientific consensus on anthropogenic climate change, rhetoric, misinformation and politicization of science have contributed to misperceptions (*high confidence)*, polarization on the severity of impacts and risks to society, indecision, and delayed action (14.3.1) (*high confidence*). In North America, this impedes adaptation efforts (14.3.4) and inflates climate risks (*high confidence*).

KR2: Risk to life, safety, and property from intensifying extreme events

Human life and safety across North America and especially along the coasts of Mexico, the Hawaiian Islands, Gulf of Mexico, Atlantic Canada and southeastern US will be placed at risk from SLR and severe storms and hurricanes, even at 1.5ºC GWL (*very high confidence*) (14.5.2,14.5.5, Box 14.4). Warming, heatwaves, and increases in wildfire activity in many regions of North America pose risks to air quality, health, lives, and property (Box 14.2). More extreme precipitation and flooding pose a risk to human morbidity, mortality, and safety in fluvial flood zones and areas downstream of levees, dams, and flood culverts. Increasing intensity of storm events poses a risk of landslides, erosion, and flooding in shoreline and urban communities, especially high bank areas along exposed coasts, in Arctic and temperate areas where winter sea ice has diminished, and in low-lying coastal areas where SLR and storm surge often overwhelm existing natural coastal features and engineered structures (14.5.5, Box 14.4).

KR3: Cumulative damages from climate hazards pose a substantial risk to economic well-being and shared prosperity

Climate change impacts are projected to cause large market and non-market damages (*high confidence*). By end-of-century under higher GWL scenarios (>4°C), these damages are expected to reach several tens of billions of dollars/annually in Canada and hundreds of billions/annually in the United States. Losses in labour productivity and wages, and damages to coastal properties will be especially large; however, all sectors in the US and most sectors in Canada are projected to see substantial relative damages on high emission pathways by mid to end-of-century compared to lower emission pathways. Economic sectors with hard limits to adaptation (i.e., winter tourism) or that are highly affected by climate variability (i.e., agriculture and fisheries) will be at more risk at lower temperatures than other economic sectors (14.5.7; 14.5.8). Strategic implementation of adaptation strategies coupled with lower emissions scenarios result in multi-billion-dollar reductions in economic damages (14.5.8, Box 14.6).

KR4: Risk of degradation of marine and coastal ecosystems, including loss of biodiversity, function, and related services with cascading effects for communities and livelihoods

Ocean warming will increase the frequency and intensity of marine heatwaves (MHWs, Box 14.3), accelerate unprecedented rates of sea ice loss, and alter ocean circulation, chemistry, and nutrient cycling in ways that profoundly impact marine productivity, biodiversity, and foodwebs (*very high confidence*) (Section 14.5.2). Collectively these impacts pose a risk to nearshore ecological and human systems (*high confidence*), increasing the probability of phenological mismatches, large-scale redistribution of species, and species population declines (14.5.4) with cascading impacts that strain cultural and economic systems reliant on marine productivity across North America (*high confidence*). Nearshore areas of Chesapeake Bay (US) and Akimiski Island, mid-western James Bay and the coasts in the Pacific ranging from of the Gulf of Alaska through Baja Peninsula have a high proportion of species near their upper thermal limit, and are areas of particularly climate change risk.

KR5: Risk to major terrestrial ecosystems leading to disruptions of species, ecosystems and their services

Major risks to terrestrial ecosystems across North America, such as semi-arid landscapes, rangelands, boreal and temperate forests, and Arctic tundra, include significant ecosystem transformations and shifts in species abundances and ranges and major vegetation types (e.g., transitions from forests to grasslands), with cascading implications for regional biodiversity (*very high confidence*). Warming increases the risk of permafrost thaw with propagating impacts on species and communities in the Canadian and US Arctic (*high confidence*; Ch. 6). Forest disturbances, including wildfire, drought, insects, and pathogens are expected to increase with warming, acting synergistically to raise the prevalence of tree mortality and ecosystem transformation (*medium confidence*; 14.5.1). These changes will reduce services provided by terrestrial ecosystems, including timber yields and carbon sequestration (*medium confidence*).

KR6: Risk to freshwater resources with consequences for ecosystems, reduced surface water availability for irrigated agriculture and other human uses.

Droughts and earlier snowmelt runoff will increase water scarcity during the summer peak water demand period especially in regions with extensive irrigated agriculture, leading to economic losses and increased pressures on groundwater as a substitute for diminished surface water supplies (*medium to high confidence*; 14.5.3). Streams in North America are expected to continue to warm, with important ramifications for aquatic ecosystems (*high confidence*), reducing habitat for salmon and trout species that are economically and culturally important (14.5.1). Warming and drying coupled with other stressors (e.g., pollutants, nutrients, and invasive species) pose a risk to ecosystem structure and function in lakes, streams and reservoirs across many parts of North America (*high confidence*) (14.5.1, 14.5.3). Warming, increases in heavy rainfall and nutrient loading pose risks for water quality and harmful algal blooms (*medium to high confidence*; 14.5.3).

KR7: Risk to human health and wellbeing, including mental health.

Heat-related human mortality is projected to increase in North America as a result of climate change and aging populations, poverty, chronic diseases and inadequate public health systems (*very high confidence*) (14.5.6.1). Gradual changes to temperature and precipitation are impacting urban ecosystems and creating ecosystem regime changes resulting in the poleward expansion among insects that bring risks related to vector-borne diseases such as West Nile virus and Lyme disease (*high confidence*) (14.5.6). Climate change is expected to lead to wide-ranging mental health challenges related to an increase in the psychological burdens of climate change (*high confidence*), particularly for individuals with existing mental health conditions, live in severely impacted areas, or who are reliant on climate for livelihoods and cultural well-being (e.g., Indigenous Peoples and farmers) (14.5.6.8).

KR8: Risk to food and nutritional security through changes in agriculture, livestock, hunting, fisheries, and aquaculture productivity and access

Cascading and interacting impacts of climate change threatens food systems and food and nutritional security for many North Americans, especially those already experiencing food and nutritional scarcity, women and children with high nutritional needs, and Indigenous Peoples reliant on subsistence resources *(high confidence*) (14.5.6). In agricultural regions experiencing aridification and where water scarcity precludes substantial expansion of irrigation, warming and extreme heat pose a risk to food and forage crop and livestock production (14.5.4) (*high confidence*). Ocean warming and marine heatwaves will continue to disrupt commercial capture fisheries through species redistribution and changes to yield (*high confidence)* and warming waters and OA will increasingly impact aquaculture production (*high confidence*) (14.5.4). Interactions between competing aspects of human security (e.g., food, energy, and water) will be exacerbated by climate change (*high confidence*) (Sections 14.5.3, 43).

KR9: Risks to major infrastructure supporting commerce and trade with implications for sustainable economic development, regional connections, and livelihoods

Climate change and extreme events are expected to increase risks to the North America economy via infrastructure damage and deterioration (*high confidence*), disruption to operations, unsafe conditions for workers (*medium confidence)*, and interruptions to international and interregional supply chains (*medium confidence*) (14.5.8, Box 14.5). These climatic impacts will have cascading implications for local livelihoods, sustainable economic development pathways, regional connectivity and will reinforce pre-existing social inequities (*medium confidence*). Infrastructure damage will also disrupt economic activities, including manufacturing, tourism, fisheries, natural resource extraction, and energy production (*high confidence*) (14.5.8).

KR10: Risk to the quality of life in North American communities, cities, and towns

In major North American cities and settlements, vulnerability to climate change has increased and is projected to continue to rise (*medium confidence*) (14.5.5). Concentrated populations with unequal adaptive capacities, exposure of valuable assets, ageing infrastructure, differing degrees of institutional capacity and effectiveness will underpin climate hazards (14.5.5). Coastal, riverine, and urban flooding displacing communities and coastal ecosystems (14.5.5.2) will become a dominant risk to urban centres (*high confidence*), will cause disruptions to transportation and trade infrastructure (14.5.8); large wildfires endangering lives, livelihoods, property and key infrastructure, and economic activities and contributing to compromised air quality and municipal water contamination (14.5.6, Box 14.2).

14.6.3 Cumulative risk, tipping points, thresholds and limits

Across North America, climate change poses a risk to social-ecological systems increasingly destabilized by compounding climate impacts and non-climate pressures (*high confidence*) (14.5.1-3) that erode the connectivity and redundancy underpinning system resilience (14.5.1-5) (Xiao et al., 2017a; Koven et al., 2020; Malhi et al., 2020; Turner et al., 2020). Accelerating climate change and increasingly severe hazards and shocks may induce abrupt changes or push systems, people, and species to critical points--i.e., tipping points, where a small additional change causes a disproportionately large response, triggering feedbacks that lock systems into novel regimes (Scheffer et al., 2001; Scheffer, 2010; Anderies et al., 2013; Lenton, 2013; Iglesias and Whitlock, 2020; Lenton, 2020a). Climate change tipping points can compound and amplify climate impacts and risk, induce disparate climate burdens and benefits across human and ecological systems, and irreversibly restructure ecosystems and livelihoods (e.g., species extinctions, fisheries collapse, community managed relocation) (Lynham et al., 2017). Examples of systems with potential tipping points in North America include permafrost and sea-ice loss triggering transformation of ecological and human systems (including substantial shipping opportunities) in the Arctic that are permanent and irreversible except on geological timescales, and which are potentially underway (*high agreement, low evidence*) (14.6.2, Box 14.3, CCP6), mid-latitude forest ecosystems at low to middle elevations in western North America where wildfire and cumulative climate and non-climate pressures may restructure forests and succession in ways that promote transition to new vegetation types (Section 14.5.1), and agricultural communities in northern Mexico and the SW United States where aridification and drought may interact with water resource policies, economic opportunities and pressures, and farm practices to induce either adaptation (via changes in irrigation practices), or farm abandonment, land-use transformation, and livelihood changes (due to heat stress, soil deterioration, or reduced economic viability) (14.5.3, 14.5.4, CCP 6) (Yumashev et al., 2019; Turner et al., 2020; Heinze et al., 2021).

Identification of critical thresholds, elements, and connections within a system may also help identify potential positive tipping points, i.e., focal components or processes in a system where a relatively small investment or intervention can induce a large benefit and enable self-reinforcing transformative adaptation (14.7, Ch 17) (Tàbara et al., 2018; Lenton, 2020b; Otto et al., 2020). Under low mitigation scenarios, compounding risks and higher carbon emission scenarios increase the potential that amplifying feedback loops and fatal synergies across sectors could lead to existential threats to the socio-ecological systems of North America (*medium confidence*). Societal collapse has been linked to shifts in climate regimes, especially when societies have lost resilience due to slowly mounting socio-ecological challenges; while other studies reveal that social continuity and flexibility enable historical climate resilience and prosperity under changing environments (Lenton et al., 2019; Otto et al., 2020; Degroot et al., 2021; Richards et al., 2021) (FAQ 14.2).

Accounting for tipping points, interactions, and reinforcing dynamics among ecological, social, and climate processes is necessary for comprehensive analyses of climate change risk, cost, and urgency, as well as effective adaptation design and implementation (14.7) (Cai et al., 2015; Steffen and et al., 2018; Lenton et al.; Narita et al., 2020; Dietz et al., 2021). Multiple lines of evidence across sectors assessed in this chapter suggest that after mid-century and without carbon mitigation, climate-driven changes to ecological and social boundary conditions may rapidly push many systems into disequilibrium (*medium confidence*), emphasizing the importance of prioritizing adaptation actions with co-benefits for mitigation (14.5.4, Box 14.3). Reducing climate hazards through mitigation and removing catalysts of system instability through adaptation measures that increase system resilience (e.g., ecosystem restoration) will help reduce the risk that systems move across a tipping point from a desirable to an alternate or undesirable state (14.5.4, 14.7, Box 14.3) (Narita et al., 2020; Turner et al., 2020; Heinze et al., 2021).

[START FAQ 14.2 HERE]

FAQ 14.2: What can we learn from the North American past about adapting to climate change?

The archaeology and history of Indigenous Peoples and Euroamerican farmers show that climate variability can have severe impacts on livelihoods, food security, and personal safety. Traditional societies developed numerous methods to cope with variability, but have always expanded to the limits of what those adaptations permit. Current knowledge and technology can buffer societies from many negative effects of climate change already experienced but will be severely challenged by the novel conditions we are now creating.

People came into North America more than 15,000 years ago and have experienced both massive and minor shifts in climate ever since. At the end of the last very cold phase of the most recent Ice Age, about 11,500 years ago, temperatures rose extremely rapidly—as much as 10ºC (18ºF) in a decade in some regions. This undoubtedly contributed to the extinction of large mammals like mammoths and mastodons that people hunted alongside many other resources (see Cross-Chapter Box PALEO in Chapter 1). There were so few people on the land though, and other resources were so abundant, that the long-standing human means of coping with climate variability—switching foods and moving on—were sufficient.

Following the end of the Ice Age, populations across North America grew for the next few thousand years, at a rate that increased once people began to domesticate corn (maize), beans, and squash (the "Three Sisters") as well as other crops. However, more people meant less mobility, and farmers are also more invested in their fields and remaining in place than foragers are to hunting grounds. Other means of coping with vulnerability to food shortage caused by climate variability included some continued hunting and gathering of wild resources, planting fields in multiple locations and with different crops, storage in good years, and exchange with neighbours and neighbouring groups.

According to archaeological evidence, however, these adaptation strategies were not always sufficient during times of climate-induced stress. Human remains showing the effects of malnutrition are fairly common, and conflict caused in part by climate-induced shortfalls in farming has left traces that include fortified sites, sites placed in defensible locations, and trauma to human bone. Larger and more hierarchical groups emerged, first in Mesoamerica and then in the US Southwest, Midwest, and Southeast. These groups offered the possibility of buffering poor production in one area with surplus from another, but they also tended to increase inequality within their borders and often attempted to expand at the expense of their neighbours, introducing new sources of potential conflict. Dense hierarchical societies also arose in other areas such as the Northwest coast where agriculture was not practiced but resources such as salmon and roots were abundant and either relatively constant or storable.

These societies were not immune to climate hazards despite their greater population and more formal organization. Archaeological evidence strongly suggests that drought, or growing conditions that were too hot or cold, contributed to the decline of groups ranging from Classic period Maya states in Mesoamerica, to the somewhat less hierarchical societies of Chaco in the US Southwest and Cahokia in the US Midwest (Figure FAQ14.2.1). The usual pattern seems to be that climatic variability compounded social and environmental problems that were already challenging these societies.

If societies in North America prior to the Euroamerican colonization were vulnerable to climate variability, surely the more recent and technologically advanced societies of North America were at lower risk? The 20th Century Dust Bowl created in the US and Canadian prairies suggests otherwise. Severe drought conditions throughout the 1930s—which to make matters worse peaked during the Great Depression—did not cause either the US or Canada to collapse. But both countries suffered massive economic losses, regional loss of topsoil, and regional human strife (including loss of crops, income, and farms) leading to migration. Yet anthropogenic global climate change was of little or no consequence in the 1930s. While farming practices made climate stress worse, the climate variability itself was either completely, or mostly within the envelope of historical climate variability that earlier human societies had experienced.

Indigenous Peoples and Euroamerican farmers and ranchers have a long history of mostly successful adaptation to changing weather patterns. The wisdom held by Indigenous families and communities includes deep knowledge of how plants, animals, and atmospheric conditions provide early-warning signals of approaching weather shifts, and stories about how past communities have tried to cope with climate-related resource shortfalls. Long-standing community-level management of resources also helps prevent shortfalls, and institutions such as kin groups, church groups, clubs, and local governments (which exist in communities of both Euroamericans and Indigenous Peoples, in different forms) can be powerful aids in ameliorating shortfalls and resolving conflict.

Still, Indigenous knowledge, and traditional knowledge among Euroamerican farming communities, provide guidelines for how to cope with *traditional* problems. Contemporary governmental restrictions (such as legal water rights allocations, international borders and tribal lands boundaries) have limited the adaptive capacity that Indigenous societies developed over the centuries. Now human-caused climate forcing, if not mitigated by reducing heat-trapping greenhouse gases, is expected to produce climates in North America that have no local analogs in human history even as it destroys heritage sites that are sources of knowledge about paleoclimates and the diverse ways of coping with them that past people have discovered. Just as past peoples often *avoided* local climate change by moving on, in a world where mobility options are severely limited a lesson from archaeology and history is that we should use our hard-won knowledge of the causes of climate change to avoid creating futures with no past analogs to provide useful guidance.

Figure FAQ 14.2.1: Examples of areas where past climate variability has contributed to crises. Climatic variability is mostly likely to lead to crisis when it is accompanied by social, demographic, and political conditions or environmental mismanagement that compound climatic impacts on societies.

[START FAQ 14.3 HERE]

FAQ 14.3: What impacts do changes in the North American Arctic have within and outside the region?

The North American Arctic is warming at nearly three times the global average, creating a cascading web of local, regional, and global impacts within and beyond polar regions. Changes in the Arctic not only effect global ocean circulation and climate regulation, but also facilitate new Arctic transportation routes and support transboundary resources with geopolitical, environmental, and cultural implications as conditions change.

Rapid warming and extreme temperatures in the Arctic is leading to unprecedented seasonal sea ice loss, permafrost thaw, and increasing ocean temperatures. Cascading from these biophysical changes are cultural, socio-economic and political consequences that are widespread and largely unprecedented in human history.

Changes in sea ice create safety hazards for Indigenous Peoples and northerners who rely on frozen seas and rivers for transportation between remote communities and to subsistence hunting areas. Thawing permafrost, especially that of ice rich permafrost, creates challenges and costs for a region with low population density and a small tax base to support major infrastructure investments. Warmer ocean temperatures induce large-scale distributional shifts and reduced productivity and access to the largest North America fisheries. Ice-associated marine mammals, such as Polar bears, seals, and walrus, have declined precipitously with decreasing sea ice in the Bering Sea, and widespread ecosystem changes from fish through birds and marine mammal species have altered the system with uncertain outcomes for these productive ice-driven ecosystems. Newly ice-free shipping routes are increasing regional and geopolitical tensions and may facilitate novel threats like the spread of invasive species and safety hazards to local hunters and fishers. The local and regional impacts of climate change in the North American Arctic are profound and span social, cultural, health, economic, and political imperatives.

Although the region is remote, changes in the Arctic impact the rest of the world. The Arctic serves as a regulator of global climate and other ecological processes through large-scale patterns related to air and ocean circulation. These vitally important processes are nearing points beyond which rapid and irreversible (on the scale of multiple human generations) changes are possible. The magnitude of cascading changes over the next two centuries includes regional warming and temperature extremes, permafrost declines, and sea ice loss beyond that experienced in human existence. This includes macro-scale risks related to sea level rise from the melting of glaciers and thermal expansion of oceans. Changes in the Arctic are more pronounced than elsewhere and portend climate change impacts in other areas of the globe.

Adaptation in the Arctic is underway and lessons learned on what works and what is effective and feasible to implement can provide global insights. Successful adaptation in the North American Arctic region has been attributed, in part, to the explicit and meaningful inclusion of Indigenous Knowledge and Indigenous self-determination, and diverse perspectives in decision making processes, strong local leadership, co-management approaches, technological investment in integrated climate modeling and projections, and multilateral cooperation.

[END FAQ 14.3 HERE]

14.7 Adaptation in North America

14.7.1 Overview of Observed Adaptation in North America

Climate adaptation efforts have increased across all North American regions and sectors (*high confidence*). Support for and implementation of adaptation policies, plans and measures have not been equal across the public and private sectors, regions or varying levels of governance (*high confidence*) (Table 14.7). To date, reactive (coping-based) and incremental adaptations have helped North Americans avoid greater damages from observed climate impacts (*medium confidence*). There is increasing agreement that worsening impacts and expanding risk conditions may exceed current adaptation capacities by mid-century under high emissions scenarios (RCP8.5) (*medium confidence*).

14.7.1.1 Individuals and Households

Across North America, individuals and households have taken action to reduce climate-influenced risks (*high confidence).* These autonomous adaptations comprise the majority of the observed responses in the peer-reviewed literature (Berrang-Ford and et al., Accepted). The increased use of cooling systems (which could be maladaptive unless there are innovations (14.5.5.3)) (Barreca et al., 2016), creating defensible space around homes in wildfire-prone areas (Box 14.2), and the modification or redesign of housing structures along coasts (Koerth et al., 2017) are important household responses to existing risks. Although these actions have played a role in reducing risks, the capacity to undertake such actions is not uniform across individuals in North America and has exacerbated existing social inequities, especially in coastal areas (Keenan et al., 2018; de Koning and Filatova, 2020). Additionally, these adaptation activities often are taken without consideration of the impact on mitigation efforts (Kates et al., 2012; Fedele et al., 2019; Shi and Moser, 2021).

14.7.1.2 Local and Sub-National Governments

A majority of local jurisdictions in North America have undertaken some level of adaptation; these efforts largely focused on planning and less on implementation (*high confidence*). Some sub-national governments, namely States and Provinces, have engaged in advanced adaptation planning efforts (*high confidence*). Indigenous Peoples in North America have undertaken substantial activities (14.4, Box 14.1).

Many cities across North America have undertaken adaptation planning (Hughes, 2015; Reich et al., 2016; Moser et al., 2017; Auditors General, 2018; McMillan et al., 2019) (14.5) with some financing adaptation implementation, for example, in the case of SLR (Box 14.4). Adaptation actions commonly implemented in cities include climate-informed building codes, enacting energy conservation measures, modifying zoning, and increasing green infrastructure (see 14.5.5.3; Box 14.7) (Binder et al., 2015; Maxwell et al., 2018a; Moss et al., 2019; Brown et al., 2021). The majority of cities have formed practitioner networks to share information (ICLEI Canada, 2016; Vogel et al., 2016; C40 Cities, 2018) and supporting learning and collaboration through regional collaborations that include utility managers and the private sector (Fünfgeld, 2015; Moser et al., 2017).

In Canada, the Map of Adaptation Actions Canada (https://changingclimate.ca/case-studies/) presents over 200 adaptation case studies addressing a variety of climate-related impacts (Warren and Lulham, 2021). The City of Saskatoon, in developing its Climate Action Plan (which includes a Corporate Climate Adaptation Strategy), engaged with local businesses, NGOs, residents and experts to identify potential risks (and benefits) requiring action (City of Saskatoon, 2019). Similarly, the City of Surrey specifically used community outreach programs to develop its Coastal Flood Adaptation Strategy (CFAS) through a value-based planning approach (City of Surrey, 2019). Municipal asset management, local services and community well-being were key considerations for the City of Selkirk, Manitoba when developing an adaptation strategy as well as ensuring a budgeting process that supports implementation (City of Selkirk, 2019). As of 2019, eight of thirteen Canadian provinces and territories have high-level climate adaptation strategies. The scope of these efforts vary by jurisdiction as a review conducted by federal and provincial auditors in Canada identified several deficiencies related to a lack of detailed implementation plans, obligated funding, and specific timelines (Auditors General, 2018).

Progress in Mexico on adaptation implementation at the local level has been extensive (INECC and Semarnat, 2018). Activities include executing programs for relocating infrastructure in high-risk zones in priority tourist sites, incorporating adaptation criteria in public investment projects that involve construction and infrastructure management, water management, application of climate adaptation norms for the construction of tourist buildings in coastal zones, and improving the security of key water, communication, and transportation infrastructure (14.5.5, 14.5.7, 14.5.8). Additionally, local capacity and protocol to respond to extreme weather events as a function of climate change have been integrated more regularly into community-based hazard mitigation plans. States and municipalities in Mexico must have climate policies that are consistent with the guidelines of national strategies (see 14.7.1.5) and state-level programs on climate change, in addition to other state and municipal laws. As a result, these entities have developed and implemented early warning systems designed to protect the population from climate-related risks, such as strong storms and hurricanes (INECC and Semarnat, 2018).

Implementation of adaptation initiatives and specific actions in US cities has increased in the approximately five years between the 3rd US National Climate Assessment (NCA3) (Melillo et al., 2014) and the 4th Assessment (NCA4), and adaptation responses have been observed widely (Lempert et al., 2018). ICLEI-USA provides numerous resources for adaptation planning and implementation for cities, Indigenous Peoples, and Regional Governments (https://icleiusa.org/). The Georgetown Center for Climate maintains a comprehensive resource for tracking adaptation progress for States (https://www.georgetownclimate.org/adaptation/plans.html). As of 2021, 18 US states have completed climate adaptation plans, and six states have plans underway as of the time of this report (Georgetown Climate Center, 2021). California, in particular, has adopted sustained climate assessment to allow for more rapid iterations on adaptation planning (Bedsworth et al., 2018; Miao, 2019). Across all US states, however, adaptation activities do not have readily accessible budgets, such that levels of funding cannot be assessed directly (Gilmore and St. Clair, 2018).

14.7.1.3 National/Multi-National Governance

The federal government of each North American country has developed policies and actions that promote climate adaptation (Figure 14.12). Recognizing the cultural, economic and social networks that span North America, the federal governments have also committed to engagement on adaptation and resilience across borders and through cooperation on domestic adaptation efforts (The White House, 2016). Each country also outlines their respective adaptation efforts through submissions under the UN Framework Convention on Climate Change (UNFCCC), including their Nationally Determined Contributions (NDCs) under the Paris Agreement. The federal governments also support adaptation efforts in other countries through international climate negotiations as well as related agreements, such as the Sendai Framework for Disaster Risk Reduction and efforts to support the achievement of the Sustainable Development Goals (SDGs).

Mexico's 2020 update to its first NDC communicated extensive adaptation efforts (Government of Mexico, 2020). The measures outlined in this document highlight the importance of co-benefits for adaptation efforts as they relate to the SDGs and to support mitigation commitments. Ecosystem- and nature-based solutions (Box 14.7) are the basis for much of the synergies between adaptation and mitigation efforts. These plans are supported by domestic legislation through the General Law on Climate Change, which includes the Climate Change Adaptation Process (CCAP). CCAP provides a holistic systems-approach for identifying instruments and institutional arrangements for adaptation implementation (Semarnat and INECC, 2015; INECC and Semarnat, 2018). This approach includes guidance for planning (e.g., the Climate Change Mid-Century Strategy, the Special Climate Change Program 2014–2018 (PECC)) and formalizes its adaptation commitments to the Paris Agreement.

In Canada, the Federal Adaptation Policy Framework (Government of Canada, 2011) guides domestic action to develop adaptation knowledge, build adaptive capacity, and mainstream adaptation into federal policy, in support of the Pan-Canadian Framework on Clean Growth and Climate Change (Government of Canada, 2016), which included specific adaptation measures and investments to build resilience. In August 2021, the government initiated a National Adaptation Strategy with development anticipated through 2022. Additionally, the government facilitates efforts and funds research, capacity building, and information sharing across sectors and amongst government departments (Government of Canada, 2021a). The Canadian Centre for Climate Services provides access to climate data, tools, and information (https://www.canada.ca/en/environment-climate-change/services/climate-change/canadian-centre-climate-services.html). In Canada's revised NDC, near-term commitments to protecting land and oceans and efforts related to sustainable and resilient energy systems are highlighted as examples of co-benefits between climate change adaptation and mitigation (Government of Canada, 2021b).

The US has experienced substantial revisions to its climate policy and its international engagement since AR5 with implications still unclear (Bomberg, 2021). Since AR5 and until early 2020, many congressionally mandated federal efforts (Beavers et al., 2016; Parris et al., 2016; Rockman et al., 2016; Caffrey and Hoffman, 2018) faced programmatic challenges, but most continued to provide research and capacity development to support adaptation implementation across the US. Importantly, the US government sustained the national climate assessments (Lempert et al., 2018). Recently, the administration has re-engaged with the Paris Agreement and the US has submitted an NDC (Government of the United State of America, 2021); however, adaptation was not directly addressed. Subsequent Executive orders mandate adaptation planning at the federal level (e.g., USEO 13754; USEO 14008). As of the time of this report, the US climate policy landscape is rapidly evolving, including major legislative initiatives (e.g., Green New Deal (Boyle et al., 2021).

14.7.1.4 Private Sector, Including Companies, NGOs, Professional Organisations, Academic Institutions, and Communities of Practice

The private sector comprises a diverse set of actors who influence, interact with and support adaptation efforts, generally through shared governance with the public sector. The weight of evidence points to the benefits of these collaborations and the importance of voluntary code-making and self-regulation (17.4.2.1.6). In North America, non-governmental organisations (NGO) and professional organisations have been important agents of change in the adaptation field (Bennett and Grannis, 2017; Stults and Meerow, 2017). Efforts included supporting community-based resilience efforts, network-building, web-based guidance and resources, case studies, workshops and other services to support adaptation action (e.g., vulnerability assessments, scenario-based planning).

Market and financial mechanisms have provided important buffering capacity against climate shocks in North America. Insurance products are being developed to meet emerging climate risks, especially related to availability and pricing of flood insurance in Canada (Thistlethwaite, 2017; Davies, 2020) and the United States (Kousky et al., 2021). Some existing US flood insurance products provided through joint public and private arrangements has led to rebuilding in flood-prone locations (Zellmer and Klein, 2016). The price of these products may limit their uptake in low income neighbourhoods (Cannon et al., 2020).

Professional organisations have participated in the development and adoption of measures to integrate climate resilience into the built environment. This includes new designs, guidelines, codes, standards, and specifications, in addition to infrastructure inventories that incorporate evaluation of vulnerabilities and identification of priority at-risk areas (Amec Foster Wheeler Environment and Infrastructure, 2017; ASCE, 2018a). These efforts are supported by provincial/state and federal initiatives (e.g., Canada's Climate Lens (Infrastructure Canada, 2018), and California's Climate-Safe Infrastructure Working Group (Climate-Safe Infrastructure Working Group, 2018)). Infrastructure Canada has undertaken Canada-wide initiatives to improve infrastructure resilience to climate change (https://www.infrastructure.gc.ca/plan/crbcpi-irccipb-eng.html). The Standards Council of Canada (SCC) established the Northern Infrastructure Standardization Initiative (NISI) (https://www.scc.ca/en/nisi) engaging stakeholders including Indigenous Peoples to develop standards specific for addressing climate change impacts on northern infrastructure design, planning and management, and community development (Standards Council of Canada, 2020).

Professional organisations in the US (e.g., National Medical Association, American Institute of Architects, Association of Metropolitan Water Agencies, Water Utility Climate Alliance, American Society of Adaptation Professionals, etc.) have engaged with their members particularly through training about urban adaptation (Stults and Meerow, 2017). The private sector and citizens (Klein et al., 2018) have been involved in the management of increasing flood risk, such as the adoption of property-level flood protection (Thistlethwaite and Henstra, 2018; Valois et al., 2019), implementing FireSmart Canada and Firewise USA guidance (Box 14.2). In Canada, Engineers Canada developed the PIEVC Protocol to provide guidance for professionals in engineering and geoscience (https://www.pievc.ca/).

Research-based institutions have accelerated the development of web-based tools for visualizing and exploring climate information, in addition to furthering the scholarship on adaptation. In the US, joint university, foundation, and government programs have contributed to advancing the field with products such as oceanographic and fishery climate forecasting tools (14.5.2), in addition to methods for evaluating water resource plans under uncertainty about future mean and extreme conditions (ASCE, 2018a; Ray et al., 2020). Some regional research centres focus on stakeholder engagement in addition to research; these include the National and Regional Climate Adaptation Science Center Network of the US Geological Survey (https://www.usgs.gov/ecosystems/climate-adaptation-science-centers), the US Department of Agriculture's Climate Hub Network (https://www.climatehubs.usda.gov/), and the Climate Program Office of NOAA (https://cpo.noaa.gov/) includes the Regional Integrated Science Assessment Network (https://cpo.noaa.gov/Meet-the-Divisions/Climate-and-Societal-Interactions/RISA/About-RISA) to support delivery of climate services. So-called "networks of networks," consisting of NGOs, state and city government programs, have provided an alternative to federal support. For example, the Science for Adaptation Network (SCAN) formed subsequent to dismantling the Federal Advisory group to the US National Climate Assessment (Moss et al., 2019).

14.7.2 The Solution Space

14.7.2.1 Incremental Adaptation, Barriers and Limits

Adaptation actions to moderate the effects of climate impacts are well-documented in North America and have buffered much of the past and currently observed climate impacts (e.g. Lempert et al., 2018; Lemmen et al., 2021). While it is challenging to catalogue adaptation activities as many are not published or are not necessarily undertaken with climate adaptation as the primary rationale (1.3.2.2), most of the activities identified by sector in this Chapter have been primarily incremental adaptation measures (*medium evidence*, *high agreement*). Many actions are extensions of existing practices for managing climate variability and there is broad agreement that worsening future conditions will exceed the capacity of many of these efforts (Kates et al.; Termeer et al., 2017; Fazey et al., 2018; Fedele et al.; Shi and Moser, 2021).

Progress in adaptation planning and implementation between regions in North America is uneven (Bierbaum et al., 2013; Moser et al., 2017; Auditors General, 2018; INECC and Semarnat, 2018; Shi and Moser, 2021) (Table 14.6, Box 14.7). At the local level (cities) in the US, commitment of elected officials, financial resources and awareness of climate change hazards and risks have been identified as driving the variation in climate adaptation (Shi et al., 2015). Adaptation programs have come under budgetary and political pressures that limit continuity of efforts (Moss et al., 2019). Implementation of adaptation has also faced challenges due to institutional arrangements, constraints, and gaps that prevent different levels of government, social organizations and academia to act in an integrated and timely way to consider biodiversity, agriculture and water systems (i.e., Box 14.7) (Bourne et al., 2016; Nalau et al., 2018).

Table 14.6: Adaptation trends and progress across sectors. Adaptation progress consists of assessment (A), planning (P), implementation of strategies (I), and evaluation of efficacy (E). L=low, M=moderate, H=high.

			Adaptation progress				Limits	
Sector	Strategies	Cases	A	P	I	E	Soft	Hard
Terrestrial Eco-Systems (14.5.1.1)	Broad use of tools such as scenario planning, structured decision making, and adaptation planning frameworks	Planning for climate refugia in the Sierra Nevada of California, USA (Morelli et al., 2016)	H	H	L-M	L	Management agency internal policies may prevent the flexibility required for implementation of adaptation strategies	Some species may face local extirpation or even extinction if adaptive capacity is overwhelmed
Oceans (14.5.2)	Proactive and rapid management approaches to minimize impacts of increasingly frequent entanglements of protected species, caused by climate-driven changes in prey and fishery activities	Dynamic closure areas to reduce loggerhead turtle bycatch in Hawaiian shallow-set longline fisheries (Howell et al., 2015; Lewison et al., 2015), blue whale ship-strike risk in near-real time (Hazen et al., 2017; Abrahms et al., 2019a), and bycatch of multiple top predator species in a West Coast drift gillnet fishery (Hazen et al., 2018).	H	H	M	M	Lack of coordination and planning at multiple scales as species redistribute across fishery areas, marine protected zones, and international and jurisdictional boundaries	Marine species mortality events
Freshwater Resources (14.5.3)	Forecasting and warning of harmful algal blooms (HABs) that affect water quality	Reduced human exposure to the increased risk of toxins from HABs in the Great Lakes	M	L-M	L-M	L-M	Financial resources required to enhance water treatment facilities to deal with HABs; technological innovation to improve treatment and removal of HABs; closure of recreational water use	Severe human health effects; mortality of aquatic species

Water Availability (14.5.3)	Water allocation policies reassessed to enhance equity, sustainability and flexibility in times of shortage through sharing agreements, improved groundwater regulation and voluntary water transfers	US Colorado River interstate shortage sharing agreement	H	H	M	L-M	Complex legal and administrative challenges, heightening lengthy disputes and costly interstate legal battles	Depletion of finite groundwater resources and reduced flow in hydrologically connected rivers
Food & Fibre (14.5.4)	Improved climate resilience through increasing income and harvest/crop portfolio diversification	Fishing communities in the US-SW and US-NE through nature-based aquaculture solutions (Messier et al., 2019; Rogers et al., 2019; Young et al., 2019; Fisher et al., 2021)	H	H	M-H	M	Lack of high resolution and locally tailored climate change information	Collapse of fisheries and loss of crops due to excessive warming and extreme events
Cities & Infrastructure (14.5.5)	Consideration of the value of green infrastructure and natural assets to meet a range of adaptation needs related to flooding, extreme urban heat, SLR, drought	Municipal Natural Assets Initiative (MNAI) assists Canadian municipalities to integrate natural assets in financial planning and asset management programs and consider projected climate changes (Municipal Natural Assets Initiative, 2018)	H	H	M	L-M	Organizations' willingness to take on solutions that are emergent and less tested; capacity for municipalities to undertake the development and assessment this new infrastructure	Rate and magnitude of climate changes exceed capacity of natural/green infrastructure to cope
Health & Communities (14.5.5, 14.5.6)	Access to green spaces, cooler infrastructure, and cooling stations	The heatwave plan for Montreal includes visits to vulnerable populations, cooling shelters, monitoring of heat-related illness, and extended hours for public pools (Lesnikowski et al., 2017)	H	H	L-M	L-M	Lack of effective warning and response systems, ability to reach at-risk populations, building designs, enhanced pollution controls, urban planning strategies, and affordable, resilient health infrastructure	Extreme increase heat-related mortality and morbidity
Tourism & recreation (14.5.7)	Diversification of winter-focused recreation and tourism opportunities	Investments in climate-resilient infrastructure within Canadian National Parks have increased visitation rates during the shoulder seasons (Fisichelli et al., 2015; Lemieux et al., 2017; Wilkins et al., 2018)	H	H	M	L	Social inequalities generated by the tourism development process not considered, such as increased property taxes leading to the marginalization of local residents in favour of wealthy tourists	Lack of precipitation that falls as snow particularly in lower elevation areas
Commerce & transportation (14.5.8)	Improved engineering and technological	For roads, changing pavement mixes to be more tolerant to	H	H	M	L	Lack of financial resources to build climate-resilient	Extreme events may cause

	solutions, in addition to innovative policy, planning, management, and maintenance approaches enhance climate resilience for transportation & related commerce	heat or frost heaving, expanding drainage capacity, reducing flood risks, enhancing travel advisories and alerts, elevating or relocating new infrastructure where feasible and changing infrastructure design requirements (Natural Resources Conservation Service, 2008; EPA, 2017; Pendakur, 2017).		infrastructure, particularly in marginalized communities	significant and irreversible impacts on the transportation sector with major implications for supply-chains and global trade

Adaptive capacity in the face of climate risks and impacts has not been equal across North American communities (Sarkodie and Strezov, 2019). Lack of representation, health inequities, and economic constraints adversely affect the capacity to respond to change and further exacerbate marginalization. For example, within many water basins in Canada and the US, planning processes are often hampered by conflicting interests, asymmetric information and differential power (ICLEI Canada, 2016; Nordgren et al., 2016; Woodruff and Stults, 2016).

The absence of evidence about the current effectiveness of proposed adaptation actions to guide future actions and investments presents a serious risk to North America, especially at higher global warming levels (GWLs) (*medium confidence*). Evaluating the limits to adaptation and the effectiveness of adaptation actions is hindered by a lack of monitoring and evaluation (Auditors General, 2018; Dilling et al., 2019; Berrang-Ford and et al., Accepted). Incremental, passive adaptations are often characterized by *soft limits* due to differing access to resources and by perceptions and tolerance of risk (Moser, 2010; Dow et al., 2013). At current warming levels, socio-ecological systems have been reaching limits to adaptation in regions with high exposure and high sensitivity (*medium confidence*). However, the implications for adaptation are unclear as soft adaptation limits are mutable and change with evolving knowledge, values, interests, and perspectives involved in decision making (Adger et al., 2009; Moser et al., 2017). *Hard* limits have been identified for some natural systems, such as species extinctions (14.5.1.3, Table 14.2, 14.5.2.1).

Adaptation actions in one place or sector can have adverse side effects elsewhere (*medium confidence*). For example, increased use of groundwater for irrigation in response to aridification can reduce baseflows into rivers with adverse impacts on stream ecology and water availability for communities far downstream (14.5.3). Additionally, across multiple sectors in North America, adaptation actions have tended to be sector-specific rather than integrating across systems (Gao and Bryan, 2017; Fulton et al., 2019), despite the increasing awareness of cascading impacts and interdependencies (Zimmerman and Faris, 2010; C40 Cities and AECOM, 2017) and risks from possible ecological and social thresholds that have been identified under higher GWL (14.6.3). For example, the water, energy and food nexus in North America has highlighted that food, water, and energy security depend on transportation infrastructure (Romero-Lankao et al., 2018) (14.5.8.1.2).

14.7.2.2 Adaptation Through Participatory and Robust Decision-Making, Indicators and Sustained Assessments

In response to some of the challenges presented in 14.7.2.1, substantial progress has been made in the North American context on the development of climate services, indicators, sustained assessments, and participatory and stakeholder-driven robust decision-making (*medium confidence*) (Fazey et al.; Fedele et al., 2019; Moss et al., 2019; Boon et al., 2021; Werners et al., 2021).

Decision-making related to adaptation policies, plans and projects has become more formalized, emphasizing participatory governance and co-production of knowledge. Canada has improved capacity with its Canadian Expert Panel on Climate Change Adaptation and Resilience Results (EPCCARR) and the recent National Adaptation Plan (14.7.1.5), with the development of a series of indicators to measure progress on adaptation (EPCCAR, 2018; Government of Canada, 2021a). In the US, indicators have been developed to communicate climate risks and guide adaptation efforts from Federal (Kenney et al., 2020) to more regional initiatives (Kenney and Gerst, 2021). These climate indicators have been used to support user-driven assessments and to articulate adaptation goals (Moss et al., 2019; Kenney et al., 2020). However, these frameworks have not sufficiently incorporated monitoring and evaluation into adaptation plans (Lempert et al., 2018; Kenney et al., 2020). Tools and services to facilitate risk assessment and action planning have been made available through federal government climate service efforts and guidance for their use has been developed (Vano et al., 2018). However, these products have been characterized as insufficiently developed to allow all adaptation practitioners to use these services (Meerow and Mitchell, 2017).

Throughout North America, co-development (or co-production) of adaptation efforts among stakeholders who share common climate vulnerabilities or risk levels (e.g., individuals, groups, communities, businesses or institutions) has been a core attribute of adaptation planning (Mees et al., 2016) and ranges across many sectors (e.g., Box 14.1, 14.5.2.2, 14.5.3.3, 14.5.4.3). Participatory efforts and robust decision-making have also been observed; some integrated watershed planning processes have high degrees of sustained stakeholder involvement (14.5.3.3) (FAQ 14.4; (Harris-Lovett et al., 2015; Cantú, 2016)).

14.7.2.3 Transformational Adaptation and Climate Resilience

Climate change and its projected impacts pose a substantial risk to North America as a region as well as to sectors, communities, and individuals (14.6.2). Incorporating different values and knowledge systems, consideration of equity and justice as core objectives, and addressing underlying vulnerabilities are principles that can guide transformational adaptation and resilience (*medium confidence*).

Approaches that advance adaptation within the existing contexts (finances, institutions, processes) have been increasingly promoted by governments to mainstream climate risk into all considerations (Rosenzweig and Solecki, 2014; Van der Brugge and Roosjen, 2015; Boon et al.; Shi and Moser, 2021). Policies and programs that build upon existing approaches that have inherent climate resilience including Indigenous knowledge-based land and resource management (14.5.4), co-management of agriculture and freshwater resources (Section 14.5.3), nature-based solutions (Box 14.7), links between health and equity, and ecosystem-based management (Section 14.5.2, 14.5.3, 14.5.4) have advanced sustainable and equitable climate resilience. Implementing the recommendations in the ASCE committee's report on adaptation to a changing climate (2018a) and Canada's Infrastructure and Buildings Working Group report has been identified as an opportunity to improve social equity by ensuring the resilience of infrastructure and the services it provides, through adoption of standards and good asset management practices (Amec Foster Wheeler Environment and Infrastructure, 2017; ASCE, 2018a).

Long-term policy signals to incentivize ongoing, scalable adaptation action that is coordinated with mitigation efforts will increase actions and avoid potential maladaptive investment (Moser, 2018; Shi & Moser 2021). Using SDG goals and the NDCs as a framework for inclusive and coordinated partnership and vertical integration across sub-national, national and regional planning can promote climate resilient development (CRD) (18.1.3). Coordination of policies and responses have been identified as supporting longer-term, transformational adaptation and minimizing risk (Termeer et al., 2017; Fazey et al., 2018). New approaches for enabling and incentivizing transformative adaptation in North America are rapidly emerging (Colloff et al. 2017, Fedel et al. 2019, Werners et al. 2021). Evaluation of the feasibility of evolving adaptation strategies is only in the early stages, but recent work has provided the foundation for assessing these considerations (Chapter 16, Table 14.7).

Table 14.7: Simplified example for transitioning from incremental to transformative adaptation approaches to support future climate-resilient sustainable development. Modified from IPCC SR1.5 adaptation feasibility assessment for Land

and Ecosystem Transitions (IPCC, 2018). Feasibility Dimensions (can be barriers and/or enablers): Economic (EC), Technological (TEC), Institutional (INST), Socio-cultural (SOC), Environmental/Ecological (ENV), Geophysical (GEO) (Chapter 16).

		Adaptation Approaches			Mitigation	Feasibility Dimensions	
Hazard	Response	Incremental	Transformational	Evidence/ Agreement	Co-benefits	Barriers	Enablers
Extreme storms causing severe flooding and erosion	Integrated Ecosystem and Watershed management	Restoration of stream corridors to incorporate environmental flows; continuing to build hardened surfaces and stream diversions in urban areas to accommodate infrequent yet extreme storm events	Restoration of streambanks and beds to stabilize and slow flows; use drought-tolerant plantings and shade trees to reduce evaporation rates; incorporate impervious surfaces in urban settings in combination with designating wide buffer area within floodplains to accommodate increased frequency of extreme events; integrate equity & justice considerations	*Medium*	Conservation of soil and increased opportunity for carbon sequestration	Sectors working in silos, inadequate financing, inability to identify shared goals (EC, INST, SOC, GEO)	Develop coordinated suite of adaptation efforts, co-produced among stakeholders and across sectors (INST, SOC, ENV)

Differing values, perspectives, interests, and needs of relevant actors (Dittrich et al., 2016) through participatory processes, such as co-production of knowledge (Meadow et al., 2015; Wall et al., 2017), have been incorporated through the Resilience Dialogues (http://www.resiliencedialogues.org/), and the development of guidance on climate scenarios (Chaumont, 2014). Framing of adaptation goals strongly determines beneficiaries of resultant policies and underscores the importance of a plurality of perspectives in adaptation governance (Cochran et al., 2013; Plummer, 2013; Allison and Bassett, 2015; Raymond-Yakoubian and Daniel, 2018). Sustained engagement through iterative knowledge development, learning, and negotiation has been identified as core for addressing climate risks (Kates et al.; Seijger et al., 2014). Interdisciplinary and inclusive adaptation programs that embrace and plan for conflict and resolution, and address inequalities have been part of broadening the opportunities for engagement (Cantú, 2016; Termeer et al., 2017; Parlee and Wiber, 2018; Sterner et al., 2019; Haasnoot et al., 2020).

Equity and justice in climate adaptation have been identified as providing a foundation for resilience in natural, social, and built systems (Cochran et al., 2013; Reckien et al., 2017; Schell et al., 2020). This approach recognizes that social vulnerability undermines efforts to increase adaptive capacity and that adaptation may also entrench existing social inequities, such as marginalization of communities of colour, gender discrimination, legacy effects of colonisation, and gentrification of coastal communities (Schell et al., 2020; Thomas, 2020). Thus, identifying systemic racism and effects colonialism within and across institutions has also been identified as part of achieving more just and equitable adaptation (Shi & Moser 2021). Acknowledgment and incorporation of Indigenous knowledge in adaptation planning and implementation also recognizes Indigenous sovereignty issues and the importance of the equitable role of Indigenous self-determination in governance and planning (Raymond-Yakoubian and Daniel, 2018) (Box 14.1; 14.4).

Strategies have been emerging to facilitate progress by including specific guidance on tools for financing and funding climate change adaptation infrastructure (Berry and Danielson, 2015; Chen et al., 2016; Zerbe, 2019). This includes facilitating transitions between incremental and transformational efforts to facilitate CRD (Chapter 18, the Five Transitions) (Fig. 14.12).

The extent to which resilient infrastructure contributes to social justice and equity has also been taken into consideration (Climate-Safe Infrastructure Working Group, 2018; Doorn, 2019). Proactive actions focused on small towns and rural areas—including the interdependencies between cities and surrounding areas—increases the potential that small and medium cities can build adaptive capacity at a pace that is commensurate with present and future risks (Moss et al., 2019; Vodden and Cunsolo, 2021). This coordination also creates greater opportunity for translation of knowledge into practice and assessing knowledge in the context that it is to be applied to improve decision-making across scales (Enquist et al., 2017; Moss et al., 2019).

Figure 14.12: Conceptual diagram of the key elements for expanding the adaptation solution space and implementing climate-resilient development (Chapter 18). Figure adapted from Shi & Moser (2021).

[START BOX 14.7 HERE]

Box 14.7: Nature-based Solutions to Support Adaptation to Climate Change

Nature-based Solutions (NbS) are "actions to protect, sustainably manage, and restore natural or modified ecosystems, that address societal challenges effectively and adaptively, simultaneously providing human well-being and biodiversity benefits" (IUCN, 2016). NbS in the context of climate change, or Nature-based Adaptation (NbA; Box 1.3), can jointly address multiple social-ecological issues related to climate change hazards, impacts, adaptation and mitigation (Figure Box14.7.1, Cross-Chapter Box NATURAL in Chapter 2). Successful NbA draws from existing adaptation approaches (Borsje et al., 2011; Temmerman et al., 2013; Law et al., 2018; Reguero et al., 2018; Buotte et al., 2019) and is applied across ecological and human systems (Table Box 14.7.1; Figure Box14.7.1; *high confidence*).

Through a capacity to evolve to keep pace with climate change, these approaches can impart self-sustaining and cost-efficient long-term protection in addition to serving as biodiverse, carbon sinks (Scyphers et al., 2011; Cheong et al., 2013; Temmerman et al., 2013; Rodriguez et al., 2014; Herr and Landis, 2016; Sasmito et al., 2016; Reguero et al., 2018). NbA is generally less expensive and strengthens over time, as compared with built infrastructure which erodes with time (*medium confidence*) (Narayan et al., 2016; Smith et al., 2017; Sutton-Grier et al., 2018). Analysis of the impacts of Hurricane Sandy determined that communities located behind wetlands experienced 20% less damage (Narayan et al., 2016). Coral reefs are providing $544M per year (Beck et al., 2018a) and mangroves $22USDB in property protection for coastal communities in the US and Mexico (Beck et al., 2018b). By 2030, flooding from changes in storms, SLR (based on RCP8.5) and increases in built infrastructure in the US Gulf Coast may result in net economic losses of up to US$176 billion, of which US$50 billion could be avoided through implementation of nature-based measures including wetland and oyster reef restoration and other green infrastructure (Box 14.4, 14.5.2) (EPA, 2015b; Reguero et al., 2018).

Innovative approaches in Canada (Borsje et al., 2011; Spalding et al., 2014; Soto-Navarro et al., 2020) and the US (Law et al., 2018; Buotte et al., 2019; Soto-Navarro et al., 2020) have led to social and environmental co-benefits and could address both future climate risk and long-standing social injustices (Hobbie and Grimm, 2020; Schell et al., 2020; Cousins, 2021). Effective NbA requires a well-coordinated suite of adaptation efforts (e.g., assessment, planning, funding, implementation, and evaluation) that is co-produced among stakeholders and across sectors (*high confidence*) (Millar and Stephenson, 2015; Kabisch et al., 2016; Dilling et al., 2019; Morecroft et al., 2019; Lavorel et al., 2020). Evaluating the efficacy of NbA may become more tractable with more uniform guidelines for implementation (Scarano, 2017; Malhi et al., 2020; Seddon et al., 2020), and coordination in scaling-up local-level NbA measures is likely to facilitate long-term success (Gao and Bryan, 2017).

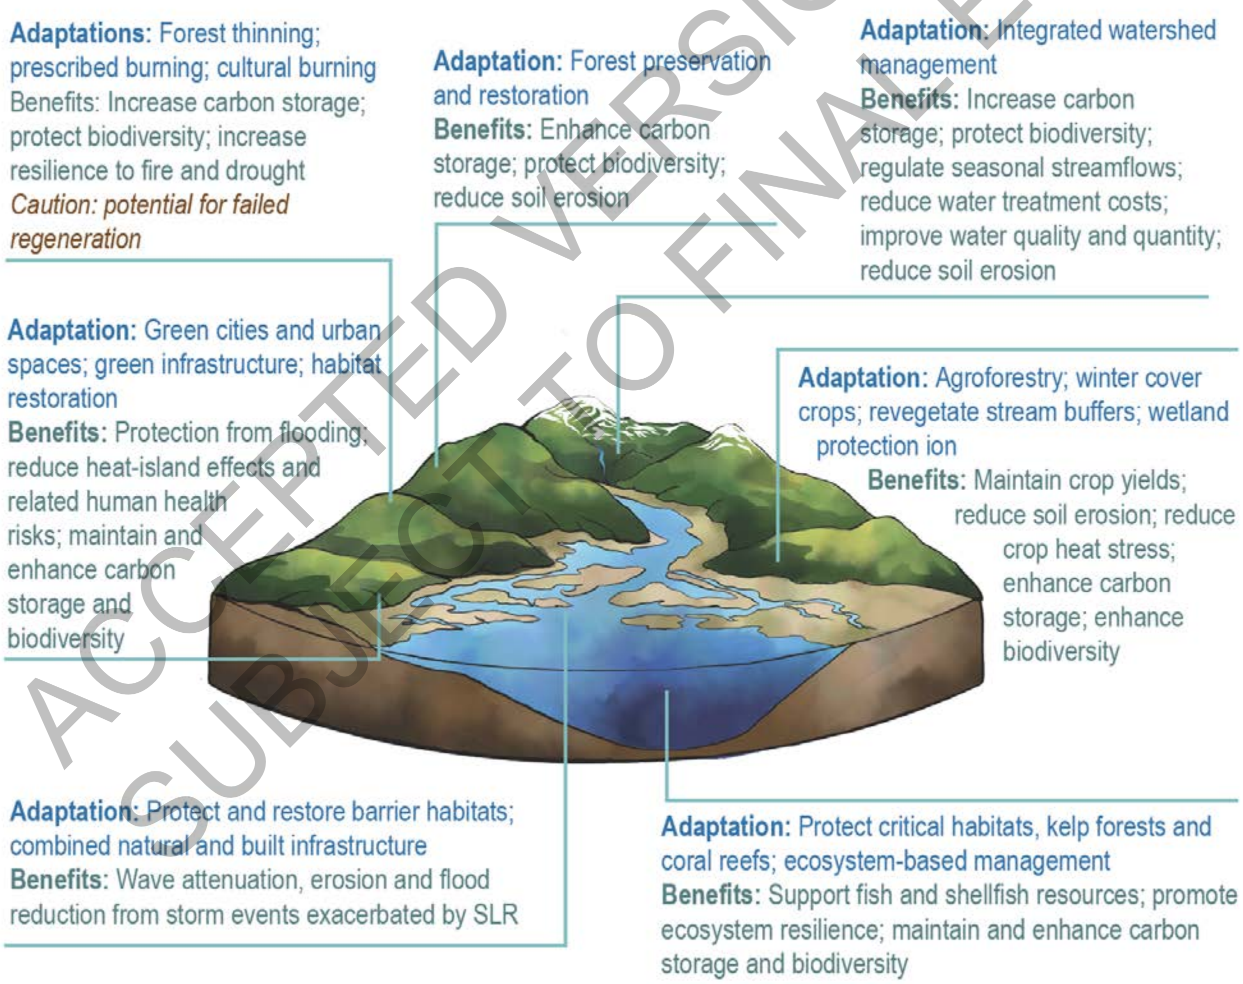

Figure Box14.7.1: Climate hazards protection services provided by nature-based solutions.

Table Box 14.7.1: Nature-based adaptation in North America.

Sector	NbS Actions	Benefits	References

Coasts	Conservation and restoration of barrier habitats, salt marshes, mangroves, coral and oyster reefs, sand dunes, and river deltas; combined natural and built infrastructure, e.g., oyster reef in front of breakwall	Wave attenuation; erosion and flood reduction from storm events exacerbated by SLR; novel, created habitats, connectivity; recreation, quality of life	(Borsje et al., 2011; Scyphers et al., 2011; Cheong et al., 2013; Pinsky et al., 2013a; Temmerman et al., 2013; Ferrario et al., 2014; Möller et al., 2014; Rodriguez et al., 2014; Spalding et al., 2014; Yates et al.; EPA, 2015b; Grenier et al., 2015; Brandon et al., 2016; Herr and Landis, 2016; Narayan et al., 2016; Sasmito et al., 2016; Ward et al., 2016; Aerts et al., 2018; Beck et al., 2018a; Morris et al., 2018b; Moudrak et al.; Reguero et al., 2018; Sutton-Grier et al., 2018)
	Watershed approaches such as protecting and restoring forests and wetlands in coastal watersheds, adopting stream buffers in agricultural areas (see agriculture below)	Create a less flashy/variable hydrology; reduce sediment, nutrient, hazardous chemical input to coastal waters and reduce eutrophication and other water quality impairments, notably in in deep waters where fish seek refuge from rising sea surface temperatures	(Deutsch et al., 2015b) Boesch 2019,CENR 2010
Aquaculture	Controlled culture of fish, bivalves, corals and other marine species	Enhance, restore and reduce pressure on wild species and ecosystems; Restore threatened species such as coral reef species. Store carbon.	(Froehlich et al., 2017; Reid et al., 2019; Theuerkauf et al., 2019)
Agriculture	Re-vegetate stream buffer zones; plant winter cover crops; wetland protection and restoration; agroforestry	Self-sustaining and cost-efficient long-term protection from soil erosion; maintain and enhance crop yields; enhance carbon sinks; enhance biodiversity; reduce nutrient input to coasts	(CENR, 2010; Boesch; Seddon et al., 2020)
Urban Areas	Replace impervious surfaces with permeable pavement, green space, parks, wetlands and green infrastructure, e.g., stormwater ponds, bioswales, rain gardens, green roofs; community gardens, urban forests; restore natural habitats;	Reduce urban heat-island effects, air pollution; self-sustaining and cost-efficient long-term protection from flooding, erosion, SLR; enhance carbon sequestration biodiversity, habitat and connectivity; improved quality of life, human health benefits	(Hobbie and Grimm, 2020; Brown et al., 2021)

Terrestrial	Forest conservation based on productivity and vulnerability to drought and fire; longer harvest rotations	Increase carbon storage and biodiversity	(Law et al., 2018; Buotte et al., 2020; Soto-Navarro et al., 2020; Mori et al., 2021)
	Forest thinning; prescribed burning; cultural burning	Reduce wildfire risk and severity; increase forest resilience to fire; reduce forest drought stress; increase carbon storage	(Box 14.2 and citations therein)
	Protecting and restoring natural forests	Regulate stream flow; reduce soil erosion; protect and enhance biodiversity	(Lawler et al., 2020; Seddon et al., 2020)
	Beaver (*Castor canadensis*) reintroduction	Regulate seasonal stream flow	(McKelvey and Buotte, 2018; Vose et al., 2018)
Freshwater	Forests to Faucets and other watershed restoration projects for stream & drinking water protection	Improve water quality; reduced drinking water treatment costs; increase and regulate streamflow	(Gartner et al., 2017; Claggett and Morgan, 2018; Price and Heberling, 2018)

[START FAQ 14.4 HERE]

FAQ 14.4: What are some effective strategies for adapting to climate change that have been implemented across North America, and are there limits to our ability to adapt successfully to future change?

Climate adaptation is happening across North America. These efforts are differential across sectors, scale and scope. Without more integrative and equitable approaches across broad scales, known as transformational adaptation, the continent may face limits to the future effectiveness of adaptation actions.

Across North America, progress in introducing climate adaptation is steady, but incremental. Adaptation is typically limited to planning, while implementation is often hindered by “soft” limits, such as access to financial resources, disparate access to information and decision-making tools, the existence of antiquated policies and management frameworks, lack of incentives, and highly variable political perceptions of the urgency of climate change.

Cities and other state and local entities are taking the lead in adaptation efforts, particularly in terms of mainstreaming the use of many approaches to adaptation. These approaches include a suite of efforts ranging from assessment of impacts and vulnerability (relative to individuals, communities, jurisdictions, economic sectors, natural resources, etc.), planning processes, implementation of identified strategies, and evaluation of the effectiveness of these strategies. Other institutions (e.g., non-governmental organizations, professional societies, private engineering and architecture businesses) also are making significant progress in the adaptation arena, particularly at local to regional levels.

The water management and utilities sectors have made significant progress toward implementation of adaptation strategies using broad-based participatory planning approaches. Consideration of climate change is now folded into some ongoing watershed-wide planning efforts. An example is provided by the One-Water-One-Watershed (OWOW) approach followed by the Santa Ana Watershed Project Authority (SAWPA) in southern California. SAWPA is a Joint Powers Authority comprising five regional water districts that provide drinking water to more than 6 million people as well as industrial and irrigation water across the 2,400-square-mile watershed. The OWOW perspective focuses on integrated planning for multi-benefit projects and explicit consideration of the impacts of any planning option across the entire watershed.

Planning is supported by stakeholder-driven advisory bodies organized along themes that consider a full suite of technical, political, environmental and social considerations. SAWPA provides member agencies with decision-support tools and assistance to implement water conservation policies and pricing regimes, and one member agency is an industry leader on potable water recycling.

The marine and coastal fisheries sector also has shown considerable progress in climate adaptation planning, particularly in terms of assessing impacts and vulnerability of fisheries. Along the Pacific Northwest coast of the US and Alaska, seasonal and sub-seasonal forecasts of ocean conditions exacerbated by warming (e.g., O_2, pH, temperature, sea ice extent) already have informed fisheries and aquaculture management. Similarly, forecasts and warnings have reduced human exposure to the increased risk of toxins from harmful algal blooms in the Gulf of Mexico, the Great Lakes, California, Florida, Texas and the Gulf of Maine.

Professional organizations and insurance play an important part in mainstreaming climate adaptation. Government and private sector initiatives can help address adaptation effort through building design guidelines and engineering standards, as well as insurance tools that reflects the damages from climate impacts. Through the identification of climate risks and proactive adaptation planning, the private sector can contribute to reducing risks throughout North America by securing operations, supply chains, and markets.

Indigenous Peoples and rural community efforts across the continent show great potential for enhancing and accelerating adaptation efforts particularly when integrated with western-based natural resource management practices, such as cultural burning, traditional forest "tending" that reduces build-up of fuels (in addition to prescribed fire and mechanical thinning). In the agricultural sector, examples include planting and cultivation of culturally significant plants, as a traditional practice of soil conservation, in addition to food crops or in lieu of synthetic or mechanical soil treatments.

Future changes in climate (e.g., more intense heat waves, catastrophic wildfire and post-fire erosion, sea level rise and forced relocations) could exceed the current capacity of human and natural systems to successfully adapt (or "hard limits"). The inclusion and equitable contribution of Indigenous Peoples and rural communities in decision-making and governance processes—including recognition of the interdependencies between cities and surrounding areas—increases the likelihood of building adaptive capacity at a pace that is commensurate with present and future climate change risks.

Large-scale, equitable transformational adaptation likely will be required to respond to the growing rate and magnitude of changes before crossing tipping points where hard limits exist, beyond which adaptation may no longer be possible. Increasingly, there are calls for accelerating and scaling up adaptation efforts, in addition to aligning policies and regulatory legislation at multiple levels of government. Improved processes for adaptation decision-making, governance, and coordination, across sectors and jurisdictions, could enhance North America's capacity to adapt to rapid climatic change. These actions include a focused societal shift, across governments, institutions, and trans-national boundaries, from primarily technological approaches to nature-based solutions that help foster changes in perception of risk and, ultimately, human behaviour.

Chapter 15: Small Islands

Coordinating Lead Authors: Michelle Mycoo (Trinidad and Tobago), Morgan Wairiu (Solomon Islands)

Lead Authors: Donovan Campbell (Jamaica), Virginie Duvat (France), Yimnang Golbuu (Palau), Shobha Maharaj (Germany/Trinidad and Tobago), Johanna Nalau (Australia/Finland), Patrick Nunn (Australia), John Pinnegar (United Kingdom), Olivia Warrick (New Zealand)

Contributing Authors: Giulia Anderson (USA/New Caledonia), Faye Abigail Cruz (Philippines), Eleanor Devenish-Nelson (United Kingdom), Kris Ebi (USA), Johanna Loehr (Germany), Roché Mahon (Trinidad and Tobago), Rebecca McNaught (Australia), Meg Parsons (New Zealand), Jeff Price (United Kingdom), Stacy-Ann Robinson (Jamaica), Adelle Thomas (Bahamas)

Review Editors: John Agard (Trinidad and Tobago), Mahmood Riyaz (Maldives)

Chapter Scientist: Giulia Anderson (USA/New Caledonia)

Date of Final Draft: 1 October 2021

Notes: TSU Compiled Version

Table of Contents

Executive Summary

Observed Impacts

A sense of urgency is prevalent among small islands in the combating of climate change and in adherence to the Paris Agreement to limit global warming to 1.5 °C above pre-industrial levels. Small islands are increasingly affected by increases in temperature, the growing impacts of tropical cyclones (TCs) , storm surges, droughts, changing precipitation patterns, sea-level rise (SLR), coral bleaching, and invasive species, all of which are already detectable across both natural and human systems (*very high confidence*[1]) {15.3.3.1, 15.3.3.2, 15.3.3.3, 15.3.4.1, 15.3.4.2, 15.3.4.3, 15.3.4.4, 15.3.4.5, 15.3.4.7}.

The observed impacts of climate change differ between urban and rural contexts, island types, and tropical and non-tropical islands (*high confidence*). Coastal cities and rural communities on small islands have been already impacted by sea-level rise, heavy precipitation events, tropical cyclones and storm surges. Climate change is also affecting settlements and infrastructure, health and wellbeing, water and food security, and economies and culture, especially through compound events (*high confidence*). As of 2017, an estimated 22 million people in the Caribbean live below 6 metres elevation and 50% of the Pacific's population lives within 10 km of the coast along with ≥50% of their infrastructure concentrated within 500 metres of the coast {15.3.4.1, 15.3.4.2, 15.3.4.3, 15.3.4.4, 15.3.4.5, 15.3.4.7}.

Tropical cyclones are severely impacting small islands (*high confidence*). The TC intensity and intensification rates at a global scale have increased in the past 40 years with intensity trends generally remaining positive. Intense TCs including categories 4 and 5 TCs have threatened human life and destroyed buildings and infrastructural assets in small islands in the Caribbean and the Pacific. Among 29 Caribbean islands, 22 were affected by at least one category 4 or 5 TC in 2017. TC Maria in 2017 destroyed nearly all of Dominica's infrastructure and losses amounted to over 225% of the annual GDP. Destruction from TC Winston in 2016 exceeded 20% of Fiji's current GDP. TC Pam devastated Vanuatu in 2015 and caused losses and damages to the agricultural sector valued at USD 56.5 million (64.1% of GDP). Coast-focused tourism is already extremely impacted by more intense TCs. {WGI 11.7.1, 12.4.7 15.2.1, 15.3.3.1, 15.3.3.3, 15.3.4.1, 15.3.4.2, 15,3.4.4, 15.3.4.5}.

Scientific evidence has confirmed that globally and in small islands tropical corals are presently at high risk (*high confidence*). Severe coral bleaching, together with declines in coral abundance have been observed in many small islands, especially those in the Pacific and Indian Oceans (*high confidence*). In the Pacific, median return time between two severe bleaching events has diminished steadily since 1980. The return time is now 6 years and often associated with the warm phase of ENSO events (*high confidence*). In Mid-2016, a new ENSO event occurred which reduced living coral cover by 75% in the Maldives {15.3.3.1.3, 15.3.4.8}.

Freshwater systems on small islands are exposed to dynamic climate impacts and are among the most threatened on the planet. An 11-36% reduction is estimated in the volume of fresh groundwater lens of the small atoll islands (area < 0.6 km^2) of the Maldives due to SLR. The El Niño related 2015-16 drought in Vanuatu led to reliance on small amounts of contaminated water left at the bottom of household tanks. A Caribbean high-resolution drought atlas spanning 1950–2016 indicates that the region-wide 2013–2016 drought was the most severe event during the multi-decadal period. In Puerto Rico, the island experienced 80 consecutive weeks of moderate drought, 48 weeks of severe drought and 33 weeks of extreme drought conditions between 2014 and 2016. Increasing trends in drought are apparent in the Caribbean although trends in the western Pacific are not statistically significant {15.3.3.2, 15.3.4.3}.

Small islands host significant levels of global terrestrial species diversity and endemism. Due to the large range of insular-related vulnerabilities, almost 50% of terrestrial species presently considered at risk of global extinction also occur on islands (*high confidence*)**.** Despite encompassing approximately two percent

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

of the Earth's terrestrial surface, oceanic and other high-endemicity islands are estimated to harbour substantial proportions of existing species including ~ 25% extant global flora, ~ 12% birds and ~10% mammals {15.3.3.3}.

Projected Impacts

Projected climate and ocean-related changes will significantly affect marine and terrestrial ecosystems and ecosystem services, which will in turn have cascading impacts across both natural and human systems (*high confidence*). Changes in wave climate superimposed on SLR will significantly increase coastal flooding (*high confidence*) and low-coastal and reef island erosion (*limited evidence, medium agreement*). The frequency, extent, duration, and consequences of coastal flooding will significantly increase from 2050 (*high confidence*), unless coastal and marine ecosystems are able to naturally adapt to SLR through vertical growth (*low confidence*). These changes are a major concern for small islands given that a high percentage of their population, infrastructure and economic assets are located in the low elevation coastal zone of below 10 metres elevation {15.3.3.1.1, 15.3.3.1.2, 15.3.3.1.3, 15.3.3.1.4}.

Projected changes in the wave climate superimposed on SLR will rapidly increase flooding in small islands, despite highly contrasting exposure profiles between ocean sub-regions (*high confidence*). A 5-10 cm additional SLR (expected for ~2030–2050) will double flooding frequency in much of the Indian Ocean and Tropical Pacific, while TCs will remain the main driver of (rarer) flooding in the Caribbean Sea and Southern Tropical Pacific. Some Pacific atoll islands will *likely*[2] undergo annual wave-driven flooding over their entire surface from the 2060s–2070s to 2090s under RCP8.5, although future reef growth may delay the onset of flooding (*limited evidence, low agreement*) {15.3.3.1.1}.

Modelling of both temperature and ocean acidification effects under future climate scenarios (RCP 4.5 and RCP 8.5) suggest that some small islands will experience severe coral bleaching on an annual basis before 2040 (*medium confidence*). Above 1.5°C, globally inclusive of small islands, it is projected there will be further loss of 70–90% of reef-building corals, with 99% of corals being lost under warming of 2°C or more above the pre-industrial period. Intact coral reefs, seagrass meadows and mangroves provide a variety of ecosystem services that are important to island communities (*high confidence*). These include provisioning services regulating services, cultural services and those that support community resilience (*high confidence)*. If coastal ecosystems are degraded and lost, then the benefits they provide cannot be easily replaced (*medium confidence*) {15.3.3.1.3, 15.3.3.1.4}.

Projected changes in aridity are expected to impose freshwater stress on many small islands, especially SIDS *(high confidence*). It is estimated that with a warming of 1.5°C or less, freshwater stress on small islands would be 25% less as compared to 2.0°C. While some island regions are projected to experience substantial freshwater decline, an opposite trend is observed for some western Pacific and northern Indian Ocean islands. Drought risk projections for Caribbean SIDS aligned with observations from the Shared Socio-Economic Pathway (SSP) 2 scenario, indicate that a 1°C increase in temperature (from 1.7°C to 2.7°C) could result in a 60% increase in the number of people projected to experience a severe water resources stress from 2043–2071. In some Pacific atolls, freshwater resources could be significantly affected by a 0.40 m SLR. Similar impacts are anticipated for some Caribbean countries with worst-case scenario (RCP8.5) indicating a 0.5-m SLR by the mid-century (2046-2065) and 1-m SLR by the end-of-century (2081-2100). In SIDS with high projected population growth rates, they are expected to experience the most severe freshwater stress by 2030 under a 2°C warming threshold scenario {15.3.3.2}

The continued degradation and transformation of terrestrial and marine ecosystems of small islands due to human-dominated will amplify the vulnerability of island peoples to the impacts of climate change (*high confidence*). New studies highlight large population reductions with an extinction risk of 100% for endemic species within insular biodiversity hotspots including within the Caribbean, Pacific and

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, and Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely*). This Report also uses the term '*likely* range' to indicate that the assessed likelihood of an outcome lies within the 17-83% probability range.

Suandaland regions by 2100 for > 3°C warming {15.3.3.3}. This is *likely* to decrease the provision of resources (e.g. potable water) to the millions of people living on small islands, resulting in impacts upon settlements and infrastructure, food and water security, health, economies, culture, and migration (*high confidence*) {15.3.3.2, 15.3.3.3, 15.3.4.1, 15.3.4.2, 15.4.3, 15.3.4.4, 15.3.4.5, 15.3.4.6, 15.3.4.7}.

Reef island and coastal area habitability in small islands is expected to decrease because of increased temperature, extreme sea levels and degradation of buffering ecosystems, which will increase human exposure to sea-related hazards (*high confidence*). Climate and non-climate drivers of reduced habitability are context specific. On small islands, coastal land loss attributable to higher sea level, increased extreme precipitation and wave impacts, and increased aridity have contributed to food and water insecurities that are *likely* to become more acute in many places (*high confidence*). In the Caribbean, additional warming by 0.2°–1.0°C, could lead to a predominantly drier region (5%–15% less rain than present-day), a greater occurrence of droughts along with associated impacts on agricultural production and yield in the region. Crop suitability modelling on several commercially important crops grown in Jamaica found that even an increase less than + 1.5 °C could result in a reduction in the range of crops that farmers may grow. Most Pacific Island Countries could experience ≥ 50% declines in maximum fish catch potential by 2100 relative to 1980–2000 under both an RCP 2.6 and RCP 8.5 scenario {15.3.4.3, 15.3.4.4}.

Future Risks

The reduced habitability of small islands is an overarching significant risk caused by a combination of several Key Risks facing most small islands even under a global temperature scenario of 1.5 degrees *(high confidence)*. These are loss of marine and coastal biodiversity and ecosystem services; submergence of reef islands); loss of terrestrial biodiversity and ecosystem services ; water insecurity ; destruction of settlements and infrastructure ; degradation of health and well-being ; economic decline and livelihood failure); and loss of cultural resources and heritage. Climate-related ocean changes, including those for slow onset events, and changes in extreme events are projected to cause and/or amplify Keys Risks in most small islands. Identification of Key Risks facilitates the selection of optimal context-specific adaptation options. Moreover, it can distil the benefits and/or disadvantages and long-term implications of choosing such options (*high confidence*) {15.3.4.9}.

The vulnerability of communities in small islands, especially those relying on coral reef systems for livelihoods, may exceed adaptation limits well before 2100 even for a low greenhouse gas emission pathway (*high confidence*). The impacts of climate change on vulnerable low-lying and coastal areas, present serious threats to the ability of land to support human life and livelihood's (*high confidence*). Climate-related migration is expected to increase, although the drivers and outcomes are highly context-specific and insufficient evidence exists to estimate numbers of climate-related migrants now and in the future (*medium evidence, high agreement*) {15.3.4.1, 15.3.4.6, CCB7-1}.

Small islands are already reporting loss and damage particularly from tropical cyclones and increases in sea-level rise *(high confidence)*. Despite the loss of human life and economic damage the methods and mechanisms to assess climate-induced loss and damage remain largely undeveloped for small islands. Further, there are no robust methodologies to infer attribution and such assessments are limited. A research gap on loss and damage includes how to assess the economic costs of loss and damage. Specific data on experienced loss and damage across socio-economic groups and demographics are needed. Monitoring and tracking slow onset events are equally important and require robust data {15.7, 15.8}.

Options, Limits and Opportunities of Adaptation

Some island communities are resilient with strong social safety nets and social capital that support responses and actions already occurring, but there is limited information on the effectiveness of the adaptation practices and the scale of needed action (*high confidence*). This is in part due to a need for a better understanding of the limits to adaptation and of what constitutes current resilience and/or successful adaptation in small island contexts. Greater insights into which drivers weaken local and indigenous resilience, together with recognition of the socio-political contexts within which communities operate, and the processes by which decisions are made, can assist in identifying opportunities at all scales to enhance climate adaptation and enable action towards climate resilient development pathways (*medium evidence, high agreement*) {15.6.1, 15.6.5, 15.7}.

In small islands, despite the existence of adaptation barriers several enablers can be used to improve adaptation outcomes and to build resilience (*high confidence*). These enablers include better governance and legal reforms; improving justice, equity and gender considerations; building human resource capacity; increased finance and risk transfer mechanisms; education and awareness programmes; increased access to climate information; adequately downscaled climate data and embedding Indigenous Knowledge and Local Knowledge (IKLK) as well as integrating cultural resources into decision-making (*high confidence*) {15.6.1 15.6.3, 15.6.4, 15.6.5}.

Small islands present the most urgent need for investment in capacity building and adaptation strategies (*high confidence*) but face barriers and constraints which hinder the implementation of adaptation responses. Barriers and constraints arise from governance arrangements, financial resources and human resource capacity. Additionally, institutional and legal systems are often inadequately prepared for managing adaptation strategies such as large-scale settlement relocation and other planned and/or autonomous responses to climate risks (*high confidence*). Adaptation strategies are already being implemented on some small islands although barriers are encountered including inadequate up-to-date and locally relevant information, limited availability of finance and technology, lack of integration of IKLK in adaptation strategies, and institutional constraints (*high confidence*) {15.5.3, 15.5.4, 15.6.3, 15.6.4, 15.6.5}.

For many small islands, adaptation actions are often incremental and do not match the scale of extreme or compounding events (*high confidence*). Much of the currently implemented adaptation measures remain small in scale (e.g., community-based adaptation projects), sectoral in focus and do not address the needed structural and system level adaptations to combat climate impacts and achieve long term sustainability of adaptation interventions. To address these shortcomings enablers are being integrated into National Adaptation Plans and Disaster Risk Reduction Plans (*high confidence*) {15.6.3}.

Although international climate finance has increased in magnitude small islands face challenges in accessing adaptation finance to cope with slow and rapid onset events (*high confidence*). In the Caribbean, 38% of flows were concessional loans and 62% were grants whereas in the Atlantic and Indian Oceans nearly 75% of the flows were in the form of concessional loans and 25% were grants. Solutions to these barriers are being explored and some small islands have started adopting enablers such as insurance and microfinance at both the national and local levels in responding to adaptation needs and to facilitate resiliency building. COVID-19 has caused, however, economic shock in many small islands which will limit adaptation, undermine the attainment of Sustainable Development Goals and slow down climate resilient development transitions {15.8.3}.

The unavailability of up-to-date baseline data and contrasting scenarios/temperature levels continue to impair the generation of local-to-regional observed and projected impacts for small islands, especially those that are developing nations (*high agreement*). Climate model data based on the most recent suite of scenarios (RCPs and especially SSPs) are still not widely available to primary modelling communities in most small island developing nations (*high agreement*). Coastal sites of small islands are not well-represented in global gridded population and elevation datasets, thereby making estimation of population exposure to SLR difficult. The lack of data continues to impede the development of robust impacts-based modelling output (e.g. for terrestrial biodiversity). Downscaling is pivotal for small islands due to their high diversity which makes generalisation invalid.

15.1 Introduction

This chapter examines the climate change impacts and projected risks faced by small islands, including the detection and attribution of observed impacts, the loss and damage they experience, and the enablers, limits and barriers to the implementation of adaptation options applicable to them. The implications of climate change impacts on the attainment of the Sustainable Development Goals (SDGs), the need for more climate-resilient development pathways based on a systems transitions approach, and how both of these intersect with future potential responses are assessed within the context of small island states.

The small islands covered in this chapter are located within the tropics of the southern, northern, and western Pacific Ocean, the central, eastern and western Indian Ocean, the Caribbean Sea, the eastern Atlantic off the coast of West Africa, and in the temperate Mediterranean Sea. In contrast to the Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment Report (AR5), non-sovereign island states and territories dependent on continental states and islands of semi-autonomous, sub-national island jurisdictions are included in this chapter. Further, Small Island Developing States (SIDS) consisting of 39 small island and low-lying coastal developing states which belong to the Alliance of Small Island States (AOSIS) are covered in this assessment. Islands in the polar and sub-polar regions, North Atlantic Ocean, the Baltic Sea, the North Sea, the Black Sea and the Arctic Ocean are not included.

Small islands share similarities such as geographical remoteness, isolation, narrow resource bases, heavy dependency on external trade, vulnerability to exogenous economic shocks, economic volatility, and limited access to development finance. Many are biodiversity hotspots and experience a disproportionate impact of natural hazards associated with climate change. They are also diverse in physical and biophysical characteristics, economic systems, political/governance systems, and exhibit social and cultural differences. Adaptation responses vary among small islands because such diversity requires place-specific and culturally-specific adaptation responses.

The chapter is structured in accordance with the overall format of the AR6 Working Group II report (Figure 15.1). This section presents points of departure from AR5 and IPCC (Section 15.2). As shown in Figure 15.1, this is followed by an assessment of current and future risks that are expected to be experienced by small islands (Sections 15.3 and 15.4), what measures have been implemented (Section 15.5) and enablers, limits and barriers that are being encountered (Section 15.6). Section 15.7 deals with the SDGs, climate-resilient development pathways and potential future responses. The chapter ends with an identification of research gaps (Section 15.8).

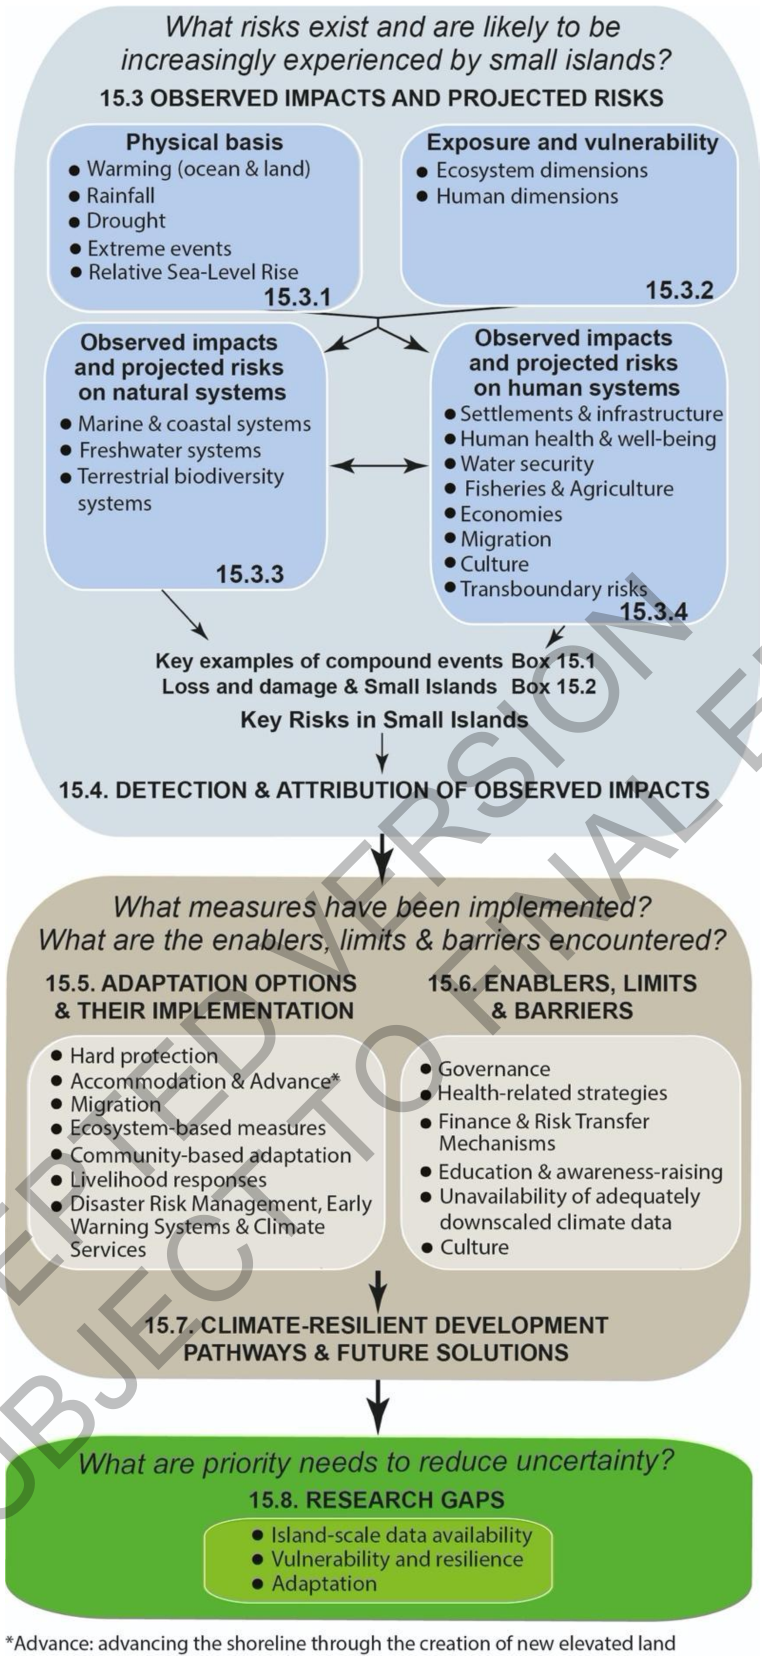

Figure 15.1: Schematic illustration of the interconnections of Chapter 15 themes, including on observed impacts and projected risks (Section 15.3) and on adaptation options and their implementation (Sections 15.5 and 15.6).

15.2 Points of Departure from AR5

Points of departure from AR5 are highlighted in this section in relation to exposure, vulnerability, impacts and risks (Section 15.2.1), and adaptation options (Section 15.2.2).

15.2.1 Points of Departure on Exposure, Vulnerability, Impacts and Risks

Scientific studies since AR5 confirm that global temperature will continue to increase even if greenhouse gas emissions are drastically reduced and will escalate the vulnerability, impacts and multiple interrelated risks experienced by small islands (*high confidence*) (IPCC, 2018). A greater sense of urgency in lowering global greenhouse gas emissions and a call for action now is resonating among small island states.

Post-AR5 new studies confirm observed impacts on the natural and human systems and indicate projected risks in both these systems over time. Over the past four decades, there was a significant increase in the probability of the global exceedances of tropical cyclones (TCs) of major intensity (Kossin et al., 2020), a trend confirmed by the occurrence of a growing number of intense TCs affecting the Atlantic and Pacific regions since AR5 (Magee et al., 2016; Bhatia et al., 2019; Knutson et al., 2019). Since AR5 also scientific evidence has confirmed that tropical corals are presently at high risk (*very high confidence*) and if global warming exceeds 1.5°C, known coral reef restoration options may be ineffective (IPCC, 2018). Even achieving emissions reduction targets consistent with the ambitious goal of 1.5°C of global warming under the Paris Agreement will result in the further loss of 70–90% of reef-building corals compared to today, with 99% of corals being lost under warming of 2°C or more above the pre-industrial period (*high confidence*) (Hoegh-Guldberg et al., 2018).

Additionally, since the last assessment more robust scientific evidence exists on the impacts of sea level rise (SLR) and extreme sea level events (ESL) on small islands. Under Representative Concentration Pathways emission scenarios, RCP2.6, RCP4.5 and RCP8.5, many low-lying coastal areas at all latitudes, including small islands, will experience SLR and ESL events such as coastal storm surges and coastal flooding more frequently in the coming decades (Section 4.2.3.4.1; IPCC, 2019). SLR and ESL events will affect atoll islands and islands with higher elevations differently. New studies forecast that small islands are *likely* to experience some of the largest increases in endemic extinctions and may substantially contribute to future global biodiversity loss, as well as to impaired ecosystem functioning (Fortini et al., 2015; Vogiatzakis et al., 2016; Cramer et al., 2018). Scientific evidence points to large population reductions with an extinction risk of 100% for endemic species within insular biodiversity hotspots by 2100 (IPBES, 2018; Manes et al., 2021). An overarching concern since AR5 is the reduced habitability of small islands. Eight key risks affecting the habitability of small islands are identified in this assessment and these are covered in the pertinent sections of this chapter which assess adaptation responses.

15.2.2 Points of Departure on Adaptation

New knowledge of adaptation responses used in small islands has grown significantly since AR5. Strategies include hard protection, land reclamation and permanent relocation, with improved appreciation for when each strategy is relevant (IPCC, 2019). Evidence of migration as an adaptation response to climate change remains limited (Roland and Curtis, 2020). Understanding of ecosystem-based adaptation (EbA) has improved considerably but there is *medium agreement* regarding its benefits (Doswald et al., 2014; Nalau et al., 2018a) and *limited evidence and low agreement* on its economic efficiency and long-term effectiveness (Renaud et al., 2016; Oppenheimer et al., 2019).

Since the previous assessment, integration of Indigenous Knowledge and Local Knowledge (IKLK) into adaptation is recognized as a major benefit in preparing and recovering from TCs and EbA (Narayan et al., 2020). The roles of social capital, health-related adaptation strategies and livelihood responses are more fully understood (Nalau et al., 2018b; Nunn and Kumar, 2018; Abram et al., 2019; IPCC, 2019). Gender equity, climate justice, climate services, early warning systems, and disaster risk reduction (Vaughan and Dessai, 2014; Newth and Gunasekera, 2018), which were data gaps in AR5, have received more treatment, especially in the context of small islands. Stronger evidence confirms that education and awareness-raising enhance household and community adaptation (*high confidence*).

Knowledge has improved on limits to adaptation, including projected timeframes of limits for hard protection (*high confidence*) and EbA (*medium confidence*) (IPCC, 2019). There is also a better understanding that barriers and governance challenges vary by island and island groups (*high confidence*) and result in them having different adaptive capacities (IPCC, 2019). A major barrier to adaptation is limited information on the feasibility, outcomes and sustainability of adaptation responses in small islands. Moreover, limited time series data on monitoring and evaluation make evaluating the feasibility of adaptation responses difficult.

Adaptation financing for small islands has increased since AR5 although leveraging finance is a constraint and remains complex (Robinson and Dornan, 2017). Informal microfinancing has grown and risk transfer mechanisms are being explored although funding and access to insurance schemes is limited (Handmer and Nalau, 2019; Nunn and Kumar, 2019a; Petzold and Magnan, 2019). In small islands the methods and mechanisms to assess climate-induced loss or damage remain undeveloped (*medium confidence*) (Thomas and Benjamin, 2017; Handmer and Nalau, 2019).

Many small islands have experienced economic shock arising from COVID-19 and have had to re-direct investment previously targeting sustainable development (Sheller, 2020). Adaptation will be affected by economic contraction and indebtedness. Framing adaptation within climate-resilient development pathways (CRDPs) that emphasise systems transition and are implemented at scale may bolster small islands' resilience to multiple shocks like COVID-19.

15.3 Observed Impacts and Projected Risks of Climate Change

Compared to larger landmasses, many climate change driven impacts and risks are amplified for small islands. This is due largely to their boundedness (surrounded by ocean), their comparatively small land areas, and often their remoteness from more populated parts of the world, which restricts the global connectivity of islands. This is true on all types of islands (Figure 15.2).

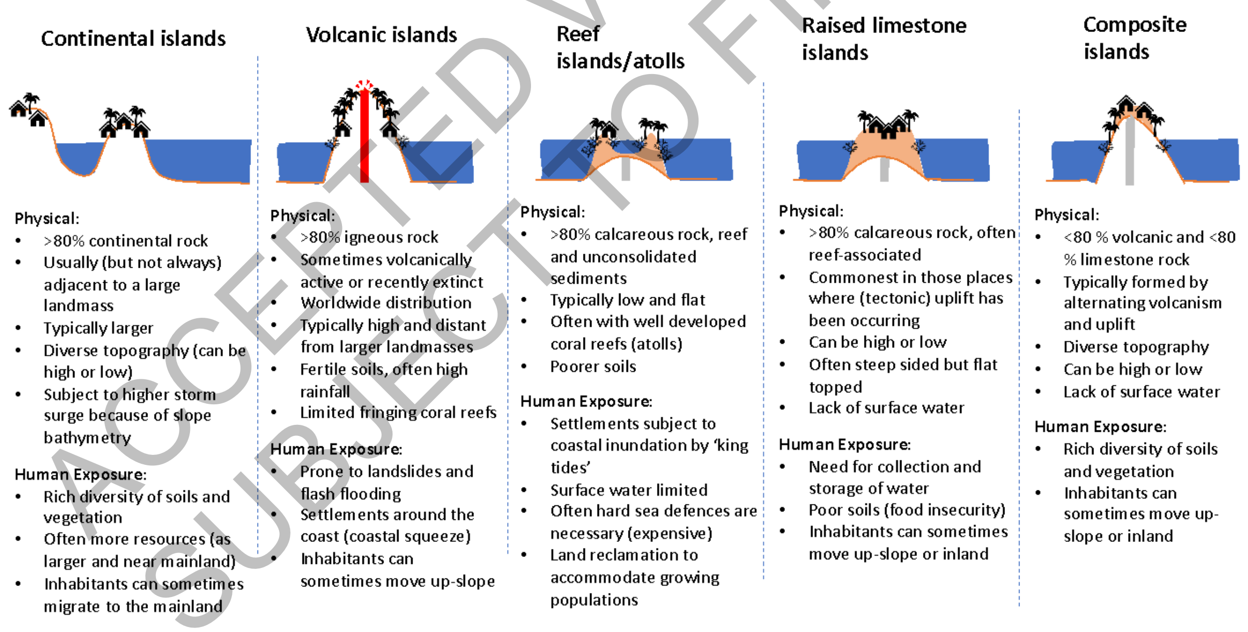

Figure 15.2: Classification of small island types - showing island characteristics and elements of human exposure (based on Nunn et al. (2016); Kumar et al. (2018)).

15.3.1 Synthesis of Observed and Projected Changes in the Physical Basis

There is increased evidence of warming in the small islands, particularly in the latter half of the 20th century (*high confidence*). The diversity of metrics and timescales used across studies makes it impossible to provide explicit comparisons, however Table 15.1 provides a summary of observed changes.

Table 15.1: Observed changes in basic climate metrics. RSLR: Relative Sea-Level Rise

Phenomenon	Location	Basic Trends	Specific Metric	Time period	Reference Literature
Air temp	West Pacific	Warmer	Increase in daily mean minimum temp by 0.14C/ decade	1951-2015	McGree et al. (2019)
Air temp	Caribbean	Warmer	Increase in daily minimum temp by 0.28C/ decade	1961-2010	Stephenson et al. (2014)
Air temp	Mediterranean	Warmer	Increase in annual mean surface temp 0.19-0.25C/ decade	1960-2005	Mariotti et al. (2015)
Land & Sea temp	Mediterranean	Warmer	Annual mean temperatures are now 1.54°C above the 1860-1890 level for land and sea		(MedECC, 2020)
Rainfall	Mediterranean	Drier	Decrease in annual mean precipitation by -0.6 mm/day/decade	1960-2005	Mariotti et al. (2015); Ducrocq et al. (2016)
Rainfall	Pacific Ocean	No clear pattern	No significant long-term trends in rainfall	1951-2015	McGree et al. (2019)
Rainfall	Indian Ocean	No clear pattern		1983-2015	Nguyen et al. (2018)
Rainfall	Caribbean	No clear pattern	No significant long-term trends in rainfall in the Caribbean over the 20th century	1901-2012	Jones et al. (2015)
Drought	Caribbean	Low confidence in the direction of change	Inconsistent between subregions and not statistically significant	1950-2016	Herrera and Ault (2017)
Drought	Pacific Ocean	Low confidence in the direction of change	Inconsistent between subregions and not statistically significant in the tropical Pacific. Significant decrease in Hawaii and sub-tropical South Pacific	1951-2015	McGree et al. (2016); McGree et al. (2019)
Tropical Cyclones	North Atlantic	Increase in intensity and decrease in frequency		1975-2009	Walsh et al. (2016)
Tropical Cyclones	Western North Pacific	Decreasing frequency	Decrease in frequency except over central North Pacific.	1977-2010	Walsh et al. (2016)
Tropical Cyclones	South Pacific	Increase in intensity and decrease in frequency		1989-2009	Walsh et al. (2016) Kuleshov et al. (2020)

Tropical Cyclones	Indian Ocean	No clear pattern	Poor data coverage	1961-2008	Tauvale and Tsuboki (2019); Kuleshov et al. (2020)
RSLR	East Caribbean	Greater than average	3-5mm/year	1993-2014	Becker et al. (2019)
RSLR	West/North Caribbean	Greater than average	2.5-3mm/year	1993-2014	Becker et al. (2019)
RSLR	Western Tropical Pacific	Greater than average	5-11mm/year	1993-2014	Becker et al. (2019)
RSLR	Mauritius/ Indian Ocean	Greater than average	4mm/year	1993-2014	Becker et al. (2019)
RSLR	Rodrigues/ Indian Ocean	Greater than average	6mm/year	1993-2014	Becker et al. (2019)

Some phenomena have no demonstrable trends in a region because of limited observed data, these include Tropical Cyclone (TC) frequency in the North-Eastern Pacific and Indian Oceans (Walsh et al., 2016); other phenomena are too variable to detect an overarching trend, including rainfall in regions where inter-annual and decadal variabilities such as the El Niño-Southern Oscillation, North Atlantic Oscillation, Pacific Decadal Variability, Atlantic Multidecadal Variability are dominant (Jones et al., 2015; McGree et al., 2019).

There are also marked regional variations in the rates of Sea Level Rise (SLR) (Merrifield and Maltrud, 2011; Palanisamy et al., 2012; Esteban et al., 2019) and Relative (that is, incorporating land movement) Sea-level Rise (RSLR). Various factors, including interannual and decadal sea level variations associated with low frequency modulation of ENSO and the Pacific Decadal Oscillation (PDO) and vertical land motion contribute to both relative sea-level variations and related uncertainties. Increased distant-source swell height from extra-tropical cyclones (ETCs) also contributes to Extreme Sea Levels (ESLs) (Mentaschi et al., 2017; Vitousek et al., 2017). Together, these stressors increase ESLs and their impacts, including coastal erosion and marine flooding and their impacts on both ecosystems and ecosystem services and human activities (Section 15.3.3.1 and Table 15.3).

Like observed impacts, projected impacts include some high confidence assessments, which are distributed across a diversity of models, timescales, and metrics. Generalised trends, and specific projections when available, are provided in Table 15.2. However, actual values and spatial distribution of precipitation changes remain uncertain as they are strongly model dependent (Paeth et al., 2017). Furthermore, the current capabilities of climate models, to adequately represent variability in climate drivers including ENSO, and the topography of small islands, limit confidence in these future changes (Cai et al., 2015a; Harter et al., 2015; Guilyardi et al., 2016).

Table 15.2: A small subset of projected changes in basic climate metric. Med=Mediterranean; NC=no change
[INSERT TABLE 15.2 HERE]

15.3.2 Trends in Exposure and Vulnerability

Most of the research that has been conducted on exposure and vulnerability from climate change demonstrates that factors including those that are geopolitical and political, environmental, socio-economic and cultural, together conspire to increase exposure and vulnerability of small islands (Box 15.1; Betzold, 2015; McCubbin et al., 2015; Duvat et al., 2017b; Otto et al., 2017; Weir et al., 2017; Taupo et al., 2018;

Barclay et al., 2019; Hay et al., 2019a; Ratter et al., 2019; Salmon et al., 2019; Bordner et al., 2020; Douglass and Cooper, 2020; Duvat et al., 2020a). Additional pressures on coastal and marine environments, including overexploitation of natural resources, may further exacerbate possible impacts in the future (Bell et al., 2013; Pinnegar et al., 2019; Siegel et al., 2019).

Furthermore, these factors exacerbate climate change induced problems such as coastal flooding and erosion faced by small islands. These impacts continue to worsen, which put small islands at increasingly higher risk to the impacts of climate change (Box 15.1). There are multiple stressors that affect the vulnerability of small islands to climate change (McNamara et al., 2019).

The problems of increasing exposure and vulnerability is most clearly seen in atoll islands. For example, in the capital of Tuvalu, economic stressors, food related stressors, and overcrowding make the islands much more vulnerable to climate impacts including changing precipitation patterns, ESLs, intense strong winds, warming SST and ocean acidification (McCubbin et al., 2015). Small islands, in trying to address the problem of limited land availability, put in place practices that lead to increasing exposure for island people. In Majuro, Marshall Islands (Ford, 2012), Tarawa, Kiribati (Biribo and Woodroffe, 2013; Duvat, 2013), and the Maldives Islands (Kench, 2012; Naylor, 2015; Duvat and Magnan, 2019b), population growth has led to land reclamation and the building of coastal protection structures, such as seawalls. Land reclamation and coastal protection structures negatively impact coastal and marine ecosystems, including reefs and mangroves, which compromise the protection services that they deliver to island communities through wave energy attenuation and sediment supply (Gracia et al., 2018; Curnick et al., 2019; Duvat and Magnan, 2019a) and may impact the long term sustainable adaptive planning of islands (Giardino et al., 2018). In addition, these construction activities disrupt natural coastal processes, thereby causing coastal erosion, which in turn increases the risk of flooding (Yamano et al., 2007; Duvat et al., 2017b) (Figure 15.3). This becomes a vicious cycle, with more land reclamation necessary to accommodate growing populations. Land reclamation requires stabilisation by protection structures, which then contributes to environmental degradation that increases the exposure and vulnerability of the communities living in these atolls (Duvat et al., 2017b).

Figure 15.3: Percentage of current population in selected small islands occupying vulnerable land (the number of people on land that may be exposed to coastal inundation—either by permanently falling below MHHW, or temporarily falling below the local annual flood height) in 2100 under an RCP4.5 scenario (adapted from Kulp and Strauss (2019) using the CoastalDEM_Perm_p50 model). Positions on the map are based on the capital city or largest town.

15.3.3 Observed Impacts and Projected Risks on Natural Systems

15.3.3.1 Impacts on Marine and Coastal Systems

15.3.3.1.1 Submergence and flooding of islands and coastal areas

Recent studies confirmed that observed ESL events causing extensive flooding generally resulted from compound effects, including the combination of SLR (Section 3.2.2.2 and Cross-Chapter Box SLR in Chapter 3) with ETCs, TCs and tropical depressions (WGI AR6 Sections 11.7.1 and 11.7.2), ENSO-related high-water levels associated with high or spring tide and/or local human disturbances amplifying impacts (*high confidence*). For example, the major floods that occurred in 1987 and 2007 in the Maldives involved the combination of distant-source swells and high spring tides and the settlement of reclaimed low-lying areas (Box 15.1; Wadey et al., 2017). In the Tuamotu atolls, French Polynesia, the 1996 and 2011 floods were due to the combination of distant-source swells causing lagoon filling and the obstruction of inter-islet channels by human-built structures (Canavesio, 2019). In 2011, the flooding of the lagoon-facing coast of Majuro Atoll, Marshall Islands, resulted from the combination of high sea levels occurring during La Niña conditions and seasonally high tides (Ford et al., 2018). Another example is the widespread flooding caused by distant TC Pam (2015) in Kiribati and Tuvalu, which was attributed to the strong swell generated, the long duration of the event and exceptionally high regional sea levels (Hoeke et al., 2021). On high tropical islands, major floods often occurred during TC events, due to the cumulative effects of storm surge and river flooding, the impacts of which were exacerbated by human-induced changes to natural processes in urban areas. This for example occurred in 2014 (TC Bejisa) in Reunion Island, France, in a harbour area favourable to water accumulation (Duvat et al., 2016); in 2015 (TC Pam) in Port Vila, Vanuatu, where urbanisation and human-induced changes to the river exacerbated flooding (Rey et al., 2017); and in 2017 (TC Irma) in Saint-Martin, Caribbean, where urbanisation had the same effect (Rey et al., 2019). Successive tropical depressions generating heavy rains were also involved in extensive flooding, for example in 2012 in Fiji (Kuleshov et al., 2014) and in 2014 in the Solomon Islands (Ha'apio et al., 2019).

Reconstructions of past storm surges and modelling studies assessing storm surge risk similarly highlighted high variations of risk along island coasts, due to variations in exposure, topography and bathymetry (*high confidence*). For example, the storm surge caused by TC Oli (2010) on the high volcanic island of Tubuai, French Polynesia, ranged from a few centimetres to 2.5 m, depending on coast exposure (Barriot et al., 2016). Investigating the contribution of reef characteristics to variations in wave-driven flooding on Roi-Namur Island, Kwajalein Atoll, Marshall Islands, (Quataert et al., 2015) found that the coasts fronted by narrow reefs with steep fore reef slopes and smoother reef flats are the most flood-prone. Modelling studies assessing storm surge risk in Fiji (McInnes et al., 2014) and Samoa (McInnes et al., 2016) confirmed the influence of coast exposure and water depth on risk distribution. In Apia, Samoa, Hoeke et al. (2015, p. 1117) found "differences in extreme sea levels in the order of 1 m at spatial scales of less than 1 km" and estimated (p. 1131) that a "1 m SLR relative to constant topography increases wave energy reaching the shore by up to 200% during storm surges." These studies reaffirmed the main control exerted by SLR on ESL events and associated storm surges compared to ENSO (*high confidence*). In Hawaii and the Caribbean, SLR is projected to exponentially increase flooding, with nearly every centimeter of SLR causing a doubling of the probability of flooding (Taherkhani et al., 2020). Simulations of SLR-induced flooding resulting from the combination of (i) direct marine flooding, (ii) flow reversal in drainage networks caused by extreme tide levels and (iii) the elevation of groundwater levels, at Honolulu, Hawaii, highlighted the major influence of this latter component (which is the most difficult to manage), as well as the increase of the proportion of triple-mechanism flooding as sea level rises (Habel et al., 2020). Where coral reefs buffer flooding through wave attenuation, flooding will be further aggravated by reef decline over time (Section 15.3.3.1.3).

Larger-scale studies confirmed that projected changes in the wave climate superimposed on SLR will rapidly increase flooding in small islands, despite highly contrasting exposure profiles between ocean sub-regions (*high confidence*) (Shope et al., 2016; Mentaschi et al., 2017; Shope et al., 2017; Vitousek et al., 2017; Morim et al., 2019). In particular, Vitousek et al. (2017) showed that even a 5-10 cm additional SLR (expected for ~2030–2050) will double flooding frequency in much of the Indian Ocean and Tropical Pacific, while TCs will remain the main driver of (rarer) flooding in the Caribbean Sea and Southern Tropical Pacific (Figure 15.3). Some Pacific atoll islands, which already experience major floods, will *likely* undergo annual wave-driven flooding over their entire surface from the 2060s–2070s (Storlazzi et al., 2018) to 2090s (Beetham et al., 2017) under RCP8.5, although future reef growth may delay the onset of flooding (*limited evidence, low agreement*) (Key Risk KR2 in Figure 15.5).

15.3.3.1.2 Reef island destabilisation and coastal erosion

Over the past three to five decades, shoreline changes were dominated by stability on reef islands and erosion on high islands; attribution of observed erosion to SLR and other climate change-related drivers is challenged by the complex interplay of multiple climatic, ecological and human drivers (*high confidence*). Since the 1950s-1970s, and even in regions exhibiting higher than global averaged SLR rates, atoll islands maintained their land area (*high confidence).* A literature review including 709 Indian and Pacific Oceans atoll islands showed that 73.1% of these islands were stable in area, while respectively 15.5% and 11.4% increased and decreased in area (Duvat, 2018). The rates of change did not correlate with SLR rates, suggesting that the impact of SLR on island land area was obscured by other climate drivers and human disturbances on some islands (*high confidence*) (Kench et al., 2015; McLean and Kench, 2015; Duvat, 2018). However, reef island disappearance and reduction in land area was clearly observed in New Caledonia and the Solomon Islands, and was attributed to the synergistic interactions of gradual SLR with stronger trade winds causing higher sea levels and local tectonics in the Solomon Islands (Albert et al., 2016; Garcin et al., 2016). Despite important knowledge gaps on coastal erosion in high tropical islands, recent studies confirmed increasing shoreline retreat and beach loss over the past decades, mainly due to TC and ETC waves and human disturbances (*high confidence*) (e.g., in the Caribbean region: Anguilla, Saint-Kitts, Nevis, Montserrat, Dominica and Grenada (Cambers, 2009; Reguero et al., 2018)), and Pacific (Hawaii (Romine and Fletcher, 2013); Tubuai, French Polynesia (Salmon et al., 2019)) and Indian Oceans (Anjouan, Comoros (Ratter et al., 2016)).

Despite storm-induced erosion prevailing along some shoreline sections, recent studies reaffirmed the contribution of TC and ETC waves to coastal and reef island vertical building through massive reef-to-island sediment transfer *(high confidence*). For example, TC Ophelia (1958) and Category 5 TC Fantala (2016), which respectively eroded the islands of Jaluit Atoll, Marshall Islands (Ford and Kench, 2016), and Farquhar Atoll, Seychelles (Duvat et al., 2017c), also contributed to island and beach expansion. Likewise, tropical depressions can have constructional effects, as reported on Fakarava Atoll, French Polynesia (Duvat et al., 2020b). On Saint-Martin/Sint Maarten and Saint-Barthélemy, the 2017 hurricanes, which caused marked shoreline retreat at most beach sites, also allowed beach formation and beach ridge development along some natural coasts (Duvat et al., 2019a; Pillet et al., 2019). Similarly, El Niño and La Niña were involved in rapid and highly contrasting shoreline changes (*high confidence*), including reef island accretion in the Ryukyu Islands, Japan (Kayanne et al., 2016), beach shifts on Maiana and Aranuka Atolls, Kiribati (Rankey, 2011), and beach erosion on Hawaii, USA (Barnard et al., 2015). These contrasting shoreline responses were respectively due to coral reef degradation from past bleaching events providing material to islands, wave directional shifts, and increased wave energy. The role of bleaching events in increasing short-term sediment generation in atoll contexts was confirmed by a study conducted on Gaafu Dhaalu Atoll, Maldives, which reported an increase of sediment production from ~0.5 kg CaCO3 m–2 yr^{-1} to ~3.7 kg CaCO3 m-2 yr^{-1} between 2016 (pre-bleaching) and 2019 (bleaching + 3 years) (Perry et al., 2020).

There is *high confidence* that accelerating SLR and increased wave height will affect the geomorphology of reef islands (Baldock et al., 2015; Costa et al., 2019; Tuck et al., 2019) and coastal systems on high islands (Grady et al., 2013; Barnard et al., 2015; Bindoff et al., 2019), and that the responses of these systems will highly depend on changes in boundary conditions (wave regime and direction, exposure to extreme events, impacts of ocean warming and acidification on supporting ecosystems, bathymetry and reef flat roughness) and the degree of disturbance of their natural dynamics by human activities (Smithers and Hoeke, 2014; McLean and Kench, 2015; Bheeroo et al., 2016; Ratter et al., 2016; Shope et al., 2016; Duvat et al., 2017a; Kench and Mann, 2017; Kench et al., 2018; Duvat et al., 2019a). Reef islands and beach and beach-dune systems that are not disturbed by human activities are respectively expected to migrate lagoonward (Webb and Kench, 2010; Albert et al., 2016; Beetham et al., 2017; Costa et al., 2019; Tuck et al., 2019) and landward (Bindoff et al., 2019), and to also experience increased erosion as well as changes in configuration, volume and elevation (Kench and Mann, 2017; Tuck et al., 2019) (Bramante et al., 2020; Kane and Fletcher, 2020). Small reef islands and narrow coastal systems affected by human disturbances will increasingly be at risk of disappearance due to SLR (KR2 in Figure 15.5), enhanced sediment loss caused by extreme events (Duvat et al., 2019a) and/or human activities (*high confidence*), as reported in Hawaii (Romine and Fletcher, 2013), Puerto Rico (Jackson et al., 2012), Sicily (Anfuso et al., 2012), and Takuu, Papua New Guinea (Mann and Westphal, 2014). SLR will also increase coastal erosion in the Mediterranean Sea, (e.g., in the Aegean Archipelago, Greece (Monioudi et al., 2017)), and Mallorca, Spain (Enríquez et al., 2017).

15.3.3.1.3 Impacts on marine and coastal ecosystems

Loss of marine and coastal biodiversity and ecosystem services is a Key Risk in small islands (see KR1 in Figure 15.5). Coral bleaching caused by elevated water temperatures is the most visible and widespread manifestation of a climate change impact on coastal ecosystems in most small islands but is far from being the only one (Section 3.4.2.1; Section 5.3.4; Spalding and Brown, 2015; Hoegh-Guldberg et al., 2017; IPCC, 2018; Bindoff et al., 2019; Sully et al., 2019). Severe coral bleaching, together with declines in coral abundance have been documented in many small islands, especially those in the Pacific and Indian Oceans,(e.g., Guam, Fiji, Palau, Vanuatu, Chagos, Comoros, Mauritius, Seychelles, and the Maldives (*high confidence*) (Box 15.1; Golbuu et al., 2007; Woesik et al., 2012; Perry and Morgan, 2017; Hughes et al., 2018). During severe bleaching events, not only do reefs lose a significant amount of live coral cover, but they also experience a decrease in growth potential, so reef erosion surpasses reef accretion (Perry and Morgan, 2017). Median return time between two severe bleaching events has diminished steadily since 1980 and is now only 6 years (e.g.,Hughes et al., 2017b; Hughes et al., 2018) and is often associated with warm phase of ENSO events (*high confidence*) (Lix et al., 2016). Modelling of both bleaching and ocean acidification effects under future climate scenarios suggested that some Pacific small islands (e.g., Nauru, Guam, Northern Marianas Islands) will experience conditions that cause severe bleaching on an annual basis before 2040 and that 90% of the world reefs are projected to experience conditions that result in severe bleaching annually by 2055 (*medium confidence*) (van Hooidonk et al., 2016). Models are currently predicting the large-scale loss of coral reefs by mid-century under even low-emissions scenarios. Even achieving emissions reduction targets consistent with the ambitious goal of 1.5°C of global warming under the Paris Agreement will result in the further loss of 70–90% of reef-building corals compared to today, with 99% of corals being lost under warming of 2°C or more above the pre-industrial period (*high confidence*) (Hoegh-Guldberg et al., 2018).

Satellite data and local field studies at 3351 sites in 81 countries including small islands show that not all coral reefs are equally exposed to severe temperature stress events, and even similar coral reefs exposed to similar conditions show local and regional variation and species-specific responses (Sully et al., 2019). There is great variability in terms of sensitivity of corals to climate change, as also demonstrated in the Comoros Archipelago (Cowburn et al., 2018), in the Pacific (Fox et al., 2019; Mollica et al., 2019; Romero-Torres et al., 2020) and globally (Sully et al., 2019; McClanahan et al., 2020). It has been hypothesised that low-latitude tropical reefs bleached less than those in higher latitudes because: (i) of the geographical differences in species composition, (ii) of the higher genotypic diversity at low latitudes, and (iii) some corals were pre-adapted to thermal stress because of consistently warmer temperatures at low latitude prior to thermal stress events (Sully et al., 2019). However, latitudinal variation was not reported in other global surveys of coral bleaching occurrence (Donner et al., 2017; Hughes et al., 2017a; Hughes et al., 2017b; McClanahan et al., 2019). Ainsworth et al. (2016) and Ateweberhan et al. (2013) showed that coral bleaching can be mitigated by pre-exposure to elevated temperatures. Regionally, recovery is also highly variable. While some reefs in the Seychelles and Maldives were shown to recover to pre-disturbance levels of coral cover after previous bleaching events (Box 15.1; Pisapia et al., 2016; Koester et al., 2020), other reefs underwent seemingly permanent regime shifts toward domination by fleshy macro algae (Graham et al., 2015), or major declines in carbonate budgets, and thus the capacity of reefs to sustain vertical growth under rising sea levels (Perry and Morgan, 2017).

Despite their vital social and ecological value, substantial declines in seagrass communities have been documented in many small islands (Section 3.4.2.5; Arias-Ortiz et al., 2018; Kendrick et al., 2019; Brodie et al., 2020), including Fiji (Joseph et al., 2019), Reunion Island (Cuvillier et al., 2017), Bermuda, Cayman Islands, US Virgin Islands (Waycott et al., 2009), Kiribati (Brodie et al., 2020), Federated States of Micronesia, and Palau (Short et al., 2016), but attribution of such declines to climatic influences remains weak (*low confidence*). Impact of climate change on seagrasses goes beyond the loss of seagrass but includes acceleration of seagrass decomposition (Kelaher et al., 2018), palatability (Jimenez-Ramos et al., 2017) and the cumulative effect of warming and eutrophication (Ontoria et al., 2019). Seagrasses face a multitude of threats including physical disturbance and direct damage caused by rapidly growing human populations, declines in water quality, and coastal erosion (Short et al., 2016). Experimental studies have shown increased mortality, leaf necrosis, and respiration when seagrasses are exposed to higher-than-normal temperatures (Hernan et al., 2017). As such, seagrass meadows growing near the edge of their thermal tolerance are at risk from rising temperatures (Pedersen et al., 2016). In the Mediterranean, seagrass meadows are already showing signs of regression, which may have been aggravated by climate change (*high confidence*). Some studies suggest seagrasses have potential for acclimation and adaptation (Duarte et al., 2018; Ruiz et al., 2018; Beca-Carretero et al., 2020). Chefaoui et al. (2018) attempted to forecast the distribution of two seagrasses in the future, including around the islands of Cyprus, Malta, Sicily and the Balearic Islands. Under the worst-case scenario, *Posidonia oceanica* was projected to lose 75% of suitable habitat by 2050. Conversely, it has been suggested that seagrasses could actually benefit from an increase in anthropogenic carbon dioxide because of increased growth and photosynthesis (Hopley et al., 2007; Waycott et al., 2011; Sunday et al., 2016; Repolho et al., 2017). However, Collier et al. (2017) argued that when faced with increased heat waves, thermal stress will rarely be offset by the benefit of elevated CO_2 and therefore that the widespread belief that seagrasses will be a ‘winner’ under future climate change conditions seems unlikely *(low confidence*).

Since 2011, the Caribbean region has been experiencing unprecedented influxes of the pelagic seaweed *Sargassum*. These extraordinary sargassum ‘blooms’ have resulted in mass strandings of sargassum throughout the Lesser Antilles, with significant damage to coastal habitats, mortality of seagrass beds and associated corals (van Tussenbroek et al., 2017), as well as consequences for fisheries and tourism. Whether or not such events are related to long-term climate change remains unclear, however it has been suggested that the influx may be related to strong Amazon discharge, enhanced West African upwelling, together with rising seawater temperatures in the Atlantic (*low confidence*) (Oviatt et al., 2019; Wang et al., 2019). Since 2011, the Pacific atoll nation of Tuvalu has also been affected by algal blooms, the most recent being a large growth of *Sargassum* on the main atoll of Funafuti, and this phenomenon has been related to anthropogenic eutrophication and high seawater temperatures (De Ramon N’Yeurt and Iese, 2014).

Mangroves face serious risks from deforestation and unsustainable coastal development (Section 3.4.2.5; Gattuso et al., 2015). Large-scale die-offs around many small islands suggest that mangrove face increased risks from climate change (Sippo et al., 2018). Mangrove seaward edge retreat has been demonstrated in American Samoa and at Tikina Wai in Fiji, in Bermuda, West Papua, Grand Cayman and attributed to long-term SLR or tectonic subsidence (Ellison, 1993; Ellison, 2005; Gilman et al., 2007; Ellison and Strickland, 2015). Inundation-related mortality of mangroves could, in theory, be mitigated if mangrove substrates can “keep up” with rising sea level by accretion. Pacific Island studies using radionuclides (e.g., 210Pb, 137Cs) have suggested that most mangroves are keeping up with current rates of sea level rise (Alongi, 2008; MacKenzie et al., 2016), while surface elevation tables SETs suggest otherwise. Lovelock et al. (2015) reported that nearly 70% of the mangroves monitored with SETs are not keeping up with current SLR rates. If SLR exceeds 6 mm/yr, mangroves may be unable to maintain their elevation relative to sea level, a threshold likely to be surpassed in the next 30 years under high emission scenarios (Ellison, 1993; Saintilan et al., 2020). In these worst-case scenarios, flooding would result in tree, root, and rhizome death and an abrupt change in elevation through peat collapse (Krauss et al., 2010; Lang'at et al., 2014), creating a positive feedback loop between SLR and elevation loss. Geomorphology, hydrology, tidal range, and suspended sediments are important factors that will determine if mangroves will survive increased rates of SLR (Lovelock et al., 2015; Sasmito et al., 2015; Rogers et al., 2019). TCs can cause extensive damage to mangroves (Short et al., 2016). While immediate physical damage is often considerable, trees can sometimes recover by re-foliating, re-sprouting or regenerating (Kauffman and Cole, 2010). Examples of substantive mangrove recovery include the regrowth of trees in the Bay Islands of Honduras following Hurricane Mitch (October 1998) (Fickert, 2018) and in the Nicobar Islands, India, following the December 2004 Indian Ocean Tsunami (Nehru and Balasubramanian, 2018).

Sandy beaches are an important ecosystem in small islands, with high socio-economic as well as ecosystem services value (Ellison, 2018). Turtles and many seabirds nest just above the high-water mark on sandy beaches or among sand dunes, but TCs, rising seas, storm surges and heavy rainfall as well as inappropriate coastal development can erode beaches (Section 15.3.1.2) resulting in damage to nests and eggs (Fuentes et al., 2011). Beach-nesting turtle populations are projected to become threatened around many small islands as a result of future climate change (e.g., Bonaire - Netherlands Antilles (Fish et al., 2005), Bioko Island - Equatorial Guinea (Veelenturf et al., 2020), Cyprus (Varela et al., 2019), Raine Island – Australia (Pike et al., 2015)), although other populations such as those around the Cape Verde Islands are projected to remain relatively robust (Abella Perez et al., 2016). Turtles are also threatened by temperature rise around some small islands as warmer temperatures on nesting beaches can lead to an unbalanced sex-ratio in the population (e.g. St. Eustatius island, (Laloë et al., 2016)).

15.3.3.1.4 Marine and coastal ecosystem services

Intact coral reefs (Woodhead et al., 2019), seagrass meadows (Hejnowicz et al., 2015), and mangroves (UNEP, 2014b) (Friess, 2016) provide a variety of ecosystem services that are key to island communities, including provisioning services (e.g., timber, fisheries, aquaculture), regulating services (e.g., coastal protection, carbon storage, filtering of pollutants), cultural services (Pascua et al., 2017) as well as supporting community resilience (Förster et al., 2019). If coastal ecosystems are degraded and lost, then the benefits they provide are also lost (Oleson et al., 2018; Förster et al., 2019; Brodie et al., 2020). In small islands where the risk of loss to ecosystem services is high (Cross-Chapter Box DEEP in Chapter 17), many of these ecosystem services cannot be easily replaced (*medium confidence*). The beneficial role that coral reefs play in coastal protection through wave attenuation, and therefore enhancing climate resilience in small islands, has been extensively studied (e.g., Elliff and Silva, 2017; Harris et al., 2018; Reguero et al., 2018). Indeed, it has been demonstrated that in small islands (such as the Cayman Islands, Grenada, Bahamas) averted damages as a result of protecting intact coral reefs, can be considerable when expressed as a percentage of GDP (Beck et al., 2018). Ferrario et al. (2014) conducted a global meta-analysis including many small islands across the Atlantic, Pacific and Indian Oceans and found that coral reefs reduce wave height by an average of 84% (and wave energy by 97%) and that reef crests alone dissipate most of this energy. Based on another meta-analysis of 69 case studies worldwide (wave heights measured before and after the habitat), Narayan et al. (2016) observed that coral reefs, mangroves, and seagrass reduced wave height by 70%, 31% and 36%, respectively (Figure 15.4) and thus perform an essential role in protecting human lives and livelihoods (*high confidence*). Post-TC studies have provided additional evidence for the protection services offered by coastal ecosystems. On some Caribbean islands (e.g., Saint-Martin/Sint Maarten) where the dense indigenous vegetation belt was preserved, the vegetative structure buffered the waves of TCs Irma and José (2017), reducing the extent of marine inundation and shoreline retreat to a 30 m-wide coastal strip against values >160 m in deforested areas (Duvat et al., 2019a; Pillet et al., 2019). By contrast, the destruction of mangrove ecosystems, even a few trees around the fringes, can accelerate coastal erosion, as exemplified by observations in Micronesia (Krauss et al., 2010; Nunn et al., 2017a).

As corals, mangroves and seagrasses disappear, so do fish and other dependent organisms that directly benefit industries such as ecotourism and fisheries (*high confidence*) (Graham et al., 2015; Cinner et al., 2016). These impacts are sometimes exacerbated by catastrophic events such as tropical storms and marine heatwaves that destroy habitats and hence the resources upon which coastal fisheries depend (Sainsbury et al., 2018). There is *high confidence* that climate change impacts, together with local human disturbances, will continue to denude coastal and marine ecosystem services in many small islands with serious consequences for vulnerable communities (Elliff and Silva, 2017; Bindoff et al., 2019).

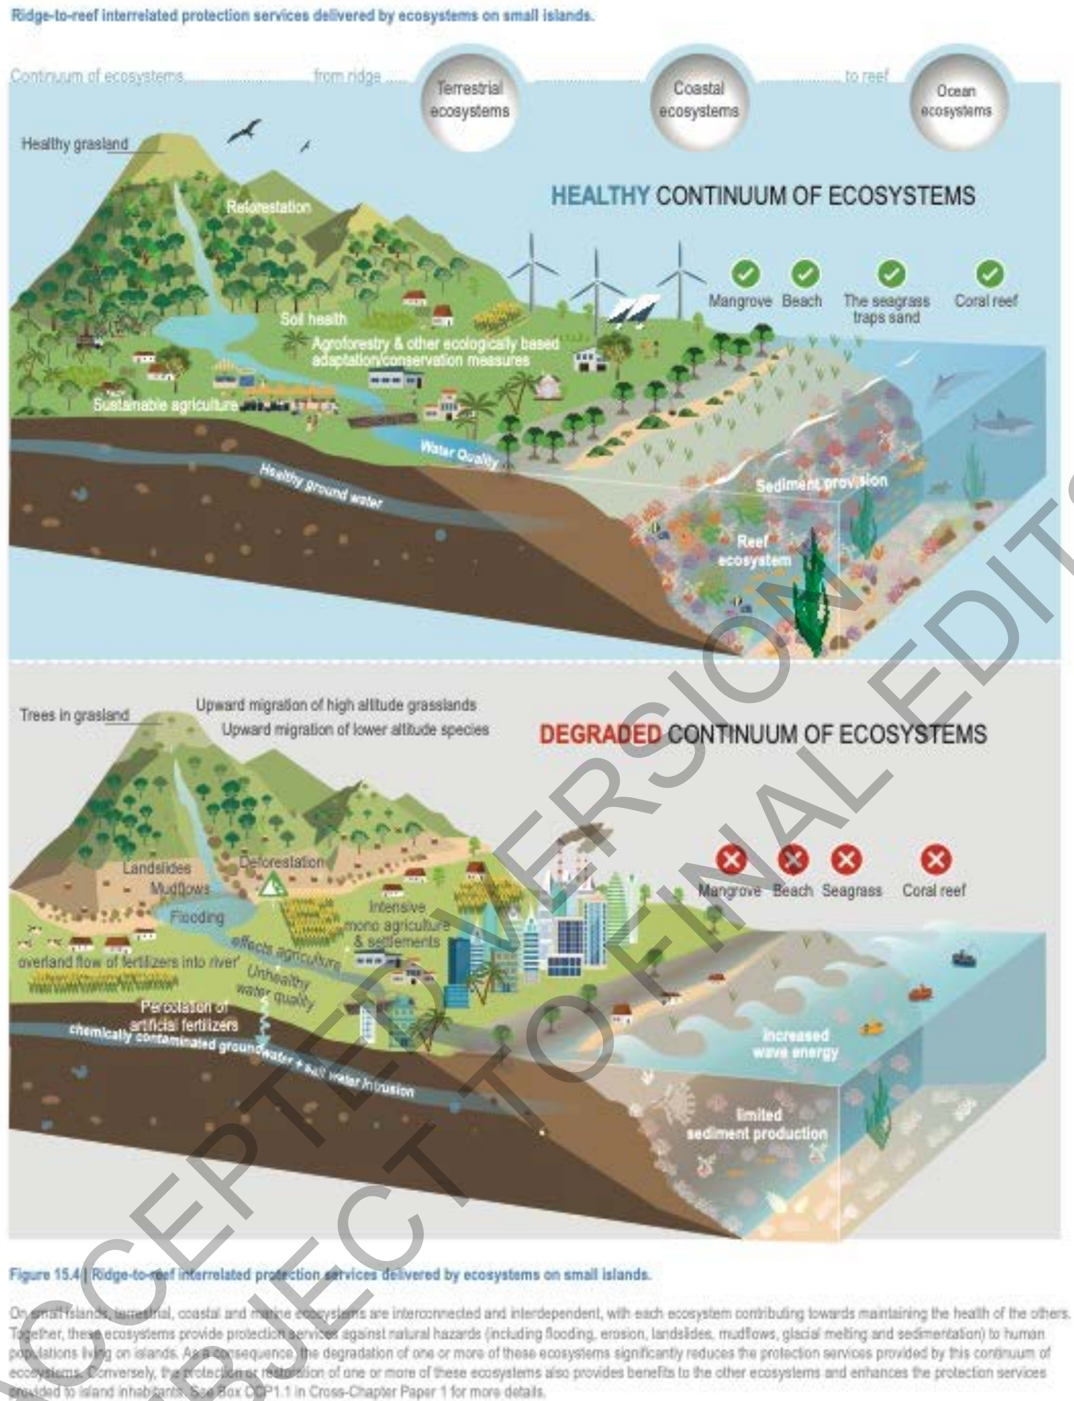

Figure 15.4: Ridge-to-reef interrelated protection services delivered by ecosystems on small islands. On small islands, terrestrial, coastal and marine ecosystems are interconnected and interdependent, with each ecosystem contributing towards maintaining the health of the others. Together, these ecosystems provide protection services against natural hazards (including flooding, erosion, landslides, mudflows, glacial melting and sedimentation) to human populations living on islands. As a consequence, the degradation of one or more of these ecosystems significantly reduces the protection services provided by this continuum of ecosystems. Conversely, the protection or restoration of one or more of these ecosystems also provides benefits to the other ecosystems and enhances the protection services provided to island inhabitants. See Box CCP1.1 for more details.

15.3.3.2 Impacts on Freshwater Systems

Freshwater systems on small islands are exposed to dynamic climate impacts and are considered to be among the most threatened on the planet (Key Risk 3 in Box 15.1; Settele et al., 2014; IPCC, 2018; Butchart et al., 2019). Hoegh-Guldberg et al. (2019) estimated that freshwater stress on small islands would be 25%

less with a warming of 1.5°C or less as compared to 2.0°C. While some island regions are projected to experience substantial freshwater decline, an opposite trend is observed for some western Pacific and northern Indian Ocean islands (Holding et al., 2016; Karnauskas et al., 2016). Island topography and ecophysiology influence water storage capacity and rainfall response potential (Dunn et al., 2018). On high volcanic and granitic islands, freshwater ecosystems are often closely connected with coastal spaces, and changes in freshwater supply from river systems have direct implications for salinity and sediment loads (*high confidence*) (Yang et al., 2015; Zahid et al., 2018). Climate impacts on streamflow patterns in tropical islands also create shifts in water supply for downstream users and habitat conditions for organisms supporting a wide range of ecosystem services (*high confidence*) (Strauch et al., 2015; Frazier and Brewington, 2019; Frauendorf et al., 2020).

Projected changes in aridity are expected to impose freshwater stress on many small islands, especially SIDS *(high confidence*).These changes are congruent with drought risk projections for Caribbean SIDS (Lehner et al., 2017; Taylor et al., 2018) and aligned with observations from the Shared Socio-Economic Pathway (SSP) 2 scenario, where a 1°C increase in temperature (from 1.7°C to 2.7°C) could result in a 60% increase in the number of people projected to experience a severe water resources stress from 2043–2071 (Schewe et al., 2014; Karnauskas et al., 2018). In the Mediterranean region, freshwater resources will decline 10–30% *(medium confidence)* (Koutroulis et al., 2016; Kumar et al., 2020). For example, analysis of annual and seasonal streamflow data on the island of Mallorca shows a decreasing trend during spring and summer, with a reduction of up to 17% in some basins (Garcia, 2017).

The influence of climate change spans several variables for atoll islands with multiple, interacting forces that exacerbate impacts on freshwater ecosystems (Connell, 2016), including groundwater and freshwater resources (Warix et al., 2017). Analysis of groundwater resources on Roi-Namur, in the Marshall Islands, reveals that the extent of salinisation of fresh groundwater lenses varies with the scale of the overwash (Gingerich et al., 2017). Alsumaiei and Bailey (2018) estimated an 11-36% reduction in the fresh groundwater lens volume of the small atoll islands (area < 0.6 km²) of the Maldives due to SLR. Small overwash events lead to saline conditions that last for up to 3 months (Oberle et al., 2017).

SLR undermines the long-term persistence of freshwater-dependent ecosystems on islands (Goodman et al., 2012) and is one of the greatest threats to the goods and services these environments provide (Box 16.1; Mitsch and Hernandez, 2013). Hoegh-Guldberg et al. (2019) posit that as sea level rises, managing the risk of salinisation of freshwater resources will become increasingly important. On Roi-Namur, Marshall Islands, Storlazzi et al. (2018) found that the availability of freshwater is impacted by the compounding effect of SLR and coastal flooding. In other Pacific atolls, Terry and Chui (2012) showed that freshwater resources could be significantly affected by a 0.40 m SLR. Similar impacts are anticipated for some Caribbean countries (Stennett-Brown et al., 2017). Such changes in SLR could increase salinity in estuarine and aquifer water, affecting ground and surface water resources for drinking and irrigation water (Mycoo, 2018a) across the region (*high confidence*). SLR also affects groundwater quality (Bailey et al., 2016), salinity (Gingerich et al., 2017), and water-table height (Masterson et al., 2014).

15.3.3.3 Impacts on Terrestrial Biodiversity Systems

Despite encompassing approximately two percent of the Earth's terrestrial surface, oceanic and other high-endemicity islands are estimated to harbour substantial proportions of existing species including ~ 25% extant global flora, ~ 12% birds and ~10% mammals (Alcover et al., 1998; Wetzel et al., 2013; Kumar and Tehrany, 2017). Islands also have higher densities of critically endangered species, hosting just under half of all species currently considered to be at risk of extinction (Spatz et al., 2017a; Spatz et al., 2017b), hence making the loss of terrestrial biodiversity and related ecosystem services a Key Risk (KR3) for small islands (Figure 15.5). Impacts from developing synergies between changing climate, natural and anthropogenic stressors on islands (Cross-Chapter Box DEEP in Chapter 17) could lead to disproportionate changes in global biodiversity. The most prominent drivers include: SLR, increasing intensities of extreme events (human activities — especially continuing/accelerating habitat destruction/degradation) and the introduction of invasive alien species (IAS) (Tershy et al., 2015). When coupled with characteristic small island traits such as spatial and other resource limitations, these synergies play a critical role towards increasing the vulnerability of these insular ecosystems (Box CCP1.1). This is likely to hinder the adaptation response of terrestrial biota ─ increasing the risk of biodiversity loss and in turn, impairing the resilience capacity of ecosystem functioning and services (*high confidence*) (Heller and Zavaleta, 2009; Ferreira et al., 2016; Vogiatzakis et al., 2016).

Current observations of insular species response to climate change generally report geographic range shifts/reductions for species and vegetation associations in addition to resulting impacts on local ecology (Virah-Sawmy et al., 2016; Koide et al., 2017; Maharaj et al., 2019). These include changes in plant/animal phenology and resulting community alterations such as for the common Mediterranean island species *Quercus ilex* (holly oak) and *Ficus carica* (common fig). Species have been shifting greater distances to access not only suitable climate conditions but also by association, suitable breeding conditions and seasonal food. Examples include: migratory birds such as *Coturnix coturnix* now having earlier spring arrival dates in the Mediterranean compared to six decades ago and the increased mortality of the iconic *Argyroxyphium sandwicense* (Hinahina) as result of warmer drier trends at Hawaiian high altitudes (Krushelnycky et al., 2012; Taylor and Kumar, 2016a; Vogiatzakis et al., 2016). There have also been die-offs of some species from temperature extremes (e.g., flying fox species: *Pteropus* species) within the Pacific islands (Taylor and Kumar, 2016a).

Recorded alterations of ecological interactions include increased competition, changes to migratory routes (Harter et al., 2015) and mismatches between species, such as increased pathogen attacks on Mediterranean forest species (Vogiatzakis et al., 2016). Also, in some areas of Madagascar there has been increased vulnerability to fire, due to the replacement of succulents by less fire resilient species (Virah-Sawmy et al., 2016). Further, the low functional redundancy of island ecosystems implies a comparatively higher proportion of keystone species than continents, many of them being endemics (Harter et al., 2015), with potentially unpredictable system consequences due to climate-induced ecological changes. For example, Caribbean land crabs have been observed to alter their food intake as a response to drying conditions (McGaw et al., 2019) and Aldabra giant land tortoises have reduced their activity in response to increasing temperature and decreasing precipitation (Falcon and Hansen, 2018); such changes in both these ecosystem engineers are of potential consequence for seed dispersal, among other ecological functions.

The majority of studies modelling geographical range changes of small island species, to even the most optimistic 21st century climate change scenarios imply a reduction in climate refugia (Table 15.3, Box CCP1.1). This is due to projected strong shifts, reductions or even complete losses of climatic niches resulting from inadequate geographic space for species to track suitable climate envelopes (*high confidence*) (e.g., Maharaj and New, 2013; Fortini et al., 2015; Struebig et al., 2015b). Because of the high proportion of global endemics hosted within small and especially isolated islands, the resulting increased extinction risk of such species (up to 100%) could lead to disproportionate losses in global biodiversity (m*edium to high confidence*) (Harter et al., 2015; Manes et al., 2021).

SLR has been projected to impact the terrestrial biodiversity of low-lying islands and coastal regions via large habitat losses both directly (e.g., submergence) and indirectly (e.g., salinity intrusion, salinisation of coastal wetlands and soil erosion) at even the 1m scenario (*medium to high confidence*). However, these impacts vary depending on the islands' topographical differences. In a study of SLR impacts on insular biodiversity hotspots, (Bellard et al., 2013a) reported that the Caribbean islands, Sundaland and the Philippines were projected to suffer the most habitat loss while the East Melanesian islands were projected to be lesser (but not minimally) affected. The most threatened of these, the Caribbean, was projected to have between 8.7% to 49.2% of its islands entirely submerged respectively from 1m to 6 m SLR (Bellard et al., 2013a). However, many current projection studies consider marine flooding directly and seldom incorporate other indirect impacts such as increased habitat losses from horizontal erosion loss, increased salinity levels, tidal ranges and extreme events. These projections are considered to be conservative, underestimating the extent of habitat loss to terrestrial biodiversity (Bellard et al., 2013b).

Marine flooding is expected to destroy habitats of coastal species, particularly range-restricted coastal and/or single-island endemics (many already listed as *at least* 'threatened' by the International Union for Conservation of Nature [IUCN]) within the limited terrain on atoll islands. These species have limited opportunities to accommodate such direct impacts of climate change apart from shifting further inland or to other neighbouring atolls which might have favourable habitat. However, fragmentation of habitat due to anthropogenic activity may hinder migration further inland, while shifting to neighbouring islands is not viable due to the water barrier between islands (*high confidence*) (Bellard et al., 2013b; Wetzel et al., 2013;

Kumar and Tehrany, 2017). Additionally, migratory birds, which use small islands (e.g. atolls) for stopovers or breeding/nesting sites, are projected to become impacted. Within the Mediterranean and Caribbean, significant losses to coastal wetlands - critical habitat for migratory birds has already been observed, with further significant habitat losses, redistribution and changes in quality being projected across island systems such as the Bahamas (Caribbean) and Sardinia (Mediterranean) (Vogiatzakis et al., 2016; Wolcott et al., 2018).

Indirect impacts of SLR may potentially result in equal or more biodiversity loss than direct impacts (*medium confidence*). Relocation of displaced coastal human populations and associated intensive agriculture and urban areas inland to natural habitat may result in greater biodiversity loss than direct impacts – especially on islands with large coastal populations and urban centres (Wetzel et al., 2012; Bellard et al., 2013b). Given the dense population of insular hotspots (~31.8% of existing humans within ~ 15.9% of inhabited global land area) and the fact that on many islands, large proportions of human populations live within coastal regions, it has been suggested that immense impacts from such relocations should be factored into projection and adaptation studies (Wetzel et al., 2012).

Tropical island natural habitats/systems are highly vulnerable to extreme weather events such as TCs, due to their small size, unique ecological systems and often low socio-economic capacity (*high confidence*) (Box 15.2; Goulding et al., 2016; Schütte et al., 2018). Growing evidence suggests high resilience of forest habitats (Keppel et al., 2014; Luke et al., 2017), especially within intact forest ecosystems to hurricanes and cyclones (Goulding et al., 2016). While initial damage can be high, relatively fast recovery rates have been reported for both floral and faunal components of these ecosystems (Cantrell et al., 2014; Shiels et al., 2014; Monoy et al., 2016; Richardson et al., 2018). Within the Caribbean in particular, high resilience of forest types has been associated with the *current* intensity and return rate of hurricanes over the last 150 years.

It should however be underscored that these relatively fast recovery rates are associated with the *present* intensity and return rate of TCs. They do not reflect the impacts of increasingly intense events such as Hurricane Dorian (2019), which resulted in almost complete inundation of several low-lying islands of the Bahamas from storm surges. Severe weather events also have indirect effects on islands' biodiversity — interacting synergistically with other stressors, such as increased invasion by non-native species and land use change. For example, TCs within Papua New Guinea resulted in the destruction of subsistence gardens, which led inhabitants to clear forest areas for new farming areas and for harvesting of timber resources to rebuild (Goulding et al., 2016).
